in Cu-H system decreases exponentially as the H-concentration increases by considering the apparent probabilities  
of various H-vacancy complexes at its ground state and the energy barrier of vacancy diffusion calculated from an  
embedded-atom-method potential. However, this H-concentration dependency of vacancy diffusivity is denied by  
the direct molecular dynamics simulations, which shows that H-atoms strongly enhance the diffusion of the vacancy  
with increasing H-concentration. It should be noted that the number of trapped H-atoms along the diffusion pathway  
was kept constant in the static energetics calculations. From the viewpoints of statistical sense, the varied number of  
trapped H-atoms along the diffusion pathway should be allowed. Therefore, we used the potential-of-mean-force  
method to study the vacancy diffusion under H-environments so that the thermodynamic equilibrium distribution of  
H around the vacancy can be achieved along the diffusion pathway. We found that the vacancy can trap more  
number of H-atoms at its saddle-point than that at its ground state, which can be characterized by an activation  
excess. According to the generalized Gibbs isotherm, the higher chemical potential of H-atoms significantly  
decreases the energy barrier of the vacancy diffusion. Thus, the vacancy diffusivity is enhanced by H-atoms, which  
is in consistent with the results of the direct molecular dynamics simulations. This effect of H is believed to be  
general in other thermal activation processes that can attract more H-atoms at its saddle-point.

**A Computational Study of Cubic Thin Films in WC-Co Cemented Carbides**  
Erik Fransson, Martin Gren and Göran Wahnström; Chalmers University of Technology, Sweden

WC-Co cemented carbides combine superb hardness with high toughness making them ideal for usage in cutting  
applications and in wear resistance tools. Thin films of cubic stacking have been observed experimentally at the  
phase boundary between WC and Co when doping with Ti and V. These films could potentially inhibit grain growth  
and are thus important to understand as grain size play a crucial role for the mechanical properties of the material.  
Experimental results have also shown that these types of films are present in undoped WC-Co.

Here we construct, using ab-initio calculations and modeling, an interface phase diagram for thin films in undoped  
and Ti doped WC-Co. We employ cluster-expansions to model mixed metal layers and carbon vacancies. Monte  
Carlo simulations are used to sample the configurational entropy. We include vibrational contribution to the free  
energy by using force-constant regression in order to extract the harmonic free energy. Configurational and  
vibrational entropy are all shown to be important factors in order to understand this stabilization of cubic thin films  
in WC-Co. The calculated thermodynamic properties of the cubic thin films are compared to experimental studies  
and show good agreement.

**icet—A Python Library for Constructing and Sampling Alloy Cluster Expansions**  
Mattias Ångqvist1, William Armando Muños1, Magnus Rahm1, Erik Fransson1, Céline Durniak2, Piotr Rozyczko2, Thomas Holm Rod2 and Paul Erhart1; 1Chalmers University of Technology, Sweden; 2European Spallation Source, Denmark

Alloy cluster expansions (CEs) provide an accurate and computationally efficient mapping of the potential energy  
surface of multi-component systems that enables comprehensive sampling of the many-dimensional configuration  
space. Here, the integrated cluster expansion toolkit (icet), a flexible, extensible, and computationally efficient software  
package, is introduced for the construction and sampling of CEs.
icet is largely written in Python for easy integration in comprehensive workflows, including first-principles calculations for the generation of reference data and machine learning libraries for training and validation. The package enables training using a variety of linear regression algorithms with and without regularization, Bayesian regression, feature selection, and cross-validation. It also provides complementary functionality for structure enumeration and mapping as well as data management and analysis. Potential applications are illustrated by several examples, including (1) studying chemical ordering and associated properties in a series of intermetallic clathrates as a function of composition and temperature and (2) by predicting the phase diagrams of bulk and surface alloys.

A Koopman's Compliant Exchange Correlation Potential for Semiconductors Michael Lorke, Thomas Frauenheim and Peter Deak; University of Bremen, Germany

Density functional theory is the workhorse of theoretical materials investigations. Due to the shortcoming of (semi-)local exchange correlation potentials, hybrid functionals have been established for practical calculations to describe surfaces, molecular adsorption, and defects. These functionals operate by mixing between semi-local and Hartree-Fock exchange semi-empirically. However, their parameters have to be optimized for every material separately. To treat materials with a more physics driven approach and without the need of parameter optimization is possible with many-body approaches like GW, but at an immense increase in computational costs and without the access to total energies and hence geometry optimization.

We propose a novel exchange correlation potential for semiconductor materials, that is based on physical properties of the underlying microscopic screening. We demonstrate that it reproduces the low temperature band gap of several materials. Moreover, on the example of defects in semicon-ductors, it respects the required linearity condition of the total energy with the fractional occupation number, as expressed by the generalized Koopman’s theorem. It is shown, that all technologically relevant Gallium-based semiconductors can be treated with a common choice of the functional. We also can treat the infamous case of ZnO with the same functional. As the parameters of the calculation can in principle be determined from ab initio calculations, our approach can be seen as a non-empirical approximation.

MT01.05.11
A Non-Empirical Method for Eliminating Delocalization and Static Correlation Errors within Density Functional Theory for Studying Correlated Materials Akash Bajaj, Fang Liu and Heather J. Kulik; Massachusetts Institute of Technology, United States

Presently available exchange-correlation functionals in density functional theory (DFT) suffer from a number of errors, including many electron self-interaction error or delocalization error. Eliminating delocalization error (i.e., deviation from piecewise linearity) has been shown to improve property estimation, including relative energies and especially properties directly tied to the improved orbital energies such as the band gap. However, all common approaches to mediating this delocalization error (e.g., global or range separated hybrid functionals or DFT+U) do so at the cost of increasing fractional spin error i.e. the static correlation error, which worsens other essential properties (e.g., bond dissociation energies and activation energies), thereby presenting a challenge for studying correlated materials where both these errors are simultaneously prevalent. We develop a general approach to avoid this trade-off by returning to the exact flat-plane constraint that arises from the union of the fractional spin and piecewise linearity constraints. We examine the shapes of semi-local DFT errors with respect to the flat plane condition and use these deviations to construct new, approximate, functional forms that can recover the flat-plane condition. Our judiciously-modified DFT (jmDFT) approach for constructing few-parameter, low-order corrections to conventional xc-functionals adds no computational overhead to semi-local DFT while recovering the flat-plane constraint. We describe how our approach relates to commonly used Hubbard corrections (i.e., DFT+U and DFT+U+J), thereby emphasizing their relation to improving DFT+U. Using this observation, we outline expressions that can be used to extract jmDFT parameters in a first-principles manner and study how such expressions compare with those employed in the ab initio computation of Hubbard parameters. Finally, we show how to employ this low-
cost, non-empirical framework to the study of transition-metal based correlated materials.

Modelling and Simulation of Mesenchymal Stem Cells Differentiation and Proliferation on PCL-Graphene Scaffold at Molecular and Cellular Level
Qi Wu¹, Pegi Haliti¹, Bhushan Dharmadhikari¹, Tolga Kaya² and Prabir Patra¹,¹; ¹University of Bridgeport, United States; ²Sacred Heart University, United States

The fast-growing field of regenerative medicine is closely related to the advances in tissue engineering and material sciences. Biomaterials have a prominent role as an architectural framework, similar to the innate Extracellular Matrix (ECM), which can re-establish normal functions of deteriorated tissues. In this research, computational methods were used to study the relationship in both molecular and cellular levels of mesenchymal stem cells (MSCs) differentiated into neuronal lineage in electrospun polycaprolactone-graphene (PCL-GRA) scaffold. Specifically, we used molecular dynamics (MD) simulation to investigate the interactions of the scaffold with actin protein and Cellular Potts Model (CPM) to study cellular behaviors such as cell attachment, differentiation, and proliferation. For a better understanding of neuron cell mobility on PCL-GRA scaffold, we investigated the interactions of F-actin protein, which controls the mobility and influences the dendritic spines for neuronal cells. For computational simplicity, we used the actin monomer; globular actin (G-actin). For the entire duration of 100 ns MD simulation, the Van der Waals (VDW) energy between F-actin and PCL-GRA scaffold shows negative values, which represent strong attractive forces between our scaffold and G-actin. We considered G-actin residues within 5 Å from PCL-GRA surface as “interacted residues.” Hydrogen bonds established between LYS 326 residue of G-actin and polycaprolactone chains, which also suggest non-bonding electrostatic interaction between two molecules. For the cellular level interaction, we are using CPM, a computational lattice-based model which uses the stochastic Monte Carlo’s probabilistic model by minimizing the system’s total energy. MSCs extend filopodia and spread along the strain orientation, where PCL fibers are stiffest. The mobility and adhesion of MSCs are controlled by cell-to-cell forces and cell-to-scaffold forces which are incorporated in our CPM model. Our CPM simulation results show that in randomly aligned PCL fibers, cells tend to travel up gradients toward the areas where the graphene concentration is higher. Addition of graphene to PCL scaffold improves cell attachment and viability as compared to only PCL scaffold. Our results indicate that besides the intrinsic factors assigned to the stem cells, the extrinsic parameters of the PCL-GRA interaction have a significant role in the creation of focal adhesion points, cell motility, and cellular attachment.

MT01.05.13
Running Collective Variable-Driven Hyper Dynamics in Parallel to Accelerate Molecular Dynamics Simulation of Initial Stage of Carbon Nanotube Growth
Satoru Fukuhara and Yasushi Shibuta; The University of Tokyo, Japan

Catalytic chemical vapor deposition (CCVD) is a widely used method to synthesize carbon nanotubes (CNTs). To control the property (e.g. length, diameter and chirality) of CNT, it is essential to understand the formation mechanism of CNT. Molecular dynamics (MD) simulation is a useful method to observe the formation process. However, MD simulation can only reach the time scale of nanoseconds and is not enough to directly observe the growth of CNTs at low temperature where catalysts remain solid. Therefore, we adopt a recently proposed acceleration method called collective variable-driven hyperdynamics (CVHD) method [1]. In CVHD method, firstly a collective variable (CV) is set and the CV is biased gradually in the same way as metadynamics [2]. Unlike metadynamics, CVHD reset the CV and the bias on it once the system undergo a transition. In this way, CVHD method can reproduce correct dynamics of the system. However, CVHD has a problem that the magnitude of acceleration decreases as the number of target reaction increases. This problem will be fatal in the simulation of CNT because CNT formation process contains migrations of multiple carbon atoms. In this study, we solve this problem by executing CVHD method in parallel (parallel CVHD hereinafter). Specifically, multiple CVs are set according to the number of carbons present in the system, and bias potentials are gradually added to each CVs. When a carbon atoms undergo a transition, the bias potential of the corresponding carbon is reset based on the CVHD method.

In order to confirm the correctness of parallel CVHD, activation energy of carbon atom migration is compared with not accelerated MD. The activation energies are derived from the Arrhenius plot of migration frequency of two carbon atoms in bulk iron. The activation energy gained with parallel CVHD was consistent with not accelerated MD. Subsequently, in order to observe the migration and segregation process of carbon atoms, which is important in the formation of CNT, 20 carbon atoms are randomly put in a slab iron of 1100 atoms and parallel CVHD is
performed at 600K. In the 1 ns calculations of not accelerated MD, almost no migration of carbon was observed. Whereas in the parallel CVHD, an acceleration rate of about 700 times is realized, and it was possible to observe atom migration to the surface.

MT01.05.15
Capturing Electron-Phonon Coupling and Electronic Stopping in Molecular Dynamics Simulations with a Unified Model
Artur Tamm1, Magdalena Caro2, Alfredo Caro3 and Alfredo Correa1; 1Lawrence Livermore National Laboratory, United States; 2Virginia Polytechnic Institute, United States; 3George Washington University, United States

We present a Langevin based stochastic model with spatial correlations and local environment dependence capable of capturing both the electron-phonon interaction as well as electronic stopping in classical molecular dynamics (MD). The model is parametrised by fitting to data from smaller scale first principles simulations, such as real-time time-dependent density functional theory (TDDFT), resulting with a solution that does not have tunable additional parameters. The framework is readily extendable to multicomponent systems and is implemented as an extension to widely used LAMMPS code. We show the application of our model in the case of Ni crystal, where we illustrate the non-equilibrium dynamics of phonon modes and a NiFeCr solid solution. In the latter case the electronic stopping regime as well as thermal equilibration is illustrated by collision cascade MD simulations at different initial conditions (PKA energies). Our model is able to excite and damp phonon modes with different wavevectors with rates in good agreement with quantum theory, which has been lacking so far in classical simulations studying non-equilibrium dynamics. Also, in collision damage simulations the model transitions smoothly from electronic stopping mode, where the coupling is strong, to the electron-phonon regime, weak coupling, as the projectile slows down and does not explore high electronic-density regions. In summary, the developed model is able to describe the non-equilibrium as well as equilibrium dynamics of a system due to electron-ion interaction and could be further applied to various phenomena such as, laser-matter interaction, compression shockwave dynamics, and radiation damage.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and funded by the Energy Dissipation to Defect Evolution Center, EDDE, an Energy Frontier Research Center of the U.S. Department of Energy (Award Number 2014ORNL1026).

First Passage Algorithms for Sink Strength Calculations—Application to Vacancy Emission and Absorption
Savneet Kaur1, Manuel Athenes1, Gilles Adjanor2 and Thomas Jourdan1; 1Commissariat à l'énergie atomique et aux énergies alternatives, France; 2EDF, France

Kinetic Monte Carlo techniques are extensively used to simulate the evolution of defects in materials and to study irradiation effects in particular. All these methods are based on a master equation involving a transition rate matrix. Transition rates are derived from an energetic model in which defects and atoms may either occupy substitute and interstitial sites of a crystalline lattice or exhibit off-lattice in a continuous space. Unfortunately, Kinetic Monte Carlo methods become inefficient when the transition rate matrix associated with the master equation exhibits a broad spectrum of frequencies. Vacancies perform a huge number of transitions between a few atomic configurations connected to each other by small energy barriers. These connected configurations form trapping basins from which the typical escape time for a particle is much higher than the typical time to cross the small barriers inside the basins. The system remains stuck in metastable thermodynamic states. Acceleration techniques based on the theory of absorbing Markov chains are currently being used in Kinetic Monte Carlo simulations to overcome kinetic trapping in low energy basins. This is achieved by drawing escaping events to distant locations.
from the exact first-passage and no-passage distributions. These two distributions can be formally expressed through the eigenvalue decomposition of the transition rate matrix. Assuming reversible diffusion processes, a property usually satisfied by defects in metals and alloys in and out of equilibrium, we show that the involved linear and eigenvalue problems to be solved can be symmetrized. Furthermore, the slowest modes, those associated with the smallest eigenvalues, are observed to contribute the most to the first-passage and no-passage distributions. As a result, Krylov subspace projection techniques implementing reverse iterations provide us with an efficient tool for accurately approximating the two desired distributions at a relatively low cost. We discuss the convergence, scalability and range of applicability of the approach. We demonstrate its efficiency by computing sink strengths and transition currents for the emission and absorption of vacancies from and to cavities in Aluminium at low defect concentrations.

Phase Field Modeling of Rapid Solidification of Ti-Ni Alloy Parameterized Using Interfacial Properties Calculated from Atomistic Simulations Sepideh Kavousi, Brian R. Novak and Dorel Moldovan; Louisiana State University, United States

We present a molecular-dynamics (MD) informed phase field simulation approach to study the microstructure evolution during solidification of Ni-Ti alloys. In the conventional phase-field model developed by Echebarria et al. (EFKP) [1] the kinetic coefficient for solidification of dilute binary alloys is assumed to be zero. However, in the newly-developed phase-field model by Pinomaa and Provatas [2], based on the Crystal Growth Model (CGM), it has been shown that consideration of the kinetic coefficient may play an important role for capturing the effect of solute trapping. Using MD simulations, we calculate the anisotropic kinetic coefficient and crystal-melt interfacial free energy by employing the free solidification and capillary fluctuation method, respectively. Then, using the MD-calculated crystal-melt interfacial properties, we parameterize both the EFKP and Pinomaa-Provatas phase field models and investigate how the partition coefficient changes with the solidification velocity. Work supported by the U.S. National Science Foundation (NSF OIA-1541079).

MT01.05.18
General Correlation between Electronic Factors and Solute-Defect Interactions in bcc Refractory Metals Yong-Jie Hu¹, Ge Zhao², Baiyu Zhang³, Zi-Kui Liu¹, Xiaofeng Qian³ and Liang Qi¹; ¹University of Michigan, United States; ²The Pennsylvania State University, United States; ³Texas A&M University, United States

The interactions between solute atoms and crystalline defects such as vacancies, dislocations, and grain boundaries are essential in determining physical, chemical and mechanical properties of alloys. Here we present a general correlation between two electronic factors and the solute-defect interaction energies in binary alloys of body-centered-cubic (bcc) refractory metals (such as W and Ta) with transition-metal substitutional solutes. One electronic factor is the bimodality of the $d$-orbital local density of states for a matrix atom at the substitutional site, and the other is related to the hybridization strength between the valence $sp$- and $d$-bands for the same matrix atom. Remarkably, the correlation is independent of the types of defects and the locations of substitutional sites, following a linear relation for a particular pair of solute-matrix elements. The correlation plus a residual-correction model can provide a novel and quantitative guidance to predict the solute-defect interactions in alloys based on electronic structures.

MT01.05.19
Study of Water Diffusion across Nanocomposite Reverse Osmosis Membranes—A Combined Molecular Dynamics and Kinetic Monte Carlo Approach Rodolfo Cruz-Silva¹, Syogo Tejima¹,², Aaron Morelos¹, Josue Ortiz-Medina¹,³, Takuya Hayashi¹, Kenji Takeuchi¹, Mauricio Terrones¹,³ and Morinobu Endo¹; ¹Shinshu University, Japan; ²Research Organization for Information Science and Technology, Japan; ³Universidad Panamericana, Mexico; ⁴The Pennsylvania State University, United States

Reverse osmosis membranes are increasingly being used for water desalination and purification. These membranes
consist of a very thin (100-200 nm thick) selective layer, often made of crosslinked aromatic polyamide (PA), on top of a porous support. Understanding the mechanism of diffusion across the selective layer is key to improve the performance of current membranes. So far, classical molecular dynamics has been very useful to explain the hydration, water diffusion, and salt rejection mechanisms in plain PA membranes. Recently, nanocomposite membranes containing carbon nanotubes (CNTs) mixed with PA have shown high permeation and salt rejection and good chlorine resistance. However, the mechanism of diffusion is still not completely understood and in fact, there is no agreement on how CNTs increase the permeability of these membranes. While some researchers suggest that water flows within the embedded nanotubes, other researchers suggest they are impermeable. Unfortunately, the characteristic dimensions of CNTs (diameter around 10-12 nm, and several hundred nm length) requires using large simulation boxes that forbids the use of molecular dynamics. In this work, we used a multiscale approach by combining classical molecular dynamics and a simplified kinetic Monte Carlo approach to study the water diffusion across CNT-PA nanocomposite membranes. Briefly, we built a relatively small cell of PA and PA containing a single CNT. By using classical molecular dynamics, we calculated the free-energy-potential field in both cells. We implemented later a simplified kinetic Monte Carlo algorithm to simulate the diffusion of water molecules across 200 nm thick CNT-PA nanocomposite membranes and we were able to study the effect of CNT's concentrations on water permeation across the membranes.

Cluster Dynamics Modelling of Materials—A New Hybrid Deterministic/Stochastic Coupling Approach
Manuel Athenes¹, Thomas Jourdan¹, Gilles Adjanor¹,² and Pierre Terrier¹,²; ¹CEA, France; ²CERMICS, France

Deterministic simulations of the rate equations governing cluster dynamics in materials are limited by the number of equations to integrate. Stochastic simulations are limited by the high frequency of certain events. We propose a coupling method combining deterministic and stochastic approaches. It allows handling different time scale phenomena for cluster dynamics. This method, based on a splitting of the dynamics, is generic and we highlight two different hybrid deterministic/stochastic methods. These coupling schemes are highly parallelizable and specifically designed to treat large size cluster problems. The proof of concept is made on a simple model of vacancy clustering under thermal ageing.

MT01.05.21
Graphene Surface Chemistry and Oxidation in High Temperature Applications
José Graña-Otero, Simon Schmitt, Siamak Mahmoudi, Evan Sullivan and Gangotri Dey; University of Kentucky, United States

The chemistry of graphene is relatively well-known at relatively low temperatures, when the ambient gas is artificially limited to atomic or molecular oxygen in ultra-low pressure conditions for Electron Microscopy studies and epoxy is typically the only adsorbed surface species. The same applies at regular ambient conditions when air consists only of molecular species such as oxygen, nitrogen or water vapor, which have negligible small degrees of dissociation. Chemisorption of these molecular species is effectively prevented by fairly large activation energies, which severely limits their chemisorption concentrations and therefore play no role in the graphene surface chemistry.

However, carbon materials are extensively used in high-temperature conditions such as Thermal Protection Systems for Hypersonic flight applications. Carbon oxidation plays in these applications a critical role because it actually gasifies carbon in the form of gaseous CO and CO₂ therefore removing the protective layer. However, the chemistry of the graphene surface is not well known in these high temperature environments, which are characterized by large concentrations of highly reactive radicals such as hydroxyl or atomic oxygen, nitrogen and hydrogen. These species chemisorb on the graphene surface with very low or even no energy barrier at all, so they can reach high surface concentrations, competing with oxygen for carbon sites and therefore effectively reducing the oxygen coverage. However, the energetics and kinetics of these species on the graphene surface is almost completely unexplored.

Using DFT calculations, we have systematically studied the kinetics and dynamics of surface processes such as chemisorption, desorption and surface hopping on the graphene surface of atomic hydrogen, nitrogen, oxygen and hydroxyl, which typically populate the graphene surface in these high-temperature environments. We have also studied the interaction and reactions among them. Our ultimate goal is to develop a detailed kinetic mechanism including surface species and reactions among them in much the same way as those already available in combustion of hydrocarbon fuels. We have found for instance that oxygen can chemisorb in an on-top-of-carbon configuration,
in addition to the well-known epoxy form. We have studied as well interaction effects among near neighbors, showing actually that clustering is energetically favored, an effect already observed in the case of atomic chemisorbed hydrogen.

On the other hand, we have studied the oxidation dynamics. Compared to the dynamics of these surface species, oxidation occurs in times scales several orders of magnitude slower, which make oxidation events very infrequent. In order to overcome this rare-event limitation, we have used kinetic Monte-Carlo simulations to study the gasification dynamics. In particular, we have been able to simulate and explain the well-known pitting, so characteristic of graphene and graphite oxidation. We show in particular how, in the more relevant conditions for applications high-temperature environments, the presence of all those other surface species modifies the oxidation and pit growth rates with respect to the corresponding values found in the highly controlled conditions of Electronic Microscopy studies.

MT01.05.22
The Hiphive Package for the Extraction of High-Order Force Constants by Machine Learning Fredrik Eriksson, Erik Fransson and Paul Erhart; Chalmers University of Technology, Sweden

The efficient extraction of force constants (FCs) is crucial for the analysis of many thermodynamic materials properties. Approaches based on the systematic enumeration of finite differences scale poorly with system size and can rarely extend beyond third order when input data is obtained from first-principles calculations. Methods based on parameter fitting in the spirit of interatomic potentials, on the other hand, can extract FC parameters from semi-random configurations of high information density and advanced regularized regression methods can recover physical solutions from a limited amount of data. Here, the hiphive Python package, that enables the construction of force constant models up to arbitrary order is presented. hiphive exploits crystal symmetries to reduce the number of free parameters and then employs advanced machine learning algorithms to extract the force constants. Depending on the problem at hand, both over and underdetermined systems are handled efficiently. The FCs can be subsequently analyzed directly and or be used to carry out, for example, molecular dynamics simulations. The utility of this approach is demonstrated via several examples including ideal and defective monolayers of MoS2 as well as bulk nickel.

MT01.05.23
Light Absorption and Refractive Index During Agglomeration and Surface Growth of Carbonaceous Nanoparticles Georgios A. Kelesidis and Sotiris E. Pratsinis; ETH Zürich, Switzerland

Optical characterization of carbonaceous materials (e.g., Laser Induced Incandescence, LII) is important in fire detection and manufacturing of various grades of carbon black and even their impact on climate largely depends on light absorption. For example, the contribution of carbonaceous materials to global warming (~25 % of the total anthropogenic contribution) has currently the highest uncertainty among all contributions (CO2, CH4, etc.), as their optical properties depend on their precise composition quantified by C/H and morphology. Understanding the light absorption of carbonaceous particles is essential to their characterization and selective sensing by fire detectors and can improve the accuracy of climate models.

Here, the impact of composition on the light absorption from carbonaceous particles is investigated by coupling mesoscale Discrete Element Modeling (DEM) [1] with Discrete Dipole Approximation (DDA) during their surface growth and agglomeration [2]. The Mass Absorption Cross-section, MAC, of these agglomerates is estimated by DDA and validated against atomistic point dipole interactions and mesoscale DDA simulations [2]. Using a refractive index, RI, for mature soot with large C/H > 4.5 [3] yields constant MAC and absorption function E overestimating the light absorption up to 75 % of nascent soot with C/H < 4.5. The RI is interpolated between those of nascent and mature soot for wavelength, $\lambda = 1064$ nm to account for quantum confinement and evolving number of clustered sp2-bonded rings. This affects the optical band gap, $E_g$, resulting in excellent agreement of the DEM-derived evolutions of MAC and E with the corresponding LII measurements in methane [4] and ethylene premixed flames [5]. The $E_g$ of nascent soot decreases during agglomeration, increasing MAC and E by 65 %. The good agreement between DEM and LII data confirms that carbonaceous particle dynamics by surface growth and agglomeration strongly correlate with particle composition and RI that are essential for quantifying carbonaceous particle light absorption.
Mesoporous materials have attracted considerable attention in the past for their applications in catalysis, sorption, separation, hydrogen storage, oil & gas extraction, etc. and as host matrices for optically and electronically active components. In the recent past, mesoporous siliceous materials (MSM’s) have also shown tremendous potential in drug delivery technologies. Their superior thermophysical, mechanical, and chemical properties such as variable pore size, pore morphology, and surface functionalizability create avenues for optimized interactions between drug molecules and carriers. A widely adopted method of synthesis of these structures is evaporation-induced self-assembly (EISA). In EISA, control of pore morphology and liquid crystalline mesophases is accomplished by controlling the environmental conditions such as temperature, orientation of micelles, pH, and also the solvent evaporation rate and the block copolymer used as precursor. An important concern is that the packing of individual mesoporous solids in to a container can result in internal pores between individual mesoporous structures of larger sizes (>50 nm). Hence a monolithic solid is desired and has to be synthesized directly from the precursors. Synthesis of monoliths is highly challenging as it results in the formation of cracks. Prior studies have shown that cracks can be partially alleviated by controlling solvent evaporation rates, supercritical CO2 drying, or by using liquid paraffin in the synthesis mixture.

While the usual practice is to experiment with the block copolymers, surfactants, rate of evaporation, and the time involved in polymerization, proper guidelines for the rational synthesis of mesoporous siliceous monoliths is not available yet. Hence, as the first stride to address this issue, here, we present a molecular dynamics (MD) simulation routine that can serve as a guideline to the synthesis of mesoporous structures. Combining non-reactive and reactive MD, we simulate the non-reactive self-assembly process followed by chemical events leading to the evolution of porous structures. We implement a 3-step process using a water-solvated pluronic-based tri-block copolymer having both hydrophilic and hydrophobic groups in it. In the first step, we equilibrate the system with concentration > critical micelle concentration and temperature higher than the critical micelle temperature allowing for the non-reactive self-assembly of the surfactant molecules. OPLSAA force field [1] is used to drive this co-operative assembly. Secondly, we introduce silicic acid as the silica precursor for the micelle system and equilibrate using ReaxFF reactive force field [2] to enable chemical reactions leading to the formation of skeletal Si-O-Si bonds. To condense the silica precursor to the organic template, we use the accelerated bond-boosting scheme [3] within the ReaxFF molecular dynamics framework, which essentially bypasses the transition state complexes with high activation energy requirements, thereby achieving laboratory timescales in MD simulations. Following this, as the final step, by preferentially evaporating water solvent, MSM structures are obtained. We study the structural and mechanical properties of MSM’s to gain insights on molecular structure, localized heterogeneities, crack formation, etc., thereby elucidating the process of synthesis of mesoporous siliceous materials.

References
Hydrogen is a promising clean fuel. A key bottleneck to its widespread utilization is the susceptibility of materials used in hydrogen distribution infrastructure (typically steels) to embrittlement and failure. This necessitates the use of permeation barriers to prevent hydrogen ingress into the steel. Al₂O₃ is a popular hydrogen barrier, due to its low hydrogen permeability. Our recent study on bulk Al₂O₃ [1] using an ab initio thermodynamics approach has shown that the hydrogen solubility and diffusivity in Al₂O₃ can be further reduced by dopant engineering. Specifically, doping with Si, Ti, Fe and Cr reduces the solubility of free protons to negligible amounts, and traps protons at aluminum vacancy sites with high binding energy (~3 eV), in turn, reducing diffusivity.

While the intrinsic hydrogen permeation resistance of bulk Al₂O₃ is attractive, it is more lucrative to use a multilayer structure of alternating Al₂O₃ and Al layers as the coating. Such a structure is advantageous on multiple fronts: (a) it has high toughness and fatigue resistance, preventing cracking of Al₂O₃, thus avoiding fast diffusion pathways for hydrogen ingress to the steel, (b) it is self-healing, and (c) space charge engineering of the high interfacial area can help reduce hydrogen permeation further. The latter is the aim of this study.

Density functional theory was used to obtain the formation energies of various native, hydrogen and dopant (Mg, Si, Ti, Fe, Cr, B, C, N) defects in the bulk and defect segregation energies to the Al₂O₃|Al interface core. Using these energies as input, a continuum model was developed, which self-consistently solved Poisson’s equation to obtain the defect concentrations at the interface. Results show that in the undoped case, free hydrogen interstitials are depleted in the space charge region and accumulate at the core. This hydrogen buildup can lead to blistering of the interface, thus, deteriorating coating performance. Dopants were then utilized to prevent hydrogen accumulation at the core and ensure trapping of hydrogen in the space-charge region. To identify the impact of the interface on hydrogen diffusivity, effect of dopants on hydrogen migration barriers across the interface was studied using nudged elastic band method. The work of adhesion of doped interfaces was also calculated, which has implications for the effect of dopants on the spall tendency of the interface.

The robust coupling of ab initio methods and continuum modeling in this study helps take advantage of the accuracy of first principles calculations while overcoming the spatial limitation of such methods. It is emphasized that the fundamental results of this study can be extended to other systems where the metal/oxide interface affects device efficiency, such as the electrode/electrolyte interface in resistive switching devices and the metal/dielectric interface in metal-oxide-semiconductor devices.

Exploration of Mechanical Control Over Chiral Magnetic Phases from Atomistic to Mesoscopic Length Scales
Daniil A. Kitchaev and Anton Van der Ven; University of California Santa Barbara, United States

Chiral (Dzyaloshinskii-Moriya) magnetic interactions give rise to a wide range of complex magnetic phases, from helical and cycloidal spin textures to topological phases such as skyrmions. Due to the sensitivity of these interactions to precise atomistic environments and their symmetry, even mild strain can profoundly change the character and relative stability of the resulting magnetic phases. We first use phenomenological arguments to chart out how strain may alter chiral magnetic interactions, identifying the strain fields necessary to stabilize various types of magnetic phases in materials of any symmetry. In order to test these predictions, we construct strain-coupled magnetic phase diagrams from first-principles, by relying on density functional theory, cluster expansions, Hamiltonian Monte Carlo, and phase field techniques. This scale-bridging model reveals that strain fields readily accessible by a wide range of experimental techniques can be used to precisely control magnetic phase behavior and the emergence of topological phases in common high-symmetry ferromagnetic materials.

Optical and Electrical Properties of Point Defects in Cubic Zirconia
Elizabeth Chavira1, Mourad Boujnah1, A. El Kenz2, M. Loulidi2, H. Ez-Zahraouy2 and A. Benyoussef3; 1Universidad Nacional Autónoma de México, Mexico; 2Mohammed V. University, Morocco; 3Hassan II Academy of Science and Technology, Morocco

Electronic, optical and electrical properties of the point defects in cubic unit cell ZrO₂ were calculated by using the density functional theory (DFT) calculation based on full potential linear augmented plane wave (FP-LAPW). The exchange-correlation potential is treated by the Gradient Generalization Approximation (GGA) and the recently proposed by Tran and Blaha the modified Becke-Johnson potential (TB-mBJ) which successfully corrects the band-gap problem found with GGA for a wide range of materials. The energetics of point defects is studied after
optimization of positions. Our results indicate that the ZrO antisite has the lowest formation energy and could thus be the acceptor defect responsible for the p-type conductivity of undoped cubic ZrO$_2$. However, based on our electronic structure obtained using the TB-mBJ method we have calculated various optical properties, including the complex index of refraction, absorption and transmittance coefficients. Furthermore, the electrical properties of each point defects have been investigated using the Boltzmann transport theory.

First-Principles Study of H$_x$WO$_3$ for Neuromorphic Computing Applications Konstantin Klyukin and Bilge Yildiz; Massachusetts Institute of Technology, United States

Neuromorphic computing paradigm holds much promise for applications that require big data analysis and artificial intelligence. The key components in neuromorphic circuits are devices that exhibit a history-dependent conductivity modulation, which could efficiently represent synaptic weights in artificial neural networks. However, an accurate and fast modulation of the conductance over a wide dynamic range is proved to be challenging. Recent experimental studies showed that a gradual change in electronic conductivity of WO$_3$ can be achieved by hydrogen doping, giving rise to the ability to have a large number of conduction states. However, the relationship between hydrogen concentration and electric conductance is not linear and WO$_3$ could undergo phase transitions upon hydrogenation. In this work, atomistic density functional theory calculation are used to establish the correlation between H content and H$_x$WO$_3$ conductivity and determine the rate-limiting steps of hydrogen intercalation process. This allows us to determine the most relevant hydrogen concentration range and guide experimental studies.

MT01.05.29
Real Space Renormalization Method for Atomic Scale Modeling of Thermoelectric Transport in Macroscopic Devices Chumin Wang and Vicenta Sanchez; Universidad Nacional Autonoma de Mexico, Mexico

Electronic transport has been traditionally studied by means of the reciprocal lattice method, which has successfully explained many physical properties of crystalline solids through the electronic band theory, such as the optical absorption and the thirty-orders-of-magnitude difference in the electrical resistivity between a good conductor and a typical insulator [1]. However, current electronic devices frequently contain multiple non-periodic structural interfaces and their presence avoids the use of reciprocal space. An alternative way to investigate the electron and phonon transport at atomic scale in macroscopic thermoelectric devices, which allow a direct conversion between thermal and electrical energies without harmful pollution, could be by using the real space renormalization method [2]. This method combined with the convolution theorem has the advantage of being numerically accurate and computationally efficient, i.e., able to address 10$^{24}$ non-periodically located atoms without introducing additional approximations [3]. It is well known that the metals are poor thermoelectric materials. In contrast, segmented metallic nanowires have a band structure by design, which combines with a properly placed chemical potential by applying a gate voltage could archive a good thermoelectric power [4,5]. In this work, we study thermoelectric properties of periodic and quasiperiodically segmented macroscopic-length nanowires with and without branches by means of the Kubo-Greenwood formula, in which tight-binding and Born models are respectively used for the calculation of electric and lattice thermal conductivities [6-8]. The results show a substantial growth of the thermoelectric figure of merit (ZT) induced by the long-range quasiperiodic disorder, because it diminishes the thermal conduction of long wavelength acoustic phonons being such phonons usually not altered by local defects neither impurities [9].

This work has been partially supported by UNAM-IN106317, UNAM-IN115519 and CONACyT-252943. Computations were performed at Miztli of DGTIC, UNAM.

Improved understanding of aqueous solutions at charged graphitic interfaces is critical for designing new carbon-based materials for energy storage and water desalination. However, many mechanistic details of the interfacial interactions remain unclear, including how interfacial structure and response are dictated by intrinsic properties of solvated ions under applied voltage. This knowledge gap is partly related to the challenge in simulating aqueous interfaces in the presence of a bias potential. Here, we combine a newly developed hybrid first-principles/continuum simulations with electrochemical measurements to investigate adsorption of several alkali-metal cations at the interface with charged graphene and within graphene slit-pores. We confirm that adsorption energy increases with ionic radius, while being highly dependent on pore size under confinement conditions. In addition, in contrast with conventional electrochemical models, we find that interfacial charge transfer contributes non-negligibly to this interaction and can be further enhanced by confinement. Overall, the measured interfacial capacitance trends result from a complex interplay between voltage, confinement, and specific ion effects—including ion hydration and degree of charge transfer. The results provide broad implications for optimizing electrochemical interfaces for energy storage and water desalination.

Effect of Surface Defects on Field-Induced Hot-Carrier Chemistry in Dielectric Polymers

Subodh C. Tiwari1, Hiroyuki Kumazoe2, Thomas Linker1, Rampi Ramprasad1, Rajiv Kalia1, Aiichiro Nakano1, Fuyuki Shimojo2 and Priya Vashishta1; 1University of Southern California, United States; 2Kumamoto University, Japan

Performance of dielectric polymers under high electric field is limited by the electrical breakdown, which is commonly understood as an avalanche of processes such as carrier multiplication and defect generation, triggered by field-accelerated hot electrons and holes. We model the hot-carriers transport in dielectric polymer, Polyethylene, with excited-state quantum molecular dynamics simulations in presence of electric field, which reveal multiple microscopic processes induced by hot electrons and holes under an electric field ranging between 100 and 1200 MV/m. We found that electronic-excitation energy is rapidly dissipated due to strong electron-phonon scattering. This, in turn, creates other electron-hole pairs to cause carrier multiplication. The key chemical damage occurs due to localization of holes of the surface of slabm which weaken carbon-carbon bonds on the surface. We will also discuss the effects of field strength and pre-existing surface defects (e.g., –COOH and –OH) on the field-induced hot-carrier dynamics and chemistry. Such quantitative information can be incorporated into first principles-informed, predictive modeling of dielectric breakdown.

This work was supported by the Office of Naval Research through a Multi-University Research Initiative (MURI) grant N00014-17-1-2656. The computations were carried out at the Center for High Performance Computing of the University of Southern California.

Towards Predictive Design of Bio/Nano Interfaces of Self-Assembled Peptides on Single Atomic Layer Materials

Siddharth S. Rath, Tatum G. Hennig, Pedro Fisher-Marques, Nitya K. Kumar, Tyler D. Jorgenson, David Starkebaum, Rene Overney and Mehmet Sarikaya; University of Washington, United States

Spontaneous self-organization of solid binding peptides on single layer atomic materials (SAP/SLAM) offers a great potential in exploiting these systems for bioelectronic and biosensing applications. The molecular interaction at the...
bio/nano soft interface between the peptide and the solid material is dependent on the conformations of the peptides and the surrounding conditions such as pH and temperature that affect the molecular structures, conformations, binding, and self-assembly in a myriad of ways. Although molecular dynamics has been used to study protein folding problems, here we demonstrate a closed-loop data pipeline molecular-dynamics implementation in SAP/SLAM systems. We perform molecular dynamics simulation on a wild type peptide, obtained from directed evolution experiments, that self-assembles on graphene at neutral pH and room temperature. Several mutants of the WT peptide are used to investigate whether they display spontaneous self-assembly under different pH and temperatures. Principal components analysis is paired with gaussian mixture model clustering to obtain full-peptide conformation propensities and automated analysis is done to obtain information about the conformations at different processing conditions on graphene and in aqueous solution. We show that while the WT peptide assembles on graphene at neutral pH and room temperature, the charge-neutral mutant assemblies under a wide range of pH (3.0 < pH < 9.0) and has a highly similar conformations over the range of pH conditions. Similarly, the tyrosine to tryptophan mutant assemblies at higher temperatures with a clear change in conformations from that of low temperature conditions. Knowing conformations of peptides and how the mutants affect conformation at different conditions is crucial in understanding the molecular footprint of the peptide on the surface. The knowledge of soft bio/nano interface structure will facilitate DFT calculations downstream to understand effect of self-assembly on the band structure changes happening in the SAP/SLAM systems. These studies eventually will lead to the predictive atomistic algorithms design of unique bio/nano systems defined by genetically selected peptides and single atomic layers materials towards biosensors, bioelectronics and biomolecular fuel cells. As part of the Materials Genome Initiative, the research is supported by NSF-DMREF program through the grant DMR-1629071.

MT01.05.34
Oxidation State and Coordination of Cu-Dimers in Cu-ssz-13—A First-Principles Study Unni Engedahl, Henrik Grönbeck and Anders Hellman; Chalmers University of Technology, Sweden

Direct methane-to-methanol conversion, which enables transformation of gas-phase methane to liquid methanol under mild conditions, is considered a dream reaction. At present the reaction is often realised via a three-step cycle; an activation phase, a reaction phase, and finally an extraction phase. Copper ion-exchanged zeolites have been suggested as promising catalysts for this reaction, although the nature of the actives sites is still under debate. Here we examine, using ab-initio molecular dynamics and first-principles thermodynamics, oxidation state and coordination of Cu-dimers inside the chabazite structure Cu-SSZ-13 under relevant experimental conditions. At room temperature, the formation energy of the Cu-dimers shows a multitude of Cu2(HxOy) clusters being exergonic. However, at the higher temperatures of the relevant reaction conditions only Cu2O and Cu2(OH) remain as thermodynamically stable structures. In the three step cycle, these are thus identified as the relevant structures for the activation and extraction phase, respectively.

There’s Room in the Middle—Nanocluster Coordination as an Approach to Mesoscale Modeling Forrest Kaatz1 and Adhemar Bultheel2; 1Mesalands Community College, United States; 2KU Leuven, Belgium

The mesoscale connects the molecular and atomic to the bulk. This size regime has posed a conundrum for modeling, as it is outside the realm of density functional theory (DFT) and molecular dynamics (MD) may not be appropriate. We use a chemical graph theory approach and compute the adjacency matrix for the clusters. This leads to identification of the coordination of each site. We demonstrate mesoscale relationships for the magic formulas of clusters, the radial distribution function (RDF) and nanocalysis. The number of bonds, atoms, and coordination numbers exhibit magic number character versus the number of shells, n, as the size of the clusters increases. Next, we use gold nanoclusters as model systems to generate their corresponding RDFs. The integrated intensity of the first peak in the RDF is related to magic formulas for the number of bonds (neighbors) and the number of atoms, as a function of n. Each unique cluster type and size has a structural fingerprint in its corresponding RDF. Lastly, the coordination style method is key to studying nanocalysis and creating a mesoscale model free of arbitrary parameters for sizes ~ 3 nm < D < 100 nm. We apply DFT, informational statistical mechanics, and thermodynamics to complete the model. This provides a theoretical scheme to determine the size and shape dependence of the entropy and enthalpy of nanocluster-adsorbate systems. We present examples from the literature, where others model cluster properties such as melting temperatures, cohesive energy, magnetic moments, Curie temperature, and the melting entropy and enthalpy using coordination numbers. We summarize the potential of these techniques to reach any mesoscale size, using magic formulas.

Vibrationally Accurate Interatomic Potentials Andrew D. Rohskopf and Asegun Henry; Massachusetts Institute of Technology, United States

Molecular dynamics (MD) simulations provide a general technique to study thermal vibrations/phonons and their contributions to thermal transport. However, despite the widespread usage of MD to study phonons, direct comparisons between experiments and simulations are often associated with low fidelity, due to a lack of accurate interatomic potentials (IPs). This issue therefore imposes a major barrier to utilizing MD for studying thermal transport and deriving new physically meaningful insights. Towards solving this problem, we present a new approach to making EIPs specifically optimized for accurately describing phonons and thermal vibrations. The approach enables nearly exact reproduction of ab initio phonon dispersion relations (i.e., < 1%) error), along with accurate forces and thermal conductivity (i.e., < 10% error), with low computational expense like that of traditional EIPs.

Structures and Transformations of Metal Nanocrystals Kristen A. Fichthorn; The Pennsylvania State University, United States

A significant challenge in the development of functional nanomaterials is understanding the growth of colloidal metal nanocrystals. One bottleneck is understanding the evolution of nanocrystal seeds from nuclei. Seeds play a critical role in nanostructure formation, as the shape of the seed often determines the final nanocrystal shape. The interplay between structural transitions, deposition, and etching as seeds grow from nuclei leads to a myriad of metastable nanocrystal morphologies. To understand this interplay and its ramifications for seed structure, we conducted replica-exchange molecular dynamics simulations to quantify how the structures Ag and Cu seeds evolve in vacuum, as well as in a solution environment, with increasing size and as a function of temperature. Using common-neighbor analysis, we create barcodes to describe the distribution of nanocrystal structures as a function of size and temperature. We obtain energy barriers for the transformations of selected seeds from one shape to another. Several critical branching sizes emerge, at which intervention by solution processing may influence the final nanocrystal shape. Knowledge from these studies will enable the development of strategic synthesis protocols to achieve selective nanostructure yields.

8:30 AM MT01.06.02
Multiscale Modeling of Phase Transformation Microstructures Ananya Renuka Balakrishna; University of Minnesota, United States

Phase transformation microstructures have an abrupt change in lattice geometry that significantly affects material properties. For example, a cubic to tetragonal lattice transformation induces polarization in ferroelectric materials, and a similar lattice transformation during charging/discharging of battery materials induces large volume changes. Current material models describe phase transformation phenomena at different length and time scales. On the one hand, continuum methods such as phase-field models describe microstructural evolution by typically homogenizing the crystallographic texture of the material, and do not model individual lattice transformations. On the other hand, atomistic models such as the first principle methods and molecular dynamics models provide atomistic insights into lattice transformation, but are not applicable to the length scale and time scales for microstructural evolution. In my talk, I will introduce a novel theoretical framework that couples a Cahn-Hilliard model (continuum scale) with a phase-field crystal model (atomistic scale) to describe phase transformation microstructures in crystalline materials. I will show how this modeling technique can be applied to engineer crystallographic features of phase transformation materials (such as battery materials, ferroelectrics, ferromagnets) to enhance their material properties.
and lifespans.

**Atomistic Analysis of Grain Boundary Segregation in Polycrystals** Malik Wagih and Christopher A. Schuh; Massachusetts Institute of Technology, United States

Nanocrystalline alloys can be designed to be stable by *intentional grain boundary segregation*: by using alloying elements that will segregate to the boundaries and lower the grain boundary energy, the driving force for grain growth can be attenuated or even eliminated. The main thermodynamic data necessary for predicting stability in nanocrystalline alloys is the segregation strength of the alloying element, quantified by the segregation energy. Segregation energy is usually calculated precisely only for specific high-symmetry boundaries that are not representative of the spectrum of states in a true polycrystal, or estimated in a semi-empirical manner for some “average” grain boundary assumed typical of a polycrystal. In this work, we outline the thermodynamic and computational framework to address equilibrium grain boundary segregation in full polycrystalline grain boundary networks, by developing a variety of atomistic tools. Specifically, we aim to understand the full spectrum of segregation energies, as well as the role of solute-solute interactions at the boundary. Our efforts to apply these methods across many alloy systems will also be addressed.

9:15 AM MT01.06.04
**Investigating Complex Grain Boundary with Solute Segregation via a Combination of Genetic Algorithm and Grand Carnonical Ensemble** Mingfei Zhang, Yong-Jie Hu, Chaoming Yang and Liang Qi; University of Michigan, United States

The interactions between solute atoms and crystalline defects such as dislocations and grain boundaries play an essential role in determining physical, chemical and mechanical properties of solid-solution alloys. In recent years, the ability to predict solute segregation at high symmetry grain boundaries from first principles have been widely studied. However, previous algorithms have mainly focused on the simple grain boundary structures for dilute solute cases due to the costly computation power needed by density functional theory (DFT). Here, we present a general atomistic approach to optimize the structures and simulate solute segregation trends of grain boundaries in multiple component systems by the combination of a highly efficient genetic algorithm and the grand canonical ensemble, in which components are not restricted to dilute or stoichiometric cases. Different chemical potential can be used as input for creating different reservoirs for the grain boundary phases. In our study, thousands-atom grain boundary systems will be investigated by well-established empirical potentials (MEAM or EAM potentials) for Mg-based alloy systems, like Mg-Y or Mg-Zn, which are potential candidates for lightweight structural components as a result of their low density and high specific strength. Because of the complicated potential energy landscapes (PEL) coming from both geometric and occupational freedom, we will either average a good amount of small configurations by Boltzmann statistics based on their energy distributions for patterned segregation systems or use a large supercell to study cluster segregation systems across the grain boundaries. Final structures will then be used to investigate the effect of solute on mechanical behaviors of grain boundary systems.

9:30 AM *MT01.06.05
**Three Stages of Work Hardening in Full Atomistic Details—No Kidding** Luis Zepeda-Ruiz1, Alexander Stukowski2, Nicolas Bertin1, Tomas Oppelstrup1, Nathan Barton1, Rodrigo Freitas3,4 and Vasily V. Bulatov1; 1Lawrence Livermore National Laboratory, United States; 2Darmstadt University, Germany; 3Stanford University, United States; 4University of California, Berkeley, United States

We will present ultra-large scale Molecular Dynamics simulations of aluminum single crystals subjected to uniaxial tension. We observe that appearance (or not) of three-stage hardening depends on the initial crystallographic orientation of the straining axis and results from crystal rotation. In its turn, crystal rotation is a direct consequence of co-axiality forced on the specimen by the testing machine, the view widely accepted in the phenomenological Crystal Plasticity community since the classical studies of Schmid predating dislocations. Remarkably, stress-strain behaviors, slip system activity and crystal rotations observed in our high-rate MD simulations are in an exact qualitative agreement with quasistatic experiments suggesting that physics of crystal plasticity scales, i.e. dislocation mechanisms defining crystal plasticity response remain the same over twelve decades of straining rates.

Uncertainty-Driven Construction of Markov Models—Finding and Evaluating Transition Rates Thomas D. Swinburne1, Danny Perez2 and Mihai-Cosmin Marinica3; 1CNRS / CINAM, France; 2Los Alamos National Laboratory, United States; 3CEA Saclay, France

When the dynamics of a high dimensional system is characterized by long periods in metastable energy basins with rare interbasin transition, a rigorous coarse grained representation is a Markov chain with suitable transition rates. If well constructed, such models can provide a valuable, robust connection between atomistic and mesoscale material models. However, with finite resources sampling is always incomplete, which if uncontrolled can have catastrophic consequences on the model validity. Furthermore, commonly used harmonic rate theories can fail at surprisingly low homologous temperatures. I will talk about recent work that uses a robust Poisson-Bayes estimator of sampling completeness to autonomously manage and optimize massively parallel sampling of defective crystal energy landscapes[1] and a novel path-based scheme to evaluate anharmonic contributions to transition state theory predictions of reaction rates[2].

Morphological Transitions in Cu Islands Grown on Strained Cu(100) Jacques G. Amar, Ehsan H. Sabbar, Indiras Khatri and Yunsic Shim; University of Toledo, United States

A variety of experiments on submonolayer metal heteroepitaxial growth have demonstrated that the combined effects of strain and bonding can lead to interesting shape transitions and/or defect formation, although the corresponding mechanisms and/or defect structure are not well understood. In order to better understand the underlying mechanisms as well as separate out the effects of strain from “chemical” effects, we have carried out temperature-accelerated dynamics simulations [1] of a simple model system corresponding to the submonolayer growth of Cu on a biaxially strained Cu(100) substrate at 200 K. In the case of 2% compressive strain we find - as was previously found for Cu/Ni(100) growth [2] – that multi-atom “pop-out” events which create open step-edges are enhanced, leading to the formation of blobby islands with a mixture of open and closed step-edges. In contrast, for larger (4%) compressive strain, the presence of submonolayer islands is found to promote the formation of substrate vacancies which eventually (once they come close to each other near an island) leads to the formation of stacking faults in both the substrate and island. The kinetics of this transition is characterized by a large activation barrier along with a prefactor which is tens of orders of magnitude larger than is typical of atomic processes in fcc metals. A theoretical estimate for the prefactor based on an estimate of the change in entropy in going from the initial state to the transition state is found to be in good agreement with our simulation results. In contrast, the prefactor for the reverse transition is much smaller, leading to a negligible rate at 200 K. Finally, we consider the case of 8% tensile strain for which the dominant monomer diffusion mechanism corresponds to exchange with the underlying substrate. In this case a shape transition is observed with increasing island size from isotropic to strongly anisotropic islands. A theoretical estimate of the critical size for the shape transition based on recent theoretical results [3] will be presented which is in good agreement with our simulations.

11:15 AM MT01.06.09
A Simple Local Expression for the Prefactor in Transition State Theory Sara Kadkhodaei1 and Axel van de Walle2; 1University of Illinois at Chicago, United States; 2Brown University, United States

We present a simple and accurate computational technique to determine the frequency prefactor in harmonic transition state theory without necessitating full phonon density of states (DOS) calculations. The atoms in the system are partitioned into an “active region,” where the kinetic process takes place, and an “environment”
surrounding the active region. It is shown that the prefactor can be obtained by a partial phonon DOS calculation of the active region with a simple correction term accounting for the environment, under reasonable assumptions regarding atomic interactions. This model enables the use of plane wave density function theory calculations for diffusion description in large systems where the full Hessian calculation becomes intractable. Convergence with respect to the size of the active region is investigated for different systems and different diffusion processes, as well as the reduction in computational costs when compared to full phonon DOS calculation. Additionally, we introduce an open source implementation of the algorithm that can be added as an extension to Large-scale Atomic/Molecular Massively Parallel Simulator software.

SESSION MT01.07: Coarse Graining Methods

1:30 PM *MT01.07.00
Next Generation Extended Lagrangian First Principles Molecular Dynamics Anders M. Niklasson; Los Alamos National Laboratory, United States

Extended Lagrangian Born-Oppenheimer molecular dynamics enables stable simulations without relying on an expensive self-consistent field optimization prior to the force evaluations. The formulation is different from extended Lagrangian Car-Parrinello molecular dynamics and samples the potential energy surface with an accuracy that is of 4th-order in the integration time step instead of 2nd-order. No fictitious mass parameters need to be tuned and the integration time steps is limited only by the integration time step of regular Born-Oppenheimer molecular dynamics. However, the formalism includes a particular metric kernel that needs to be approximated. For most systems a simple scaled delta function is sufficient, but for more challenging materials a more accurate approximation is needed. I will present some recently developed low-rank kernel approximations using Krylov subspace expansions in combination with preconditioners that allow stable (SCF-free) simulations even of highly challenging systems including chemical reactions.

2:00 PM *MT01.07.01
Phase Field Crystal Modeling of Electromigration in Metals Nikolas Provatas and Nan Wang; McGill University, Canada

This talk will present the results of a recent phase field crystal modelling study of electromigration. The newly formulated model successfully captures some well-known electromigration induced phenomenologies like the Blech effect and mean time to failure, as well as the failure mechanisms in interconnects at atomic scale through formation of voids at triple junctions and surface steps motion. We also discuss extensions and future directions of coupling this approach with first principles calculations.

SESSION MT01.08: Rough Energy Landscapes
Session Chairs: David Aristoff and Thomas Swinburne

Sampling on Rough Energy Landscapes Gideon Simpson¹ and Petr Plechac²; ¹Drexel University, United States; ²University of Delaware, United States
Rough energy landscapes appear in a variety of applications including disordered media and soft matter. In this work, we examine challenges to sampling from Boltzmann distributions associated with rough energy landscapes. Here, the roughness will correspond to highly oscillatory, but bounded, perturbations of a fundamentally smooth landscape. Through a combination of numerical experiments and asymptotic analysis, we demonstrate that the performance of Metropolis Adjusted Langevin Algorithm can be severely attenuated as the roughness increases. In contrast, we prove, rigorously, that Random Walk Metropolis is insensitive to such roughness. We also formulate two alternative sampling strategies that incorporate large scale features of the energy landscape, while resisting the impact of roughness; these also outperform Random Walk Metropolis. Numerical experiments on these landscapes are presented that confirm our predictions. Open analysis questions and numerical challenges are also highlighted.

3:45 PM MT01.08.02
**Strengthening of Al-Cu Alloys by Guinier-Preston Zones—Predictions from Atomistic Simulations**
Gustavo Esteban-Manzanares¹, Bárbara Bellón¹, Ioannis Papadimitriou¹, Enrique Martínez² and Javier Llorca¹,³; ¹IMDEA Materials Institute, Spain; ²Los Alamos National Laboratory, United States; ³Technical University of Madrid, Spain

A multiscale modelling strategy based on molecular statics and molecular dynamics simulations in combination with transition state theory has been developed to determine the flow stress of Al-Cu alloy containing Guinier-Preston zones as a function of temperature. The flow stress is assumed to depend on two contributions. The athermal contribution is given by the Taylor model and only depends on the elastic constants of the Al alloy, the dislocation density and the Burgers vector. The thermal contribution can be calculated following transition state theory from the obstacle strength and the free energy barrier.

Molecular statics simulations in combination with thermal annealing was used to determine the obstacle strength (the stress necessary to overcome the obstacle in the absence of thermal energy) for edge dislocations interacting with Guinier-Preston zones in two different orientations (0 and 60 degrees). It was found that the introduction of thermal annealing after each strain increment was critical to avoid the locking of the simulations in local minima which leads to an overestimation of the obstacle strength and to unrealistic interaction mechanisms between the dislocation and the Guinier-Preston zone in both orientations. The rate at which dislocations overcome the Guinier-Preston zone was determined as a function of the applied strain and temperature from molecular dynamics simulations. This information was used to determine the thermodynamic quantities that control this process, namely the activation energy, the activation entropy and the activation volume for both dislocation/Guinier-Preston zone orientations.

The predictions of the model were compared with experimental data in the literature as well as new data obtained by means of micropillar compression tests in an Al - 4 wt. % Cu alloy naturally aged at ambient temperature to obtain a homogenous distribution of Guinier-Preston zones. They were in good agreement at ambient temperature although modelling results overestimated the flow stress at low temperature. Overall, this talk presents a coherent multiscale methodology to determine the effect of Guinier-Preston zones in the flow stress of Al alloys by means of atomistic simulations.

**Modelling the Solidification of Glasses**
Steven D. Kenny, Jamieson K. Christie and Ying Zhou; Loughborough University, United Kingdom

Glass is used in a wide variety of fields, from nuclear waste encapsulation to biomedicine. Computer simulation is often used to understand the connection between glass composition, structure and properties. Existing modelling typically uses Molecular Dynamics approaches to simulate the cooling of glass and these simulations can only simulate cooling rates down to about $10^{9}$K/s. This is several orders of magnitude faster than experimental cooling rates even for the most rapidly quenched glasses.

The cooling rate of the glass is known to affect the structure of the glass including the connectivity of the 3D structure and how ions are incorporated into the glass. The gap between experimental and modelling cooling rates thus make it difficult to compare results and to gain insight into the role of glass composition on its properties.

In this work we will discuss using a parSplice approach to model the cooling of glasses. We will discuss the
differences observed in the glass structure when lower cooling rates are explored through this approach and the potential for the application of this methodology to other systems. The efficiency of the methodology and the limits this places on its applicability will also be discussed.

4:30 PM *MT01.08.04
Configuration-Based Energy Minimization of 2D Incommensurate Heterostructures Mitchell Luskin; University of Minnesota, United States

We derive and analyze a novel approach for modeling and computing the mechanical relaxation of incommensurate 2D heterostructures. Our approach parametrizes the relaxation pattern by the compact local configuration space rather than real space, thus bypassing the need for the standard supercell approximation and giving a true aperiodic atomistic configuration. Our model extends the computationally accessible regime of weakly coupled bilayers with similar orientations or lattice spacing, for example materials with a small relative twist where the widely studied large-scale moire patterns arise. Our model uses a generalized stacking fault energy for interlayer interactions and makes possible the simulation of the relaxation of multi-layer heterostructures for which a planar moire pattern does not exist.

SESSION MT01.09: Accelerated Molecular Dynamics

8:30 AM *MT01.09.01
Mathematical Foundations of Accelerated Molecular Dynamics Methods Tony Lelièvre1,2; 1Ecole des Ponts, France; 2Imperial College London, United Kingdom

We will present recent works which aim at understanding the mathematical foundations of first order kinetics and the harmonic transition state theory. The cornerstone of the analysis is the notion of quasi stationary distribution. This analysis sheds a new light on the accelerated molecular dynamics algorithms which have been proposed by Arthur Voter and co-workers in the late nineties. It also opens the route to generalizations of the original algorithms, in particular of the Parallel Replica algorithm.

References:

9:00 AM *MT01.09.02
Long-Time Dynamics Without Predefined States—A Data-Driven Parallel Replica Dynamics Approach Danny Perez; Los Alamos National Laboratory, United States

One of the most stringent limitation of conventional molecular dynamics is the extremely short timescales that are amenable to direct simulation, even when massively-parallel resources are invested in the calculation. The Parallel Replica Dynamics (ParRep) method, introduced by A. Voter, unlocks the potential of parallel architectures by allowing for an effective parallelization of the problem in the time-domain. However, in order to benefit from this extension of timescales, practitioners of ParRep need first address two issues: i) the identification of metastable sets on the energy landscape of the system, and ii) the accurate estimation of the time required to relax to the quasi-stationary distribution in each set. Both these problems can be readily addressed on smooth energy landscapes, but become extremely difficult for complex systems, where considerable prior knowledge often needs to be injected in the construction of the metastable states; a process which, even then, remains error prone.
We show how both these problems can be tackled simultaneously using data analysis techniques derived from the stochastic Koopman operator formalism. In this new method, states are locally defined and characterized on-the-fly by analyzing the trajectories produced as part of the ParRep simulation itself. To do so, the algorithm requires only the specification of a (potentially large) number of atomistic descriptors in terms of which the states will be implicitly defined. We demonstrate the new approach through long-time simulations of biomolecules and of soft defects in metals.

9:30 AM MT01.09.03  
Shape Fluctuation of Metallic Nanoclusters—Observations from Long-Timescale Simulations  
Rao Huang¹ and Danny Perez²; ¹Xiamen University, China; ²Los Alamos National Laboratory, United States

Metallic nanoclusters are functional materials with many applications owing to their unique physical and chemical properties, which are sensitively controlled by their shapes and structures. An in-depth understanding of their morphology stability is therefore of crucial importance. It has been well documented by transmission electron microscopy (TEM) studies that metallic nanoclusters can interconvert between different isomers. However, the relevant mechanisms remain elusive because the timescales of such shape fluctuations are too short to be resolved experimentally and yet too long for conventional atomistic simulations. By employing a recently introduced Accelerated Molecular Dynamics method, Parallel Trajectory Splicing, we present simulations that reached timescales of milliseconds and thus provide a clear description of the dynamic process of the experimentally observed shape fluctuation in metallic nanoclusters. We observe transformations back and forth between face-centered-cubic (fcc) and structures with five-fold symmetry (decahedron or icosahedron). These transitions occur following either by a partial-dislocation-mediated twinning mechanism or by a surface-reconstruction driven process. The identified pathway is in remarkable agreement with the existing microscopy results and serves as further evidence that shape fluctuation can occur directly through thermal activation, without involving melting or other external factors.

9:45 AM MT01.09.04  
Parallel Trajectory Splicing for the Exascale  
Andrew Garmon¹,² and Danny Perez²; ¹Clemson University, United States; ²Los Alamos National Laboratory, United States

A range of specialized Molecular Dynamics (MD) methods have been developed in order to overcome the challenge of reaching longer timescales in systems that evolve through sequences of rare events. In this talk, we consider Parallel Trajectory Splicing (ParSplice) which works by generating large number of trajectory segments in parallel in such a way that they can later be assembled into a single statistically correct state-to-state trajectory, enabling parallel speedups up to the number of parallel workers. In practice, the ability for ParSplice to scale significantly improves when it is possible to predict where the trajectory will be found in the future. With this insight in mind, we develop a maximum likelihood transition model that is updated on the fly and make use of an uncertainty-driven estimator to approximate the optimal distribution of trajectory segments to be generated next.

This work was supported by the U.S. Department of Energy Office of Science Graduate Student Research (SCGSR) program, administered by the Oak Ridge Institute for Science and Education under DE SC0014664 and by the Exascale Computing Project (17-SC-20-SC).

10:30 AM MT01.09.05  
Accelerated Molecular Dynamics Simulations of Dislocation Climb in Nickel  
Lauren T. Smith¹,², Anne Marie Z. Tan³,², Thomas D. Swinburne⁴,³, Danny Perez² and Dallas R. Trinkle²; ¹University of California, Santa Barbara, United States; ²University of Illinois at Urbana-Champaign, United States; ³University of Florida, United States; ⁴CNRS, CINAM, France; ²Los Alamos National Laboratory, United States

The mechanical behavior of materials operating under high temperatures is strongly influenced by creep mechanisms such as dislocation climb which are controlled by the diffusion of vacancies. However, atomistic simulations of these mechanisms have traditionally been impractical due to the long time scales required. To
overcome these time scale challenges, we use Parallel Trajectory Splicing (ParSplice), an accelerated molecular
dynamics method, to simulate dislocation climb in nickel. We focus on modeling the activity of a vacancy near a jog
on an edge dislocation in order to observe vacancy pipe diffusion and vacancy absorption at the jog. Using
ParSplice, we are able to achieve a total simulation time of over 4 μs for a system containing approximately 16,000
atoms, during which over 2000 vacancy diffusion and absorption events occurred. Based on these results, we
estimate average rates for pipe diffusion and vacancy absorption into the jog; results are in good agreement with
molecular static calculations.

Atomistic/Discrete-Dislocations/Continuum Coupling in 3D William A. Curtin¹, Max Hodapp² and Guillaume
Anciaux¹; ¹Ecole Polytechnique Federale Lausanne, Switzerland, Switzerland; ²Skolkovo Institute of Science and
Technology, Russian Federation

Capturing plasticity at realistic dislocation densities with high configurational complexity requires a continuum-
level discrete dislocation dynamics (DDD) description. However, many features controlling dislocation motion are
inherently atomistic, such as the interaction of dislocations with solutes, precipitates, cracks, and interfaces. Here,
we review a recent multiscale concurrent coupled atomistic/discrete-dislocation model in 3d that couples the DDD
code Paradis and the MD code LAMMPS [1]. The need for precise matching of continuum dislocation properties to
atomistic dislocation properties is demonstrated, and issues in making this connection are also discussed. A full
coupling of atomistic and continuum domains requires solution of an elasticity problem in the continuum domain.
Standard methods such as FE are computationally infeasible. We thus present a Greens function implementation
where H-matrices and a Newton-Krylov solution scheme are employed to achieve computational efficiency with
controllable accuracy [2].

Multi-Scale Modeling of Structural and Heat Transport Properties of 2D Materials Tapio Ala-Nissila¹,²; ¹Aalto
University, Finland; ²Loughborough University, United Kingdom

Novel 2D materials have unusual properties, many of which are coupled to their large scale structural properties.
Microscopic modeling of structure and transport is a formidable challenge due to a wide span of length and time
scales involved. I will review recent progress in structural multiscale modeling of 2D materials and thin
heteroepitaxial overlayers [1], and graphene and h-BN [2,3] in particular, based on the Phase Field Crystal (PFC)
model combined with Molecular Dynamics and Quantum Density Functional Theory. The PFC model allows one to
reach diffusive time scales at the atomic scale, which facilitates quantitative characterisation of domain walls,
dislocations, grain boundaries, and strain-driven self-organisation up to micron length scales. I will discuss how PFC
generated multigrain systems can be further used for Molecular Dynamics simulations of thermal conduction in
selected 2D materials [3,4].

Modelling Native Defects in Transparent Conducting Oxides Using the hybrid QM/MM Embedded Cluster Technique

Qing Hou, John Buckeridge, Alexey A. Sokol, Jingcheng Guan and Richard Catlow; University College London, United Kingdom

For n-type transparent conducting oxide (TCO) materials such as SnO₂, In₂O₃ and ZnO, native defects play a key role in electronic conductivity. Depending on their electronic structure, energetics and geometries, defects can act as donors, resulting in intrinsic n-type conductivity, or can compensate extrinsic donors such as Sn in In₂O₃. Predictive modelling of the properties of defects in such systems requires a detailed description of the dielectric response of the host material, which can be difficult to obtain using standard supercell techniques. Here, we employ the hybrid quantum mechanical/molecular mechanical (QM/MM) embedded cluster method, a multi-region approach that allows us to model defects at the true dilute limit, with polarisation effects described in an accurate and consistent manner. Moreover, we develop techniques to analyse the energetic balance between electrons bound to donors in diffuse and compact states, a difficult problem regardless of the model employed. We benchmark our results where possible and find good agreement with experiment for a variety of defect-related properties.

Systematic Saddle Point Searches from a Given Initial State Minimum

Hannes Jonsson; University of Iceland, Iceland

In long time scale simulations based on the adaptive kinetic Monte Carlo (AKMC) method (sometimes referred to as on-the-fly KMC, or self-learning KMC) the essential task is to find all relevant, low lying first order saddle points on the energy ridge surrounding a given initial state minimum without preconceived notion of the possible final states. In current implementations of the method, several random initial displacements from the minimum are used as starting points for climbs up the energy surface to sample the saddle points. While schemes have been developed to improve the sampling and reduce the occurrence of reconvergence on known saddle points [1], a significant concern are saddle points that are hard to reach for example when the basin of attraction does not reach the boundary of the convex region around the local minimum, and the waisted computational effort when the same saddle point is found repeatedly. A systematic approach where a scalar quantity based on semi-local information about the energy surface is used to move from a local minimum along a linear path with bifurcation points so as to map out all first order saddle points will be presented [2]. Also, the use of Gaussian process regression in this context to reduce the number of energy and atomic force evaluations will be discussed, analogous to what has already been reported for nudged elastic band calculations [3].

Identification and Comparison of Interstitial Defect Configurations in Alumina

Alina Kononov, Ethan Shapera and Andre Schleife; University of Illinois at Urbana-Champ, United States

Aluminum is well-known for its exceptional resistance to high-temperature corrosion via oxidation. This is attributed to the formation of a scale, i.e. a thin oxide film on the surface. This protective layer acts as a barrier to diffusion and prevents further deterioration. However, despite tremendous efforts, the mechanisms that underlie the slow diffusion through the scale are poorly understood. Unfortunately, this limits the development of highly
corrosion resistant materials that are required, for instance, in the high-temperature environments encountered in the petrol industry.

In this work, we lay the foundation for further computational research on diffusivity of defects by computing formation energies of point defects in aluminum oxide from first-principles. We specifically explore the influence of exchange and correlation by comparing standard density functional theory to hybrid-functional results and we also study the influence of spin polarization. This allows us to confirm previous studies showing that a peroxide split interstitial defect is energetically favorable to the traditionally considered, quasi-atomic oxygen interstitial defect at the octahedral site. Interestingly, we also find such a displaced ground-state configuration for aluminum interstitials. In order to efficiently sample possible starting atomic geometries for these as well as extrinsic interstitials, we explore using Bayesian analysis. In our work, we also investigate the viability of octahedral configurations for extrinsic interstitials and we examine the impact of defect charge state on the ground-state geometry. These so far overlooked lower-energy geometries possibly point at the possibility of a more general mechanism in this material for interstitial formation and can, hence, influence defect migration paths and predictions for diffusion properties.

Fast First-Passage Algorithms for Reversible Markov Processes on a Lattice—Application to Cluster Diffusion and Aggregation in α-Iron Manuel Athenes1, Savneet Kaur1, Gilles Adjanor2 and Thomas Jourdan1;
1CEA, France; 2EDF, France

Transport properties of point defects are crucial physical quantities governing the microstructural evolution of metals and alloys. Characterizing the kinetics of defects in presence of energetic and entropic traps is notoriously difficult due to the emergence of well separated time scales in the simulations. We herein describe fast first-passage algorithms based on the theory of absorbing Markov chains assuming that defects undergo reversible diffusion. We show that the absorbing transition rate matrix can be transformed into a symmetric definite-positive matrix and that this similarity transformations considerably simplifies the computational tasks. The efficiency of the approach is demonstrated in simulations of diffusion and aggregation of Copper and Manganese clusters in α-iron. Substantial accelerations are achieved by directly sampling the important rare events contributing to atomic transport.

Generalized Numerical Solutions for Stochastic Dynamics of First-Order Phase Transformations Nicholas Julian1,2, Enrique Martinez2 and Jaime Marian1; 1University of California, Los Angeles, United States; 2Los Alamos National Laboratory, United States

Modeling physical systems as stochastic processes helps capture natural fluctuations and improves long-time accuracy. Yet, the physical processes which may be confidently formulated in terms of an easily computable stochastic process are limited to those which are driven exclusively by either rare events or Gaussian white noise. Additionally, the stochastic integration schemes used in the development and implementation of these algorithms have been traditionally based on solving the Itô and Stratonovich integrals, which do not preserve the chain rule for differentiation or the Newton-Leibniz integration rule when applied to Lévy processes driven by combined rare events and continuous-in-time Brownian motion, e.g. liquid-solid phase transformations. In this presentation we explore the consequences of solving the Marcus canonical integral, which preserves the aforementioned rules when applied to Lévy processes, to stochastic simulations of material phase transformations.

Systematic Development of Reliable Machine Learning Interatomic Models
Ellad B. Tadmor; University of Minnesota, United States

The recent development of machine learning interatomic models (IMs) provides a promising avenue to extend the scope of first principles methods to materials problems on larger length and time scales. Machine learning IMs interpolate a training set of density functional theory (DFT) calculations and can provide close to DFT accuracy at a fraction of the computational cost. A challenge is the inherent lack of transferability of machine learning IMs; their predictions "far" from the training set are suspect. Using 2D materials as a test system, we address this limitation in two ways: (1) we develop a hybrid IM that combines the known physics of long-range dispersion with a neural network (NN) to model short-range interactions for multilayer graphene systems; (2) we apply an NN dropout technique to assess the uncertainty in predictions of the IM to prevent its use outside its range of validity. These techniques along with tools for automated training have been implemented within a general-purpose fitting framework called KLFF (KIM-Based Learning-Integrated Fitting Framework). KLFF is an open source Python package compatible with the Knowledgebase of Interatomic Models (KIM) application programming interface (API) standard, allowing IMs fit with it and distributed through https://openkim.org to be used by a wide variety of simulation codes compatible with the KIM API.

An Initial Design-Based Deep Learning Framework for ReaxFF Force Field Training
Mert Y. Sengul1, Ying Hung2, Tirthankar Dasgupta2 and Adri van Duin1; 1The Pennsylvania State University, United States; 2Rutgers, The State University of New Jersey, United States

Atomistic level investigations are required for the discovery of novel material properties which, in turn, results in advancements in technology such as batteries, capacitors, etc. Most of the atomistic-scale modeling methods that have been developed to conduct these investigations are restricted to small systems due to associated computational costs. On the other hand, it is possible to simulate large atomistic systems using ReaxFF, which is a very reliable and transferable reactive force field concept used by a broad academic and industrial user community. In ReaxFF, inter and intra-atomic interactions are calculated by functionals that involve system-specific parameters. These parameters must be optimized for each materials system, a task requiring exploration of multi-dimensional parameter landscape to obtain a high level of accuracy. However, the current ReaxFF optimization method is a sequential search algorithm which is limited in terms of exploring a wider parameter space. Moreover, due to the consecutive nature of the method, the optimization algorithm is non-parallelizable. In this respect, this study develops an initial design-based machine learning (ML) framework to enable a fast and high-quality force field development to improve the ReaxFF optimization algorithm.

Initially, a Latin Hypercube Design (LHD) algorithm is used to explore the parameter landscape extensively. The LHD passes the information about explored regions to the ML method for model training. The ML method is composed of regression and classification models. A deep learning model finds the minimum discrepancy regions, while a classification model classifies the physically-feasible/unfeasible regions in parameter landscape. This ML method eliminates unfeasible regions, which originate from the unphysical atomistic interactions, and constructs a more comprehensive understanding of a physically meaningful parameter landscape. In addition, the developed framework is easily parallelizable; thus, it will significantly reduce the force field optimization time while increasing the quality by benefitting from ML. The performance of the framework will be evaluated by its application to systems with available force field parameter sets including 2D materials and alloys.

4:15 PM MT01.11.03
Estimating Machine Learning Uncertainty for Kinetic Monte Carlo Migration Barrier Regression
Jyri Kimari, Jussi Määttä, Viacheslav Bazaliy, Teemu Roos, Kai H. Nordlund and Flyura Djurabekova; University of Helsinki, Finland

Kinetic Monte Carlo (KMC) is the method of choice for studying diffusion in solid materials. The method is often limited in accuracy by the quality of the migration energy barriers used to describe the system of interest. Here is KMC's tradeoff between precision and computational cost - a more detailed description of the energy barriers will typically require either heavier precalculations, or resolving barriers on-the-fly.

Like in the realm of potential energy functions, machine learning (ML) offers a way to bridge the computational gap
in this problem also. We have expanded a KMC model for the Cu surface, earlier developed in our group, by employing ML for the purpose of avoiding some of the barrier calculations. Our most recent pursuit is for an active learning scheme, which as a first stepping stone requires the ability to estimate uncertainties of the predicted barrier values. For some ML methods, such as Gaussian process regression, this property comes out-of-the-box, while for others, like artificial neural networks, we have had to resort to more specialized tricks. In this talk, we present the progress we have made in estimating the uncertainty of various regression models, as well as the developing framework around the active learning scheme — when to trust the regressor during the KMC simulation, and when should the oracle be queried for more precise data.

4:30 PM MT01.11.04
Computational Study on the Dielectric Strength of the Crosslinked Polyethylene Using e-ReaxFF Reactive Force Field Dooman Akbarian, Dundar Yilmaz, Hunter Woodward, Jonathan Moore and Adri van Duin; 1The Pennsylvania State University, United States; 2The Dow Chemical Company, United States

Cross-linked Polyethylene (XLPE) has been recognized as an outstanding insulator for high-voltage power cables due to its favorable structural integrity at high temperature, lower moisture sensitivity, chemical resistance, and lower rates of failure due to aging. Dicumyl Peroxide (DCP) is the main PE crosslinking agent, however, DCP-initiated crosslinking leads to the formation of different byproducts such as cumyl alcohol, acetonitrile, methylvinylnitrene, water and methane that remain in the final product and may have adverse effects on cable function and its long-term properties. Previous studies stated that the byproducts such as cumyl alcohol (CA), acetonitrile (AN), α-methylstyrene and antioxidant additives can cause a space charge formation in the final product and affect electrical properties of the XLPE. Currently, our knowledge is limited about the effects of the byproducts on the properties of the final XLPE product. By understanding on how the crosslinking byproducts change the XLPE properties, improvements may be formulated relative to the conventional XLPE cable. In order to design and optimize the XLPE cables, it is crucial to obtain detailed, atomistic-scale insight of the XLPE chemistry since each and every byproduct in the XLPE affect differently to the polymer’s electrical properties, thus the effects of each of the byproducts should be investigated. Quantum Mechanic (QM) methods are considered the most accurate technique among atomistic simulation methods, however, due to high computational costs, these first-principles techniques can only be viable for relatively small length and short time scales events. The ReaxFF reactive force field method can model chemical reactions based on the bond order concept without the full expense of QM methods, and it has been successfully applied to a wide range of systems such as polymeric fibers, covalent, metallic, and metal oxide/hydride/carbide materials. e-ReaxFF method is an extension of the ReaxFF method with description of an explicit electron-like or hole-like particle. In this study, we used e-ReaxFF technique to investigate the role of XLPE byproducts, and processing variables on the dielectric strength of the PE. To achieve this, we developed an e-ReaxFF reactive force field verified against DFT data obtained for XLPE chemistry. Then, using this force field, we performed MD simulations to find the effects of different byproducts, temperature, density, the ratio of byproducts to PE on the dielectric strength of the PE.

4:45 PM MT01.11.05
Machine Learning Assisted Hybrid Reactive Molecular Dynamics Simulations Dundar E. Yilmaz, Karthik Ganesan, Muraleedharan Gopal, Chen Chen, Dooman Akbarian and Adri van Duin; The Pennsylvania State University, United States

Molecular dynamics (MD) simulations with Reactive force field (ReaxFF) provide valuable insight due to accurate description of chemistry of the material. This comes with a computational cost which limits size and time scale of the simulation. Non-reactive models, such as OPLS, may provide accurate description of the dynamics of the system without chemical reactions. Typically OPLS runs fifty times faster compared to ReaxFF. We developed a hybrid framework which utilize ReaxFF for chemical reactions while using non-reactive force field to accelerate MD simulation. In this framework, chemically active regions such as surfaces, radical sites, described with ReaxFF and rest of the system described with OPLS. A tracking tool utilized to define reactive and non-reactive regions during the simulation. ReaxFF uses a unique parameter set for each atom, bond, angle and dihedral types, however OPLS parameters depends on local bond topology. Since ReaxFF allows chemical reactions, bond topology of the system changes during the simulation. We used a Machine Learning based model to predict OPLS parameters in order to dynamically transfer atoms from reactive to non-reactive regions. As a test case, we consider cross-linking of poly ethylene with dicumyl peroxide with large scale hybrid simulations. We achieved significant improve in the computational efficiency and were able to simulate realistic size systems.
TUTORIAL: Applied Machine Learning for Materials Research and Development
December 1 - December 1, 2019

This will be a hands-on tutorial. We will begin with an overview of applied machine-learning fundamentals. Then will showcase successful applications of machine learning to solve materials R&D challenges including diagnosis, process optimization and discovery/design. We will also review some of the hardware developments that have emerged in parallel with machine-learning tools. In closing, a perspective on future challenges in this field will be offered.

8:30 AM
Hands-On Deep Learning for Materials Edward Kim, Citrine Informatics

A brief conceptual overview of basic deep learning concepts will be provided, and these concepts will be introduced alongside more familiar (e.g., linear) machine learning methods. Attendees will then have the opportunity to build and train their own neural network models in Jupyter + Python.

8:00 AM *MT02.01.01/MT03.01.01
Autonomous Research Systems for Materials Development—2019 Workshop Summary Benji Maruyama¹, Eric A. Stach², Gilad Kusne³, Jason R. Hattrick-Simpers³ and Brian L. DeCost³; ¹Air Force Research Laboratory, United States; ²University of Pennsylvania, United States; ³National Institute of Standards and Technology, United States

This presentation will summarize the results of our “Autonomous Research for Materials Development Workshop,” where a multidisciplinary group of materials researchers, computer scientists and AI/ML experts explored the
opportunities, barriers and future investments. Closed-loop autonomous research systems are disrupting the research process. The current materials research process is slow and expensive; taking decades from invention to commercialization. Researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of doing iterative experimentation orders of magnitude faster than today.

We propose a “Moore’s Law for the Speed of Research,” where the rate of advancement increases exponentially, and the cost of research drops exponentially. We consider a renaissance in “Citizen Science” where access to online research robots makes science widely available. This presentation will highlight advances in autonomous research and consider the implications of AI-driven experimentation on the materials landscape.

8:30 AM *MT02.01.02/MT03.01.02
Self-Driving Laboratories for Accelerating Discovery of Thin-Film Materials Curtis P. Berlinguette1,1, Jason E. Hein1, Alan Aspuru-Guzik2,3, Benjamin P. MacLeod1, Fraser G. Parlane1 and Brian Lam1; 1The University of British Columbia, Canada; 2Canadian Institute for Advanced Research (CIFAR), Canada; 3The University of Toronto, Canada

This presentation will focus on our self-driving laboratory for thin film materials discovery and optimization. Discovering high-performance, low-cost materials is an integral component of technology innovation cycles, particularly in the clean energy sector. The linear methodology currently used to develop optimal materials can take decades, which impedes the translation of innovative technologies from conception to market. Our interdisciplinary team is utilizing advanced robotics and machine learning to overcome this challenge. We are closing the feedback loop in thin film materials research by enabling our self-driving robotics platform named “Ada” to design, perform, and learn from its own experiments efficiently and in real time. As a proof-of-principle set of experiments, we will show how Ada discovers and optimizes high-performance, low-cost hole transport materials for use in advanced solar cells. I will also showcase how Ada’s modular design can enable the automated and autonomous discovery of materials for other clean energy technologies.

9:00 AM MT02.01.03/MT03.01.03
An Inter-Laboratory High Throughput Experimental and Open Materials Data Study of Sn-Zn-Ti-O Jason R. Hattrick-Simpers1, Andriy Zakutayev2, Sara Barron1, Zachary Trautt1, Nam Nguyen1, Kamal Choudhary1, John D. Perkins2, Caleb Phillips2, Gilad Kusne1, Feng Yi1, Apurva Mehta3 and Martin Green1; 1National Institute of Standards and Technology, United States; 2National Renewable Energy Laboratory, United States; 3SLAC National Accelerator Laboratory, United States

We present the results of an inter-laboratory high-throughput experimental (HTE) study which focused on measurement reproducibility and data exchange. Over the past 20 years, a great number of HTE techniques for synthesizing and characterizing thin-film oxides have been developed and reported. To date, however, there has not been a comprehensive study of how values measured for a series of properties (e.g. conductivity or optical band gap) on the same library compare across labs. Nor has there been a study that has attempted to normalize the hand-off of HTE samples and data. Here we report on the first such study using the Sn-Zn-Ti-O transparent conducting oxide system.

A series of Sn-Zn-Ti-O samples were deposited via Pulsed Laser Deposition and magnetron co-sputtering. At each institution a set of HTE measurements were made for typical properties including structure, thickness, conductivity, and optical bandgap. The samples were then exchanged between the two labs and the same set of properties were measured at the other lab and the data exchanged via an agreed upon uniform format. A few lessons learned and several scientific observations regarding the reproducibility of HTE results gathered during this process will be discussed. An important lesson was the importance of deciding upon, and using, consistent measurement grids within a lab (and during exchanges) for all measurements, as this will impact future data archiving and retrieval. It was observed that qualitative trends are well reproduced even when two labs use very different methods for measuring a property, for instance ellipsometry versus transmission-reflection UV-VIS spectroscopy. However, quantitative comparisons were found to be measurement specific and spanned from excellent (bandgaps measured within a mean absolute error < 0.1 eV) to relatively poor (log resistivity measurements within a mean absolute error of 2). In the latter case, we believe that differences in sample probe geometries coupled to large changes in the properties of small composition regions were the most likely source of the poor correlation. The lessons learned and best practices obtained will be discussed.
Automated Microcrack Inspection in Photovoltaics Silicon Wafers by Unsupervised Anomaly Detection via Variational Auto-Encoder

Zhe Liu, Felipe Oviedo, Emanuel M. Sachs and Tonio Buonassisi; Massachusetts Institute of Technology, United States

The presence of microcracks in silicon wafers significantly reduces wafer strength, yielding wafer breakage during the manufacturing process, transportation and field operation. With the trend of decreasing wafer thickness for cost reduction purposes, thinner wafers are more prone to breakage in the presence of microcracks [1]. To enable a smooth transition to thin wafers for even cheaper photovoltaic modules, we recently developed a high-throughput prototype for in-line crack detection for silicon wafers [2]. This tool scans silicon wafer in the near-edge regions for micro-cracks and outputs linescan signals from a linescan camera, where no crack shows a smooth, undisrupted profile. As an in-line detection tool, it also requires a rapid and reliable algorithm that automatically identifies the presence of a micro-crack within a second after wafer scanning. In this work, we adopted an unsupervised machine learning method for anomaly detection, because the presence of microcracks above the critical length is typically a statistically rare event in the current PV production line (typically less than 5%). Specifically, a generative machine learning algorithm variational auto-encoder (VAE) is used to identify scans with microcracks [3]. The working principle of this algorithm is that: (1) VAE encodes the linescan profiles into lower-dimension vectors of latent variables, and then the latent variables are reconstructed back to linescan profile with the goal of minimized error; (2) because of most linescan profiles are very similar smooth curves without any cracks, the VAE model is trained to be biased toward linescan without cracks; (3) whenever a linescan profile for a crack appears, the trained VAE model generates a vastly different profile with a significant reconstruction error; (4) the crack is then detected by monitoring anomalous reconstruction error. The advantage of this unsupervised VAE method over the previous neural network method [4] is that it does not require a large amount of labelled crack data with different crack shapes (which can be very difficult to obtain). We demonstrate successful crack detections with several different wafer types (e.g., multi, mono, as-cut, and textured) and crack shapes (e.g., line-shape, cross-star, L-shape). We show that, with statistical analysis, this VAE-based anomaly detection could be a reliable and versatile method to enable the rapid detection of microcracks in silicon wafers.

Reference:
machine regression model was trained for the prediction of the OSC at each measured temperature. This model uses descriptors in which physical properties are considered to represent the features of the OSC. These features were automatically extracted using grid search to achieve each model with the highest accuracy. It is found that the features related to the stability of the oxygen atoms in the crystal and the crystal structure itself such as cohesive energy, which is obtained from the first-principles calculation, are highly correlated with the OSC. The present model predicts the OSC of 1,300 existing oxides registered in the in-house electronic structure calculation database. Several dozen materials with promising high OSC were proposed through this virtual screening. We synthesized one of the screened materials and experimentally confirmed that it indicates higher OSC than the conventional OSM, p-CZ.

The Metaphysics of Chemical Reactivity and Materials Discovery Lee Cronin; University of Glasgow, United Kingdom

Discovery in chemistry falls mainly into one of four types of areas with the discovery of new molecules, new reactions, new reactivity, and finally new physical properties of the resulting compounds or materials. Establishing new reactivity leads to new reactions which also leads to new molecules. This is therefore the order of impact for discoveries in terms of the amount of chemical knowledge that they contribute. Such findings must, by definition, belong outside the known or predictable; and they are outliers and as such can oppose conventions, assumptions and biases. By developing the meta-physics of chemistry and chemical reactivity we should be able to establish a new set of ontologies in chemistry that relate back to the practical core operations, but also can be translated into molecular structures and the discovery of function. The truth of chemistry lies with finding the intrinsic reactivity of the input chemicals, and then encouraging or enabling reactivity by process control. Whilst the new discovery and reaction should be translatable to chemical bonding theory, chemists need to grapple with the fact that the application of the current rules will not allow discovery, instead they will act to restrict it to the known rules. So chemical discovery requires that the current rules are updated, broken, or new ones are made where before there were none. The discovery of Diels-Alder or cross-coupling reactions are excellent examples of new rules that were just discovered without any prior warning.

Without a deeper development of a meta-physics of chemistry the use of big data and artificial intelligence will just tell us what we already know we know, and maybe predictable extensions, rather than enabling discovery. The challenge for the chemist is not the use of artificial intelligence, but the intelligent use of algorithms and automation for novel discoveries. In this talk I will explain how this might be possible.

Robot-Accelerated Perovskite Investigation and Discovery (RAPID)—A High-throughput Approach Towards Metal Halide Perovskite Single Crystal Discovery Zhi Li1, Mansoor Ani N. Nellikkal2, Liana Alves2, Peter Parrilla2, Ian M. Pendleton2, Matthias Zeller3, Joshua Schrier4, Alexander Norquist5 and Emory Chan1;
1Lawrence Berkeley National Lab, United States; 2Haverford College, United States; 3Purdue University, United States; 4Fordham University, United States

Metal halide perovskites have emerged as promising materials for next-generation photovoltaic and optoelectronic devices. The discovery and full characterization of new metal halide perovskite-derived materials have been limited by the difficulty of growing high quality single crystals needed for single crystal X-ray diffraction studies. The formation of large single crystals is non-trivial, owing to the vastness of the chemical search space with enormous compositional degrees of freedom. We present the first automated, high-throughput approach for metal halide
perovskite single crystal discovery based on inverse temperature crystallization (ITC) as a means to rapidly identify and optimize synthesis conditions for the formation of high quality single crystals. Using our automated approach, we have carried out a total of over 5000 metal halide perovskite synthesis reactions spanning six chemical systems. Through this unbiased search of the experimental space, we have more than doubled the number of metal halide perovskite materials accessible by ITC method and discovered a new perovskite structure. Combining machine learning and other statistical methods, we quantify the total experimental space and the likelihood of large single crystal formation. Moreover, machine learning models have been constructed for each chemical system, in which single crystal formation is modeled. This work is a proof of concept that a combined approach of high throughput experimentation and machine learning can be effective in the study of metal halide perovskite crystallization. The approach presented here is designed to be generalizable to different synthetic routes for the acceleration of materials discovery.

11:00 AM MT02.01.08/MT03.01.08
Optimizing Hole Transport Materials with a Self-Driving Thin-Film Laboratory Benjamin P. MacLeod1,1, Fraser G. Parlane1,1, Thomas D. Morrissey1,1, Florian Häse2,3,4, Loïc M. Roch2,3,4, Kevan Dettelbach1, Raphael Moreira1, Lars Yunker1, Michael Rooney1, Joseph Deeth1, Veronica Lai1, Gordon Ng, Henry Situ1, Ray Zhang1, Alán Aspuru-Guzik2,3,4, Jason E. Hein1 and Curtis P. Berlinguette1,1,1; 1The University of British Columbia, Canada; 2Harvard University, United States; 3University of Toronto, Canada; 4Vector Institute for Artificial Intelligence, Canada

Self-driving laboratories combine algorithmic data analysis and experiment planning with robotic workflows to autonomously optimize one or more experimental figures of merit. This approach is applicable to challenging multi-parameter and multi-objective optimization problems such as the optimization of thin film materials within the vast design space of composition, deposition, and processing conditions. Here we describe a self-driving laboratory capable of formulating inks, depositing films via spin-coating, characterizing the resulting thin films using multiple techniques, and planning new experiments based on previous experimental data using the ChemOS experiment orchestration software. The utility of this self-driving laboratory is demonstrated by autonomously optimizing optical and electronic properties of hole transport materials, which are crucial to the operation of a variety of thin-film-based optoelectronic devices. The autonomous optimization manipulates the film composition and annealing protocol to maximize a hole-mobility surrogate obtained by fusing data from transmission-reflection UV-Vis-NIR spectroscopy and 4-point probe conductivity measurements.

11:15 AM MT02.01.09/MT03.01.09

In the development of next-generation photovoltaics and light-emitting diodes, colloidal inorganic perovskite quantum dots (PQDs) have drawn notable attention for their highly tunable bandgap properties, high-charge carrier mobility and defect tolerance, and adaptability towards solution phase processing. However, studies of this material group and other colloidal semiconductor nanocrystals requires extensive exploration of their massive reaction parameter space within highly controlled reaction environments. Conventional flask-based, trial-and-error approaches are, therefore, highly unlikely to effectively capture the full potential and optimal synthesis conditions of these high-priority materials. Further complicating this process, across the accessible bandgap range, optimal synthesis parameters will vary significantly. Flow synthesis platforms have recently been demonstrated as a time- and material-efficient reaction monitoring strategy for synthesis, screening, and optimization of colloidal nanomaterials. The high sampling rate, low chemical consumption, and precise process control (automation) of flow reactors greatly reduces the challenges in exploring complex reaction spaces; however, high-throughput reaction screening technologies alone are likely not able to make significant breakthroughs, due to the massive scope of relevant colloidal synthesis conditions.

In this work, we present a modular microfluidic platform integrated with a machine learning (ML)-enhanced reaction optimization algorithm for on-demand synthesis of high-quality inorganic perovskite QDs with desired optical properties using a homogeneous anion exchange reaction. The intelligent QD synthesis platform consists of
multiple computer-controlled pumps for on-demand reagent delivery/dosing, a flow path selector valve for automated selection of the halide salt source, and an in-line flow cell for automatic UV-Vis absorption and photoluminescence spectroscopy. Utilizing a utility function, an array of trained neural networks, and a global optimization algorithm, the intelligent QD manufacturing platform, approaches a target emission bandgap, while minimizing emission linewidth and maximizing quantum yield by tuning the concentrations of the precursors. Halide salt precursors are mixed within a highly efficient inline micromixer before combining with the perovskite QDs and gas-liquid segmentation. Monitoring each halide exchange condition requires less than 180 uL of total halide salt precursor and 170 uL of starting perovskite QDs per sample. Integration with a ML-enhanced optimization algorithm enables the system to reach optimized synthesis conditions, across all six variables, for a target emission energy of 2.2 eV in 238 samples and 83 mL of chemicals without any prior training. More advanced optimization methods and pre-training with archived experimental data will further reduce this optimization time and cost. The versatility and modularity of the developed intelligent QD synthesis platform make it readily adaptable for on-demand synthesis of other colloidal nanomaterials.

11:30 AM MT02.01.10/MT03.01.10
Autonomously Optimizing Thin Film Morphologies Using Machine Vision Fraser G. Parlane, Benjamin P. MacLeod, Nina Taherimakhsousi, Alan Aspuru-Guzik, Jason E. Hein and Curtis P. Berlinguette; University of British Columbia, Canada; University of Toronto, Canada

The morphologies of solution-deposited thin films are frequently governed by complex combinations of processes from domains including multi-phase fluid flow, heat transfer, nucleation, solid mechanics, and interfacial phenomena. This complexity can frustrate both theoretical and empirical attempts to understand and control the morphologies of such films. Here we report an autonomous robotic system that uses machine vision feedback to determine optimal experimental parameters to achieve homogeneous, high-quality films via spin coating. An ink-formulating and spin-coating robot equipped with an imaging system provides images of thin films to a computer vision algorithm which grades the quality of the thin films. This grading assessment provides input to an optimization algorithm that chooses the next ink formulation with the goal of identifying regions in the parameter space of ink formulation and spin-coating conditions that result in high-quality films.

Quantum Machine Learning in Chemical Space Anatole von Lilienfeld and Guido Falk von Rudorff; University of Basel, Switzerland

Many of the most relevant chemical properties of matter depend explicitly on atomistic and electronic details, rendering a first principles approach to chemistry mandatory. Alas, even when using high-performance computers, brute force high-throughput screening of compounds is beyond any capacity for all but the simplest systems and properties due to the combinatorial nature of chemical space, i.e. all compositional, constitutional, and conformational isomers. Consequently, efficient exploration algorithms need to exploit all implicit redundancies present in chemical space. I will discuss recently developed alchemical perturbation theory and quantum machine learning based approaches for interpolating quantum mechanical observables in compositional and constitutional space. Numerical results of our models indicate controlled accuracy and favourable computational efficiency.

2:00 PM *MT02.02.02/MT03.02.02
AI for Automating Materials Discovery Carla Gomes and Bruce van Dover; Cornell University, United States
Artificial Intelligence (AI) is a rapidly advancing field. Novel machine learning methods combined with reasoning and search techniques have led us to reach new milestones with increasing frequency, from self-driving cars to computer vision, machine translation, computer Go trained on human play, to Go and Chess world-champion level play using pure self-training strategies. These ever-expanding AI capabilities open up exciting new avenues for automating scientific discovery. I will discuss our work on using AI for accelerating and automating materials discovery. In particular, we have focused on high-throughput structure determination for combinatorial materials discovery and on solving the phase map diagram problem for composition libraries. While standard statistical and machine learning methods are important to address this challenge, they fail to incorporate relationships arising from the physics of the underlying materials. I will introduce an effective approach based on a tight integration of machine learning methods, to deal with noise and uncertainty in the measurement data, with optimization and inference techniques, to incorporate the rich set of constraints arising from the underlying physics. Finally, I will describe our vision and progress concerning Scientific Autonomous Reasoning Agent (SARA), a multi-Agent system to accelerate materials discovery integrating in a synergistic and complementary way, first principles quantum physics, experimental materials synthesis, processing, and characterization, and AI based algorithms for reasoning and scientific discovery, including the representation, planning, optimization, and learning of materials knowledge.

2:30 PM MT02.02.03/MT03.02.03
Machine Learning Methodologies to Enhance Automated Synthesis of New Materials Jonathan Fine, Armen Beck and Gaurav Chopra; Purdue University, United States

Functional groups link analytical, physical, organic, and materials chemistry and are therefore central to the chemical sciences. In both analytical and organic chemistry functional groups are used to predict the reactivity of molecules, select a solvent for a given reaction, and validate a reaction using measurable changes in the properties of a molecule. Current approaches to incorporate functional groups in the prediction, planning and verification of reaction conditions rely on human intervention and input. For example, the solvent used for a given transformation is chosen by a skilled organic chemist using intuition gained from the study of how the functional groups in a molecule dictate its solubility in a solvent. To verify if the reaction took place resulting in an unknown chemical entity, the state-of-the-art method is to accurately identify all functional groups of the reactants and products. This process is time-consuming, involves manual or database dependent analysis and interpretation of a Fourier Transform Infra-Red (FTIR) spectrum or Mass Spectroscopy (MS) data using previously established rules and experience of a skilled spectroscopist. These processes are subject to trial and error for compounds with multiple functional groups and for compounds that not well characterized in the literature. Such issues hinder the automated development and characterization of truly new materials with minimal human intervention. We present fast deep learning methods to select the optimal solvent for a given reaction in a transformation-free manner and identify all the functional groups for both the products and reactants for any given reaction. Our methods do not use any database, pre-established rules or procedures to perform either task and use the general definition of functional groups as a ‘collection of atoms’ instead of simple chemical groups traditionally assigned by chemists. We use Artificial Neural Networks (ANNs) to derive patterns and correlations between these collections of atoms and the solvents used to carryout a given chemical reaction using 2.3 million patented reactions available from the United States Patent and Trademark Office. Our methodology is the first to differentiate solvents by their precise chemical structure instead of simply choosing a solvent class and yields a 5-fold cross-validated average F1-score greater than 0.9. Solvent predictions obtained from this model have been validated both in silico using Density Functional Theory and using experimental in situ techniques. To verify that a reaction has occurred, we trained separate ANNs on 7393 publicly available FTIR and MS combined spectra obtained from the NIST Webbook. Instead of using multiple binary classifiers used in previous works to assign functional groups, our approach treats the classification problem in a multi-class, multi-label fashion. The model has a cross-validated F1 score higher than 0.82 for 14 out of 17 defined functional groups. To showcase the practical utility of our method, we introduce two new metrics (Molecular F1 score and Molecular Perfection rate) to measure the performance of identifying all functional groups on molecules. The optimized model has a Molecular F1 score of 0.92 and a Molecular Perfection rate of 72%. Additionally, backpropagation of our model reveals IR patterns typically used by human chemists to identify standard groups, suggesting a convergence of the model on known spectral features that are diagnostic of particular functional groups. We further show that the introduction of additional functional groups does not decrease the performance of our model. Finally, we show redundancy in FTIR and MS data by encoding all our features in a latent space that retains the accuracy of the original model. These results reveal the importance of using machine learning for automated identification of new reaction conditions and functional groups to achieve autonomous
processes in the future.

2:45 PM MT02.02.04/MT03.02.04
Autonomous Research Systems—Phase Mapping & Materials Optimization Gilad Kusne; National Institute of Standards and Technology, United States

The last few decades have seen significant advancements in materials research tools, allowing researchers to rapidly synthesize and characterize large numbers of samples - a major step toward high-throughput materials discovery. Machine learning has been tasked to aid in converting the collected materials property data into actionable knowledge, and more recently it has been used to assist in experiment design. In this talk we present the next step in machine learning for materials research - autonomous materials research systems. We first demonstrate autonomous measurement systems for phase mapping, followed by a discussion of ongoing work in building fully autonomous systems. For the autonomous measurement systems, machine learning controls X-ray diffraction measurement equipment both in the lab and at the beamline to identify phase maps from composition spreads with a minimum number of measurements. The algorithm also capitalizes on prior knowledge in the form of physics theory and external databases, both theory-based and experiment-based, to more rapidly hone in on the optimal phase map. The phase map is then exploited for functional material optimization.

3:00 PM BREAK

3:30 PM *MT02.02.05/MT03.02.05
Information Extraction and Learning by Large-Scale Text-Mining of the Scientific Literature Gerbrand Ceder; University of California, Berkeley, United States

The overwhelming majority of scientific knowledge is published as text, which is difficult to analyze by either traditional statistical analysis or modern machine learning methods. In contrast, the main source of machine-interpretable data for the materials research community has come from structured property databases which encompass only a small fraction of the knowledge present in the research literature. Beyond property values, publications contain valuable knowledge regarding the connections and relationships between the data items as interpreted by the authors. I will show multiple ways to extract useful information from scientific text in both supervised and unsupervised ways. I will show that materials science knowledge present in the published literature can be efficiently encoded as information-dense word embeddings (vector representations of words) without human labelling or supervision. These embeddings capture complex materials science concepts such as the underlying structure of the periodic table and structure-property relationships in materials. Furthermore, we demonstrate that an unsupervised method can recommend materials for functional applications several years before their discovery. This suggests that latent knowledge regarding future discoveries is to a large extent embedded in past publications. In a more supervised way, we have also demonstrated the extraction of codified synthesis recipes from text. Extraction the details of synthesis, including precursor compounds, synthesis operations and their numerical details, requires a very high precision of information extraction, and a tolerance to deal with imprecise and non-standard language. I will show how a large data set of codified solid-state synthesis reactions has been obtained and be queried to obtain interesting information on choice of synthesis operations and precursors is related to the target material.

4:00 PM *MT02.02.06/MT03.02.06
Autonomous Scanning Droplet Cell for On-Demand Alloy Electrodeposition and Characterization Brian L. DeCost, Howie Joress, Trevor Braun, Zachary Trautt, Gilad Kusne and Jason R. Hattrick-Simpers; National Institute of Standards and Technology, United States

We are developing an autonomous scanning droplet cell (ASDC) capable of on-demand electrodeposition and real-time electrochemical characterization for investigating multicomponent alloy systems for favorable corrosion-resistance properties. The ASDC consists of a millimeter-scale electrochemical cell and an array of programmable pumps that can be used to electrodeposit an alloy film and immediately acquire polarization curves to obtain electrochemical quantities of interest, such as the passive current density and oxide breakdown potential. We model these quantities using Gaussian Process regression to select the most informative series of alloys to synthesize and characterize, continuously updating the model as new electrochemical data is acquired. Our initial studies focus on systems that are likely to form corrosion-resistant metallic glasses (MGs) and single-phase multi-principle element
alloys (MPEAs).

The ASDC is an open exemplar autonomous system that provides insight into both technical and methodological aspects of building and deploying robust closed-loop synthesis and characterization platforms. Our approach is to build loosely-coupled modular experimental, automation, and communications systems to 1. support rapid prototyping, debugging, and verification while producing meaningful scientific output and 2. enable integration into future large-scale multi-user and multi-instrument distributed laboratory systems. We address both of the main challenges that autonomous science systems face: learning to reliably synthesize materials and mapping material specification and processing to structure and properties. We will discuss the incorporation of prior knowledge in the form of theoretical and data-driven predictive models, as well as the integration of online and offline multi-modal experimental data streams. Ultimately, closed-loop automated materials synthesis and characterization platforms offer much more than a means of engineering materials properties and performance through black-box optimization algorithms: they offer the potential to develop and deploy new algorithms for generating and testing scientific hypotheses.

4:30 PM MT02.02.07/MT03.02.07
Autonomous Electrolyte Discovery for Batteries with Experimentally Informed Bayesian Optimization
Adarsh Dave, Sven Burke, Jared Mitchell, Kirthevasan Kandasamy, Biswajit Paria, Barnabas Poczos, Venkatasubramanian Viswanathan and Jay F. Whitaacre; Carnegie Mellon University, United States

An autonomous battery electrolyte experimental platform capable of mixing multi-component electrolyte systems and characterizing the transport and electrochemical properties in a high-throughput manner is disclosed. A Bayesian optimization software package found novel electrolyte compositions through optimization of the high-dimensional electrolyte design space over key design objectives like electrochemical stability and conductivity. Electrolyte optimization is difficult because 1) electrolyte evaluation is expensive and takes time, and 2) the space of possible electrolytes is expansive, formed by many possible choices for solvents (often in ternary blends), salts (often in binary mixtures), and trace additives. Bayesian optimization methods are well suited for the optimization of high-dimensional functions with costly evaluations, often producing an efficient design-of-experiments to converge on multi-objective optimal formulations in few experiments. To expedite the optimization over the expansive design space, theoretical predictions of electrolyte properties via the Advanced Electrolyte Model were utilized as “priors” in the statistical model.

Implementation of the novel experimental platform was carried out by two novel test stands developed to automate the mixing and characterization of electrolytes: Otto (for aqueous systems) and Clio (for aprotic/organic systems). The test stands characterized the ionic conductivity and electrochemical stability of electrolyte systems, featuring a four-electrode conductivity probe, pH meter, and a flow-through three-electrode cell and potentiostat. Clio also integrated electrochemically active electrodes for optimization of electrolyte/electrode systems. The active electrode systems used were common functional ceramic metal oxides.

A software orchestration and data layer linked the test-stands to human experimenters and machine-learning packages through a web-services architecture; all experiment data and meta-data is saved in a database. Additional out-of-the-loop characterization was conducted on cathodic systems to validate composition, structure, and oxidation state.

The aqueous design space consisted of aqueous blends of lithium and sodium salts, including nitrates, sulfates, and other commonly-used battery salts. High-concentration aqueous electrolyte candidates were discovered by optimizing of electrochemical voltage stability and conductivity, including low-cost, high-performing alternatives to known but costly aqueous electrolytes (e.g. LiTFSI). Clio’s design space includes blends of both aprotic organic solvents and solutes in addition to various compositions of electrochemically active electrodes. The test-stands are demonstrated to be significantly faster than common human experimentation techniques, converging on novel, optimized electrolyte mixtures in mere hours or days of experimentation.
MT02.03.01
Autonomous Experimental Phase Analysis of Oxide Systems Demonstrated via Optical Imaging and Spectroscopy  
Aine Connolly, Duncan Sutherland, Max Amsler, Sebastian Ament, Michael O. Thompson, Bruce van Dover and Carla Gomes; Cornell University, United States

Efficient autonomous exploration of phase behavior requires real-time dynamically coupled experiments and characterization that can lead to intelligent search trajectories through high-dimensional system parameter space. Employing lateral gradient Laser Spike Annealing (lg-LSA) with a combination of optical microscopy and optical spectroscopy, we demonstrate such a closed loop experimental protocol that enables efficient and rapid mapping of transition boundaries across a wide range of thin film oxide stoichiometry and synthesis conditions. Laser Spike Annealing (lg-LSA) rapidly heats thin oxide films which quench to various metastable phases depending on the peak temperature and cooling rate. With a lateral annealing temperature gradient of 2 – 3 K/μm, spatially localized probes (e.g. microbeam X-ray diffraction or optical spectroscopy) can readily characterize the resulting structures. However, only a few temperatures near transitions are necessary to establish the phase behavior, and an autonomous search must efficiently probe those neighborhoods. Coupling immediate post-exposure imaging and spectroscopy of critical temperature bands after each individual lgLSA exposure, subsequent experiments can be optimized to guide the search with loop-times of one to two minutes. This autonomous closed-loop experimental process thus enables rapid identification of synthesis condition boundaries at phase transitions. Results are shown for a variety of oxide thin films including Bi$_2$O$_3$ and MnTiO$_3$.

MT02.03.02
Accelerating Materials Discovery with Autonomous Job Control Systems Aided by Machine Learning  
Chenru Duan, Jon Paul Janet, Aditya Nandy, Fang Liu and Heather J. Kulik; Massachusetts Institute of Technology, United States

Computational high throughput data generation is essential in materials discovery. Although automation of first-principles simulation has enabled rapid data generation, challenges remain in the most compelling materials spaces (e.g., open-shell transition metal chemistry) to ensure that the data is of sufficient quality, either for automated determination of design rules or in training of machine learning property prediction models. For inorganic chemistry, two key challenges remain at the stage of first-principles data generation: i) chosen ligands and metals may not form a stable complex and ii) calculations may fall outside the domain of applicability of the first-principles method. When such challenges are encountered, they can erode the value of data points in a data set, and such points may need to be removed. Typically, one detects these failures only after a calculation is completed, wasting computational resources. To address this problem, we incorporated machine learning (ML) models into our high-throughput discovery tools for inorganic chemistry. These ML models are capable of predicting the outcomes of a calculation. We built a calculation outcome classifier directly from topological, heuristic features prior to simulation to prescreen a large pool of candidate materials without requiring any first-principles calculations. Inspired by the data distribution in the latent space, we designed an uncertainty quantification metric specifically for classification tasks, lowering the risk of terminating jobs that are likely to be fruitful. To achieve higher transferability in inorganic complex discovery, an ML model that utilizes the information generated during simulation is also developed, which directs the on-the-fly decision of whether to abandon an in-progress calculation. Upon implementing this “dynamic” classifier in current high-throughput screening workflows, we achieve around two-fold acceleration in data generation with no loss of feasible lead compounds. We expect our meta-decision approach to be broadly useful in data set generation with first-principles calculations for the accelerated design of materials.

MT02.03.03
Autonomous Experimentation for Mechanical Design  
Aldair E. Gongora$^1$, Bowen Xu$^1$, Wyatt C. Perry$^1$, Chika S. Okoye$^1$, Patrick F. Riley$^2$, Kristofer Reyes$^3$, Elise F. Morgan$^1$ and Keith A. Brown$^1$; $^1$Boston University, United States; $^2$Google Research, United States; $^3$University at Buffalo, The State University of New York, United States

The high level of control afforded by additive manufacturing presents innumerable possibilities for design with each design choice potentially influencing mechanical performance. While tools exist for optimizing many facets of mechanical performance, improving failure properties, however, poses a challenge due to the stochastic nature of failure and the difficulty in reliably predicting the role of the microstructure introduced during manufacturing. As a
result, design for failure performance typically occurs manually through iterative manufacture and testing. In this work, we present the realization and use of an autonomous research system (ARS) for designing and optimizing a model family of additively manufactured structures for mechanical performance. This novel approach to mechanical design combines high-throughput automated experimentation with active learning-guided experimentation to enhance the speed of experimental campaigns and the knowledge gained from each experiment. In order to evaluate this approach, the ARS was tasked with exploring and optimizing a parametric model family of structures for energy absorption. Not only was the ARS able to identify higher performing structures with an order of magnitude fewer experiments than a grid-based design of experiments approach, but it was able to do so in 36 hours. Additionally, evaluating the performance of different learning approaches on the ARS showed fascinating deviations from purely computational studies, highlighting the importance of experimental validation in the active learning community. The use of autonomous research systems for the design of structures for properties that cannot be effectively simulated represents a shift in the conventional design process and could have an impact in materials development and mechanical design in a manner that facilities the convergence of machine learning, physical experimentation, and design.

**MT02.03.04**

**Efficient Selection of Categorical Process Variables for Autonomous Experimentation**

Florian Häse¹,²,³, Loïc M. Roch¹,²,³ and Alan Aspuru-Guzik³,²;¹;¹Harvard University, United States;²Vector Institute for Artificial Intelligence, Canada;³University of Toronto, Canada

Self-driving laboratories provide promising opportunities to enable autonomous experimentation for a substantial acceleration of scientific discovery. By combining automated experimentation platforms with algorithmic experiment planning strategies based on machine learning, self-driving laboratories implement a closed-loop approach to experimentation. The performance and acceleration of a self-driving laboratory critically depend on the efficiency of its experiment planning strategies to operate in low-data regimes while executing only the most informative experiments. Experimentation procedures can be governed by gradually changeable parameters such as temperature or residence time, but can also involve distinct choices, for example the selection of a catalyst or a solvent. Although a plethora of algorithms have been developed to determine the optimal values of continuous variables, the efficient selection of categorical variables still remains challenging under the constraints posed by typical experimentation settings. Here, we introduce Gryffin, a framework developed to facilitate autonomous experimentation for processes involving categorical variables. Gryffin is built upon concepts from Bayesian optimization and Bayesian kernel density estimation, which have previously been shown promising performance for continuous parameter selection. Contrary to existing methods, Gryffin can accelerate the optimization process by leveraging domain knowledge in the form of user-provided descriptors for the categorical choices. Balancing the provided domain knowledge with the collected experimental feedback on-the-fly, Gryffin is capable of learning more informative representations of the categorical experimentation parameters. These learned representations can evidence relevant properties of the categorical parameters to enable the derivation of design choices. We highlight the applicability and performance of Gryffin on three different problems bridging materials science and chemistry: (i) the design of hybrid organic-inorganic perovskites, (ii) the discovery of non-fullerene acceptor candidates for organic photovoltaics, and (iii) the optimization of Suzuki-Miyaura cross-coupling reactions. Gryffin outperforms existing methods in all three applications, and identifies the best performing material compositions or experimental conditions by probing only a fraction of the search space. Finally, we outline our recent results with Gryffin as an experiment planning strategy in self-driving laboratories for thin-film materials and reaction optimization.
Dynamics Tian Xie, Arthur France-Lanord, Yanning Wang, Yang Shao-Horn and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Understanding the dynamical processes that govern the performance of functional materials is essential for the design of next generation materials to tackle global energy and environmental challenges. Many of these processes involve the dynamics of individual atoms or small molecules in condensed phases, e.g. lithium ions in electrolytes, water molecules in membranes, molten atoms at interfaces, etc., which are difficult to understand due to the complexity of local environments.

In this talk, we will present Graph Dynamical Networks (G DyNets) [1], an unsupervised learning approach to learn atomic scale dynamics from molecular dynamics trajectories for arbitrary phases and environments. We demonstrate that learning local dynamics is exponentially easier than global dynamics in material systems. Then, we apply this approach to two complex systems -- silicon atoms at liquid-solid interfaces, and lithium ions in amorphous polymer electrolytes. We show that our approach gains important dynamical information for both materials that is otherwise difficult to obtain, and provides atomic scale explanations to some experimental observed phenomena. With the large amounts of molecular dynamics data generated every day in nearly every aspect of materials design, this approach has the potential to provide a broadly applicable, automated tool to understand atomic scale dynamics in material systems.

9:15 AM MT02.04.03
Fast and Accurate Interatomic Potentials by Genetic Programming Alberto Hernandez, Adarsh Balasubramanian, Fenglin Yuan, Simon Mason and Tim Mueller; Johns Hopkins University, United States

In recent years there has been great progress in the use of machine learning algorithms to develop interatomic potential models. Machine-learned potential models are typically orders of magnitude faster than density functional theory but also orders of magnitude slower than physics-derived models such as the embedded atom method. We demonstrate that machine learning, in the form of genetic programming, can be used to develop accurate and transferable many-body potential models that are as fast as the embedded atom method, making them suitable to model materials on extreme time and length scales. The key to our approach is to explore a hypothesis space of models based on fundamental physical principles and to select models from this hypothesis space based on their accuracy, speed, and simplicity. We demonstrate our approach by developing fast and accurate interatomic potential models for copper that generalize well to properties they were not trained on. Our approach requires relatively small sets of training data, making it possible to generate training data using highly accurate methods at a reasonable computational cost. We discuss the open-source implementation of our algorithm and additional features including extensions to systems with multiple elements.

On-the-Fly Bayesian Active Learning of Interpretable Force Fields for Atomistic Rare Events Jonathan Vandermause¹, Steven B. Torrisi¹, Simon L. Batzner¹, Yu Xie¹, Lixin Sun¹, Alexie Kolpak² and Boris Kozinsky¹; ¹Harvard University, United States; ²Massachusetts Institute of Technology, United States

Recent machine learning (ML) approaches to modeling the Born-Oppenheimer potential energy surface have been shown to approach first principles accuracy for a number of molecular and solid-state systems. However, most ML potentials return point estimates of the quantities of interest (typically energies, forces, and stresses) rather than a predictive distribution that reflects model uncertainty. Without uncertainty estimates, a laborious fitting procedure is required, which usually involves selecting thousands of reference structures from a database of first principles calculations. Here, we show that active learning based on Gaussian process (GP) regression can accelerate the training of high-quality force fields by making use of accurate Bayesian estimates of model error.

Through a series of tests on randomly generated bulk aluminum structures, we demonstrate that the Bayesian error of our GP potentials correlates strongly with the true error of the model on out-of-sample structures. We then use the Bayesian error to implement an active learning molecular dynamics method, in which DFT is called only when the Bayesian error of the GP model rises above an adaptive threshold based on the optimized noise hyperparameter of
the GP. All model hyperparameters are optimized whenever an atomic environment and its force components are added to the training set, allowing the error threshold to adapt to novel environments encountered during the simulation.

We discuss applications of this on-the-fly learning method to crystal melts, vacancy diffusion, and adatom diffusion for a range of single- and multi-component systems. By combining DFT with GP regression in a single molecular dynamics simulation, an accurate multi-phase force field for bulk aluminum is obtained with fewer than 100 DFT calls. Moreover, we demonstrate that our Bayesian potentials can be flexibly and automatically updated when the system deviates from previous training data. Because of the low-dimensional structure of our kernel function, we show that our potentials can be mapped to a much cheaper regression model approaching the efficiency of classical potentials. Such a reduction in the computational cost of training, updating, and applying machine-learned potentials promises to extend ML modeling to a wider class of materials than has been possible to date.

Predicting Potential Energy Surfaces with Machine Learning Matti Hellström; Software for Chemistry & Materials BV, Netherlands

Atomistic simulations of molecules and materials require a reliable way to evaluate the underlying potential energy surface. Furthermore, realistic simulations of materials with complexities such as grain boundaries, vacancies, impurities, and interfaces, often imply large scale models comprising many thousands or even millions of atoms and thus, the use of very efficient computational chemistry methods. Machine learning (ML) methods can bridge the gap between often prohibitively expensive electronic structure calculations and efficient but often not sufficiently accurate force fields. In this contribution, we describe how an ML method based on artificial neural networks can be applied to describe chemical reactions in several complex systems, such as electrolyte solutions [1] and at solid/liquid interfaces [2]. These simulations provide unprecedented detail and insight into the working and degradation mechanisms of batteries, fuel cells, and other electrochemical systems.

Although neural networks are ideally suited for describing complex non-linear functions like potential energy surfaces, they are still not routinely employed for this purpose [3]. Here, we will present our work for overcoming the main obstacles for widespread adoption, relating to (i) construction of suitable training and validation sets, (ii) automation of the featurization of different molecules and materials, and (iii) the choice of loss function for the neural network optimization.

The neural network method is implemented as part of the Amsterdam Modeling Suite, a software package containing a sophisticated molecular dynamics engine and first-principles, semi-empirical, and atomistic potential methods. This software environment allows for seamless transitions between the different levels of theory and greatly simplifies the construction of the neural network potential. Our ultimate goal is to provide the chemistry, biochemistry, and materials science communities with an all-purpose computationally inexpensive method that can be used in simulations related to solving challenging problems in energy, renewables, climate change reduction, and health care.

Data-Driven Materials Design and Machine Learning Using the Materials Project Kristin A. Persson1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

The powerful combination of supercomputing resources, robust algorithms for solving the laws of physics and state-of-the-art software infrastructure are enabling rapid, systematic calculations of real materials properties from
quantum mechanics across chemistry and structure. A result of this paradigm change are databases like the *Materials Project* (www.materialsproject.org) which is charting the properties of all known inorganic materials and beyond, designing novel materials and offering the data free of charge to the community together with online analysis and design algorithms. The growing body of available, reliable data has reached the stage where automated learning algorithms can be effectively trained and utilized to accelerate all aspects of the materials design cycle: from property prediction, to materials synthesis and characterization. To exemplify the approach of data-driven materials design, we will survey a few in-house case studies and the application of accelerated learning – from prediction, to synthesis and characterization - showcasing rapid iteration between ideas, computations, insight and new materials development.

**Constructing Reliable Machine-Learning Potential for Solid-State Reaction: Example of Ni Silicidation**  
Wonseok Jeong, Dongsun Yoo, Kyuhyun Lee and Seungwu Han; Seoul National University, Korea (the Republic of)

Molecular dynamics (MD) using classical interatomic potentials can provide valuable information at the atomistic scale. However, when the simulation involves chemical reactions of bond breaking and forming along with mixed bonding characters, it is challenging to develop an accurate force field for the system and sometimes practically impossible. In this respect, the machine-learning potentials (MLPs) are highly anticipated since they are based on flexible mathematical structures with no pre-fixed form. The parameters in the machine-learning model are automatically optimized on the reference data, often from the density functional theory. Nevertheless, MLP has a critical drawback; it can produce unphysical results when MLP is applied on configurations that are not included in the training set. This is particularly problematic in the solid state reaction that involves constant bonding breaking and formation. In this presentation, we discuss the process of developing a reliable neural network potential (NNP) for a challenging solid-state reaction - thermal silicidation of nickel at the Ni-Si interface. We present a systematic way to build up the training set that can describe the interface reaction. In order to obtain the prediction uncertainty for certain local configurations, we utilize replica NNPs that are trained directly on the atomic energy of the reference NNP. We find that the temporal variation of compositions across the interface agrees well with the experiment.

11:15 AM MT02.04.08
**Gaussian Process-Based Refinement of Dispersion Corrections**  
Stefan Gugler¹, Markus Reiher¹ and Jonny Proppe²; ¹ETH Zürich, Switzerland; ²University of Goettingen, Germany

We employ Gaussian process (GP) regression to account for systematic errors in D3-type dispersion corrections.[1] We refer to the associated, statistically improved model as D3-GP. It is trained on differences between interaction energies obtained from PBE-D3(BJ)/ma-def2-QZVPP and DLPNO-CCSD(T)/CBS calculations of 1,248 molecular dimers, which resemble the dispersion-dominated systems contained in the S66 data set. To train our D3-GP model, we used features derived from the matrix of atom-pairwise D3(BJ) interaction terms: (a) a distance-resolved interaction energy histogram, histD3(BJ), and (b) eigenvalues of the interaction matrix ordered according to their decreasing absolute value, eigD3(BJ).

We demonstrate that the posterior variance can be approximately updated from only the input variables (features) of the new training system, which are obtained efficiently from D3(BJ) calculations. In this way, we can collect a batch of new training systems before the corresponding electronic-structure calculations are carried out at the same time. We refer to this selection approach as batchwise variance-based sampling (BVS).

BVS-guided active learning is an essential component of our D3-GP workflow, which is implemented in a black-box fashion.

Once provided with reference data for new molecular systems, the underlying GP model automatically learns to adapt to these and similar systems.

This approach leads overall to a self-improving model (D3-GP) that predicts system-focused and GP-refined D3-type dispersion corrections for any given system of reference data.

Doing Less for More—Multi-Information Bayesian Optimization and the Computational Sciences
Henry C. Herbol, Matthias Poloczek and Paulette Clancy; 1Johns Hopkins University, United States; 2The University of Arizona, United States

For half a century, computational methods such as Density Functional Theory (DFT) and Molecular Dynamics (MD) have allowed scientists to study atomic-scale systems. These methods and approaches have consistently been characterized as either “slow, small, and accurate” or “fast, large, and inaccurate” and virtually any combination in-between (with the exception of the most desirable combination: “fast, large, and accurate”). For instance, DFT is well established in modeling electronic properties of materials; however, due to scaling issues, DFT is typically limited to smaller atomic systems, or fully periodic crystals. For phenomena, such as nanoparticle nucleation, which demand large system sizes, MD is typically the method of choice. Adding to the complexity, within each method the user has to select a choice of functional or force field, which possess different degrees of computational complexity.

In recent years, Machine Learning (ML) methods have begun to be used to ameliorate these computational costs, while maintaining acceptable levels of accuracy. From Neural Nets, to Random Forests, to Gaussian Process Regressions, machine learning approaches are increasingly being used to replace DFT and MD as objective functions. Methods such as Bayesian Optimization are of particular interest in situations where data is scarce and expensive, which covers a number of important materials processes. As a result, ML is becoming an attractive tool in the computational sciences as a means to minimize the number of required expensive calculations.

In this work, we discuss the merging of these fields, ML and computational sciences, with a primary focus on showing how to utilize multiple information sources in the context of computational science problems. Multi Information Source Optimization using a Knowledge Gradient (misoKG) as an acquisition function was developed in 2017 by Poloczek and Frazier for a Gaussian Process Bayesian Optimization approach. Their initial design, tested against the well-known Rosenbrock benchmark, used a noisy alternative with a presumed lower cost to minimize the Rosenbrock at a smaller total cost than that of standard (“workhorse”) Expected Improvement and Knowledge Gradient methods. The statistical model in the original paper involved replicating the kernel for each information source, potentially scaling the number of hyperparameters to unreasonable high levels. Here, we extend their original statistical model to produce a more scalable approach, as well as applying misoKG to several computational problems, showcasing the benefits of using cheap, but at times inaccurate, calculations to model atomic systems.

Our new method employs an Intrinsic Coregionalization Model that avoids the addition of hyperparameters, and is shown to minimize the Rosenbrock benchmark in considerably less cost than the alternatives. We test the base method against the interatomic DFT binding energy of metal halide perovskite salts and solvents, using different solvents and different levels of theory as alternative information sources. A more direct study of functionals and their uses as alternative information sources is then made with the study of carbon monoxide.

Machine Learning-Assisted Acceleration of DFT without Machine-Learning Errors
Alexander Shapeev; Skolkovo Institute of Science and Technology, Russian Federation

Machine-learning potentials are a promising alternative combining both, efficiency of the empirical interatomic potentials and accuracy of quantum-mechanical interatomic interaction models. Unlike empirical potentials that are reused for solving a new problem with the old materials, machine-learning potentials are usually re-parametrized for a new problem at hand. Hence a major bottleneck of such potentials: it takes large amounts manual work to construct a database and fit a new potential.

I will present an approach based on moment tensor potentials [Shapeev (2016)] active learning of automatically constructing machine-learning potentials [Gubaev (2019)]. For example, in the problem of computing the vibrational free energy of a compound, an actively learning potential will select those configurations for which predicting energy and forces results in extrapolation during molecular dynamics. These configurations will be evaluated with DFT and added to the training set. This procedure will run until the potential can run molecular dynamics completely without extrapolation. Special care it taken to make sure that changing the potential on-the-fly would not hinder the accuracy of statistical averaging. Active learning, thus, closes the loop and makes the algorithm of computing free energy fully automatic.

The resulting automatic algorithm would still contain small systematic and often uncontrollable errors due to approximation of quantum mechanics with a surrogate model. However, in some applications, this error can be corrected for at the last stage of the algorithm. For instance, the last step of computation of the free energy can be a...
thermodynamic integration computing the difference between the free energy as given by the machine-learning potential and the DFT free energy. This results into an automatic algorithm without the systematic error in the final answer. Only the statistical error remains which is still much smaller compared to using DFT alone.

The proposed approach of accelerating DFT calculations by automatically constructing machine-learning potentials and correcting for their systematic errors will also be illustrated on the problems of constructing of convex hulls of stable alloy structures and computing high-temperature elastic constants of crystals.

References

dimensionality reduction techniques applied to stress-strain curves. Results show that CNN is able to effectively predict latent space representations of stress-strain curves, with a training set orders of magnitude smaller than the design space. These results demonstrate the potential to use machine learning to accelerate composite design characterization and optimization.

**Accelerating Discovery in Inorganic Chemistry with Machine Learning** Heather J. Kulik, Jon Paul Janet, Chenru Duan, Aditya Nandy, Naveen Arunachalam and Daniel Harper; Massachusetts Institute of Technology, United States

Although the discovery and synthesis of new materials, catalysts, and functional molecules represents the foremost effort that unifies thousands of researchers in the chemical science community, presently characterized compounds represent a minute fraction of chemical space. The highly tunable electronic structure properties of inorganic complexes (i.e., variable spin, oxidation state, and coordination number) make them attractive targets for applications in energy storage, functional materials, and catalysis but present a daunting combinatorial challenge. This vast transition metal compound space cannot be fully enumerated by any traditional Edisonian approach. In order to advance quantitative structure-activity relationships, reveal emergent phenomena, and accelerate design of materials and catalysts, smarter and faster computational approaches are needed. I will outline our efforts to accelerate first-principles (i.e., with density functional theory, or DFT) screening of inorganic complexes for catalysis and materials science applications. We develop machine learning (ML) models (e.g., artificial neural networks) that predict both properties and simulation outcomes. We integrate these tools into an automated design workflow that can make essential decisions on which simulations are best to carry out and why, with awareness of ML model and DFT model uncertainty. I will describe applications of these tools for advancing understanding in catalysis and functional spin crossover materials.

2:30 PM *MT02.05.04  
**Advances in Interatomic Potentials for Materials** Gabor Csanyi; University of Cambridge, United Kingdom

Modelling the deformation of metals is one of the success stories of atomic scale modelling over the past four decades. Increasingly complex functional forms, from pair potentials to embedded atom models and bond order potentials, allowed the quantitative description of different crystal structures, point and line defects, shedding light on many elementary processes governing failure, phase stability, surface phenomena etc. Interestingly, the accuracy with which these models describe the potential energy surface corresponding to the electronic ground state has not changed over the decades and is rather limited. The success is thus largely empirical in nature - and follows from the sophistication of the modeller and the judicious compromises made in order to solve specific problems. The parallel developments in electronic structure theory on the other hand provided exquisite quantitative agreement with experiments e.g. for thermomechanical properties, phase stability, and defect energetics. I will report on recent work of a growing community, who have managed to bring these two worlds together, and construct extremely accurate functional representations of the interatomic potential. These developments rely on a very large amount of highly accurate electronic structure data, on non-parametric function fitting, and on sophisticated representation theory that brings with it guarantees of completeness and convergence.

**Polymer Informatics—Current Status and Critical Next Steps** Ramamurthy Ramprasad; Georgia Institute of Technology, United States

The Materials Genome Initiative (MGI) has heralded a sea change in the philosophy of materials design. In an increasing number of applications, the successful deployment of novel materials has benefited from the use of computational, experimental and informatics methodologies. Here, we describe the role played by computational and experimental data generation and capture, polymer fingerprinting, machine-learning based property prediction models, and algorithms for designing polymers meeting target property requirements. These efforts have culminated in the creation of an online Polymer Informatics platform (https://www.polymergenome.org) to guide ongoing and future polymer discovery and design [1-3]. Challenges that remain will be examined, and systematic steps that may be taken to extend the applicability of such informatics efforts to a wide range of technological domains will be
Present polymer synthesis techniques excessively strain research resources properties as they are largely Edisonian in approach.[1] Coupled with largely manual experimentation, the timeline for new polymer innovation are prohibitively slow.

While the global materials science community has recognized that machine learning could be a viable technique to accelerate materials discovery, it’s application towards experimental polymer design has been lacking. One of the reasons could be the inherent difficulty of modelling polymer systems due to their complexity multiple length scales. There have been efforts in fingerprinting,[2] which have shown success to DFT generated data. However, these are gross over-simplifications which do not generalize well towards experimental data.

Through a case study, we demonstrate the critical steps that are needed when building machine learning algorithms in polymer property prediction and polymer design. Building on this, we present the future of polymer design via a combination of intelligent data management, high throughput experimentation, high speed diagnostics and machine learning towards closed-loop autonomous experimentation.

Chemical design of SiO$_2$-based glasses with high elastic moduli and low weight is of great interest. However, it is difficult to find a universal expression to predict the elastic moduli according to the glass composition before synthesis since the elastic moduli are a complex function of interatomic bonds and their ordering at different length scales. Here we show that the densities and elastic moduli of SiO$_2$-based glasses can be efficiently predicted by machine learning (ML) techniques across a complex compositional space with multiple (>10) types of additive oxides besides SiO$_2$. Our machine learning approach relies on a training set generated by high-throughput molecular dynamic (MD) simulations, a set of elaborately constructed descriptors that bridges the empirical statistical modeling with the fundamental physics of interatomic bonding, and a statistical learning/predicting model developed by implementing least absolute shrinkage and selection operator with a gradient boost machine (GBM-LASSO). By just training with a dataset that only composed of binary and ternary glass samples, our model shows remarkable learning accuracy and outstanding extrapolation ability to predict the density and elastic moduli for k-nary glasses that beyond the training set. Finally, as an example to illustrate the potential applications of our ML model, we perform a rapid screening ~100,000 compositions of a quinary glass system to construct a compositional-property database that allows for a fruitful overview on the glass density and elastic properties.

Combining Polymorphism and Machine Learning for Materials Discovery Fadwa El Mellouhi; QEERI-HBKU, Qatar
The computer-aided design of materials has witnessed important progress over the past few years. This being said, it depends crucially on the crystal structure and the polymorphs considered. I will show how we considered various polymorphism to obtain new stable and undiscovered compounds based on the assessment of the relative stability of various phases with respect to a reference structure. These calculations rely on the calculation of the thermodynamic stability by computing the convex hull energy aided by open-source computational databases.
I will also summarize some of our recent findings using DFT combined with machine learning to perform a systematic analysis of the structure-to-property relations exploring fully inorganic ABC$_3$ chalcogenide (I-V-VI$_3$), halide (I-II-VII$_3$) and some hybrid perovskites. The analysis focused on the role of BC$_6$ octahedral deformations, rotations and tilts over the thermodynamic stability and optical properties of the compounds. Machine learning algorithms helped to estimate the relations between the octahedral deformation and the bandgap, and established a similarity map among all the calculated compounds. We propose that compositions grouped together on the similarity map are amenable to form mix-ion compounds, offering interesting guidelines on how to engineer mix-phase perovskites.

This work have been supported by the Qatar National Research Fund (QNRF) through the National Priorities Research Program (NPRP8-090-2-047).

Data-Driven Accurate Positioning of the Band Edges of MXenes Avanish Mishra$^{1,2}$, Arunkumar C. Rajan$^2$, Rinkle Juneja$^2$ and Abhishek K. Singh$^2$; $^1$University of Connecticut, United States; $^2$Indian Institute of Science, Bangalore, India
MXenes are a vast class of two-dimensional (2D) materials exfoliated from corresponding MAX phases, which get functionalized due to the availability of unsaturated surface charges. A total of 25,000 MXenes has already been generated and are stored in a functional materials database named, aNANt, which are metallic or semiconducting in nature depending upon the surface termination. MXenes possess variability in their properties and are considered...
promising for electronic, photovoltaic, and photocatalytic applications. However, other than the band gap, these properties rely on the accurate position of the band edges. Hence, to synthesize MXenes for various applications, a prior knowledge of the accurate position of their band edges at an absolute scale is essential; computing these with conventional methods would take years for all the MXenes. A local or semilocal functional-based approach within density functional theory always underestimates the band gap. Furthermore, it fails to predict the accurate position of the band edges. We develop a machine learning model for positioning the band edges with GW level of accuracy having a minimum error of 0.12 eV. An intuitive model is proposed based on the combination of Perdew–Burke–Ernzerhof band edge and vacuum potential having a correlation of 0.93 with GW band edges, which is able to capture the physical origin behind the shift of reference level and unravel the role of surface functionalization in controlling it. These models can be utilized to identify MXenes for the desired application in an accelerated manner.

Predicting Nanoscale Static Friction of 2D Materials via Machine Learning Techniques Behnoosh Sattari Baboukani1, Kristofer Reyes1, Zhijiang Ye2 and Prathima Nalam1; 1University at Buffalo, United States; 2Miami university, United States

Shear properties of two-dimensional (2D) materials such as graphene, molybdenum disulfide (MoS2) or boron nitride exhibit significant dependence on interlayer interactions and lattice orientations. The static friction of 2D materials originates from the stick-slip pattern generated during shearing of the layers. Within the framework of Prandtl-Tomlinson model, the corrugated potential Energy Surface (PES) barrier of the shearing interface results in stick-slip instabilities and tuning the interlayer interactions such as van der Waals, electrostatic forces and identifying the appropriate lattice orientations between two similar 2D materials can enable the identification of promising ‘candidates’ with super lubricating properties. Currently, over few dozen 2D materials have been successfully synthesized and other thousand 3D materials have been identified with potential exfoliation properties, and hence to identify the 2D material with highest lubricity machine learning tools are highly valuable.

In this study, 15 different 2D materials from two different families i.e. the graphene family (includes graphene, hydrogenated graphene, fluorographene and hexagonal boron nitride) and transition metal dichalcogenide family (TMDs includes MX2, M: Mo, Nb, W, Ti - S: S, Se, Te) were selected. PES for five 2D materials, estimated via molecular dynamics (MD) simulations or density function theory (DFT) approximations, were extracted from the literature and employed as the training data. We use a combination of geometric, electronic, mechanical, phonon vibration-related and physical descriptors of 2D material in Bayesian modeling and transfer learning techniques to predict maximum PES for 10 different 2D materials. Strong pairwise correlations were observed among the 2D materials within the same family. Posterior predictions showed hydrogenated graphene presented the lowest corrugation barrier i.e. ~45 % smaller than graphene. To validate the model, potentials for hydrogenated graphene were established and molecular dynamics simulations was performed to estimate a PES value of 1.8 meV/A°2, which was found to be 10% smaller and within the range of the uncertainty as estimated by the Bayesian modeling. Further, the band gap energies for 3 TMDs were predicted using same descriptor set and the predicted values were found to be similar with the DFT-calculated band gap values. Descriptor sensitivity analysis indicates that the maximum energy barrier values were controlled mostly by structural, mechanical and phonon vibrational properties of the system, not by the electronic properties. Finally, the PES for TMDs were found to be highly correlated to the polarizability and the size of the chalcogen atom. The robust model generated in our current study creates a platform for predicting and estimating the lubrication of properties for other novel and unexplored 2D materials and as well for 2D-based heterostructures.

MT02.06.04
Linking Predictions of Protein Structure and Disorder through Molecular Simulation Claire Hsu1, Anna Tarakanova2 and Markus J. Buehler1; 1Massachusetts Institute of Technology, United States; 2University of Connecticut, United States

Intrinsically disordered proteins (IDPs) and intrinsically disordered regions within proteins (IDRs) have been shown to serve an increasingly expansive list of biological functions, including regulation of transcription and translation, protein phosphorylation, cellular signal transduction, regulation of self-assembly of large protein complexes, as well as mechanical roles. The link between function and protein disorder has motivated several recent advances in experimental techniques for identifying disordered regions. Common current techniques include X-ray crystallography, NMR spectroscopy, mass spectrometry, electron microscopy, and small-angle X-ray scattering;
recent advances have extended the length and time-scales of such methods, often combining multiple techniques together to better capture dynamic regions that signal disorder. However, experimental methods for disorder classification still do not scale to the level of experimentally curated structural information in folded protein structure databases. In addition, disorder predictors rely on several different definitions of disorder and fail to account for the continuous order-disorder spectrum. To better capture disorder in protein structure, we link disorder predictions to the performance of secondary structure predictor algorithms developed for folded proteins and conduct molecular dynamics simulations on representative proteins from the Protein Data Bank to determine regions of high motion. We find that secondary structure predictor performance can be leveraged to confirm regions of disorder identified by disorder predictors. In addition, low accuracy secondary structure predictions coupled with high dynamics as suggested by molecular simulations suggest a lack of static structure and, thus, a presence of disorder in regions that may not have a consensus disorder prediction. While disorder databases scale to size and experimental techniques continue to develop, secondary structure predictors and molecular simulations can improve disorder predictor performance, which can lead to the discovery of novel functions of IDPs and IDRs.

**MT02.06.05**  
**Metadynamics Sampling for Training Machine-Learning Interatomic Potential** Dongsun Yoo, Wonseok Jeong, Kyuhyun Lee and Seungwu Han; Seoul National University, Korea (the Republic of)

Machine-learning interatomic potential (MLIP) is getting much attention as a promising computational tool that can give the accuracy of quantum mechanical calculations with the cost of classical force-fields. Among many forms of MLIP suggested to date, neural network potential and Gaussian approximation potential are the two most popular models.

The construction of reliable MLIP requires a careful selection of training set. The training set is usually selected by intuition and experience; practitioners select a set of structures that are expected to appear during the simulations. However, unexpected structures can emerge during the simulation, giving unreliable results or even catastrophic failures. This is a major obstacle against wide use of MLIP. Several methods were proposed to remedy this problem: the detection of out-of-training-set structures, e.g. query-by-committee method, and on-the-fly training. Still, the selection of training set is the major bottleneck to the construction of MLIP.

In this presentation, we suggest a new form of metadynamics to efficiently sample a wide range of local environments, enabling easier construction of MLIP. We use a descriptor vector, which is a direct input to machine-learning model, as collective variables. That is to say, collective variables represent atomistic local environment rather than the state of the entire system. Metadynamics simulations starting from certain structures can sample a wide range of local environments so that it is easier to construct general-purpose potential. Metadynamics sampling also increases the stability of trained potential. We will demonstrate its performance with neural network potential.

**Computational Exploration of Near-Infrared Absorbing Polymethine Dyes** Daniele Padula¹, Roland Hany¹, Frank Nuesch¹ and Mark P. Waller²; ¹Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; ²Pending.ai, Australia

In this contribution, we present a Machine Learning/Quantum Chemical approach aimed at identifying new organic molecules able to absorb in the NIR region of the spectrum. We obtain a pool of potential candidates exploiting Machine Learning models able to generate text representations of molecules. The molecules obtained through this generative model are biased towards classes of compounds that are well known to absorb in the NIR region, such as squaraines, cyanines, croconates and other organic semiconductors. The generated molecules are then clustered with Cheminformatics approaches, and their synthetic accessibility assessed through Monte Carlo Tree Search approaches to retrosynthesis. Finally, their electronic properties are screened through quantum chemical methods of increasing complexity to progressively reduce the pool of candidate materials. Additionally, to reduce the computational cost of future quantum chemical screenings, we will assess whether it is possible to formulate new descriptors that are good predictors of the electronic properties of a molecule.

**MT02.06.09**  
**A General Machine Learning Framework for Impurity Level Prediction in Semiconductors** Arun Kumar Mannodi Kanakkithodi and Maria K. Chan; Argonne National Laboratory, United States
Electronic levels introduced by impurities and defects in the middle of the band gap are critically important in semiconductors for optoelectronic, photovoltaic (PV) and quantum sensing applications. While "deep" defect levels can prove catastrophic for PV performance by causing non-radiative carrier recombination, impurity levels in the band gap could also be entangled for quantum sensing or lead to increased absorption of sub-gap photons which can enhance efficiencies. Predicting formation energies and charge transition levels for defects in semiconductors is thus paramount; density functional theory (DFT) calculations have been widely applied for such studies to overcome experimental bottlenecks. However, the requirement of large supercells, advanced levels of theory, and inclusion of charge corrections make these computations very expensive, and trends and knowledge from previous calculations are not exploited in subsequent ones.

In this work, we combine high-throughput DFT and machine learning (ML) to develop general predictive models for the formation enthalpy and charge transition levels of impurities in two broad semiconductor classes: (a) ABX3 halide perovskites, and (b) group IV, III-V and II-VI semiconductors. DFT data is generated for impurity atoms selected from across the periodic table and simulated in various possible cation, anion or interstitial sites. Any "semiconductor + impurity" combination is converted into a unique feature vector based on the identity and electronic properties of the semiconductor, the tabulated elemental properties of the impurity atom, information about the defect site coordination environment, as well as some electronic and energetic properties computed using low cost unit cell defect calculations. State-of-the-art neural networks, random forest and ridge regression methods are applied to train models for (a) impurity formation enthalpy, and (b) impurity charge transition levels, based on the input feature vector. Model performance is evaluated for different ML techniques, sets of features, and size and nature of training dataset; the best predictive models thus obtained are deployed for comprehensive prediction and design purposes. It is seen that models trained on defects and impurities in end point compositions are applicable to intermediate compositions as well: for instance, by training on data from pure canonical AB semiconductors like CdTe, ZnO, GaAs and SiC, the ML models can make accurate predictions for impurities in alloyed compositions of the same compounds, such as CdTe₁₋ₓSeₓ, Cd₁₋ₓZnₓO, Al₁₋ₓGaₓAs₁₋ₓSbx, etc. This versatility of the machine learned-models provides an avenue to access the energetic and optoelectronic impact of any atomic impurity in any possible pure or mixed composition semiconductor belonging to the same chemical space. We use the predictive models to quickly screen for dominating impurities, that is impurities that shift the equilibrium Fermi level in the semiconductor as determined by dominant native defects, in hundreds of possible compositions in the halide perovskite and groups IV, III-V and II-VI semiconductor spaces. The quick and accurate estimation of interesting dopants/impurities in semiconductors would not be possible without machine learned models, and the strategy applied in this work is applicable to any class of semiconductors.

Machine Learning Study of Magnetic Two-Dimensional Materials Trevor David Rhone, Shaan Desai, Wei Chen, Amir Yacoby and Efthimios Kaxiras; Harvard University, United States

The discovery of intrinsic magnetism in monolayer CrI3 and bilayer Cr2Ge2Te6 created great interest in two-dimensional (2D) materials with intrinsic magnetic order. How many of these materials exist? What are their properties? We present a study of 2D materials with intrinsic magnetic order, materials at the forefront of physics research. We use materials informatics (machine learning applied to materials science) to study the magnetic and thermodynamic properties of 2D materials. Crystal structures based on monolayer Cr2Ge2Te6, of the form A₂B₂X₆, are studied using density functional theory (DFT) calculations and machine learning tools. Magnetic properties, such as the magnetic moment are determined. The formation energies are also calculated and used to estimate the chemical stability. We show that machine learning, combined with DFT, provides a computationally efficient means to predict properties of two-dimensional (2D) magnets. In addition, data analytics provides insights into the microscopic origins of magnetic ordering in 2D. This novel approach to materials research paves the way for the rapid discovery of chemically stable 2D magnetic materials.

Machine-Learning-Based Band Gap Predictions of Functionalized MXenes Arunkumar C. Rajan, Avanish Mishra, Swanti Satsangi and Abhishek K. Singh; Indian Institute of Science Bangalore, India

MXene is a recent addition to the ever-growing family of two-dimensional (2D)-materials, promising for optical, electronic, energy storage and photocatalytic applications. Utilizing a statistical learning-based approach, we electronically characterize this vast class of materials by predicting their band gaps with GW level accuracy. Using a
classification model, MXene having finite band gaps are filtered out and few of them are selected to build a machine learning model. The model is built by correlating the easily available elemental and computed properties as features with respect to calculated GW band gaps of selected MXene. Depending upon feature combinations, Gaussian process regression method resulted in an optimized model yielding low root-mean-squared-error of 0.14 eV, which can be employed to estimate the accurate GW band gaps of tens of thousands of MXenes [1] within minutes. Our results demonstrate that machine learning model can bypass band gap underestimation problem of local and semi-local functionals used in DFT calculations, without subsequent correction using time-consuming GW approach [2].

Machine Learning the Fundamental Tradeoffs between Conductivity and Voltage Stability in Solid State Electrolytes Karun Kumar Rao, Michael Nikolaou, Yan Yao and Lars Grabow; University of Houston, United States

All solid state batteries provide many safety advantages over traditional lithium-ion batteries by replacing the combustible organic liquid electrolyte with a ceramic solid-state electrolyte. However, reported superionic conductors with conductivities approaching that of liquid electrolytes are unstable in contact with a lithium anode leading to increased internal cell resistance and poor cyclability. Conversely, compounds stable at the anode or cathode interfaces often do not exhibit useful bulk ionic conductivities. Although \textit{ab initio} methods exist to study each ionic conductivity and voltage stability range independently, there is no established theory to connect these two properties. Here, we leverage machine learning (ML) to investigate the role of crystal structure in the tradeoff between voltage stability and ionic conductivity. To this end, we trained a partial least squares (PLS) machine learning algorithm using the valence electronic density as a descriptor of 60 known solid-state electrolytes along with their corresponding ionic conductivity, anodic voltage limit, and cathodic voltage limit. In addition to exploring electron density, we also evaluate translationally invariant Fourier-based descriptors. The trained model has an 80% prediction accuracy and suggests that within the search space of crystal structures, the voltage stability and ionic conductivity are inherently inversely correlated. A multi-objective optimization also suggests that materials with positively correlated ionic conductivity and voltage stability may be highly anisotropic. Our PLS machine learning model, compared to the more conventional neural networks and other such models, has the benefit of being able to predict and explore the relationship between multiple properties and retains a high level of interpretability versus other ‘black box’ machine learning models. Moreover, we successfully quantify the uncertainty and confidence intervals in our model predictions which are often overlooked in other methods. The PLS model successfully identifies and quantifies the BCC anion substructure and channels as effective descriptors, which is in good agreement with prior work.\cite{Wang:2015} Using this model, we screened through a database of ca. 14,000 materials and identified five new promising solid state electrolyte candidates to have conductivities greater than 16 mS/cm. The model predictions were subsequently verified with \textit{ab initio} molecular dynamics simulations. The proposed ML model and electron density based descriptors may be used in future studies to elucidate other complicated structure-property relationships for other applications with high accuracy and without sacrificing interpretability.

Spectral Optimization and Temperature Control for Electronic and Optoelectronic Devices Using Machine Learning Po-Ying Chen\textsuperscript{1}, Quang-Tuyen Le\textsuperscript{1}, Nan-Yow Chen\textsuperscript{2}, An-Cheng Yang\textsuperscript{2} and Yu-Chieh Lo\textsuperscript{1}; \textsuperscript{1}National Chiao Tung University, Taiwan; \textsuperscript{2}National Center for High-Performance Computing, Taiwan

The temperature and the cooling power of electronic components are important to many kinds of commercial electronic devices. There are lots of factors that could raise the temperature, and sunlight is one of them. However, when using solar cell as the power resource of devices, we can’t prevent it from sun exposure. Therefore, finding a proper material which has the best ability to reduce the temperature becomes inevitable. Recently, applying machine learning on material design has been significantly promoted, so we introduced machine learning to help us find out the better cooling materials. TensorFlow is the machine learning module in this work, and an optical simulation
software called DiffractMOD is used to produce training data. At first, besides the refractive index and extinction coefficient of different materials, a variety of geometric structures were also set as input. Next, DiffractMOD would output the transmittance, reflectance, and absorptance of corresponding wavelength. Furthermore, to calculate the equilibrium temperature and cooling power, we performed Fourier-transform infrared spectroscopy. By feeding those data into an autoencoder which is based on convolutional neural network, we could train the model and predict the optical coefficients and geometries for optimal performance. In this case, it can cool down the devices most effectively.

**Deep Learning for Multiscale Atomistic Modeling of Multicomponent Crystal Chemistries Coupled with Hirshfeld Surface Analyses**

Arpan Mukherjee, Aparajita Dasgupta, Tianmu Zhang, Scott Broderick and Krishna Rajan; University at Buffalo, United States

Hirshfeld Surfaces are coupled to machine learning to map information on the impact of each pair-wise interaction between bond chemistry and bond geometry in multicomponent systems. The Hirshfeld Surfaces encode both chemical bonding and molecular geometry information and are extremely effective in providing a multiscale electronic structure signature for accelerated materials selection and design, while providing an electronic fingerprint which captures both bond geometry and bond chemistry. Based on their geometric and chemical bonding interactions, we have developed libraries of fingerprints which are computationally ready to be analyzed with various machine learning methods. From the new library of Hirshfeld Surface calculations, when coupled with new analysis approach, we rapidly define similarity in compounds computationally. We show the application of machine learning approaches, such as convolutional neural networks, to quantitatively find and extract characteristics in the material fingerprints to develop rapid classifications across multiple material classes, chemistries and properties.

**Phase-Field Modeling and Machine Learning of Electric-Thermal-Mechanical Breakdown of Polymer-Based Dielectrics**

Jianjun Wang¹, Zhonghui Shen², Yang Shen² and Long-Qing Chen²; ¹The Pennsylvania State University, United States; ²Tsinghua University, China

Polymer nanocomposites are attracting rapidly increasing attention due to their many of advantages and promising potentials, arising from the designable and optimizable synergetic interaction between the polymer matrix and the functional filler nanoparticles. For example, they can be used in capacitors which are crucial components in energy storage for advanced electrical and power systems, such as electric hybrid vehicles and solar power generators. To achieve a high-energy-density storage in a dielectric capacitor, a combination of high dielectric constant and high breakdown strength is required. However, normal dielectrics with high dielectric constants tend to have low breakdown strength while those with high breakdown strength tend to have low dielectric constant. Therefore, optimizing a combination of dielectric constant and breakdown strength has been a grand challenge. A common approach to overcoming this dilemma is making polymer-ceramic nanocomposites which own the high breakdown strength of the polymer and the high dielectric constant of ceramics, so as to give rise to a high energy density which is proportional to the product of the dielectric constant and the square of the breakdown strength. In my presentation, I will show a computational approach by combining high-throughput phase-field simulations and machine learning to understand the breakdown mechanisms of polymer nanocomposite dielectrics under different operating conditions, as well as to design novel microstructures to achieve optimized breakdown strength, maximized energy storage and operating temperature. An analytical expression of the breakdown strength as function of the dielectric constant, electrical conductivity, and Young’s modulus was obtained from machine learning, which can be used to semiquantitatively predict the breakdown strength of the P(VDF-HFP)-based nanocomposites. I will also take about some targeted experiments which were designed to verify the high-throughput phase-field simulations and machine learning results.

Using Data Driven Models to Gain Insight on Spin- and Oxidation-State Dependent Behavior of Reaction Energetics for Light Alkane Oxidation

Aditya Nandy, Jon Paul Janet, Chenru Duan and Heather J. Kulik;
Massachusetts Institute of Technology, United States

Biological systems readily catalyze difficult chemical transformations such as direct methane to methanol conversion with high selectivity using earth abundant transition metals (e.g. Fe and Cu). Computational high-throughput virtual screening (HTVS) with first-principles density functional theory (DFT) can play a valuable role in unearthing design rules for scalable, industrially viable synthetic analogues that preserve this selectivity and activity. Single-site catalysts represent the most promising analogues to these enzymes, often enabling atom-economy and selectivity not possible with bulk heterogeneous catalysts. Simultaneously, a wide chemical space must be explored to uncover potential single-site catalysts to simultaneously address other constraints, such as high turnover number or robustness, earth abundance, and synthesizability. Single-site catalysts have the added dimensionality of spin- and oxidation-state—which can drastically impact the structure-property relationships of molecular complexes—and remain unexplored for catalyst reaction energetics. The large dimensionality of the single-site catalyst chemical space becomes quickly intractable with DFT. Thus, we demonstrate our developments on data-driven models for key steps in single-site light alkane oxidation catalysts, which enable the prediction of reaction energetics in a spin- and oxidation-state dependent manner close to the accuracy of DFT. We first compare prediction of reaction energetics to other quantum mechanical properties that we have predicted, such as spin-splitting energetics, ionization potential, and frontier orbital energetics. We then discuss insights on representative catalytic reaction steps such as oxo formation and hydrogen atom transfer, including their dependence on spin- and oxidation-state. Lastly, we demonstrate the power of artificial neural-network and kernel ridge regression models for purposes of screening, enabling screens of large design spaces that would be infeasible to screen by DFT, even with the reduction in number of calculations through the use of descriptor energies. We uncover cases of molecules that would be overlooked by quantum mechanical descriptors, or would be missed by chemical intuition. Having separate data driven models for different reaction energy steps allows predictions of reaction energies that contain weak or nonexistent linear free energy relationships (LFERs), commonly employed in heterogeneous catalysis, but less prevalent in homogeneous catalysis.

Self-Evolving Neural Network Potentials for Supramolecular Interactions

Wujie Wang, William Harris and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Neural networks based on atomic embeddings have demonstrated accurate force and energy evaluations to simulate physical systems [1-5]. However, training neural potentials requires expensive sampling of configurational space and one needs to perform ab initio MD simulations to generate training data [6]. For the purpose of high throughput discovery, such brute force sampling is computationally infeasible to screen thousands of molecules. To this end, we propose a self-consistent strategy that accelerates the sampling and training of transferable neural networks over molecular space of interests, particularly to capture supramolecular interactions that are critical for applications like designing chelating agents and electrolytes. The proposed method combines deep neural network training and active sampling of both chemical and configurational space in an end-to-end fashion to 1) bypass expensive ab initio MD sampling and 2) leverage the transferable configurational information across species. We show that this active learning [7] method can improve neural network potentials in a self-consistent way and demonstrate its use in performing high throughput screening of lithium binding molecules.

Artificial Intelligence Design of Tunable Nanocomposites for Crack Resistance  
Chi-Hua Yu, Zhao Qin and Markus J. Buehler; Massachusetts Institute of Technology, United States

Here we report a new design approach for nanocomposite materials using artificial intelligence (AI). The algorithm consists of a machine learning predictor conjoined with an AI improved genetic algorithm, applied to discover materials designs in a vast space of possible solutions. Facilitated by a generative neural network that is trained with a dataset of thousands of combinations of soft and brittle materials to generate high resolution tessellate geometries, we design the material properties of novel graphene nanocomposites without running conventional simulations. Through the algorithm, we extend the capability of physical simulations beyond property predictions to optimize the fracture toughness by altering the material distribution. The solutions are generated by our AI model at a dramatically lower computational cost compared to brute-force searching methods. We further investigate the physical mechanism for improving the performance behind the AI approach and demonstrate the ability of AI to search for optimal designs with very limited sampling. Molecular dynamics simulations of the nanocomposite designs show that our AI design improves the performance by effectively decreasing the stress concentration at crack tips.

The AI approach reported here can be easily applied to other nanocomposites, biomaterials, and other material classes, and provides a transferrable, efficient and reliable design approach.

Automating Experiments and Data Interpretation in Solar Fuels and Catalysis Research  
John M. Gregoire; California Institute of Technology, United States

Automating critical steps of synthesis and screening experiments enables a variety of modes of materials exploration. High throughput experimentation comprises a family of techniques wherein materials systems can be comprehensively explored, and the resulting data relationships, e.g. composition-property and composition-structure-property relationships, are emblematic of the knowledge obtained from the experiments. Application of high throughput experimentation for solar fuels technology, in particular (photo)electrocatalysis of the oxygen evolution reaction, has led to a breadth of discoveries, many of which are based on high throughput computational screening. The resulting database of experiments, which is publicly released as the JCAP Materials Experiment and Analysis Database (MEAD) containing 6.5 million measurement files collected on 1.5 million materials samples, is a key resource for developing and evaluating algorithms that automate data interpretation. Successes to date include application of machine learning techniques to learn, identify, and communicate hidden data relationships. At a high level, these algorithms automatically generate answers to human-identified research questions, moving the frontier of artificial intelligence in materials discovery to the automatic identification of the interesting research questions.
8:30 AM MT02.07.02/MT03.08.02
Cooperative Learning for Materials Systems Valentin Stanev; University of Maryland, College Park, United States

Recently, materials scientists have started to utilize machine learning to accelerate experimental research. Active learning – an AI field dedicated to optimal experimental design – is a particularly promising tool; it provides systematic means to identify the shortest path toward a material with some desired properties or the experiments that maximize knowledge of the explored space. In many materials science tasks, however, the goal is to obtain a mapping between two or more experimentally measured quantities. Standard active learning algorithms may not be optimal for such complex scientific problems. Reducing the experimental effort to obtain such mappings can be optimized not by independently running several active learning tasks but rather by a strategy coordinating different experiments performed simultaneously. In this talk I will present the idea of cooperative learning, and illustrate it with examples from several different high-throughput studies.

8:45 AM MT02.07.03/MT03.08.03
Exploring Catalyst Chemistries beyond Scaling Laws using Statistical Learning Scott Broderick, Aparajita Dasgupta, Thaicia Stona and Krishna Rajan; University at Buffalo, United States

We have significantly expanded the knowledge-base of metal catalysts through a unique combination of manifold learning, Gaussian process regression and clustering approaches. Given the complexity in performing catalytic measurements, the amount of data available for selecting ‘optimal’ catalysts for specific reactions is limited. The work described here develops an analysis framework suitable to the small number of measurements available, while also developing a large relevant descriptor-base. We have performed the foundational work needed to develop a catalyst discovery toolkit. Using volcano plots as a platform, we have fused manifold learning methods and graph network methods from which one can rapidly explore new chemistries for single atom alloy (SAA) catalysts. We use single atom systems for testing our robustness, with the added benefit that prior work on single atom systems has not utilized machine learning. Using SAAs allows for a rapid screening of the combinatorial design space. We developed a machine learning logic for screening chemistries to define necessary detailed DFT calculations and have identified 28 alloys which are most promising for further exploration.

9:00 AM MT02.07.04/MT03.08.04
Graph Theory and Machine Learning Uncover Zeolite Transformation Pathways Daniel Schwalbe Koda, Wujie Wang and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Zeolites are inorganic nanoporous materials with broad industrial applications as catalysts, ion exchangers, and separators. Despite sustained research, controlling polymorphism is still a critical challenge in their design, relying mostly on trial-and-error. First-principles calculations could aid the search for new frameworks, but the number of theoretically accessible topologies and the complexity of their kinetic mechanisms render this approach computationally prohibitive. Here, we employ a suite of computational tools such as big-data, graph theory, structural kernels, density functional theory (DFT), and machine learning to explain and predict zeolite transformations. We first relate solid-state transformations to materials descriptors by combining crystallography with a graph-theoretical metric. Supported by exhaustive literature, we then show that interzeolite diffusionless transformations occur only between graph-similar pairs. Moreover, all known instances of intergrowth take place between either structurally- or topologically-similar structures. Our metric suggests hundreds of low-distance pairs between known frameworks and thousands of hypothetical frameworks for realizing novel transformations and intergrown crystals. Such insights are further refined by atomistic simulations. Building on millions of DFT calculations, we parameterize interatomic interactions in pure-silica zeolites using neural network models and active learning. The method enables accurate structural optimizations and off-equilibrium energy sampling with low computational cost, allowing the selection of favorable graph-driven phase transitions between frameworks and uncovering new synthetic pathways for zeolites.

9:15 AM MT02.07.05/MT03.08.05
Automatic Processing of the Scientific Literature to Accelerate Nanomaterials Design and Discovery Anna M. Hiszpanski, Brian Gallagher, Karthik Chellappan, Peggy Pk Li, Shusen Liu, Hyojin Kim, Jinkyu Han, Bhavya
A significant challenge in utilizing machine learning approaches to accelerate materials development is the lack of large and structured data sets. While there are ongoing community efforts to create collaborative materials databases and repositories for this purpose, the diversity and breadth of data types, length scales, and applications still makes it challenging to create such all-encompassing materials databases that are of broad practical use. However, if tools are developed to automatically process the vast scientific literature and extract and structure information of interest to a given user, then such tools can enable the easy creation of personalized databases with user-specified relevant information to which data mining approaches can then be applied.

We developed such tools for the automated extraction of a suite of information from the text of articles pertaining to nanomaterials synthesis and demonstrate their utility for nanomaterials synthesis. Attaining nanomaterials of desired composition, dimension, and morphology is critical for end-use applications but challenging to do, often requiring time-consuming iterations of synthesis and characterization. Using a corpus of 35k nanomaterials-related articles, we first use a simple unsupervised classification algorithm based on the frequency of occurring terms to identify the primary nanomaterial composition and morphology in each article. Classifying and analyzing articles based on their targeted nanomaterial composition and morphology by itself provides a bird’s eye view and can help identify “hot topics” in the field or alternatively under-studied or challenge-to-synthesize nanomaterials. Next, we apply a supervised machine learning approach to our corpus to identify and extract from articles’ text the sentences related to the nanomaterials’ synthesis protocols, thereby yielding a useful synthesis reference library. Interestingly, we find that function words (i.e., to, in, for, of, at) commonly omitted in natural language processing of non-scientific text are in fact a characteristic trait in discriminating between synthesis- and non-synthesis-related sentences in scientific text. With synthesis protocols in-hand, we further process these via chemical entity recognition (CER) to identify and extract the chemicals used in various nanomaterials’ syntheses. We evaluate a variety of open-access CER tools, as well as our own in-house developed CER tool, that each utilize different tokenizers for parsing the text and techniques for identifying chemicals, and we find that, despite the variety of approaches undertaken, most tools have comparable performance with a peak f1 score of 87%. Normalizing the chemicals names extracted from articles, we then have the opportunity to compare the frequency of use of chemicals for various nanomaterial morphologies. We demonstrate how such analysis provides useful insights as to the importance of chemicals in directing the growth of nanoparticles during synthesis to desired morphologies, like for example nanowires versus nanospheres versus nanocubes. We package this database created entirely by extracting information from existing nanomaterials literature into a browser-based visualization tool we developed that enables easy exploration of the data, thereby helping guide hypothesis generation and reduce the potential parameter space during experimental design.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-777678

High Throughput Experimental Materials Research Methods at NREL. Andriy Zakutayev; National Renewable Energy Laboratory, United States

Bridging the gap between computational predictions and industrial applications requires acceleration and automation of experimental synthesis, characterization and data analysis. High Throughput Experimentation (HTE), also known as combinatorial experiments, is one possible approach to accelerate materials research. Thus, HTE combinatorial methods have been regarded as a promising approach to fulfill the promise of the materials genome initiative (MGI)[1], complementary to high throughput computations and industrial research and development. This presentation will focus on the state of high throughput experimental materials research methods at National Renewable Energy Laboratory (NREL). First, I will discuss methods for creating later gradients of thin film sample properties, in particular going beyond chemical composition of metals [1]. Then, I will talk about spatially-resolved characterization methods, including interlaboratory exchange of samples [2]. Finally, I will highlight our efforts in streamlining data analysis in combinatorial materials science, including a recently published COMB1gor software package [3]. These methods will be illustrated by a broad range of materials examples, including oxides, chalcogenides, and nitrides.

10:30 AM MT02.07.08/MT03.08.08
Machine Learning-Assisted High Throughput Synthesis and Characterization of Hybrid Polymer-Carbon Nanotubes Composites for Thermoelectric Application Daniil Bash1,2, Anas I. Abutaha2, Yang Xu2, Yee Fun Lim2, Vijila Chellappan2, Zekun D. Ren3, Isaac S. Tian1,1, Pawan Kumar2, Swee Liang Wong2, Jose Recatela Gomez2,4, Jayce J. Cheng2, Tonio Buonassisi5,3 and Kedar Hippalgaonkar2; 1National University of Singapore, Singapore; 2Institute of Materials Research and Engineering, Singapore; 3Singapore-MIT Alliance for Research and Technology (SMART), Singapore; 4University of Southampton, United Kingdom; 5Massachusetts Institute of Technology, United States

The so-called 4th revolution in science began with the advent of machine learning (ML), as well as high-throughput (HT) experimentation and robotization. Herein, we describe a workflow that enables rapid screening of a parameter space of hybrid composites, comprised by carbon nanotubes and poly-3-hexylthiophene (CNTs:P3HT) for thermoelectric (TE) applications, with Bayesian optimization embedded in the feedback loop in order to explore the space in a more efficient fashion.

The parameter space under scrutiny includes 4 types of nanotubes (both single- and multiwall), 16 CNTs:P3HT ratios, 2 solvents (o-DCB, and chloroform) and 3 doping conditions, which result in 384 unique synthetic parameters. The setup used involves a robotic pipettor and the microfluidic flow reactor with XY stage for automatic drop casting. We synthesize more than 150 samples per hour, as compared to 4 samples per hour with traditional manual procedures. Characterization was done with means of hyperspectral imaging and 4-point-probe measurements to ascertain optical properties and electrical conductivity.

The conductivity data of the initial experiments was used to train the ML algorithm. After training, the algorithm inferred new experimental conditions for achieving highest possible conductivity, closing the feedback loop. In the end, 3 iterations of the experiments yielded the value of conductivity higher than 150 S cm⁻¹.

Further work includes the optimization of the experimental setup as well as the ongoing effort to use hyperspectral imaging to bypass the bottleneck step i.e. profilometry, as it is the main source of error.

10:45 AM MT02.07.09/MT03.08.09
Data-driven Materials Design of Halide Perovskites for Photovoltaic Applications Shijing Sun1, Noor Titan Putri Hartono1, Felipe Oviedo1, Zekun D. Ren1, Janak Thapa1, Zhe Liu1, Armi Tiihonen1, Ian Marius Peters1, Juan Pablo Correa Baena2, Tonio Buonassisi1 and Savitha Ramasamy3; 1Massachusetts Institute of Technology, United States; 2Georgia Institute of Technology, United States; 3Institute of Infocomm Research, Singapore

To meet increasing global energy demand, it is critical yet challenging to explore new methods to accelerate the development of novel energy materials. In recent years high-throughput experimentation (HTE) and machine-learning techniques have become increasingly accessible to scientific researchers. We herein demonstrate a case study on the data-driven design of perovskite-inspired materials for photovoltaic applications, where we employed machine-learning techniques to guide the synthesis of new halide perovskites for photovoltaic applications. Halide perovskites (ABX₃, where A = Cs, methylammonium (MA), formamidinium (FA); B = Pb, Sn; and X = Cl, Br, I) have shown great promise as light absorbers. Solar cells based on perovskites have surprised the energy community as an emerging low-cost photovoltaic technology with a record power conversion efficiency (24.2%) now exceeding polycrystalline Si cells (22.3%).[1] In this study, we developed a high-throughput experimental platform for thin-film synthesis and characterization, and investigated 75 unique perovskite compositions interest for energy-harvesting applications in a two-month period. To achieve desired optoelectronic properties, we established a set of selection criteria for screening. A deep neural network is employed to classify compounds into 0D, 2D, and 3D perovskite structures via X-ray diffraction patterns analysis. [2] The combination of fast synthesis and machine-learning assisted data diagnostics achieves an acceleration of over an order of magnitude per experimental learning cycle over our laboratory baseline. Among the 41 Pb-free perovskite compositions studied, we identified the optimised doping level in a multi-site alloy series, Csₓ(Bi₁₋ₓSbx)(I₁₋ₓBrx)₉, where a desired structural (2D) and optical properties (< 2 eV). [3] Our work contributes to the prospect of automated materials discovery and we envision an accelerated development in functional materials in the next decade aiming to provide new energy solutions.
11:00 AM MT02.07.10/MT03.08.10
Application of Variational Autoencoders to Create Thin Film Structure Zone Diagrams Lars Banko, Yury Lysogorskiy, Ralf Drautz and Alfred Ludwig; Ruhr-Universität Bochum, Germany

Structure zone diagrams (SZD) are frequently used to estimate thin film microstructures based on a few chosen synthesis parameters. Despite their usefulness, the predictive power of classical SZD is very limited due to the complexity of the synthesis-microstructure relationship of thin films. Furthermore, the complicated interplay of many synthesis parameters and compositional complexity hinders a generalisation. Classical SZD have in common that they are based on a small number of observations. Underlying trends were extracted by the scientists’ expertise and in a creative process abstracted into a diagram representation of microstructural features. Several refined SZD were proposed, which implemented more physical parameters. With emerging developments in combinatorial thin film synthesis and high-throughput characterization a fast, high-quality acquisition of microstructure data is now possible. This and progress in machine learning of images now provides tools to handle complex image data and improve SZD: We present a dataset containing > 100 samples of SEM surface images from Cr-Al-O-N material libraries, each featuring a different chemical composition and synthesis condition such as deposition temperature, ion energy and sputter frequency of high power impulse magnetron sputtering (HiPIMS). We train convolutional variational autoencoders (VAE) on this dataset of augmented SEM surface image data. Results show that VAEs can cluster microstructure data through latent space representations. The performance of different neural network architectures is discussed. The VAEs generative capabilities to predict SEM surface images from chemical composition and synthesis parameters are investigated. By sampling of the latent representation, we are able to generate SZDs for different variations and combinations of input parameters like temperature, ion energy and chemical composition. The qualitative trends which we observe demonstrate the prediction of microstructure by generative deep learning models.

11:15 AM MT02.07.11/MT03.08.11
Generative Adversarial Networks with Molecular Graph Convolution for Learning Secondary Structures of Functional Biomolecules Siddharth S. Rath1,1,1, Oliver Nakano-Baker1,1, Jonathan Francis-Landau1,1, Ximing Lu1,1, Kevin Jamieson1,1, Burak B. Ustundag1,2 and Mehmet Sarikaya1,1,1; 1University of Washington, United States; 2Istanbul Teknik Universitesi, Turkey

Generative models, a recent paradigm in machine learning has revolutionized the industry by generating ‘natural looking’ data. While such models have found limited applications in the domain sciences, they display untapped potential in generating materials or molecular structures commensurate with target properties and desired functionalities. While the protein folding problem has been addressed previously by multilevel computational methods and various deep convolutional neural networks, unfortunately, the key step of encoding atomic structures for computational treatment is a challenge. Historical efforts have focused on pre-process featurization that relies upon traditional string representation without any structural information, expert-designed heuristics-based inputs, or on volumetric modeling that presumes a specific predetermined conformation without associated functionality. Here we demonstrate the first implementation of generative models, more precisely, generative adversarial networks with graph encoding of atomic connectivity within the biomolecules, for data-driven prediction of peptide and protein conformations associated with particular functionalities such as binding to atomically flat surfaces and biomineralization. In the graph input, atoms are considered as nodes and the bonds are considered edges, while angles in the molecule are encoded as a third order tensor between any three nodes. The generator tries to output secondary structures in terms of the bond edges and angle tensors while the discriminator network learns from

existing sequences and their secondary structures from pdb files and MD simulations. We test the predicted results with MD simulations as well as circular dichroism experiments. Results show that the generative model developed herein is generalizable to any functionality and more accurate than existing methodologies for predicting functionality-associated peptide conformations for practical implementations in disease diagnostics, drug screening, biosensing and bioelectronic devices. As part of the Materials Genome Initiative, the research is supported by NSF-DMREF program through the grant DMR-1629071.

Prediction Interpretability in Data-Driven Materials Development Julia Ling, Astha Garg, James Peerless, Erin Antono, Edward Kim, Yoolhee Kim, Nils Persson and Malcolm Davidson; Citrine Informatics, United States

Sequential learning is a data-driven workflow for accelerating materials development. In this iterative workflow, machine learning models are used to explore a “design space,” the set of possible experiments that could be performed, to surface promising candidate materials. Experimental data for those candidate materials are used to retrain the models so that they can provide successively better-informed suggestions.

For sequential learning to be effective, a relevant design space of candidate materials must first be constructed. These design spaces often include complex constraints, as well as a mix of continuous and categorical variables. The machine learning model can be used to sift through the design space to surface the most promising candidates. For these top candidates, it is valuable to have insights into how the model made its predictions and why it predicts high performance. Interpretability analysis can increase confidence in the model predictions, uncover sample bias in the underlying training data, and provide information on the robustness of the predicted performance. This talk will discuss approaches for constructing relevant design spaces and for interpreting model predictions, and show how these approaches fit into the overall sequential learning workflow.

2:00 PM *MT02.08.02/MT03.09.02
Network Theory Meets Materials Science Vinay Hegde1, Muratahan Aykol2 and Christopher Wolverton1;
1Northwestern University, United States; 2Toyota Research Institute, United States

One of the holy grails of materials science, unlocking structure-property relationships, has largely been pursued via bottom-up investigations of how the arrangement of atoms and interatomic bonding in a material determine its macroscopic behavior. Here we consider a complementary approach, a top-down study of the organizational structure of networks of materials, based on the interaction between materials themselves. We demonstrate the utility of applying network theory to materials science in two applications: First, we unravel the complete “phase stability network of all inorganic materials” as a densely-connected complex network of 21,000 thermodynamically stable compounds (nodes) interlinked by 41 million tie-lines (edges) defining their two-phase equilibria, as computed by high-throughput density functional theory. We find that the node connectivity in the materials network has a lognormal distribution, and the connectivity decreases with the number of elemental constituents in a material. Analyzing the topology of this network of materials has the potential to uncover new knowledge inaccessible from traditional atoms-to-materials paradigms. Using the connectivity of nodes in this phase stability network, we derive a rational, data-driven metric for material reactivity, the “nobility index”, and quantitatively identify the noblest materials in nature. Second, we apply network theory to the problem of synthesizability of inorganic materials, a grand challenge for accelerating their discovery using computations. We combine the above phase stability network with timelines for the first experimental synthesis of each compound from literature citations. This allows us to create a time-dependent network, and from the time-evolution of the underlying network properties, we use machine-learning to predict the likelihood that hypothetical, computer generated materials will be amenable to successful experimental synthesis. **In collaboration with S. Kirklin, L. Hung, S. Suram, P. Herring, and J. Hummelshoj

A Database to Enable the Discovery and Design of Atomically Precise Nanoclusters
Sukriti Manna, Peter Lile, Alberto Hernandez and Tim Mueller; Johns Hopkins University, United States

Atomically precise nanoclusters can be used for numerous applications due to the unique properties they possess. Despite their wide range of applications, the structures and properties of many small elemental clusters remain unknown. We present the “The Quantum Cluster Database,” an open-access source containing the structures and properties of tens of thousands of cluster structures of up to 55 atoms for 55 elements. The structures are compared against previous computational and experimental data where available. We discuss the methods that are being used to accelerate the construction of the database and describe how the database can be accessed for cost-effective, data-driven materials design.

3:45 PM MT02.08.04/MT03.09.04
Data Driven Experimental Discovery of New Nitride Materials
Sage Bauers1, Elisabetta Arca1, Wenhao Sun2, Chris Bartel3, John D. Perkins1, Aaron Holder3, Stephan Lany1, Gerbrand Ceder2 and Andriy Zakutayev1; 1National Renewable Energy Laboratory, United States; 2University of California, Berkeley, United States; 3University of Colorado Boulder, United States

New materials enable new technologies, so discovery of new materials is one of the most important directions in materials research. Oxides and some other materials chemistries, which have been extensively explored in the past, yielded many spectacular properties. Other chemistries, such as nitrides, have been barely touched: for every 14 documented oxides there is only 1 known nitride.

We will present on data-driven experimental discovery of new nitride materials, focusing on experimental synthesis and characterization, while also featuring computational predictions and machine learning. The data mining efforts followed by first-principles calculations and machine learning analysis indicated that there are 93 unexplored ternary metal nitride chemical spaces, with 244 new predicted stable ternary materials, and explained the stability trends among these and other nitrides [1].

Experimental synthesis using high-throughput combinatorial methods realized 7 of these compounds, including Zn-M-N (M= Sb, Mo, W) with wurtzite-derived crystal structures and Mg-TM-N (TM = Nb, Ti, Zr, Hf) with rocksalt-derived crystal structures. Physical property characterization results of the ternary rocksalts indicate that they are semiconductors with 1.8-2.1 eV optical absorption onsets and large dielectric constants [2]. The Zn-Sb-N wurtzite is the first ever reported Sb-containing nitride, with Sb in unusually high 5+ valence state, and measured room-temperature photoluminescence near 1.6-1.7 eV solar matched band gap [3].

Overall, these results both demonstrate the power of data-driven materials discovery, and suggest that many new previously unreported nitride materials remain to be synthesized.

4:00 PM *MT02.08.05/MT03.09.05
Active Learning for Nanophotonic Design via Multi-Fidelity Physical Models
Harry A. Atwater1, Jialin Song1, Yury S. Tokpanov1, Yuxin Chen1, Dagny Fleischman1, Katherine T. Fountaine2 and Yisong Yue1; 1California Institute of Technology, United States; 2Northrop Grumman Corporation, United States

We have explored the design of nanophotonic structures, such as subwavelength-scale spectral filters, using an advanced active machine learning algorithm that efficiently explores multiple physical models with different approximation fidelities and costs. Our method, which is applicable to a variety of nanophotonics optimization problems, employs a novel strategy consisting of a mutual information based multi-fidelity Gaussian process optimization algorithm (MF-MI-Greedy). It consists of two components: an exploratory procedure to gather information about the target (i.e., the highest fidelity) function via querying lower fidelity functions, followed by an exploitative procedure to optimize the target level fidelity with the previously gathered information. Our results on
several pre-collected nanophotonics datasets demonstrate the compelling performance of the multiple-fidelity Bayesian optimization approach. These experiments suggest that there is a significant potential in utilizing cheap, multi-fidelity simulations to aid the discovery of optimal photonic nanostructures.

4:30 PM MT02.08.06/MT03.09.06
Accelerating Materials Discovery through Rapid Construction of Processing Phase Diagrams
Duncan Sutherland, Aine Connolly, Sebastian Ament, Michael O. Thompson, Carla Gomes and Bruce van Dover; Cornell University, United States

Exhaustive experimental mapping of non-equilibrium processing phase diagrams demands a prohibitively huge allocation of resources for even a single realistic system with more than two compositional degrees of freedom, even with current state-of-the-art high-throughput techniques. Advanced data analysis methods are thus called for to accelerate such explorative efforts, focusing on multimode analysis of critical boundary points in the phase diagram where transitions are observed. Here, we present a hierarchical, prioritized data analysis structure to optimize usage of costly experimental resources. By combining data analysis methods based on optical characterization and x-ray diffraction with sophisticated active learning algorithms, we can efficiently map phase boundaries in composition-time-temperature processing phase diagrams. We demonstrate the utility of our approach by constructing processing phase diagrams for spike annealed multicomponent oxide materials.

High-Throughput Screening of Perovskite-Inspire Materials Using Steady-State Photoconductivity and Bayesian Optimization
Jose D. Perea, Felipe Oviedo, Han Yin, Janak Thapa, Armi Tiihonen, Zhe Liu, Ian Marius Peters, Shijing Sun, Rafael Jaramillo and Tonio Buonassisi; Massachusetts Institute of Technology, United States

Hybrid organic-inorganic perovskites solar cells have recently increased scientific interest for their manufacturing simplicity and high performance, challenging the best thin-film photovoltaic devices. Perovskites solar cells have broad and strong light absorption along with excellent transport properties that partly explain their record power conversion efficiency above 24% [1, 2, 3]. Compositional engineering of perovskites is a time-consuming effort. Reaching high efficiency in compositions with complex and diverse dopants that usually requires significant trial and error and hundreds of measurements of full solar cells [4]. In addition to the abundance of applied research on this subject, there is great interest in understanding the fundamentals of transport and photophysical properties of various perovskites compositions [5]. High-throughput methods for screening compositions at the film level could be a potentially powerful alternative to investigate the complex perovskite composition space efficiently. Nevertheless, screening for high-efficiency perovskite compositions with high-throughput methods is not yet firmly established, in part due to the complexity of photophysical characterization experiments at the film level. In this work, we report for the first time a combination of high-throughput conventional steady-state photoconductivity method, (SS-PC) to determine diffusion lengths and Bayesian optimization methodology. This approach allows us to investigate the complex compositional space efficiently by just making films and not full solar cells. By using QSS-PC as a proxy for efficiency, we use Bayesian optimization to guide compositional changes and obtain the best solar cell efficiency for a given material, accelerating material screening by 10X.

Machine Learning for Revealing Aging Mechanisms of Perovskite Solar Cells
Armi Tiihonen, Shijing Sun, Jose D. Perea, Felipe Oviedo, Zhe Liu, Noor Titan Putri Hartono, Janak Thapa and Tonio Buonassisi; Massachusetts Institute of Technology, United States

Perovskite solar cells are among the most promising new photovoltaic technologies, boasting with rocketing efficiency records and raising interest as a component of tandem solar modules. Although the stability of perovskite solar cells is steadily improving and the most stable perovskite devices already pass 1000-hour aging tests under operating conditions [1], insufficient lifetime still remains a major bottleneck of the technology.

The aging mechanisms of perovskite solar cells need to be understood better for suppressing them. Several aging mechanisms, such as perovskite decomposition or ion migration in the device [1], have been identified in literature, and the observed aging mechanisms depend highly on the environmental conditions the devices are facing, such as temperature, humidity, and visible or ultraviolet illumination. More information about the activation and ground causes of the degradation of the devices is still needed, but the majority of aging tests in the literature do not demonstrate clear degradation of the devices [2]. The next step is to shift the focus of research community towards longer aging tests producing clear degradation with detailed analysis [1-2], and new working methods, such as machine learning, are required for extracting all the possible information from the laborious aging test.

In this contribution, we create a comprehensive mapping of the degradation of perovskite solar cells by aging devices until clear degradation under several different combinations of environmental stress conditions, such as illumination, increased humidity, and high temperature. Automated measurement systems are utilized for collecting densely sampled aging data with sample sizes that are statistically significant. We utilize machine learning methods for analyzing the relatively large data set our approach produces. This way, we are able to extract more refined information on the activation and interlinking of the detected aging mechanisms.

High-Throughput Discovery of Next Generation Sequencing-Based Peptide-Guided New Materials via Machine Learning
Jacob Rodriguez, Deniz T. Yucesoy, Siddharth S. Rath, Jason Stephany, Doug Fowler and Mehmet Sarikaya; University of Washington, United States

A crucial problem in the development of nanobiotechnology is control of the interface between the organic molecule and the substrate. Mastery of the field would enable highly sensitive biosensors capable of detecting disease biomarkers, affinity-tunable drugs, and efficient synthesis of solid biomaterials, among many other applications. Peptides are short amino acid sequences (4-40 long) that can have diverse conformational states when placed near a bias (i.e., 2-D materials, e.g., MoS2, electrical fields, etc.) and/or in solution (i.e., PBS, deionized water, etc.). These sequences can be found in larger proteins or designed in silico when the conformational behavior is often well-defined. Machine learning approaches may be used in many applications including drug design and continues to produce successful results. However the large data sets are required to train the ML algorithms to enable them to identify the dominant features. In a convergent science approach, here we identified three biological replicas of ~2.5 million unique 12-amino acid long peptide sequences with affinity for MoS2 using a novel method that combines Next-Generation Sequencing and Phage-Display directed evolution approaches. The massive size of this dataset grants a much greater understanding of why peptides bind to MoS2 upon development of the correct model or a large amount of experimental validation. We have developed a multitude of machine learning applications for the prediction of binding behavior including linear regression and recurrent neural network methods. Both methods seek to predict the functional affinity of this massive MoS2 binding set using the data from the combinatorial libraries that
are indirectly related to the solid-binding affinity. Further, the diversity in our approach yielded informative conclusions about the types of ML applications appropriate for this genetic dataset. Our results show that the functionality of peptides can be predicted using linear regression within and across replicates with high accuracy (0.75 to 0.9 Pearson/Spearman Rank Correlation). Encouraged by the preliminary results, we are currently implementing ML-assisted directed evolution experiment along with recurrent neural networks to determine the evolution path for high throughput labelling towards creating custom libraries. The research is supported by NSF-DMREF program through the grant DMR-1629071 as part of the Materials Genome Initiative.

**Data Driven Analysis of Dielectric Constants in Inorganic Materials**  
Kazuki Morita¹, Daniel W. Davies¹, Keith Butler²,¹ and Aron Walsh¹,³; ¹Imperial College London, United Kingdom; ²Rutherford Appleton Laboratory, United Kingdom; ³Yonsei University, Korea (the Republic of)

Dielectric constants are crucial to understanding optical and electric properties of materials. A low-cost predictor of dielectric behaviour would be highly valuable in materials science. Models such as Clausius-Mossotti and Penn's model are well known and have been used intensively, however, they are known to only hold for limited types of compounds. Previously, Han and co-workers have screened ~2000 compounds to find high dielectric constant materials with a large band gap[1,2]. They reported several materials that do not follow the existing models. Simple physical models are generally inadequate to capturing the trends in dielectric constants, which derive from many-body interactions. We propose the use of statistical approaches to describe them. We train multiple machine learning models using database of 1636 compounds. Our analysis show that some models were successful in capturing the complex trends in dielectric behaviour. Comparing with conventional models, the machine learning model gave an order of magnitude improvement in predictive power. The chemical trends in dielectric constants will also be discussed.

**A Semi-Automatic Pipeline for Efficient and Sustained Polymer Data Capture**  
Pranav Shetty and Rampi Ramprasad; Georgia Institute of Technology, United States

Machine Learning (ML) has enabled huge strides to be made in fields as diverse as Computer Vision, Natural Language Processing, Robotics etc [1][2]. Materials Science has also seen a flurry of work in recent years involving use of statistical techniques to predict material properties. ML models are data-hungry and their predictive accuracy improves asymptotically with the amount of data fed into it. As most materials property data is in journal papers and not in an easy to use database, prospective researchers must painstakingly extract this data manually. We hope to address this issue in the polymer space by building a framework that can automatically extract polymer property data from published literature. Data can be extracted systematically from 1000’s of papers to generate insight that would be very difficult to do manually.

Our framework aims to capture data from text in published literature and from tables. We generate word vectors [3], a mathematical way of representing words in a high dimensional space, from our corpus of polymer papers and use those to tokenize the text and thus extract polymer property information. We extract properties such as glass transition temperature, polymer melting temperature, dielectric constant, refractive index etc from tens of thousands of papers to generate ~1000’s of data points for each property. Similar work has been done in the space of extracting synthesis parameters for inorganic materials from literature [4][5] but this is the first such framework for the polymer domain. With the extracted data, we can power ML models that can be used to accelerate materials discovery and design new polymers.

Beyond Just Fitting Numbers—Artificial Intelligence for Identifying Statistically Exceptional Materials
Matthias Scheffler1,2 and Luca Ghiringhelli1; 1Fritz-Haber-Institut der MPG, Germany; 2Humboldt-Universität zu Berlin, Germany

Several issues hamper progress in data-driven computational science. In particular, these are a missing FAIR [1] data infrastructure and appropriate data-analytics methodology [2].

Significant efforts are still necessary to fully realize the A and I of FAIR. Here the development of metadata, their intricate relationships, and data ontology need more attention. Obviously, a FAIR data infrastructure – for being accepted by the community – should work without bureaucratic hurdles or the needs for special training. In this talk, I will discuss the challenges and progress, focusing on computational materials science.

Concerning the data-analytics, we note that the number of possible materials is practically infinite, but only 10 or 100 of them may be relevant for a certain science or engineering purpose. In simple words, in materials science and engineering, we are often looking for “needles in a hay stack”. Fitting or machine-learning all data (i.e. the hay) with a single, global model may average away the specialties of the interesting minority (i.e. the needles). I will discuss methods that identify statistically-exceptional subgroups in a large amount of data, and I will discuss how one can estimate the domains of applicability of machine-learning models. Crystallographic Information and Thermoelectric Properties Obtained from High-Throughput Experiments of Ca1-xBixMnO3 Powder Kenjiro Fujimoto1, Yusuke Yamada1, Akihisa Aimi1, Keishi Nishio1 and Shingo Maruyama2; 1Tokyo University of Science, Japan; 2Tohoku University, Japan
Material prediction by machine learning in recent years requires huge data, and in many cases it is supplemented by text mining and computational chemical simulation. I think that development of high-throughput experimental tools should also be continued in order to interpolate diversity in data and to construct a new database. In case of high-throughput materials preparation and evaluation, we treat about several hundred samples in one day. As an example, in conventional method for synchrotron powder X-ray diffraction, we have to fill fine capillaries (c.a. 0.2 mmΦ) with well-grounded powder. We need at least 10 hours for only sample filling when we measure 100 sample in one day. Therefore, we have made a prototype for effective and high-throughput evaluation in synchrotron X-ray powder diffraction measurements. Tools made with 3D printers made it possible to continuously measure powder libraries transferred to tape. In this study, as an example, powder library of perovskite-type Ca$_{1-x}$Bi$_x$MnO$_3$ was prepared and obtained X-ray diffraction data using the our developed high throughput evaluation tool. Then, we studied which parameter contributed to the improvement of the thermoelectric performance from crystallographic information obtained our developed automated Rietveld analysis program.

As the amount of Bi substitution increased, lattice constant was linearly increased based on Vegard's law. From the change of the bond length of Mn-O and the tilt angle of MnO$_6$ octahedron depending on the Bi substitution amount, the decrease of the electrical conductivity is ideally expected. However, the power factor ($PF = S^2 \times \sigma$) increased as the substitution amount increased. From these results, it was thought that the increase in $PF$ value was related to the carrier concentration more strongly than the other parameters.

These XRD and XAFS experiments were conducted at the BL5S1 and BL5S2 of Aichi Synchrotron Radiation Center, Aichi Science & Technology Foundation, Aichi, Japan (Approval No.2018P0104).
as well as single and co-alloying compositions of each of the 5 alloying elements, resulting in a high dimensional dataset that is not amenable to manual analysis. Interpretation of this high dimensional dataset is facilitated by analyzing the trained CNN model by evaluating local partial derivatives (Gradient Analysis), revealing key data relationships that are not readily identified by human inspection or traditional analyses. Statistical analysis of the ensemble of ~1 million gradients provides quantitative composition-structure-property and structure-property relationships as well as the similarity of the chemical role of different alloying elements, which collectively provide insight into the fundamental material science. Furthermore, automated reporting of these key data relationships illustrates a key mechanism by which machine learning methods accelerate scientific discovery.

9:45 AM MT02.10.05
A Data Driven Approach for the Accelerated Discovery of Photocathode Materials Evan Antoniuk¹, Yumeng Yue¹, Yao Zhou², Bruce Dunham³, Piero Pianetta³, Theodore Vecchione² and Evan J. Reed¹; ¹Stanford University, United States; ²Google, United States; ³SLAC National Accelerator Laboratory, United States

In this work, we utilize a data driven approach for the development of photocathode materials, which have served an integral part in developing modern x-ray light sources. In turn, these high-brightness light sources have enabled exciting discoveries. Recently, the hard x-ray free electron laser (FEL) at SLAC National Accelerator Laboratory has enabled researchers to monitor bond formation in the active site of proteins, optically tune the interlayer interactions in two-dimensional materials and probe the formation of diamonds from laser-compressed hydrocarbons. Through the further development of ultra-high brightness light sources, previously unthinkable experiments may be imagined.

Perhaps the most cost-effective method for improving the performance of FELs is through the discovery of new photocathode materials that can produce higher-brightness beams. However, past efforts for the discovery of photocathode materials have primarily used trial and error approaches with very low throughput. To date, less than 30 materials have been reported in the literature for photocathode applications. In this work, we screen over 10,000 bulk crystals in the Materials Project database to discover candidate photocathode materials. We utilize the Materials Project calculated electronic band structures as well as a newly developed photoemission model to rapidly identify materials with ideal photoemission properties. To ensure our candidate materials can be readily integrated into photocathode devices, we then filter out materials that have not yet been synthesized.

Following this filtering process, we discover over 300 candidate photocathode materials with a predicted brightness that is 10x larger than the current state-of-the-art photocathodes. We further characterize these high-brightness photocathode materials by performing high-throughput DFT work function calculations including multiple surface terminations and Miller indices. The photoemission properties of the photocathode materials are then further explored by utilizing DFT to calculate the photoexcitation probability of all possible optical excitations in a material. Through close partnerships with experimental collaborators, we discuss the possibilities for these newly discovered photocathode materials to shape the next generation of FELs.

Adding Domain Knowledge and Causality to Materials Informatics Vladan Stevanovic; Colorado School of Mines, United States

Today’s materials science deals with data sets that are much smaller than what would be desired by the contemporary statistical methods. Historically, this problem has been dealt with using “modern” scientific method – formulation, via induction, of causally related hypotheses and their measurement-based testing through deduction. However, the complexity of materials’ behavior and the insufficient knowledge of all factors influencing experimental outcomes, in combination with the successes of AI in other fields (e.g. targeted advertising) motivated recent surge of activities in utilizing machine learning, neural networks, random forests and other methods in materials science. While of unquestionable practical value, the statistically obtained relationships suffer from the absence of causality and non-uniqueness. In this talk I will discuss ways of adding domain knowledge and causality to the data driven materials discovery and design. The approach we recently adopted starts from the appropriate theory and the analytically deduced relationships between quantities of interest. In the next step we replace hard-to-access physical quantities appearing in those relationships with physically motivated proxies that are easily
accessible from materials data bases or are inexpensive to compute from first-principles. The price for this replacement is the introduction of free parameters into the models, which are then obtained by fitting to existing, usually experimental data. In this way one integrates domain knowledge with materials informatics and creates causal and interpretable models of relevant materials properties. I will review successes in applying such an approach to the discovery and design of novel semiconductors for thermoelectric, photovoltaic and power electronics applications.

11:00 AM MT02.10.07
Mapping and Understanding Large-Scale Stability Trends across the Ternary Metal Nitrides
Wenhao Sun\textsuperscript{1,2}, Chris Bartel\textsuperscript{2,3}, Elisabetta Aca\textsuperscript{4}, Sage Bauers\textsuperscript{4}, Bethany Matthews\textsuperscript{4}, Janet Tate\textsuperscript{5}, Bor-Rong Chen\textsuperscript{6}, Michael F. Toney\textsuperscript{6}, Laura T. Schelhas\textsuperscript{6}, Andriy Zakutayev\textsuperscript{4}, Stephan Lany\textsuperscript{4}, Aaron Holder\textsuperscript{4} and Gerbrand Ceder\textsuperscript{2}; 1University of Michigan–Ann Arbor, United States; 2Lawrence Berkeley National Labs, United States; 3University of Colorado Boulder, United States; 4National Renewable Energy Laboratory, United States; 5Oregon State University, United States; 6SLAC National Accelerator Laboratory, United States

Exploratory synthesis in novel chemical spaces is the essence of solid-state chemistry. However, uncharted chemical spaces can be difficult to navigate, especially when materials synthesis is challenging. Nitrides represent one such space, where stringent synthesis constraints have limited the exploration of this important class of functional materials. Here, we employ a suite of computational materials discovery and informatics tools to survey, visualize, and explain stability relationships across the inorganic ternary metal nitrides. First, we use crystal structure prediction algorithms to probe the stability landscapes of previously unexplored ternary nitride spaces, identifying hundreds of promising new ternary nitrides for further exploratory synthesis. Next, we use unsupervised machine-learning algorithms to cluster together cations with a similar propensity to form stable or metastable ternary nitrides. To visualize these clustered nitride families, we construct a large and comprehensive stability map of the inorganic ternary metal nitrides. Our map reveals broad overarching relationships between nitride chemistry and thermodynamic stability, and inspires us to rationalize these trends from their underlying chemical origins. To do so, we extract from the DFT-computed electron density the mixed metallicity, ionicity, and covalency of solid-state bonding, which we use to formulate data-driven insights into the thermochemical and electronic origins of ternary nitride stability.

Combinatorial Synthesis and High-Throughput Characterization of Microstructure and Phase Transformation in NiTiCu-X Quaternary Thin-Film Libraries for Elastocaloric Cooling
Naila Al Hasan\textsuperscript{1}, Huilong Hou\textsuperscript{1}, Jonathan Counsell\textsuperscript{2}, Tieren Gao\textsuperscript{1}, Suchismita Sarkar\textsuperscript{3}, Sigurd Thienhaus\textsuperscript{4}, Apurva Mehta\textsuperscript{3}, Alfred Ludwig\textsuperscript{5} and Ichiro Takeuchi\textsuperscript{1}; 1University of Maryland, United States; 2Kratos Analytical Ltd., United Kingdom; 3SLAC National Accelerator Laboratory, United States; 4Ruhr-Universität Bochum, Germany

Ni-Ti based shape memory alloys (SMAs) have found widespread use in the last 70 years but improving their functional stability remains a key quest for more robust and advanced applications. Named as such due to their ability to retain their processed shape as a result of a reversible martensitic transformation, they are highly sensitive to compositional variations. Alloewing with ternary and quaternary elements to fine tune the lattice parameters and the thermal hysteresis of an SMA, therefore, becomes a challenge in materials exploration. Combinatorial materials science allows streamlining of the synthesis process and data management from multiple high throughput characterization techniques. In this study, composition spreads of Ni-Ti-Cu-X (X = V, Fe, Co) thin film libraries were synthesized by magnetron co-sputtering on thermally oxidized Si wafers. Composition dependent phase transformation temperature and microstructure were investigated and determined using high throughput wavelength dispersive spectroscopy, synchrotron x-ray diffraction, and temperature-dependent resistance measurements. Composition-structure-property phase maps for the quaternary systems are used to discuss correlations of functional properties with respect to local microstructure and composition of the thin film libraries. This work was supported by the National Science Foundation Graduate Research Fellowship Program under Grant No. DGE 1322106.

11:30 AM MT02.10.09
Discovery of Promising Salt Hydrates for Thermal Energy Storage Using High Throughput Computation and Machine Learning
Steven G. Kiyabu and Donald Siegel; University of Michigan, United States
Salt hydrates demonstrate promise as heat storage materials as they possess high energy densities and reversibility at moderate temperatures. Despite their promise, a great number of salt hydrate compositions have not been explored. The goal of this work is to identify new salt hydrates that can outperform known materials in terms of energy density and are predicted to be thermodynamically stable. A total of 5,292 hypothetical salt hydrates were generated by systematically substituting cations and halides into 76 salt hydrate crystal structures mined from the Inorganic Crystal Structure Database. These hypothetical hydrates were characterized according to their enthalpy of dehydration (from which stability, energy density, and heat-storing temperature are derived) in one of two ways. 2,954 of these hydrates were characterized using high-throughput density functional theory calculations. A machine learning model with extensive feature selection was then developed and trained on these hydrates. The initial set of structural and ionic features was expanded to a set of several thousand physically meaningful combinations of the original features. A two-step feature selection process using LASSO and a genetic algorithm was then employed before the final model was trained. The remaining 2,338 hypothetical salt hydrates were then characterized using this predictive model. Several promising hypothetical hydrates were identified with higher energy densities than experimentally-known salt hydrates. Furthermore, the machine learning model illuminated several new property-performance relationships in salt hydrates.

11:45 AM MT02.10.10
Accelerating the Search for Lithium-Ion Conductors with Machine Learning Interatomic Potentials
Koutarou Aoyagi1,2, Chuhong Wang1 and Tim Mueller1; 1Johns Hopkins University, United States; 2Toyota Motor Corporation, Japan

All-solid-state lithium-ion batteries are leading candidates for the next generation of batteries, but interfacial resistance needs to be improved for commercialization. Interfacial impedance can be improved through the use of cathode coating materials between the active electrode material and the solid state electrolyte. As experimentally exploring candidate coating materials is time-consuming and resource-intensive, the development of new coating materials can be accelerated by computationally screening candidate materials in a high-throughput manner. One of the most important criteria for coating materials is lithium-ion conductivity. As the mechanism for lithium-ion conduction is generally not known for a candidate coating material, computational assessment of lithium-ion conductivity is best accomplished through molecular dynamics simulations. Sufficiently accurate simulations can be performed using density functional theory, but the computational cost of this approach limits its use to materials that are fast ionic conductors. We demonstrate that this problem can be addressed through the use of machine learning to develop interatomic potentials on the fly. We present a method for using moment tensor potentials, a recently developed class of machine learning interatomic potentials [1], for automatically calculating lithium-ion conductivity with molecular dynamics simulations and demonstrate that this approach results in improved agreement with experiments over ab-initio molecular dynamics while requiring less computing time.

discuss the surprising difficulty of this problem and introduce efficient, nonmyopic policies to solve it, demonstrating our method on large-scale materials and drug discovery experiments. Nonmyopic active search increases search efficiency dramatically across a wide range of settings, suggesting it may be a promising approach to automating discovery pipelines.

2:00 PM MT02.11.02
Pan-Sharpening Algorithm for Spectral Map Reconstruction Nikolay Borodinov¹, Natasha Bilkey², Alison Pawlicki¹, Marcus Foston², Anton V. Ievlev¹, Alex Belianinov¹, Stephen Jesse¹, Rama K. Vasudevan¹, Sergei Kalinin¹ and Olga S. Ovchinnikova¹; ¹Oak Ridge National Laboratory, United States; ²Washington University in St. Louis, United States

Recent advances in chemical imaging allow material composition characterization at the nanoscale. Such methods (optical spectroscopy, secondary ion spectrometry, mass spectrometry to name a few) vary in data acquisition, sample preparation, and spatial resolution; and thus offer common yet nonidentical applicability for different samples [1].

Coupling atomic force microscopy with infrared spectroscopy is a recent addition to the chemical imaging toolkit. A pulsed infrared laser triggers periodic thermal expansion of the sample, which is then detected by an AFM tip. Recent advances in AFM-IR allow imaging of polymer blends and nanocomposites, biological tissue, and ion migration; which makes it a highly relevant technique [2]. Currently there are two operational modes: an acquisition of a single wavenumber map, which has full AFM resolution, and an acquisition of a sparse arrays at full spectral resolution. A direct attempt to measure full spectral response at each point of an AFM scan would be prohibitively long, and very likely to be disturbed by sample drift. In order to yield a full resolution dataset which could be used for correlative analysis, the two types of data – a spectral array and a set of single wavenumber maps, have to be combined in a physically meaningful way. Methods for combining multiple data channels with different spectral and spatial resolution have been intensively explored and overall are commonly referred to as pan-sharpening. One of these approaches, which is very suitable for the case of AFM-IR, relies on coupled non-negative matrix factorization (CNMF) of the data.

We demonstrate the applicability of CNMF-PS algorithm for synthetic data, experimental AFM-IR with known ground truth and an experimental AFM-IR with unknown ground truth. We analyze the algorithm parameters (downsampling rate, number of NMF components, number of single wavenumber maps used) on the quality metrics of the PS operation. We use our method for the analysis of plant cell wall materials and derive the correlation between the spatial distributions of chemically dissimilar components provided by CNMF-PS and local physical property (mechanical stiffness measured as the shift in AFM tip contact resonance). In addition, we use this method for the chemical characterization of tribofilms which are easily destroyed by exposure to the IR. These examples highlights the utility of PS algorithm for in-depth nanoscale characterization of various materials. This work can be readily adopted by other chemical imaging techniques generating spectral images.

Accelerated Catalyst Discovery through Gaussian Processes and Active Learning Kiran Vaddi, Olga Wodo and Krishna Rajan; University at Buffalo, United States

We introduce an active learning procedure to query and uncover highly catalytic regions within a design space. We
have identified key challenges related to the high dimensional responses of cyclic voltammetry experiments and derived a Bayesian Model Selection (BMS) method to efficiently label the responses and to guide the active learning within the identified design space. Applying the proposed methodology on a simulated kinetic zone diagram as the design space, we show that actively learning within the design space can improve the design of experiments for catalyst discovery and characterization. We have reduced the total number of experiments required to discover the high catalytic zones in the design space by an order of magnitude, thereby significantly accelerating design and minimizing experimental requirements. Using an active batch search, we derive a mechanism to actively learn highly catalytic zones in a high-throughput combinatorial search for catalyst.

Insights in Chemical Features Impacting the Quality and Lifecycle of 3D Printed Model System—An Integrated Experimental, Modeling and Data Sciences Approach Amra Peles, William S. Rosenthal, Francesca C Grogan, Yulan Li, Erin I Barker, Zachary C Kennedy, Timothy Pope, Christopher Barrett and Marvin Warner; Pacific North West Laboratory, United States

Additive manufacturing is causing fundamental changes in the way complex 3D objects are produced from their digital designs. It is well known that product quality, ease of reproducibility and often open-source nature of digital model design possess pressing concern about utilizing this fast-developing technology to produce safety and security critical parts. Our ability to understand additive manufacturing process from conceptual design to the life-long printed part performance and to uncover critical features that are the best indicators of future failure of the part is critical. Here the elements forming a part of the holistic integrated approach are presented, which are also the backbone for the materials discovery framework.

We employ the polymer nylon 12 as the feedstock to print the specimens for the mechanical testing and as a model system. We report on initial polymer feedstock characterization for the details of compositional chemistry and powder-specific qualities; the mathematical model for powder geometry and material property representation; the implementation of phase-field models to study sintering and aging properties of selective laser sintering (SLS) process; few-shot learning strategy to train and characterize micro-CT images; and coupled to the uncertainty quantification an implementation of long short term memory (LSTM) algorithm to optimize error back flow in time dependent aging study. The insights into sensitivity analysis and the adaptive inference modeling to guide the design of build experiments, aging of printed specimens and set of static and dynamic mechanical tests will be presented. The micro-CT studies are used to look at structural features and their changes due to variable processing and aging of printed specimens. The experimental micro-CT images and details of experimentally aged specimens serve as the ground truth for the structural and aging study features from phase-field model.

The Machine Learning Route to Accelerated Discovery and Inverse Design Johannes Hachmann; University of New York, Buffalo, United States

The use of modern machine learning, informatics, and data mining approaches is a relatively new development in the chemical and materials domain. These techniques have been exceedingly successful in other application fields, and since there is no fundamental reason why they should not have a similarly transformative impact on chemical and materials research, there is now a concerted effort by the community to introduce data science in this new context. They hold tremendous promise for the practical realization of accelerated discovery and inverse design. However, adapting techniques from other application domains for the study of chemical and materials systems requires a substantial rethinking and redevelopment of the existing methods.

In this presentation, we will discuss our work on designing advanced, physics-infused neural network architectures, the fusion of unsupervised clustering with supervised regression for local ensemble models, active and transfer learning techniques, bootstrapping approaches to minimize our training data footprint, methods to increase the applicability domain of data-derived models, and automated hyperparameter optimization.
Predictive materials modeling can provide properties of real and virtual compounds and will be available on demand, thereby enabling rapid iteration time in materials design. However, the allure and necessity of accelerated discovery that motivates computational materials design is diminished by the prevalent heuristic approaches to materials synthesis and optimization. This presentation will outline our collaborative work to extract information from peer reviewed academic literature across a range of materials science texts. We have demonstrated not only the potential of the natural language processing (NLP) approach to assemble materials data from the literature, but we have also shown that one can develop hypotheses for what synthesis conditions drive a particular target material outcome using learning approaches. The presentation will describe application of NLP and machine learning to a few cases of materials discovery as well as issues with current and historical writing conventions in materials science literature to propose a structured way to facilitate reproducibility, clarity, and machine readability.

We present a computing and data science effort at PNNL for an end-to-end analysis pipeline for chemical dynamics studies using High-Performance Computing (HPC) resources. The current computing model uses DIRAC (Distributed Infrastructure with Remote Agent Control) for its workflow and data management. A detailed meta-data assignment using the DIRAC File-Catalog is used to automate the stages of data processing. The DIRAC system is deployed on containers managed using a Kubernetes cluster to provide a scalable infrastructure. A modified DIRAC agent provides the ability to submit jobs using singularity on dedicated and opportunistic HPC sites. The data products from this pipeline are feed into a graphics processing unit (GPU) cluster that runs various Machine Learning (ML) tasks, such as 3D convolution networks and/or physics aware temporal models.

The performance of most organic electronics is critically dependant on the bulk morphology. Subsequently it becomes important to identify distributions of morphologies that have high performance. While computational studies and high-throughput analysis promise drastic improvement of time to delivery, they are nonetheless limited in several aspects, primarily two-fold — (a) the size of morphology space, even for simplistic descriptions (2D, binary) is practically unlimited and (b) the resources required for quantification are still limited (limited physics models) and time consuming. In this work, we address the first issue of efficiently exploring the practically infinite morphology space using state-of-the-art machine learning and artificial intelligence algorithms. More specifically, we take a completely data-driven approach to generate morphologies that show high performance. We used a combination of invariance obeying generative adversarial networks along with robust and interpretable CNN based structure-property map to generate extremely high performing morphologies. The generated morphologies consistently showed high performance and simultaneously sampled remote regions of the morphology space that were previously not reported. Finally, we quantified the generated morphologies against full physics simulations to find that the novel AI approach predicts high performing morphologies in most of the cases.

Materials informatics (MI) has attracted a great deal of interest over the past decade in efforts to accelerate materials discovery. Virtual screening is a frequently employed MI procedure to link a target property to an explanatory feature of materials, i.e., a descriptor. The model is then applied to predict and rank the target property in materials
registered in the database. However, a major bottleneck of the MI model is an insufficient amount of supervised data. To overcome this issue, we took three approaches, namely, high-throughput (HT) computations for an extension of the database,\textsuperscript{1,2} a newly developed ensemble-scope descriptor for the virtual screening with a limited supervised data,\textsuperscript{3} and a HT experiment that facilitates efficient materials discovery within a certain chemical search space MI suggested.\textsuperscript{4} In this presentation, we demonstrate applications of the method to an exploration of oxygen ion conductors, aiming to find new materials superior to the conventional high-temperature conductor, yttria-stabilized zirconia (YSZ), which is used for solid oxide fuel cells.

The ensemble-scope descriptor includes the physical and chemical knowledge, and short- and long-range representations of the crystal structure. This multifaceted feature augments information acquired from a relatively small number of supervised data to improve the prediction power; in addition, it provides physical insights in the prediction, which facilitate to get new knowledge and extend a search space. Given only 29 supervised data, we successfully discovered more than 5 compounds, such as EuKGe\textsubscript{2}O\textsubscript{6} and Ca\textsubscript{3}Fe\textsubscript{2}Ge\textsubscript{3}O\textsubscript{12}, which were verified by experiment. The MI prediction was then used to focus a chemical search space where the HT experiment performed. We implemented HT combinatorial synthesis, HT-XRD measurement, and HT conductivity measurement. The application of the method to oxygen ion conductors led to the discovery of materials in the Ca-(Nb,Ta)-Bi-O system that exhibited high conductivity and durability.

**Effect of Dielectric Particle Heterogeneity on Capacitance—A Machine Learning Biased Genetic Algorithm Approach**

Venkatesh Meenkshisundaram\textsuperscript{1,2}, David Yoo\textsuperscript{1,2}, Andrew S. Gillman\textsuperscript{1} and Phil Buskohl\textsuperscript{1}, \textsuperscript{1}Air Force Research Laboratory, United States; \textsuperscript{2}UES, Inc., United States

Microscale spatial and material heterogeneities in 3D printed electrical devices present significant challenges to predictable electrical performance and device reliability. Dielectric particles are often added to dielectric inks to tailor the macro level permittivity of printed dielectric substrates and coatings. In these inks, the combined role of particle morphology, discrete spatial arrangement and material properties on variance is difficult to distinguish experimentally and hence poorly understood. This is primarily due to the large parameter space of processing variables as well as electrical sensitivity to local heterogeneities. We address this challenge by combining a finite element capacitor model with a neural network biased genetic algorithm (NBGA) to optimize the volume fraction, particle size and permittivity distributions of dielectric particles to identify systems with high capacitance variance. Comparison of the optimized system to an equivalent system with monodisperse particles revealed that heterogeneity in particles could be key to achieving larger variance that is not available to system with monodisperse particles. A closer look at the optimized system revealed that variance in distance between particles and the electrodes was larger than the monodisperse system. This can be attributed to larger packing configurations accessible to the system with polydisperse particles as compared to system with monodisperse particles. Classification-based machine learning techniques were also applied to the NBGA-created database to extract correlations between the spatial/material distributions of the dielectric particles and the capacitance variance. Collectively, the study provides a useful framework to correlate electrical performance with both macro- and microstructural variation sources, which is key to accelerating the development of 3D printing materials.
Machine Learning Based Data Driven Approach for Optimized Inkjet Printed Electronics Fahmida Pervin
Brishty, Ruth Urner and Gerd Grau; York University, Canada

Machine Learning (ML) has not been explored extensively to optimize printed electronics manufacturing. As a predictive methodology, it has the potential to efficiently minimize printing configuration workload. Inkjet printing is a promising method of additive manufacturing due to its attractive attributes including low-cost, scalability, non-contact printing and microscale on-demand customization. It generates droplets of electronic materials with a piezoelectrically actuated dispenser controlled through voltage pulse and timing parameters. This will enable novel electronics development on flexible plastic and paper substrates such as wearable sensors, RFID tags or flexible displays in a drop-on-demand (DOD) way. A major challenge in inkjet printing is the rapid optimization of stable jetting conditions. Several problems can occur: no ejection, perturbation, satellite drop, multiple drops, drop breaking, nozzle clogging etc. These non-idealities can lead to significant uncertainty in the behavior of mass-produced electronic devices and circuits. Steady drop speed and volume generation requires numerous time and material consuming trial and error experiments. Theoretical modeling and prediction is limited and difficult due to the complexity of the printing process. Here, an intelligent ML algorithm is demonstrated to forecast the jetting window based on machine and material properties.

Optimal inkjet system parameters vary from material to material and printer to printer, so stable jetting is interpreted here as a data-driven optimization problem. A major challenge was the lack of an established dataset in this context. Data was extracted from academic papers as well as experimentally collected in our lab. Printers from different manufacturers and different inks (pure solvents and nanoparticle inks) were included in the dataset. The input factors were printer-dependent (printer make, nozzle size), material-dependent (density, viscosity, surface tension) and printing control parameters (dwell time, echo time, rise time, fall time, jetting frequency, dwell voltage, echo voltage and waveform shape). The measured outputs were drop velocity and volume.

The merged dataset has 13 features out of which the 9 most important features were identified during a first stage of exploratory data analysis. A detailed analysis was then performed to compare various (linear and non-linear) regression models with the goal to identify a type of model with high predictive capacities while at the same time allowing for interpretation of the underlying implied dependencies of the involved features. The models were trained on 80% of the data and the mean absolute error was calculated on 20% test data. Simple linear relationship consideration between the input and output features did not yield accurate predictions. Instead, small ensembles of decision trees (boosted decision trees and random forests) were explored further to estimate jet drop velocity, and volume. The models were applied to an experimentally collected data set with a material that was not included in the training set. The learned regression model predicted drop velocity with test root mean square error (RMSE) of 0.53 m/s. Drop volume was forecasted for the same dataset with RMSE of 14.88 pico-liter.

In conclusion, we demonstrated that employing machine learning for drop behavior prediction can be used for forecasting new fluid drop formation which were not available at training time. This will enable more efficient materials selection as well as tuning of printing parameters. It has the potential to considerably speed up the development of novel materials and inks for printed electronics by eliminating extensive jetting experiments that are costly in terms of money, time and material.

MT02.12.03
Scientific Data Infrastructure for Combinatorial Material Science Lars Banko, Sigurd Thienhaus and Alfred Ludwig; Ruhr-Universität Bochum, Germany

Data mining by statistical/machine learning methods is an emerging topic in material science. Advanced algorithms are able to find patterns in large datasets beyond human capabilities. Additionally, these techniques can accelerate the analyses of complex data. Combinatorial material science generates large, comparable data sets of materials libraries that are designated for data mining applications. Aggregation of those data sets within a research group or even within a certain scientific community provides the opportunity to generate knowledge based on non-trivial correlations. The basis for this approach is a solid data management which ensures a high degree of reusability by appropriate data curation. Here, we demonstrate our recent achievements in the development of a customized scientific data infrastructure. The solution consists of a commercially available, customizable document management system, a terminal server-based IT infrastructure and in-house developed software tools. The main purpose of this data infrastructure is to track all data and information about a materials library throughout the whole sample lifecycle, from experimental planning and synthesis over processing to characterization and analyses. It is demonstrated that standardization of data acquisition, pre-processing and storage promote time efficient, machine assisted data analyses. The use of terminal servers guarantees access from various devices (computers, tablets,
smartphones) and operating systems (Windows, Linux, OS X, iOS, android etc.) and improves data security at the same time. Maintenance is reduced by remote applications which are easy to deploy and update. An additional benefit is the structured storage of knowledge which counteracts fast personnel cycles in university research.

Machine Learning Prediction of Glass-Forming Ability and Elastic Modulus for Bulk Metallic Glasses Jie Xiong, San Qiang Shi and Tong-Yi Zhang; The Hong Kong Polytechnic University, Hong Kong; Shanghai University, China

There is a genuine need to shorten the development period for new materials with desired properties. Bulk metallic glasses (BMGs) are a unique class of materials that are gaining attention in a wide variety of applications due to their attractive physical properties. One limitation to the wide-scale use of these materials is the lack of predictable tools for understanding the relationship between alloy composition and ideal properties. In this work, machine learning (ML) approach was applied on a dataset of 6312 alloys. The resulting ML model predicted the glass forming ability and elastic moduli of unseen alloys in good agreement with most experimentally measured values. It will promote the development of basic theories of metallic glasses to reveal the intrinsic correlation of physical properties through material big-data mining. This work indicates the great potential of ML in the design of advanced materials with target properties.

MT02.12.05
Accelerated Development of High-Performance Nanocomposite Solar Absorbers Using Bayesian Optimization Qiangshun Guan, Afra S. Alketbi, Aikifa Raza and TieJun Zhang; Khalifa University of Science and Technology, United Arab Emirates

Machine learning-based approach is desired for accelerating materials design, development and discovery, especially when it is coupled with high-throughput experiments and simulations. In this work, we propose to apply the Bayesian optimization to design ultrathin multilayer W-SiC nanocomposite absorbers for high-temperature solar power generation. The optical properties of nanocomposite depends on the filling factors as predicted by the effective medium theory. The spectrally averaged solar absorptance of various absorber designs is evaluated with a semi-analytical scattering matrix method. The design of spectrally selective nanocomposite absorber is optimized over a range of filling factors and layer thicknesses to maximize the overall solar absorptance. Our nanofabrication and experimental characterization results demonstrate the capability of the proposed close-loop approach for solar energy materials development. Comparison with other global optimization methods (Random Search, Simulated Annealing and Genetic Algorithm) shows that the Bayesian optimization can expedite the design of multilayer nanocomposite absorbers and hence reduce their development cost significantly. This work sheds light on the high-throughput discovery of materials for solar energy and sustainability applications.

MT02.12.06
Recommender System of Processing Conditions for Inorganic Compounds Based on a Parallel Experimental Dataset Hiroyuki Hayashi, Atsuto Seko and Isao Tanaka; Kyoto University, Japan; PRESTO, Japan; National Institute for Materials Science, Japan

Studies on high throughput material-screening through calculations based on density functional theory and/or machine-learning methods have increased rapidly in the last decade. However, data-centric approaches for successful processing conditions are still in the very early stage. Little works have yet been reported except for literature-data based approaches [1,2]. In this study, we propose a machine-learning approaches for successful processing conditions for inorganic compounds based on parallel experiments [3]. Initially, an experimental database was constructed for 67 pseudobinary oxides registered in the Inorganic Crystal Structure Database (ICSD) [4] by parallel experiments using 23 starting materials and 23 cation mixing ratios. Precursor powders were obtained by four synthesis methods (solid-state reaction, polymerized complex, cyclic ether sol-gel, and spray co-precipitation), which were fired at five different temperatures. This resulted in 1,648 unique chemical synthesis conditions and database entries. The reactants were characterized sequentially using powder X-ray diffraction equipment with an automatic sample exchanger. The synthesis results were rated as a score, which was placed into a fifth-order tensor with 243,340 elements. The Tucker decomposition method was used to predicted yet-to-be-rated scores for unexperimented processing conditions. Good predictive performance of the present model was demonstrated by leave-one-experimental-composition-out cross validation. It was further evaluated by examining
the presence of highly rated compositions in another database, ICDD-PDF (International Center for Diffraction
Data-Powder Diffraction File) [5]. The prediction performance was about twice when the compositions are chosen
randomly and was as good as the existing method of the composition-recommender system [6]. Moreover, the
present method can recommend not only the compositions that are likely to exist stably but also successful synthesis
conditions of them at the same time. The chemical similarities regarding the chemical processing conditions
evaluated through the tensor decomposition seem to be consistent with our heuristics. Superiority of the
recommender system with the synthesis data to accelerate the discovery of as-of-yet-unknown compounds can be
demonstrated.

Designing Stretchable MoS2 Kirigami Using Deep Reinforcement Learning Pankaj Rajak1, Beibei Wang2, Ken-
ichi Nomura2, Aiichiro Nakano2, Rajiv Kalia2 and Priya Vashishta2; 1Argonne National Laboratory, United States;
2University of Southern California, United States

Mechanical properties of 2-D materials such as MoS2, MoSe2, WS2 and WSe2 can be tuned by the ancient art of kirigami. Experiments and atomistic simulations show that these 2-D materials can be stretched more than 50% by strategic insertion of cuts. However, designing kirigami structures with desired mechanical and thermal properties is highly sensitive to the pattern and location of kirigami cuts on a flat sheet. Furthermore, the search space of kirigami design increases exponentially with an increase in the system size. We have used a reinforcement learning (RL) model, which after training can generate a wide range of MoS2 kirigami structures with high stretchability. Our model consists of an RL agent, whose goal is to design kirigami cut patterns, and a convolution neural network-based reward model. The latter is trained using molecular dynamics simulation data, which gives no reward to patterns generated by the RL agent if the stretchability is less than 30%. The remaining structures are given rewards proportional to their stretchability. The RL model is trained for a MoS2 kirigami structure state space of 4,826,809 candidates, and after training the model is able to synthesize structures with more than 50% stretchability from a space consisting of up to 6 cuts.

Materials Discovery by Machine Learning and Single Particle Diagnosis Yukinori Koyama1, Atsuto Seko2,1, Isao Tanaka2,1, Shiro Funahashi1 and Naoto Hirosaki1; 1National Institute for Materials Science, Japan; 2Kyoto University, Japan

Discovery of new materials often leads to breakthroughs in a variety of applications, and thus exploration of new materials is a major subject in materials research. Space of chemical compositions is too wide to search for novel compounds without convincing guidelines. Therefore, it is important to establish a reasonable methodology for materials exploration. In this study, we propose an approach of materials exploration using a machine-learning technique to estimate relevance of chemical compositions followed by single-particle-diagnosis experiments. We also demonstrate discovery of novel nitrides by this approach.

First, we developed a machine-learning model of a descriptor-based recommender system to estimate relevance of chemical compositions, i.e. whether the compositions form stable structures or not. Training dataset includes
chemical compositions registered in the Inorganic Crystal Structure Database (ICSD) as positive cases, and compositions not registered in the ICSD as negative cases. A set of descriptors composed of means, standard deviations, and covariances of elemental representations are used to define similarity of chemical compositions. Random forest classifier is used to estimate probabilities of chemical compositions as the positive cases. The expectant probabilities can be used as indicators of the relevance.

After screening by the machine-learning model, we tried to synthesize compounds of the relevant chemical compositions. Then, we analyzed crystal structures of the obtained samples by the single-particle-diagnosis approach, as follows. The samples are first analyze by a conventional powder X-ray diffraction (XRD). If XRD patterns are not fitted well by known crystals, the samples might contain unknown structures. Then, particles of about several micrometers in size, which are like single crystals, are picked up. Single-crystal XRD data of the individual particles are collected and their crystal structures are refined.

The proposed approach is efficient for materials exploration. We have found novel nitrides having new crystal structures.

**Predicting Carbon Nanotube Forest Synthesis-Structure-Property Relationships Using Physics-Based Simulation and Deep Learning** Taher Hajilounezhad, Zakariya Oraibi, Ramakrishna Surya, Filiz Bunyak, Kannappan Palaniappan, Prasad Calyam and Matthew R. Maschmann; 1University of Missouri-Columbia, United States; 2University of Cincinnati, United States

Carbon nanotubes (CNTs) are promising candidate materials for numerous advanced applications due to their significant mechanical, thermal, optical and electrical properties. CNT forests represent population of CNTs that self-assemble into arrays, with CNTs oriented perpendicular to their growth substrate. Unfortunately, a remarkable performance degradation is observed when individual CNTs self-assembled into CNT forests. Structural disorder plays a major role in this performance gap. To date, there is a lack of understanding about how numerous CNT synthesis processing parameters influence structural disorder and the relationship of CNT structural morphology to CNT forest properties. Further, physical experiments can sample only a limited number of CNT forest growth parameter combinations because of time and financial restrictions. A comprehensive and multidimensional exploration of all synthesis growth parameters is impractical.

The recent advances in high-performance computing, parallel computing and artificial intelligence has opened a new door to employ simulation modeling and computational approaches to prevent costly and frequently biased interpretation of physical experiments. The integration of artificial intelligence and high-throughput physical experiments has given rise to autonomous materials research systems that can direct smart material synthesis experiments via reinforcement learning algorithms. This approach may vastly accelerate material discovery, understanding, and adoption into various industrial applications. We foresee that numerical simulations that compliment physical experiments will provide a vital new data pipeline to train deep learning (DL) algorithms for such systems moving forward. By utilizing coupled physical and numerical experimental campaigns, autonomous research systems may operate faster and at a reduced cost.

In this work, we develop DL models that analyze CNT forest image data prepared by a timeresolved and physics-based numerical simulation. The DL models are used to predict both the CNT synthesis attributes (CNT diameter, CNT areal density) and the resultant mechanical stiffness based on the structural morphology of the CNT forest. The physics-based finite element simulation first models the growth and self-assembly of CNT forests based on stochastic CNT physical parameters and then models the compression of the resultant CNT forest. The simulated CNT forest structural morphology images train the DL models to predict synthesis parameters. Different machine learning algorithms and deep learning architectures are used to find underlying processstructure correlations. The trained model then predicts CNT synthesis attributes based on forest characteristics. Classification accuracies of up to 95.5% are achieved by applying deep convolutional neural networks. This study represents an early step to implement a highthroughput computational and experimental synthesis set-up that yields application-tailored CNT forests with prescribed properties.

**MT02.12.10**

**Automation of Electron Microscopy to Enable Atomic Datasets for Machine Learning** Matthew Hauwiller, Abinash Kumar and James M. LeBeau; Massachusetts Institute of Technology, United States
Theory, synthesis, and characterization form the essential components of the materials informatics cycle. While significant emphasis has been placed on theory and synthesis, comparatively limited progress has been made in the area of materials characterization. Preliminary efforts to apply machine learning to characterization have focused largely on the backend data analysis, but capturing reproducible data in a statistically significant way remains a major challenge. Although electron microscopy can provide atomic-level structural measurements of materials to unravel structure-property relationships, there are some critical limitations to the current workflow that severely limit the current usage and future potential for materials informatics. The largely manual nature of the technique requires a significant amount of time to characterize an extremely small volume of material. This makes it difficult to collect large enough datasets that truly represent the material, especially when the material is inhomogenous or contains various defects. The human input in collecting images and spectroscopic data inherently contains both bias and random error that is undesirable for any comprehensive and systematic study.

In this presentation, we will present a core component to enable the autonomous electron microscope, the Universal Scripting Engine for Transmission Electron Microscopy (USETEM). We will show that this scripting engine is widely applicable and simplifies scripting to enable high-throughput atomic-level imaging of materials. The object-oriented code allows the microscope, detector, and any other components to be controlled through either a visual build tool (similar to LabView) or simple python scripts. We will discuss how the USETEM framework can make it easier to foster collaborations between microscopists at different universities, national laboratories, and industry as researchers develop creative ways to use their instruments to study materials. Machine learning for instrument control will also be discussed with insight into how it opens new opportunities in autonomous image acquisition. As a first step towards this vision, a deep convolutional neural network is demonstrated that can be used to automate convergent beam electron diffraction pattern analysis. The process enables, for example, autonomous determination of sample thickness to within 1 nm and tilt to within a fraction of a milliradian, at real-time speeds. Automating the electron microscope using artificial intelligence will address data size, bias, and documentation concerns, providing improved inputs for machine learning algorithms for faster discovery of emergent materials.

Small-Data Driven Machine Learning Screening Framework for Accelerated Discovery of Ferroelectric Oxides

Yang Hao and Achintha Ihalage; Queen Mary University of London, United Kingdom

The application of machine-learning (ML) to accelerate materials discovery, synthesis, optimization and characterization has significantly reduced the time and resource consumption of first principal calculations or experimental measurements. Especially after the launch of programs such as Materials Genome Initiative and the recent popularity of data science, many open access materials databases have now reached “big data” status, resulting an exponentially growing trend in ML based materials discovery. However, some technologically important materials such as ferroelectrics are scarce in nature and therefore the available datasets do not reveal much information about these materials. Ferroelectric materials can be electrically, mechanically or thermally excited which makes them intriguing candidates for many device applications. The shortage of data has hindered the applicability of ML, or more specifically deep learning (DL), in discovering new ferroelectric materials. The use of “small data” to train a machine learning algorithm and yet achieving state-of-the-art results has been a popular research topic. Specifically, in the field of ferroelectrics and tunable materials where the data is very scarce, machine learning algorithms that perform well even with a small amount of data can be fairly effective and can make it as an effective platform for new material discovery. The available material datasets, either first principle calculated (MP, OQMD), experimental (ICSD, HTEM) or both (CSD, Citrination), despite being huge, however, lack of ferroelectric information.

Most of the regularly updated databases contain over 100,000 materials which makes it tedious to search and discover new ferroelectric materials manually. Another important point to note is that significant portion of first principle calculated materials available in the datasets have not yet been synthesized and their ferroelectric behaviour is not reported in the calculations. Hence, we adopt two machine learning methods for accelerated screening of large databases to find previously unreported ferroelectric oxides. The emphasis of this work is to use an extremely small dataset to train the two machine learning algorithms and later combine the results to discover new ferroelectric oxide materials.

In this work, we propose a combined ML – DL framework for accelerated discovery of ferroelectric oxide materials by learning from an extremely small dataset, thus breaking the shackles between ML and big data.
classification algorithms are trained on a small literature-collected database and the classification is performed on the materials project (MP) database. By combining the results, we report 24 promising ferroelectric candidate materials along with their structure, band gap, chemical stability status and ferroelectric likelihood information. Our results suggest that the developed framework is able to identify ferroelectric materials at an accuracy of 89% and the results were mutually confirmed by the two algorithms. Materials are synthesized, processed and measured with results to be presented at the conference.

Creating Glasswing Butterfly-Inspired Durable Antifogging Superomniphobic Supertransmissive, Superclear Nanostructured Glass through Bayesian Learning and Optimization Sajad Haghanifar and Paul Leu; University of Pittsburgh, United States

The creation of durable superomniphobic surfaces with optical functionality has been extremely challenging. Major challenges have included low optical transmission, low optical clarity, lack of scalable fabrication, condensation failure, and inability to self-heal. Inspired by recent research on the transmission advantages of the random nanostructures on the glasswing butterfly, we report on a strategy to create self-healing, random re-entrant nanostructured glass with high liquid repellency and antifogging properties with supertransmission (99.5% at 550 nm wavelength for double-sided glass) and superclarity (haze under 0.1%). Our approach to creating these random nanostructures is to utilize a multiobjective learning and Bayesian optimization approach to guide the experiments of glass substrate fabrication. The surface demonstrates static water and ethylene glycol contact angles of 162.1 ± 2.0° and 155.2 ± 2.2°, respectively. The glass exhibits resistance to condensation or antifogging properties with an antifogging efficiency more than 90% and demonstrates the departure of water droplets smaller than 2 μm. The surface can restore liquid-repellency after physical damage through heating for 15 minutes. We envision that these surfaces will be useful in a variety of optical applications where self-cleaning, antifouling, and antifogging functionalities are important.

MT02.12.13
Machine Learning and Optimization in Shape Memory Alloys Using a Large Experimental Database William F. Trehern and Ibrahim Karaman; Texas A&M University, United States

Shape memory alloys (SMA) are martensitically transforming materials that exhibit interesting functional properties when undergoing transformation. One of the most well-known of SMA functional properties, the shape memory effect, can be observed when an SMA is deformed in the lower temperature martensitic phase and then heated to the austenitic phase, recovering the original shape and reversing the deformation strains. Upon cooling the material back to martensite, a twinned martensitic structure forms to accommodate for Bain strains that would otherwise change the shape of the sample. Another functional property, superelasticity, occurs when the SMA is deformed in the higher temperature austenitic phase. In this case, the austenite will transform to martensite through the applied strain, forming a detwinned martensite structure allowing for large amounts of deformation. Upon unloading, the material returns to the austenitic phase, recovering the deformation strains and returning to the pre-deformed shape. Both of these functional properties are subject to many different variables (such as material composition, production method, forming processes, and heat treatments) that influence the property characteristics (transformation temperatures, transformation strain, irrecoverable strain, enthalpy of transformation, and fatigue life to name a few). The test parameters also have a great influence on these properties, thus should also be accounted for. In this study, more than 80 independent variables coupled with nearly 30 different response variables are used to find hidden correlations or patterns in 6,000 raw, real experimental data entries. Through exploitation of this database, important and highly influential variables were extracted and utilized in a prediction process for a targeted material property to use in an application. These predictions are then selected based on expected improvement and experimentally validated. I will discuss the
methodology used for database development, necessary data cleaning steps, model development and feature extraction, model prediction, prediction selection using optimization, and experimental procedures for prediction validation. Assessment of related research and possibilities of this informatics approach in other systems will also be discussed.

MT02.12.14

Discovery Paradigm for Novel Organic-Inorganic Halide Perovskites for Optoelectronic Applications through Automated Synthesis Katherine N. Higgins¹, Maxim Ziatdinov², Rama Vasudevan², Sergei Kalinin² and Mahshid Ahmadi¹; ¹University of Tennessee, Knoxville, United States; ²Oak Ridge National Laboratory, United States

Hybrid organic-inorganic perovskites (HOIPs) are rapidly emerging as one of the most fascinating materials for photovoltaic, light emission, lasing, and sensing applications¹-⁴. In general, three-dimensional (3D) HOIPs adopt the typical perovskite crystal structure of ABX₃, where A, B, and X denote monovalent organic or inorganic cations (e.g., CH₃N⁺ (MA⁺), CH₅N₂⁺ (FA⁺), guanidinium (GA⁺), Cs⁺ and Rb⁺), divalent inorganic cations (Pb²⁺, Sn²⁺), and halide anions (I⁻, Br⁻, Cl⁻), respectively. These compounds are among more than one thousand perovskite-inspired candidate compounds that have been theoretically predicted during the last few years⁵-⁶. However, despite extensive theoretical studies, only a small fraction of predicted compounds has been experimentally realized since synthesis of each new material involved complex and time-consuming optimization cycle for synthesis. In addition, optimizing these materials for specific applications requires careful balance between intrinsic properties such as bandgap, defect chemistry, charge transport and crystal structures that affects material microstructure, and poorly understood parameters such as chemical stability of surfaces and interfaces. In this presentation we will demonstrate the first results on the automated synthesis and characterization for the combinatorial libraries of HOIPs. Using automated laboratory synthesis, we demonstrate formation of the library of HOIP compositions. Next, an automated characterization tool with capability of UV-Vis absorption and photoluminescence (PL) spectroscopy is used to rapidly measure the band gap energy and PL properties across the composition library. Finally, machine learning applied to the optical properties allows rapid elucidation of property evolution along 2- and 3-dimensional phase fields. We further discuss application of Gaussian process optimization for evolutionary search in the high dimensional composition spaces and balance between exploration and exploitative searches targeting individual aspects of figure of merits and their combinations. The synergy of compositional, and optical properties such as band gap and photoluminescence spectroscopy developed here allows a comprehensive picture of the functionality evolution across the composition series and attempts to establish predictive relationships across the composition in these material systems.

ML-Aided Thermal Management Materials Design and Small Data Strategy Yibin Xu; National Institute for Materials Science, Japan

Materials informatics has been expected to accelerate the process of materials design and development. More and more research results have been reported recently on study of material property prediction and material design using materials data and machine learning method. We have developed some machine learning models to predict thermal properties and design new materials with ultra-high/low thermal conductivities. In this talk, our recent work on development of thermal insulating coating and high thermal conductive polymer will be introduced. These results demonstrate the effectiveness of machine learning, meanwhile show that data availability and quality are the key issues of this method. A “small data” strategy is proposed to decrease the amount of data needed in machine learning and to make the best use of existing data.

9:00 AM MT02.13.02
Using Advanced Decision Policies in Bayesian-Optimized Machine Learning to Control Carbon Nanotube Growth Rahul Rao1, Pavel Nikolaev1, Ahmad E. Islam1, Kristofer Reyes2 and Benji Maruyama3; 1UES Inc Air Force Research Laboratory, United States; 2University at Buffalo, The State University of New York, United States; 3Air Force Research Laboratory, United States

Control over the properties (length, defect densities) and structure (diameter, semiconducting/metallocratic type) of carbon nanotubes (CNTs) is highly desirable for a number of applications. In this regard, we developed ARES (Autonomous Research System), which utilized a Random Forest algorithm to optimize carbon nanotube growth rate by evaluating in situ feedback from Raman spectroscopy during the growth process.1 Here we utilize Bayesian Optimization (BO) to control carbon nanotube diameters, which are critical for electronics applications. Previous implementations BO in materials development often use statistical models such as Gaussian Processes (GPs) to represent the experimental response function of interest. GPs make it difficult to specify fine-grained structure in the response function other through the specification kernel functions, which are often used to identify smoothness and periodicity of the function. In materials applications, however, other important structures of the response function must be considered. For example, the kinetics of materials synthesis can be parameterized through input variables such as temperature and gas flow rates, which affect certain kinetic processes over others. Hence, such a kinetic response is best modeled locally so that each local model captures only the relevant physics specific to input variables such as temperature. Here we demonstrate the use of local approximation belief models for to control CNT diameters. We show how to use such Bayesian beliefs inside the Knowledge Gradient (KG) decision policy to select information-rich experiments to run inside a closed-loop experimental system. Through this combination of local approximation belief models and the KG decision policy, we show how specific CNT properties such as diameter can be tuned and optimized over a small number of experiments.

9:15 AM MT02.13.03
Predicting Solid-Solution Formation—Machine-Learning and a New Physics-Based Rule Zongrui Pei1, Junqi Yin2, Jeffrey Hawk1, David Alman1 and Michael Gao1; 1National Energy Technology Laboratory, United States; 2Oak Ridge National Laboratory, United States

There are various empirical rules proposed to predict the formation of single-phase solid solution, but they are based on very small datasets and of very limited predictability. In the present work, we perform a machine-learning (Gaussian Process Classification) study on a large dataset consisting of 1252 alloys, including binary and high-entropy alloys, and we achieved a success rate of 93% in predicting single-phase solid solution. More importantly, the present machine-learning results also identify the most important features, among which are the Molar Volume and Bulk Modulus. Inspired by this machine-learning insight, a new physics-based thermodynamic rule is constructed. The new rule is nonetheless slightly less accurate (73%) than the machine learning algorithm, but employs only the elemental properties, which is in line with the spirit of Hume-Rothery rules. Therefore, it has advantages of simplicity and efficiency that render it very useful for high throughput application.
freud—Powerful Particle Simulation Analysis Tools for Machine Learning and Materials Design
Bradley D. Dice, Vyas Ramasubramani, Eric S. Harper, Matthew Spellings, Joshua A. Anderson and Sharon C. Glotzer;
University of Michigan, United States

Although particle simulations span a wide range of length and time scales, most well-established analysis tools are strongly focused on biomolecular simulations, and few tools exist for studying colloidal and coarse-grained material simulations. This presentation will showcase freud, a Python package that aids in calculating quantities that are frequently of interest in colloidal and nanoparticle simulations. We will discuss machine learning applications, including crystal structure identification in both supervised and unsupervised settings, which are enabled by the wide range of particle environment descriptors that freud implements. The freud library scales to extremely large systems, which has been crucial to studying complex phenomena such as the hexatic phase transition in systems of hard polygons that becomes most evident in simulations of over one million particles. It is also well-suited for building user-defined, computationally efficient analysis methods that can be adapted for analyzing new systems. We will show how the package’s efficiency and flexibility have enabled its use in such diverse applications as the inverse design of isotropic pair potentials and the optimization of shape-driven solid-solid phase transitions. Finally, we will demonstrate how output from freud can be coupled with visualization tools such as OVITO to render per-particle quantities in complex systems. Its flexibility allows freud to be used to engineer materials by design, including in cutting-edge applications such as analyzing simulations on-the-fly to study complex phenomena as they occur.

Revealing the Spectrum of Unknown Layered Materials with Super-Human Predictive Abilities
Gowoon Cheon¹, Ekin D. Cubuk², Evan Antoniuk¹, Joshua E. Goldberger³ and Evan J. Reed¹; ¹Stanford University, United States; ²Google Brain, United States; ³The Ohio State University, United States

We use semi-supervised learning to discover over 1000 new two-dimensional layered materials that have yet to be discovered or synthesized. We accomplish this by combining physics with machine learning on experimentally obtained data and verify a subset of candidates using density functional theory. Our model accelerates the discovery of layered materials by 13 times compared to random trial-and-error approaches. Even compared to expert scientists working in the field of two-dimensional materials, it is five times better than practitioners in the field at identifying layered materials and is comparable or better than professional solid-state chemists. We also of course find that our model is orders of magnitude faster than any human.

To achieve super-human performance, we employ semi-supervised learning techniques for the first time in materials discovery. Semi-supervised learning utilizes unlabeled data in addition to labeled data, which is powerful in cases where labels are expensive to obtain or are noisy. We find that semi-supervised learning provides benefits over supervised learning in identifying layered materials. In the field of materials physics, labeled data can be scarce, such as rare materials known to possess certain properties; they can also be noisy, such as property measurements with large errors. Semi-supervised learning may be applicable to a wide range of problems in materials science.

Microstructure Informatics—Expanding Descriptors from Molecular to Microstructural Level
Olga Wodo;
State University of New York at Buffalo, United States

The holy grail of materials science is to discover the mechanism governing the material properties and describe them in terms of a small set of physically meaningful descriptors. The discovery and exploration of materials and their properties critically depend on the availability of easily computable descriptors. At the atomistic level, descriptors played a key role in the area of materials design via first-principle combinatorial methods for photovoltaic, battery, or catalytic materials. More than a dozen software is available to calculate descriptors at the electronic and atomistic level. Descriptors at the next scale – microstructure– are relatively less explored and consist of various application specific and disparate clusters of descriptors. Most frequently, descriptors are tailored for characterizing specific mechanisms. In this talk, we present our unified framework to compute a library of generic descriptors. We describe our microstructure representation that facilitates the descriptor calculation. Our representation is based on the graph and skeleton and enables microstructure characterization in terms of shape (i.e., morphology), geometry, and
connectedness (i.e., topology). We explain how this work lays the foundation for machine learning of microstructure-property relationships and enables information fusion between multiple scales. We showcase our framework using examples from organic electronics.

11:00 AM MT02.13.07
High-Throughput Electron Microscopic Analysis of Nanomaterials Based on Machine Learning Techniques
Byoungsang Lee¹, Seokyoung Yoon¹ and Jung Heon Lee¹,²; ¹Sungkyunkwan University, Korea (the Republic of); ²SKKU Advanced Institute of Nanotechnology (SAINT), Korea (the Republic of)

Many important physical and chemical properties of nanomaterials, such as their optical, electronic, and catalytic properties, are strongly influenced by their morphological characteristics such as their shape, structure, and size.¹-⁵ Although it is desirable to synthesize mono-disperse nanomaterials for many applications, poly-disperse nanomaterials with substantially different shapes, structures, and sizes are generally obtained. Therefore a method suitable for precise characterization of the morphological properties of nanomaterials is highly demanded. Furthermore, it would be very important for this method to fulfill statistical analysis of the morphological characteristics of the nanomaterials as well.

Spectroscopy techniques such as UV-vis spectrometry, small-angle X-ray scattering (SAXS), and dynamic light scattering (DLS) are commonly used to assess morphological characteristics of nanomaterials. But it is very difficult to find exact morphological characteristic of nanomaterials using these techniques.

On the other hand, as electron microscopy (EM) allows images of individual nanomaterials to be taken, it is one of the best ways to analyze the morphological characteristics of nanomaterials. Furthermore, as the images of hundreds of nanomaterials can be easily obtained at the same time, if EM characterization is taken at low magnification, it can be a powerful way to acquire morphological characteristics of nanomaterials in a statistical manner. However, morphological analyses of nanomaterials are still carried out manually by individual researcher as the size of nanomaterials are generally measured from only several of the hundreds of nanomaterials collected from the researcher and the shapes and structures of nanomaterials can only be described in a qualitative manner. Thus, an innovative method to analyze the morphological characteristics of nanomaterials in a quantitative manner is highly demanded.

Here we have developed highly precise method to analyze the morphological characteristics of nanomaterials from EM images. [precise/facile/simple] Among over 50,000 nanomaterials we tested, this method were capable to identify the size and shape of nanomaterials with high precision of 99.7% and low false discover rate of 0.2%. This method was also capable to automatically identify and either separate or exclude overlaid nanomaterials to minimize misidentification of their morphological characteristics. To achieve this, we processed individual EM images of nanomaterials in various routes, including diverse pre- and post- treatments and varied edge detection (multiple thresholds), using machine learning and stacked all the processed.

On the other hand, it is impossible to measure all the population of nanoparticles with EM equipment. Therefore, we tried to find the number of samples needed through repeated measures multivariate analysis, but it was difficult to find the point to be saturated. The significance (p-value) in the multivariate analysis only affects the null hypothesis (effect size = 0), not only the correlation but also the size of the sample. On the other hand, the effect size is expressed in standard deviation units, which can be compared between any studies and utilized in meta-analysis. Therefore, we calculated the effect size using Hedges' g according to the number of repeated measurements and the number of particles per measurement and found a point where the decreasing slope saturates.

In addition, it was possible to cluster nanoparticles effectively using Fourier transform and Gaussian mixer models, and to classify optical effects according to morphological characteristics analyzed by EM through comparison of far-field optical responses of nanoparticles through clustering there was. As a result, we propose the need for new analytical techniques using EM.

Inverse Learning of Material Physics Through In Situ Image Data and Continuum Modeling
Hongbo Zhao and Martin Z. Bazant; Massachusetts Institute of Technology, United States

With the availability of spatio-temporal imaging data of energy materials at the nano to micron scale, there is a tremendous amount of information about the material properties that can be extracted. As an example, we show that the thermodynamic model, or free energy landscape of a phase-separating system can be learned through inversion of models such as Cahn-Hilliard or Allen-Cahn equations. Other models that involve reaction kinetics can also be used to model the dynamics of imaged particles when they are chemical driven. Here, we demonstrate that the
inverse problem technique can be applied to lithium-iron phosphate (LFP). By imaging the evolution of lithium concentration in the particle, we are able to extract its free energy and reaction kinetics, which typically are difficult to obtain through electrochemical measurements alone due to mosaic phase separation at the porous electrode scale.

11:30 AM MT02.13.09
Evaluating Machine Learning as a Tool for Segmentation of In Situ TEM Data James Horwath¹, Dmitri Zakharov² and Eric A. Stach¹; ¹University of Pennsylvania, United States; ²Brookhaven National Laboratory, United States

In situ and operando experimental techniques afford scientists the ability to observe dynamic processes in material systems with high spatial and temporal resolution. However, such experiments can generate enormous amounts of data in very short amounts of time. Without frameworks to efficiently and quickly analyze data, the benefits of these novel experimental techniques cannot be fully realized. Simultaneously, while the field of deep learning for image classification and segmentation has developed to a point where non-experts can implement and extend models to a variety of applications, we face a need for reproducibility and physical understanding of the results these models provide. Here, we evaluate the use of machine learning as a segmentation tool for the measurement and localization of supported nanoparticles in a high temperature Environmental Transmission Electron Microscopy (ETEM) experiment. Our methods are capable of segmenting high-resolution images at rates greater than one image per second, with only minimal post-processing steps required for quantitative analysis.

To begin, we have developed a method to automate the creation of reliable training labels for high resolution ETEM images using traditional computer vision techniques. With this training data in hand, we study the role of convolutional neural network (CNN) architecture on the practical utility of different models, and the learnability of our dataset. We also demonstrate the impact of image resolution on the ability of a standard CNN model to learn seemingly simple image features. Our experiments show the importance of regularization, particularly for image analysis, and we expose the danger in engineering machine learning architectures to better fit data rather than learning features of physical importance. In a final test case, we exhibit the use of a simple, single-layer CNN to process high resolution images which confirms that important image features are learned in the earliest layers of a deep learning model, and promotes the notion of scaling back the depth of a model in favor of increased interpretability and extensibility. The use of deep learning to solve physical problems is an area of active research, however a bridge is needed to relate learning theory and development to practical approaches for applying these techniques in other fields. In this work we attempt to systematically determine and investigate important features of machine learning models and datasets so that general tools for high-throughput data analysis can be developed.

11:45 AM MT02.13.10
Robust Microstructure Representation Devyani G. Jivani and Olga Wodo; SUNY Buffalo, United States

Microstructure quantification and design require a detailed and informative representation that uses a small number of design variables and at the same time allow to explore large microstructure spaces. The representation should capture the material features that are critical for establishing quantitative microstructure-property relationships. This work introduces skeletal-based microstructure representation that has capabilities to address all the above requirements. The modeling with skeletons is analogous to vertebrate animals and trees where the skeleton represents the underlying structure. Skeletons allow for the distillation of shape, size, and topological information. In principle, this paradigm allows the creation of models of arbitrary geometry and topology. The shape recognition algorithm – SpeedSeg is used to segment the skeleton into basic primitives to further decrease the design/storing space. In this set-up, a combination of arcs and line-segments is used.

The research demonstrates that using this representation shapes can be constructed incrementally and stored compactly. Moreover, the flexibility of this representation is demonstrated by modeling microstructures with a high level of spatial heterogeneity. The Cahn-Hilliard equation is used to model microstructure evolution between two polymers in the thin film. The microstructures are synthetically generated for varying blend ratios and interaction parameters. The study reveals that this representation leads to two orders of magnitude reduction in terms of storage required and associated number of variables. A similar analysis is performed for several other types of microstructures, including fibrous and cellular structures.

8:00 AM *MT03.01.01/MT02.01.01
Autonomous Research Systems for Materials Development—2019 Workshop Summary Benji Maruyama1, Eric A. Stach2, Gilad Kusne3, Jason R. Hattrick-Simpers3 and Brian L. DeCost3; 1Air Force Research Laboratory, United States; 2University of Pennsylvania, United States; 3National Institute of Standards and Technology, United States

This presentation will summarize the results of our “Autonomous Research for Materials Development Workshop,” where a multidisciplinary group of materials researchers, computer scientists and AI/ML experts explored the opportunities, barriers and future investments. Closed-loop autonomous research systems are disrupting the research process.

The current materials research process is slow and expensive; taking decades from invention to commercialization. Researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of doing iterative experimentation orders of magnitude faster than today.

We propose a “Moore’s Law for the Speed of Research,” where the rate of advancement increases exponentially, and the cost of research drops exponentially. We consider a renaissance in “Citizen Science” where access to online research robots makes science widely available. This presentation will highlight advances in autonomous research and consider the implications of AI-driven experimentation on the materials landscape.

8:30 AM *MT03.01.02/MT02.01.02
Self-Driving Laboratories for Accelerating Discovery of Thin-Film Materials Curtis P. Berlinguette1,1,1, Jason E. Hein1, Alan Aspuru-Guzik2,3,3, Benjamin P. MacLeod1, Fraser G. Parlane1 and Brian Lam1; 1The University of British Columbia, Canada; 2Canadian Institute for Advanced Research (CIFAR), Canada; 3The University of Toronto, Canada

This presentation will focus on our self-driving laboratory for thin film materials discovery and optimization. Discovering high-performance, low-cost materials is an integral component of technology innovation cycles, particularly in the clean energy sector. The linear methodology currently used to develop optimal materials can take decades, which impedes the translation of innovative technologies from conception to market. Our interdisciplinary
team is utilizing advanced robotics and machine learning to overcome this challenge. We are closing the feedback loop in thin film materials research by enabling our self-driving robotics platform named “Ada” to design, perform, and learn from its own experiments efficiently and in real time. As a proof-of-principle set of experiments, we will show how Ada discovers and optimizes high-performance, low-cost hole transport materials for use in advanced solar cells. I will also showcase how Ada’s modular design can enable the automated and autonomous discovery of materials for other clean energy technologies.

9:00 AM MT03.01.03/MT02.01.03
An Inter-Laboratory High Throughput Experimental and Open Materials Data Study of Sn-Zn-Ti-O Jason R. Hattrick-Simpers¹, Andriy Zakutayev², Sara Barron¹, Zachary Trautt¹, Nam Nguyen¹, Kamal Choudhary¹, John D. Perkins², Caleb Phillips², Gilad Kusne¹, Feng Yi¹, Apurva Mehta¹ and Martin Green¹; ¹National Institute of Standards and Technology, United States; ²National Renewable Energy Laboratory, United States; ³SLAC National Accelerator Laboratory, United States

We present the results of an inter-laboratory high-throughput experimental (HTE) study which focused on measurement reproducibility and data exchange. Over the past 20 years, a great number of HTE techniques for synthesizing and characterizing thin-film oxides have been developed and reported. To date, however, there has not been a comprehensive study of how values measured for a series of properties (e.g. conductivity or optical band gap) on the same library compare across labs. Nor has there been a study that has attempted to normalize the hand-off of HTE samples and data. Here we report on the first such study using the Sn-Zn-Ti-O transparent conducting oxide system.

A series of Sn-Zn-Ti-O samples were deposited via Pulsed Laser Deposition and magnetron co-sputtering. At each institution a set of HTE measurements were made for typical properties including structure, thickness, conductivity, and optical bandgap. The samples were then exchanged between the two labs and the same set of properties were measured at the other lab and the data exchanged via an agreed upon uniform format.

A few lessons learned and several scientific observations regarding the reproducibility of HTE results gathered during this process will be discussed. An important lesson was the importance of deciding upon, and using, consistent measurement grids within a lab (and during exchanges) for all measurements, as this will impact future data archiving and retrieval. It was observed that qualitative trends are well reproduced even when two labs use very different methods for measuring a property, for instance ellipsometry versus transmission-reflection UV-VIS spectroscopy. However, quantitative comparisons were found to be measurement specific and spanned from excellent (bandgaps measured within a mean absolute error < 0.1 eV) to relatively poor (log resistivity measurements within a mean absolute error of 2). In the latter case, we believe that differences in sample probe geometries coupled to large changes in the properties of small composition regions were the most likely source of the poor correlation. The lessons learned and best practices obtained will be discussed.

9:15 AM MT03.01.04/MT02.01.04
Automatic Microcrack Inspection in Photovoltaics Silicon Wafers by Unsupervised Anomaly Detection via Variational Auto-Encoder Zhe Liu, Felipe Oviedo, Emanuel M. Sachs and Tonio Buonassisi; Massachusetts Institute of Technology, United States

The presence of microcracks in silicon wafers significantly reduces wafer strength, yielding wafer breakage during the manufacturing process, transportation and field operation. With the trend of decreasing wafer thickness for cost reduction purposes, thinner wafers are more prone to breakage in the presence of microcracks [1]. To enable a smooth transition to thin wafers for even cheaper photovoltaic modules, we recently developed a high-throughput prototype for in-line crack detection for silicon wafers [2]. This tool scans silicon wafer in the near-edge regions for micro-cracks and outputs linescan signals from a linescan camera, where no crack shows a smooth, undisrupted profile. As an in-line detection tool, it also requires a rapid and reliable algorithm that automatically identifies the presence of a micro-crack within a second after wafer scanning. In this work, we adopted an unsupervised machine learning method for anomaly detection, because the presence of microcracks above the critical length is typically a statistically rare event in the current PV production line (typically less than 5%). Specifically, a generative machine learning algorithm variational auto-encoder (VAE) is used to identify scans with microcracks [3]. The working principle of this algorithm is that: (1) VAE encodes the linescan profiles into lower-dimension vectors of latent variables, and then the latent variables are reconstructed back to linescan profile with the goal of minimized error; (2) because of most linescan profiles are very similar smooth curves without any cracks, the VAE model is trained to be biased toward linescan without cracks; (3) whenever a linescan profile for a crack appears, the trained VAE
model generates a vastly different profile with a significant reconstruction error; (4) the crack is then detected by monitoring anomalous reconstruction error. The advantage of this unsupervised VAE method over the previous neural network method [4] is that it does not require a large amount of labelled crack data with different crack shapes (which can be very difficult to obtain). We demonstrate successful crack detections with several different wafer types (e.g., multi, mono, as-cut, and textured) and crack shapes (e.g., line-shape, cross-star, L-shape). We show that, with statistical analysis, this VAE-based anomaly detection could be a reliable and versatile method to enable the rapid detection of microcracks in silicon wafers.

Screening of High-Capacity Oxygen Storage Materials with Machine Learning Approach Nobuko Ohba1, Takuro Yokoya2, Seiji Kajita1 and Kensuke Takechi1; 1Toyota Central R&D Laboratories, Inc., Japan; 2Toyota Motor Corporation, Japan

The oxygen storage material (OSM), such as CeO2 or pyrochlore type CeO2-ZrO2 (p-CZ), is used as a catalyst support for a three-way catalyst in automotive emission control systems. It has oxygen storage capacity (OSC) that is an ability to release and store oxygen reversibly by the fluctuation of cation valence depending on the reducing and oxidizing atmosphere. In this study, we explore high-capacity OSMs by using materials informatics (MI), which combines material science with inference algorithms in machine learning. The OSC of 60 metal oxides supported Pd were experimentally estimated by the amount of produced CO2 while switching between oxidizing (O2) and reducing (CO) atmosphere every 2 minutes at temperature of 973, 773, and 573K. These experimentally measured OSC data were used as supervised data in our MI scheme. The support vector machine regression model was trained for the prediction of the OSC at each measured temperature. This model uses descriptors in which physical properties are considered to represent the features of the OSC. These features were automatically extracted using grid search to achieve each model with the highest accuracy. It is found that the features related to the stability of the oxygen atoms in the crystal and the crystal structure itself such as cohesive energy, which is obtained from the first-principles calculation, are highly correlated with the OSC. The present model predicts the OSC of 1,300 existing oxides registered in the in-house electronic structure calculation database. Several dozen materials with promising high OSC were proposed through this virtual screening. We synthesized one of the screened materials and experimentally confirmed that it indicates higher OSC than the conventional OSM, p-CZ.

10:15 AM *MT03.01.06/MT02.01.06
The Metaphysics of Chemical Reactivity and Materials Discovery Lee Cronin; University of Glasgow, United Kingdom

Discovery in chemistry falls mainly into one of four types of areas with the discovery of new molecules, new reactions, new reactivity, and finally new physical properties of the resulting compounds or materials. Establishing new reactivity leads to new reactions which also leads to new molecules. This is therefore the order of impact for discoveries in terms of the amount of chemical knowledge that they contribute. Such findings must, by definition, belong outside the known or predictable; and they are outliers and as such can oppose conventions, assumptions and
biases. By developing the meta-physics of chemistry and chemical reactivity we should be able to establish a new set of ontologies in chemistry that relate back to the practical core operations, but also can be translated into molecular structures and the discovery of function. The truth of chemistry lies with finding the intrinsic reactivity of the input chemicals, and then encouraging or enabling reactivity by process control. Whilst the new discovery and reaction should be translatable to chemical bonding theory, chemists need to grapple with the fact that the application of the current rules will not allow discovery, instead they will act to restrict it to the known rules. So chemical discovery requires that the current rules are updated, broken, or new ones are made where before there were none. The discovery of Diels-Alder or cross-coupling reactions are excellent examples of new rules that were just discovered without any prior warning.

Without a deeper development of a meta-physics of chemistry the use of big data and artificial intelligence will just tell us what we already know we know, and maybe predictable extensions, rather than enabling discovery. The challenge for the chemist is not the use of artificial intelligence, but the intelligent use of algorithms and automation for novel discoveries. In this talk I will explain how this might be possible.

Robot-Accelerated Perovskite Investigation and Discovery (RAPID)—A High-throughput Approach Towards Metal Halide Perovskite Single Crystal Discovery
Zhi Li1, Mansoor Ani N. Nellikkal2, Liana Alves2, Peter Parrilla2, Ian M. Pendleton2, Matthias Zeller2, Joshua Schrier2, Alexander Norquist2 and Emory Chan3;
1Lawrence Berkeley National Lab, United States; 2Haverford College, United States; 3Purdue University, United States; 4Fordham University, United States

Metal halide perovskites have emerged as promising materials for next-generation photovoltaic and optoelectronic devices. The discovery and full characterization of new metal halide perovskite-derived materials have been limited by the difficulty of growing high quality single crystals needed for single crystal X-ray diffraction studies. The formation of large single crystals is non-trivial, owing to the vastness of the chemical search space with enormous compositional degrees of freedom. We present the first automated, high-throughput approach for metal halide perovskite single crystal discovery based on inverse temperature crystallization (ITC) as a means to rapidly identify and optimize synthesis conditions for the formation of high quality single crystals. Using our automated approach, we have carried out a total of over 5000 metal halide perovskite synthesis reactions spanning six chemical systems. Through this unbiased search of the experimental space, we have more than doubled the number of metal halide perovskite materials accessible by ITC method and discovered a new perovskite structure. Combining machine learning and other statistical methods, we quantify the total experimental space and the likelihood of large single crystal formation. Moreover, machine learning models have been constructed for each chemical system, in which single crystal formation is modeled. This work is a proof of concept that a combined approach of high throughput experimentation and machine learning can be effective in the study of metal halide perovskite crystallization. The approach presented here is designed to be generalizable to different synthetic routes for the acceleration of materials discovery.

11:00 AM MT03.01.08/MT02.01.08
Optimizing Hole Transport Materials with a Self-Driving Thin-Film Laboratory
Benjamin P. MacLeod1,1, Fraser G. Parlane1,1, Thomas D. Morrissey1,1, Florian Häse2,3,4, Loïc M. Roch1,3,4, Kevan Dettelbach1, Raphael Moreira1, Lars Yunker1, Michael Rooney1, Joseph Deeth1, Verónica Lai1, Gordon Ng, Henry Situ1, Ray Zhang1, Alán Aspuru-Guzik1,2,3,4, Jason E. Hein1 and Curtis P. Berlinguette1,1,1; 1The University of British Columbia, Canada; 2Harvard University, United States; 3University of Toronto, Canada; 4Vector Institute for Artificial Intelligence, Canada

Self-driving laboratories combine algorithmic data analysis and experiment planning with robotic workflows to
autonomously optimize one or more experimental figures of merit. This approach is applicable to challenging multi-parameter and multi-objective optimization problems such as the optimization of thin film materials within the vast design space of composition, deposition, and processing conditions. Here we describe a self-driving laboratory capable of formulating inks, depositing films via spin-coating, characterizing the resulting thin films using multiple techniques, and planning new experiments based on previous experimental data using the ChemOS experiment orchestration software. The utility of this self-driving laboratory is demonstrated by autonomously optimizing optical and electronic properties of hole transport materials, which are crucial to the operation of a variety of thin-film-based optoelectronic devices. The autonomous optimization manipulates the film composition and annealing protocol to maximize a hole-mobility surrogate obtained by fusing data from transmission-reflection UV-Vis-NIR spectroscopy and 4-point probe conductivity measurements.

11:15 AM MT03.01.09/MT02.01.09

In the development of next-generation photovoltaics and light-emitting diodes, colloidal inorganic perovskite quantum dots (QDs) have drawn notable attention for their highly tunable bandgap properties, high-charge carrier mobility and defect tolerance, and adaptability towards solution phase processing. However, studies of this material group and other colloidal semiconductor nanocrystals requires extensive exploration of their massive reaction parameter space within highly controlled reaction environments. Conventional flask-based, trial-and-error approaches are, therefore, highly unlikely to effectively capture the full potential and optimal synthesis conditions of these high-priority materials. Further complicating this process, across the accessible bandgap range, optimal synthesis parameters will vary significantly. Flow synthesis platforms have recently been demonstrated as a time-and material-efficient reaction monitoring strategy for synthesis, screening, and optimization of colloidal nanomaterials. The high sampling rate, low chemical consumption, and precise process control (automation) of flow reactors greatly reduces the challenges in exploring complex reaction spaces; however, high-throughput reaction screening technologies alone are likely not able to make significant breakthroughs, due to the massive scope of relevant colloidal synthesis conditions.

In this work, we present a modular microfluidic platform integrated with a machine learning (ML)-enhanced reaction optimization algorithm for on-demand synthesis of high-quality inorganic perovskite QDs with desired optical properties using a homogeneous anion exchange reaction. The intelligent QD synthesis platform consists of multiple computer-controlled pumps for on-demand reagent delivery/dosing, a flow path selector valve for automated selection of the halide salt source, and an in-line flow cell for automatic UV-Vis absorption and photoluminescence spectroscopy. Utilizing a utility function, an array of trained neural networks, and a global optimization algorithm, the intelligent QD manufacturing platform, approaches a target emission bandgap, while minimizing emission linewidth and maximizing quantum yield by tuning the concentrations of the precursors. Halide salt precursors are mixed within a highly efficient inline micromixer before combining with the perovskite QDs and gas-liquid segmentation. Monitoring each halide exchange condition requires less than 180 uL of total halide salt precursor and 170 uL of starting perovskite QDs per sample.

Integration with a ML-enhanced optimization algorithm enables the system to reach optimized synthesis conditions, across all six variables, for a target emission energy of 2.2 eV in 238 samples and 83 mL of chemicals without any prior training. More advanced optimization methods and pre-training with archived experimental data will further reduce this optimization time and cost. The versatility and modularity of the developed intelligent QD synthesis platform make it readily adaptable for on-demand synthesis of other colloidal nanomaterials.

11:30 AM MT03.01.10/MT02.01.10
Autonomously Optimizing Thin Film Morphologies Using Machine Vision Fraser G. Parlane¹, Benjamin P. MacLeod¹, Nina Taherimakhsousi¹, Alan Aspuru-Guzik², Jason E. Hein¹ and Curtis P. Berlinguette¹; ¹The University of British Columbia, Canada; ²University of Toronto, Canada

The morphologies of solution-deposited thin films are frequently governed by complex combinations of processes from domains including multi-phase fluid flow, heat transfer, nucleation, solid mechanics, and interfacial...
phenomena. This complexity can frustrate both theoretical and empirical attempts to understand and control the morphologies of such films. Here we report an autonomous robotic system that uses machine vision feedback to determine optimal experimental parameters to achieve homogeneous, high-quality films via spin coating. An ink-formulating and spin-coating robot equipped with an imaging system provides images of thin films to a computer vision algorithm which grades the quality of the thin films. This grading assessment provides input to an optimization algorithm that chooses the next ink formulation with the goal of identifying regions in the parameter space of ink formulation and spin-coating conditions that result in high-quality films.

Quantum Machine Learning in Chemical Space Anatole von Lilienfeld and Guido Falk von Rudorff; University of Basel, Switzerland

Many of the most relevant chemical properties of matter depend explicitly on atomistic and electronic details, rendering a first principles approach to chemistry mandatory. Alas, even when using high-performance computers, brute force high-throughput screening of compounds is beyond any capacity for all but the simplest systems and properties due to the combinatorial nature of chemical space, i.e. all compositional, constitutional, and conformational isomers. Consequently, efficient exploration algorithms need to exploit all implicit redundancies present in chemical space. I will discuss recently developed alchemical perturbation theory and quantum machine learning based approaches for interpolating quantum mechanical observables in compositional and constitutional space. Numerical results of our models indicate controlled accuracy and favourable computational efficiency.

2:00 PM *MT03.02.02/MT02.02.02
AI for Automating Materials Discovery Carla Gomes and Bruce van Dover; Cornell University, United States

Artificial Intelligence (AI) is a rapidly advancing field. Novel machine learning methods combined with reasoning and search techniques have led us to reach new milestones with increasing frequency, from self-driving cars to computer vision, machine translation, computer Go trained on human play, to Go and Chess world-champion level play using pure self-training strategies. These ever-expanding AI capabilities open up exciting new avenues for automating scientific discovery. I will discuss our work on using AI for accelerating and automating materials discovery. In particular, we have focused on high-throughput structure determination for combinatorial materials discovery and on solving the phase map diagram problem for composition libraries. While standard statistical and machine learning methods are important to address this challenge, they fail to incorporate relationships arising from the physics of the underlying materials. I will introduce an effective approach based on a tight integration of machine learning methods, to deal with noise and uncertainty in the measurement data, with optimization and inference techniques, to incorporate the rich set of constraints arising from the underlying physics. Finally, I will describe our vision and progress concerning Scientific Autonomous Reasoning Agent (SARA), a multi-Agent system to accelerate materials discovery integrating in a synergistic and complementary way, first principles quantum physics, experimental materials synthesis, processing, and characterization, and AI based algorithms for reasoning and scientific discovery, including the representation, planning, optimization, and learning of materials knowledge.

2:30 PM MT03.02.03/MT02.02.03
Machine Learning Methodologies to Enhance Automated Synthesis of New Materials Jonathan Fine, Armen Beck and Gaurav Chopra; Purdue University, United States
Functional groups link analytical, physical, organic, and materials chemistry and are therefore central to the chemical sciences. In both analytical and organic chemistry functional groups are used to predict the reactivity of molecules, select a solvent for a given reaction, and validate a reaction using measurable changes in the properties of a molecule. Current approaches to incorporate functional groups in the prediction, planning and verification of reaction conditions rely on human intervention and input. For example, the solvent used for a given transformation is chosen by a skilled organic chemist using intuition gained from the study of how the functional groups in a molecule dictate its solubility in a solvent. To verify if the reaction took place resulting in an unknown chemical entity, the state-of-the-art method is to accurately identify all functional groups of the reactants and products. This process is time-consuming, involves manual or database dependent analysis and interpretation of a Fourier Transform Infra-Red (FTIR) spectrum or Mass Spectroscopy (MS) data using previously established rules and experience of a skilled spectroscopist. These processes are subject to trial and error for compounds with multiple functional groups and for compounds that are not well characterized in the literature. Such issues hinder the automated development and characterization of truly new materials with minimal human intervention. We present fast deep learning methods to select the optimal solvent for a given reaction in a transformation-free manner and identify all the functional groups for both the products and reactants for any given reaction. Our methods do not use any database, pre-established rules or procedures to perform either task and use the general definition of functional groups as a ‘collection of atoms’ instead of simple chemical groups traditionally assigned by chemists. We use Artificial Neural Networks (ANNs) to derive patterns and correlations between these collections of atoms and the solvents used to carryout a given chemical reaction using 2.3 million patented reactions available from the United States Patent and Trademark Office. Our methodology is the first to differentiate solvents by their precise chemical structure instead of simply choosing a solvent class and yields a 5-fold cross-validated average F1-score greater than 0.9. Solvent predictions obtained from this model have been validated both in silico using Density Functional Theory and using experimental in situ techniques. To verify that a reaction has occurred, we trained separate ANNs on 7393 publicly available FTIR and MS combined spectra obtained from the NIST Webbook. Instead of using multiple binary classifiers used in previous works to assign functional groups, our approach treats the classification problem in a multi-class, multi-label fashion. The model has a cross-validated F1 score higher than 0.82 for 14 out of 17 defined functional groups. To showcase the practical utility of our method, we introduce two new metrics (Molecular F1 score and Molecular Perfection rate) to measure the performance of identifying all functional groups on molecules. The optimized model has a Molecular F1 score of 0.92 and a Molecular Perfection rate of 72%. Additionally, backpropagation of our model reveals IR patterns typically used by human chemists to identify standard groups, suggesting a convergence of the model on known spectral features that are diagnostic of particular functional groups. We further show that the introduction of additional functional groups does not decrease the performance of our model. Finally, we show redundancy in FTIR and MS data by encoding all our features in a latent space that retains the accuracy of the original model. These results reveal the importance of using machine learning for automated identification of new reaction conditions and functional groups to achieve autonomous processes in the future.

2:45 PM MT03.02.04/MT02.02.04
Autonomous Research Systems—Phase Mapping & Materials Optimization Gilad Kusne; National Institute of Standards and Technology, United States

The last few decades have seen significant advancements in materials research tools, allowing researchers to rapidly synthesize and characterize large numbers of samples - a major step toward high-throughput materials discovery. Machine learning has been tasked to aid in converting the collected materials property data into actionable knowledge, and more recently it has been used to assist in experiment design. In this talk we present the next step in machine learning for materials research - autonomous materials research systems. We first demonstrate autonomous measurement systems for phase mapping, followed by a discussion of ongoing work in building fully autonomous systems. For the autonomous measurement systems, machine learning controls X-ray diffraction measurement equipment both in the lab and at the beamline to identify phase maps from composition spreads with a minimum number of measurements. The algorithm also capitalizes on prior knowledge in the form of physics theory and external databases, both theory-based and experiment-based, to more rapidly hone in on the optimal phase map. The phase map is then exploited for functional material optimization.

3:00 PM BREAK

3:30 PM *MT03.02.05/MT02.02.05
Information Extraction and Learning by Large-Scale Text-Mining of the Scientific Literature  
Gerbrand Ceder; University of California, Berkeley, United States

The overwhelming majority of scientific knowledge is published as text, which is difficult to analyze by either traditional statistical analysis or modern machine learning methods. In contrast, the main source of machine-interpretable data for the materials research community has come from structured property databases which encompass only a small fraction of the knowledge present in the research literature. Beyond property values, publications contain valuable knowledge regarding the connections and relationships between the data items as interpreted by the authors. I will show multiple ways to extract useful information from scientific text in both supervised and unsupervised ways. I will show that materials science knowledge present in the published literature can be efficiently encoded as information-dense word embeddings (vector representations of words) without human labelling or supervision. These embeddings capture complex materials science concepts such as the underlying structure of the periodic table and structure-property relationships in materials. Furthermore, we demonstrate that an unsupervised method can recommend materials for functional applications several years before their discovery. This suggests that latent knowledge regarding future discoveries is to a large extent embedded in past publications. In a more supervised way, we have also demonstrated the extraction of codified synthesis recipes from text. Extraction the details of synthesis, including precursor compounds, synthesis operations and their numerical details, requires a very high precision of information extraction, and a tolerance to deal with imprecise and non-standard language. I will show how a large data set of codified solid-state synthesis reactions has been obtained and be queried to obtain interesting information on choice of synthesis operations and precursors is related to the target material.

4:00 PM *MT03.02.06/MT02.02.06
Autonomous Scanning Droplet Cell for On-Demand Alloy Electrodeposition and Characterization  
Brian L. DeCost, Howie Joress, Trevor Braun, Zachary Trautt, Gilad Kusne and Jason R. Hattrick-Simpers; National Institute of Standards and Technology, United States

We are developing an autonomous scanning droplet cell (ASDC) capable of on-demand electrodeposition and real-time electrochemical characterization for investigating multicomponent alloy systems for favorable corrosion-resistance properties. The ASDC consists of a millimeter-scale electrochemical cell and an array of programmable pumps that can be used to electrodeposit an alloy film and immediately acquire polarization curves to obtain electrochemical quantities of interest, such as the passive current density and oxide breakdown potential. We model these quantities using Gaussian Process regression to select the most informative series of alloys to synthesize and characterize, continuously updating the model as new electrochemical data is acquired. Our initial studies focus on systems that are likely to form corrosion-resistant metallic glasses (MGs) and single-phase multi-principle element alloys (MPEAs).

The ASDC is an open exemplar autonomous system that provides insight into both technical and methodological aspects of building and deploying robust closed-loop synthesis and characterization platforms. Our approach is to build loosely-coupled modular experimental, automation, and communications systems to 1. support rapid prototyping, debugging, and verification while producing meaningful scientific output and 2. enable integration into future large-scale multi-user and multi-instrument distributed laboratory systems. We address both of the main challenges that autonomous science systems face: learning to reliably synthesize materials and mapping material specification and processing to structure and properties. We will discuss the incorporation of prior knowledge in the form of theoretical and data-driven predictive models, as well as the integration of online and offline multi-modal experimental data streams. Ultimately, closed-loop automated materials synthesis and characterization platforms offer much more than a means of engineering materials properties and performance through black-box optimization algorithms: they offer the potential to develop and deploy new algorithms for generating and testing scientific hypotheses.

4:30 PM MT03.02.07/MT02.02.07
Autonomous Electrolyte Discovery for Batteries with Experimentally Informed Bayesian Optimization  
Adarsh Dave, Sven Burke, Jared Mitchell, Kirthivasan Kandasamy, Biswajit Paria, Barnabas Poczos, Venkatasubramanian Viswanathan and Jay F. Whitacre; Carnegie Mellon University, United States

An autonomous battery electrolyte experimental platform capable of mixing multi-component electrolyte systems
and characterizing the transport and electrochemical properties in a high-throughput manner is disclosed. A Bayesian optimization software package found novel electrolyte compositions through optimization of the high-dimensional electrolyte design space over key design objectives like electrochemical stability and conductivity. Electrolyte optimization is difficult because 1) electrolyte evaluation is expensive and takes time, and 2) the space of possible electrolytes is expansive, formed by many possible choices for solvents (often in ternary blends), salts (often in binary mixtures), and trace additives. Bayesian optimization methods are well suited for the optimization of high-dimensional functions with costly evaluations, often producing an efficient design-of-experiments to converge on multi-objective optimal formulations in few experiments. To expedite the optimization over the expansive design space, theoretical predictions of electrolyte properties via the Advanced Electrolyte Model were utilized as “priors” in the statistical model.

Implementation of the novel experimental platform was carried out by two novel test stands developed to automate the mixing and characterization of electrolytes: Otto (for aqueous systems) and Clio (for aprotic/organic systems). The test stands characterized the ionic conductivity and electrochemical stability of electrolyte systems, featuring a four-electrode conductivity probe, pH meter, and a flow-through three-electrode cell and potentiostat. Clio also integrated electrochemically active electrodes for optimization of electrolyte/electrode systems. The active electrode systems used were common functional ceramic metal oxides.

A software orchestration and data layer linked the test-stands to human experimenters and machine-learning packages through a web-services architecture; all experiment data and meta-data is saved in a database. Additional out-of-the-loop characterization was conducted on cathodic systems to validate composition, structure, and oxidation state. The aqueous design space consisted of aqueous blends of lithium and sodium salts, including nitrates, sulfates, and other commonly-used battery salts. High-concentration aqueous electrolyte candidates were discovered by optimizing of electrochemical voltage stability and conductivity, including low-cost, high-performing alternatives to known but costly aqueous electrolytes (e.g. LiTFSI). Clio’s design space includes blends of both aprotic organic solvents and solutes in additional to various compositions of electrochemically active electrodes. The test-stands are demonstrated to be significantly faster than common human experimentation techniques, converging on novel, optimized electrolyte mixtures in mere hours or days of experimentation.

A Comparative Study of Experiments and Simulations on Grain-Boundary Formation of Polycrystalline Ba122 Phase Iron-Based Superconductors

Yuki Okada1, Shinnosuke Tokuta1, Yusuke Shimada2, Akimitsu Ishii1, Akinori Yamanaka1 and Akiyasu Yamamoto1; 1Tokyo University of Agriculture and Technology, Japan; 2Tohoku University, Japan

Iron-based superconductors are promising materials for high magnetic field applications because of their high transition temperature, high upper critical filed and small electromagnetic anisotropy [1]. Grain-boundaries (GBs) play a dominant role on the transport current performance of superconducting materials. Katase et al. reported that the critical current density through artificial bicrystal grain boundary is strongly dependent on grain boundary misorientation GB angles (θGB) and nearly constant up to a critical angle θc of ~9 degrees, which is substantially larger than the θc of ~5 degrees for YBa2Cu3O7−δ. [2]. Foreseeing the future applications such as long-length wires and large bulk materials, it is important to understand the mechanisms of the grain-boundary formation during the solid-state sintering of polycrystalline iron-based superconductors. However, the mechanism of grain-boundary formation during the solid-state sintering has not been elucidated because in situ observation of grain-boundary at high temperature is technically not easy. In this sense, the numerical modeling of grain-boundary formation is a promising approach for understanding and controlling the grain-boundary structure in the sintered materials. In particular, phase-filed modeling [3,4] is a powerful tool to solve free boundary problems, such as the grain-boundary migration in polycrystalline materials. In this study, we performed the comparative study of experiments and phase-
field modeling on grain-boundary formation of polycrystalline K-doped Ba122 iron-based superconductors. K-doped Ba122 polycrystalline bulk samples at different stages of sintering were fabricated by systematically changing heating conditions of mechanically alloyed powder. Their microstructure was analyzed by SEM and STEM to understand the mechanisms of grain-boundary formation during sintering. These experimental results were compared with the extended multi-phase-field modeling of solid-state sintering based on the model proposed by Wang [5].

MT03.03.02
Raman Mapping of Graphene-Based Materials—a Statistical Guide to Significance Stuart Goldie and Karl Coleman; Durham University, United Kingdom

Recent publications analysing some commercially available graphene and GNP (graphite nanoplatelets) samples have highlighted the need for a robust metrology if graphene and related technologies are to develop. Raman spectroscopy is a widely used tool for probing carbon due to the wealth of information that can be gained, however it is a highly localised probe and recording a single spectrum over a wide area often produces a distorted result dominated by minor features. This can be problematic when measuring inhomogeneous materials that contain a mixture of graphite flake sizes, thicknesses and various degrees of functionalization and defect concentrations.

To overcome these limitations, spectra can be recorded from a number of different points on a sample surface; however this poses a new question: how many points are needed? To answer this we have measured a selection of common graphitic materials including commercial GNPs and liquid exfoliated graphene to generate large data sets of Raman spectra from many points. A bespoke computer program has been developed in this study and was used to automatically fit the Raman signals for each independent spectrum; these parameters can then be used to infer some of the properties of the material. For example the heights of the D peak and G peak are often compared to estimate the concentration of defects in the sp² network.

The convergence of these parameters is used to identify the approximate sample size required for robust characterization by plotting summary statistics (mean, interquartile range and P10 & P90) against the size of the data set; followed by a Monte Carlo based approach to resample data in smaller sets and probe the potential error when using an insufficient number of measurements. Whilst the focus of this work was on Raman spectroscopy, the methodology is applicable to other analysis techniques that require multiple measurements. Whilst different materials behave differently, in most cases it is clear that an average value can be derived after approximately one hundred data points however a full distribution describing the variety of materials present is only obtained after many hundreds of spectra are analysed. We also find many of these distributions are not normal, and simple metrics like mean and standard deviation fail for graphene materials, as reported previously.

It is hoped this statistical approach can be applied in a variety of settings, both academic and industrial to inform the careful characterization and reporting of graphene materials. Raman spectroscopy is a non-destructive technique that is already in routine use and the spectral fitting program developed to accurately process these data sets will be freely available.

**High-Throughput Screening of p-Type Transparent Oxide Semiconductors**

*Miso Lee*¹, Yongs Youn¹, Kanghoon Yim² and Seungwu Han¹; ¹Seoul National University, Korea (the Republic of); ²Korea Institute of Energy Research, Korea (the Republic of)

The transparent devices require complementary pairs of n-type and p-type transparent semiconductors to fabricate high efficient electronic devices. However, only a few p-type transparent oxide semiconductors were identified while there are a lot of n-type transparent oxide semiconductors like ZnO and In₂O₃, and InGaZnO with good device performances. Recently, several studies have been performed to search for p-type oxides using high-throughput screening with the band gap and effective mass (or branch point energy) as descriptors. However, these descriptors do not well distinguish the n-type and p-type oxide groups. Furthermore, none of suggested materials was verified experimentally, which means we need a better theoretical predictor. In this presentation, we propose a reliable descriptor for the p-type dopability based on the formation energy of hydrogen impurity (FEH). The predictive power of FEH is validated by that it can distinguish well known p-type and n-type oxides. Using FEH, we screen binary oxides and selected ternary compounds by considering the known design principles of p-type oxides (containing Sn²⁺ and Cu¹⁺ as well as oxychalcogenides). Considering FEH, band gap, and hole effective mass, we suggest La₂O₂Te and CuLiO as promising p-type oxides, which are validated through the full intrinsic defect calculations. [1] Furthermore, to enable high-throughput screening, we identify two coarse but simple descriptors - the band gap and oxygen partial weights at valence band maximum which correlate with FEH. Using the simplified descriptors, we screen over 17,700 oxygen-containing compounds in AFLOW database and select 426 compounds for the calculation of FEH. Finally, we identify 156 oxide semiconductors with the band gap larger than 1.1 eV and good p-type dopability. Furthermore, we classify the identified p-type oxides according to their valence band character and reveal chemical principles underlying the p-type dopability. [2]

**Spectrum Adapted Expectation-Maximization Algorithm for High-Throughput Peak Shift Analysis in Synchrotron X-Ray Operando Spectromicroscopy**

*Naoika Nagamura*¹², Tarojiro Matsumura³, Shotaro Akaho³, Kenji Nagata¹² and Yasunobu Ando³; ¹National Institute for Materials Science, Japan; ²Japan Science and Technology Agency, PRESTO, Japan; ³National Institute of Advanced Industrial Science and Technology, Japan

Recently, various kinds of high resolution and multi-parameter spectral analysis is available by using high brilliant quantum beams like synchrotron radiation X-rays. Such advanced spectroscopy measurements potentially produce huge number of datasets. Developing the efficient method for the spectral data analysis is an urgent issue in the multi-dimensional measurements.

For example, operando SR X-ray scanning photoelectron microscopy system, called “3D nano-ESCA” (three-dimensional nanoscale electron spectroscopy for chemical analysis)[1], provides spatial, time and electric field dependence of photoemission spectra. This equipment has bias voltage application circuit for “operando analysis”, i.e. spectroscopy analysis during device operation, so we perform electric potential mapping by detecting the spatial distribution of XPS core-level peak shift in microscopic device structures under operation with high spatial resolution (~ 70 nm). However, the 3D nano-ESCA has been performed only for the pin-point or line-scan analysis that deals with few tens of spectral datasets by the inefficiency of peak fitting procedure, although spatial and time resolved measurement potentially provides over thousands of the datasets.

The method of spectral data analysis using machine learning technique has been studied to improve the resorting to the manual trial and error, e.g. applying a Bayesian peak separation with the exchange Monte Carlo method[2]. However, the computational cost was paid little attention because the number of datasets was not so large in conventional spectroscopy measurements.

**Final Program 1/13/2020 1927**
Here we introduce the spectrum-adapted expectation-maximization (EM) algorithm for the high-throughput peak shift detection analysis of the large number of spectral datasets by considering the weight of the intensity corresponding to the measurement energy steps\[3\].

The EM algorithm is one of the machine learning techniques for estimating the parameters of the mixture model, including latent parameters, based on maximum likelihood estimation with iterative calculation between the expectation (E) step and the maximization (M) step. When ordinally EM algorithm is applied to the peak separation using a linear superpositions of distributions such as Gaussian distributions, the analyzed data are required to be one-dimensional, but the spectral data consists of N measurement steps of energy \( (x = \{x_1, \ldots, x_n, \ldots, x_N\}) \) corresponding to the intensity \( (w = \{w_1, \ldots, w_n, \ldots, w_N\}) \). So we solved this disadvantage by using the intensity \( (w) \) as a weight for each measurement step \( (x) \).

We applied the proposed method to the experimental datasets taken by the 3D nano-ESCA. Spectral datasets were collected from FETs using atomically thin films such as graphene and MoS\(_2\) monolayer sheets. We confirmed drastic acceleration of peak fitting in comparison to the manual approach. In the presentation, we show concrete applications to the synthetic data of graphene field effect transistors (FETs) and other semiconductor fine devices.

This paper is based on results from a project (P16010) commissioned NEDO, JST-CREST(JPMJCR1761), JST PRESTO(JPMJPR17NB), and CORE lab (2016002) of "Five-star Alliance" in "NJRC Mater. & Dev."

**MT03.03.06**

**Fabrication of Composition Gradient Polymer Films at Elevated Temperatures for High-Throughput Characterization**

Ezgi M. Dogan-Guner\(^1\), Aaron L. Liu\(^1\), Michael A. McBride\(^1\), Zihao Qu\(^1\), Martha A. Grover\(^1\), J C. Meredith\(^1\), Elsa Reichmanis\(^1\), Jun Amano\(^2\) and Karsten Bruening\(^2\); \(^1\)Georgia Institute of Technology, United States; \(^2\)Konica Minolta Laboratory USA, United States

Materials informatics has been a relevant focus for accelerated materials development in an industry where traditional research methodologies demand a considerable investment in time and resources. In order to implement these informatics-enabled approaches, curation of well-structured datasets can be facilitated via high-throughput methods\(^1\). An effective combinatorial screening procedure can be constructed with the fabrication of composition gradient polymer thin-film libraries via solution processing. High-throughput property characterization can then be applied to these gradient libraries to rapidly map the composition space for the response variable of interest. Here, we present work toward the high-throughput discovery of process-structure-property relationships in polymer composites. Many such polymer systems present challenges in solution processing due to low ambient solvent interactions and high viscosities. An automated flow system capable of high temperature operation was constructed for the solution-casting of polymer films. This system includes a custom-designed serpentine grooved-channel mixing component suitable for flow of high viscosity solutions and filler particles, allowing for fabrication of gradient films with spatial variations in composition. We discuss high-throughput characterization on these gradient libraries, which demonstrates the feasibility of our solution processing apparatus and gradient film approach.

**MT03.03.07**

**Enabling Correlative Spatially-Resolved Non-Uniformity Analysis of Perovskite Degradation via Machine Learning**

Zhe Liu, Shijing Sun, Noor Titan Putri Hartono, Armi Tiibonen, Janak Thapa, Felipe Oviedo and Tonio Buonassisi; Massachusetts Institute of Technology, United States

Despite a rapid ramp-up of record efficiencies of lab-scale solar cells, perovskite as an absorber for solar cells has a great challenge to achieve large-area spatial uniformity \([1]\), and long-term operation stability \([2]\). Both spatial uniformity and operation stability are important metrics to scale up the perovskite solar cells toward industrial commercialization. Particularly, during the degradation tests, the non-uniform film changes \((e.g., local color change)\) are observed. We hypothesize this non-uniformity of degradation is likely due to process-induced defects acting as the degradation seed point \((e.g., water ingression)\), which could be reduced by a capping/buffer layer \((e.g., ammonia salt 2D thin layer)\) on perovskite absorber. We examine this hypothesis by correlating multiple spatially resolved characterization tools along with the degradation tests. First, photoluminescence (PL) imaging is used to reveal the location of structural and electrical defects in the perovskite films. Second, calibrated red-green-blue
(RGB) camera imaging is used to monitor spatial differences of degradation under various harsh environmental conditions (e.g., humid, hot and illuminated). Third, X-ray diffraction (XRD) mapping is used to identify the material phase change over time at different locations in the film. As a comparison, the experiments are repeated for the perovskite samples with a thin capping layer. With the correlative dataset of spatially resolved characterization results, we develop a machine learning method (i.e., convolutional neural network) that predict the material phase change (i.e., the results of XRD maps) from the fast and easy-to-implement PL and RGB images, because XRD mapping is a relatively slow process. Hence, we will be able to gain more understanding of the mechanism of non-uniform degradation by this correlative analysis.

Data-Driven Sliding Mode Control for Pulses of Fluorescence in STED Microscopy Based on Förster Resonance Energy Transfer Pairs Maison Clouatre and Makhin Thitsa; Mercer University, United States

Pairs of conjugate donor-acceptor fluorescent probes have proven themselves useful in stimulated emission depletion (STED) microscopy in recent years. For instance, it has been shown that the lifetime of said probes directly correlates to the resolution of the microscope [1]. However, once the lifetimes of the probes have been optimized, it is desirable to control their fluorescence in order to improve the resolution further. Here, we propose combining model-free control with sliding mode control to track nanosecond pulses of blue-shifted acceptor fluorescence in order to inhibit visible light emitted from the image plane, shrink the point spread function, and subsequently improve the resolution of the microscope. This is achieved by automatic adjustment of the STED laser beam pump power. This controller is numerically simulated against a generic model created from Förster resonance energy transfer (FRET) theory. However, since it is innately model-free and data-driven, it can be easily applied to various physical systems with drastically different dynamics. It is the goal of this paper to demonstrate that common fluorescent dyes can be used to increase the resolution in modern super resolution microscopy—paving way for biological imaging previously unachievable.

Realizing Bulk, Stable Low Work Function Materials Lin Lin, Ryan Jacobs, Dane Morgan and John Booske; University of Wisconsin--Madison, United States

The work function is a fundamental property defined as the minimum energy to remove an electron from the material, and depends sensitively on the bulk electronic structure and surface chemistry, such as surface orientation, surface termination, and presence of surface adsorbates. The work function is a crucial parameter to understand and control in numerous applications, including electron emitters, thermionic energy converters, oxide electronics, solar photovoltaics, (photo)electrochemical reactions and memristors.[1] In particular, there has been tremendous interest in the engineering of low work function materials, such as metals with adsorbed alkali species, semiconductors with functionalized organic species, and 2D materials such as graphene and MXene compounds which are both doped and functionalized with surface species. However, all of these solutions to create low work function materials rely on utilizing surface functional species or monolayers of electropositive elements which are unstable, particularly at elevated temperatures above room temperature. Therefore, a fundamental materials science research question is the following: How does one engineer a material with low work function (e.g. less than 2 eV), and have this low work function realized in a bulk, stable monolithic material?

To answer this question we turn our focus to perovskite oxides, a class of materials with applications ranging from catalysis to piezoelectrics to light absorbing layers in solar cells, which possess broad compositional flexibility.
enabling the tunability of many properties, including the work function.[2, 3] In particular, engineering of perovskite oxides presents the unique opportunity for realizing low work functions in a bulk, monolithic material by virtue of the intrinsic polar and stable \{001\} surfaces of the perovskite structure. Our recent work used Density Functional Theory (DFT) calculations to explore a representative set of 20 perovskite oxides for the dual purpose of (1) searching for perovskites which possess a low work function and (2) gaining an improved fundamental understanding of the factors governing the work function in perovskite oxides. From this work, we discovered that pure and Ba-doped SrVO3 could exhibit low work functions of about 1.9 and 1.1 eV, respectively.[2]

Following this path, we have performed detailed experiments on pure, bulk polycrystalline samples of SrVO3. The sol-gel method is used to produce high purity SrVO3 powder, which is pressed into pellets and sintered in a reducing atmosphere. X-ray photoelectron spectroscopy (XPS) measurements indicate that bulk SrVO3 exhibits a low work function of 1.8-2 eV, and similar values are obtained across the entire bulk sample surface to within +/- 0.2 eV, and is consistent with our DFT predictions. These results suggest that SrVO3 is the first example of a bulk, monolithic material with an intrinsically low work function, potentially impacting a large array of technological applications and suggesting that engineered perovskite materials are a new class of low work function compounds.

OpenKIM—Reliable Interatomic Models for Multiscale Simulations Ryan S. Elliott and Ellad B. Tadmor; University of Minnesota, United States

Multiscale and Atomistic simulations of materials using empirical interatomic potentials (also called "force-fields", or more generically "models") play a key role in realistic scientific and industrial applications. The Open Knowledgebase of Interatomic Models project (https://OpenKIM.org) includes an automated user-extendable framework for testing the predictions of models for a host of material properties. Visualization tools have been developed to compare model predictions to help select the most appropriate one for a given application. Verification checks ensure the integrity of the models. Models in OpenKIM that conform to the KIM application programming interface (KIM API) can be seamlessly used with several major molecular simulation codes. Although KIM's objective is to have all models conform to the KIM API, this is not always immediately possible or practicable. So, OpenKIM also supports "Simulator Models" (SMs), i.e., models that are currently only available within a single molecular simulation code. SMs are treated just like any other model in OpenKIM so that results for verification checks, material properties predictions, and visualizations are available for SMs as well. This talk will describe the OpenKIM project and how the testing framework can assist materials researchers.

Density Functional Theory Simulation on Material Science—Bridging the Gap Between Theory and Experiment ChunYu Lu, Srinivasa R. Tamalampudi, Nitul S. Rajput, Boulos Alfakes, Tuza Olukan and Matteo Chiesa; Khalifa University, United Arab Emirates

Thanks to the consistent effort in making DFT simulation more reliable and bringing this powerful tool to the engineer, first-principles quantum physics calculations can reliably be utilized to design materials and further to give insights into the material characterization results. In this work, we perform DFT simulation and experimental characterization on 2D material layers, such as InSe and graphene, and doped semiconductor ZnO, to explore and design material properties for different applications. We combine the DFT-atomic force microscopy (AFM)[1], DFT-Optical/Raman spectroscopy[2], DFT-predicted macroscopic surface wettability[3] and DFT device simulation[4] as an integration tool to directly compare the experimental results, such as AFM characterization, contact angle measurement, reflectance/Raman/FTIR spectroscopy, and solar cell IV curve. These full set of comparisons offer a great opportunity to allow the bottom-up realization of material structures that are tailored to deliver the desired device performances.

Interest in the application of big data and artificial intelligence to the manufacturing industry is increasing. However, this is feasible when all the structures of facilities/environment - sensor - communication - data acquisition - analysis are balanced. It is difficult to expect remarkable achievement in a short time considering the situation of small and medium-sized manufacturing companies. Especially in the foundry industry, there are many difficulties in introducing big data and artificial intelligence technology because it traditionally tends to depend on worker's know-how in controlling processing parameters. Nevertheless, there is still a need to build a smart factory, so it is necessary to study IoT sensing system for collecting big data of processing parameters and machine learning technique for prediction.

In this presentation, the difference of concepts between artificial intelligence, machine learning and deep learning is introduced. In connection with data acquisition using IoT sensors, an example of application to the centrifugal casting field using an Arduino-based module is introduced. In addition, a case study of machine learning model for prediction of hydrogen concentration in molten aluminum is introduced. The development of machine learning technology is very fast and it is necessary to grasp the flow while applying it in the manufacturing field even though it is quite simple case.

Current piezoelectric materials rely on a unique resilience of the polar response to disorder which produces a stable structure near a morphotropic phase boundary (MPB). However, many piezoelectric materials are not amenable to disorder, and are thus unusable in MPB systems. In this work, we apply a sensitivity analysis approach to ab initio calculated piezoelectric properties to determine the effect of disorder on the piezoelectric response. Vibrational properties are found to drive degradation in the piezoelectric effect with disorder, rather than the dielectric, or internal strain components. In well-known piezoelectric systems, (perovskites and tungsten bronze structures) multiple stable optical phonon modes are found to contribute to the piezoelectric response, providing a fingerprint for disorder tolerance. Hence, a multiple-phonon mode criteria is used to evaluate candidate materials suggested by the Materials Project and to screen the database for novel, disorder-tolerant piezoelectrics. Eight prototype structures are altered through chemical substitution to generate novel systems with high piezoelectric effect. These structural families may be explored to replace PZT as MPB systems beyond perovskites.

Laser Aided Additive Manufacturing (LAAM) is a kind of metal additive manufacturing process using the high-powered laser beam to melt the powdered or wire feedstock to build the near-net three-dimensional components. Studying thermal field induced by different laser parameters is important to evaluate and optimize the resultant residual stress and distortion distribution. However, it is very computationally expensive to simulate multi-bead deposition process using existing numerical model to analyze and select appropriate process parameter. This work proposed a laser process parameter planning frame to design an appropriate laser process parameter sequence for the
LAAM process. The frame utilizes a recently developed finite element (FE) model to predict the thermal behaviour during the deposition process, and a reinforcement neural network to modify the laser process parameter based on the temperature field in process. The optimized process parameter is able to improve the temperature distribution homogeneity of the deposited part.

MT03.03.18
Classifying and Predicting the Electron Affinity of Hydrocarbons Using Machine Learning

Dooman Akbarian1, Behzad Damirchi1, Hunter Woodward2, Jonathan Moore2 and Adri van Duin1; 1The Pennsylvania State University, United States; 2The Dow Chemical Company, United States

Hydrocarbons include a wide range of chemical substances that can be found in many products ranging from oil extracted directly from the reservoir to drug products and occur in a range of mixtures, degrees of purity and molecular size. Electron Affinity (EA) has been identified as an important factor for predicting the chemical properties of hydrocarbons. For instance, previous investigations found that the EA is a principle descriptor for modeling the gas phase oxidation rates of polyaromatic hydrocarbons (PAH) in diesel combustion which indicates that the initial step in the destruction of PAHs is capturing an electron. Additionally, previous studies could find a non-linear correlation between the phototoxicity and the EA of the PAHs. There are experimental and Quantum Mechanics (QM) techniques to calculate the EA of species. However, due to high experimental and computational costs, it is beneficial to develop machine learning (ML) methods based on reasonable amount of available data that can accurately and quickly estimate the EA of hydrocarbons. Supervised ML can be implemented on available data sets to predict properties based on individual structural features. In this study, we used Density Functional Theory (DFT) to calculate the EA of more than 1500 hydrocarbons including PAH, alkanes, cycloalkanes and alkenes. Then a ML technique was developed to explore the relationship between the EA and the physical structure of the species. Using this method, we could reveal the role of different geometrical features and functional groups on the EA of the hydrocarbons.

Accelerated Materials Discovery Using Theory, Computation, Optimization and Natural Language Processing

Anubhav Jain; Lawrence Berkeley National Laboratory, United States

For the past several decades, the standard method of materials discovery has involved a combination of research intuition and comprehensive experimental investigation. Recently, a variety of new computational and experimental tools have been introduced to go beyond this standard paradigm. In this talk, I will describe our group's effort in creating an automated pipeline for suggesting and discovering new materials in silico. We have recently coupled our capability to perform high-throughput density functional theory calculations for a variety of materials properties (software implementation: https://atomate.org) with inverse optimization techniques that allow machine learning surrogate models to suggest the most promising compounds for exploration. This allows a computational optimization to be performed on supercomputing resources in a closed loop without any human intervention (software implementation: https://github.com/hackingmaterials/rocketsled). The machine learning model used for the optimization can be provided by the user, be chosen from a set of standard optimization routines, or use a new machine learning surrogate that we have developed that can be trained automatically and without any human intervention on any materials composition-property or structure-property data set (software implementation: https://github.com/hackingmaterials/automatminer). Finally, I will outline a collaborative effort at LBNL in which we analyze text data from materials abstracts to predict "gaps" in the research literature, and use this information to power an algorithm to suggest promising new compounds for functional applications. These tools make it possible to leverage large computing resources and the past scientific literature to focus and accelerate the experimental phases of materials discovery.
8:30 AM MT03.04.02

**Machine Learning of Reaction Pathways in Chemical Vapor Deposition for Directed Synthesis of Two-Dimensional Chalcogenides**

Aravind Krishnamoorthy\(^1\), Pankaj Rajak\(^1\)\(^2\), Sungwook Hong\(^1\), Ken-ichi Nomura\(^1\), Aiichiro Nakano\(^1\), Rajiv Kalia\(^1\) and Priya Vashishta\(^1\); \(^1\)University of Southern California, United States; \(^2\)Argonne National Laboratory, United States

Scalable synthesis of two-dimensional (2D) materials is a major bottleneck to more widespread adoption of layered material-based devices. Chemical vapor deposition (CVD) has emerged as a viable method for large-scale synthesis of 2D materials. However, neither experiment nor theory has been able to decipher mechanisms and selection rules for different growth scenarios or make predictions of optimized growth parameters. Experimental challenges stem from the use of atomic-resolution probes like TEM to characterize CVD growth reactions *in situ* under elevated temperatures and pressures. Computational synthesis, which simulates CVD processes using reactive molecular dynamics simulations provides the atomistic resolution necessary for the identification of reaction mechanisms and synthesis pathways. Here we use recurrent neural networks and reinforcement learning methods trained on trajectories from several hundred simulations of computational synthesis of a prototypical two-dimensional semiconductor, monolayer MoS\(_2\), to uncover the dependence of product stoichiometry, crystallinity and phase distribution on reaction parameters like temperature, sulfur and hydrogen partial pressures, thus paving the way for rational design of CVD synthesis techniques for MoS\(_2\) and other layered materials.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607. Simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE program and at the Center for High Performance Computing of the University of Southern California.

**High-Throughput Design of Organic Friction Reducers in Engine Oils**

Jing Yang, Jon Paul Janet, Fang Liu and Heather J. Kulik; Massachusetts Institute of Technology, United States

Computational modeling and high-throughput techniques have the promise to enable the atom-by-atom design of nanoscale properties that give rise to essential changes in macroscale properties. In the quest for increasing energy efficiency and resource utilization, energy losses remain an outstanding challenge that can be solved in part through computational materials design. For example, during the operation of a car engine, only 15% of the fuel energy is used for car movement, whereas the remaining is lost. Friction reducers (FRs) additives can minimize the friction loss in these engines by reducing friction between moving parts at the contact area. Traditional FRs contain metals, sulfur, and phosphorus, which can poison exhaust system catalysts and diesel particulate filters. Thus, if suitably designed, organic friction reducers (OFRs) present a promising alternative solution. Here, we apply non-equilibrium molecular dynamics simulations together with density functional theory methods under a high-throughput workflow to enable the atom-by-atom design of OFRs. We directly compute the coefficients of friction (COFs) of OFRs on model-engine iron oxide surfaces. This atomistic simulation allows us to develop direct physical insight into the nanoscale properties of OFRs that give rise to the criteria of friction reducing characteristics. By carrying out coverage- and temperature-dependent simulations, we can explore several conditions not easily probed during experiments. These studies allow us to build a quantitative-structural-property relationship for predicting good OFR characteristics, enabling an iteratively improving materials design workflow.

**High-Throughput Computational Discovery of In\(_2\)Mn\(_2\)O\(_7\) as a High Curie Temperature Ferromagnetic Semiconductor for Spintronics**

Wei Chen\(^1\), Janine George\(^1\), Joel B. Varley\(^2\), Gian-Marco Rignanese\(^1\) and Geoffroy Hautier\(^1\); \(^1\)Université catholique de Louvain, Belgium; \(^2\)Lawrence Livermore National Laboratory, United States

Ferromagnetic semiconductors are valued for their potential applications in spintronics. For spin-polarized transport, combining strong ferromagnetism and attractive semiconducting properties in one material is highly desirable, but yet this remains an open problem. Here we conduct a search for concentrated ferromagnetic semiconductors through high-throughput computational screening. Our screening reveals the limited availability of semiconductors combining ferromagnetism and a low effective mass. Among the identified ferromagnetic semiconductors are Eu
chalcogenides, Cr spinel chalcogenides, Bi manganites, Mn pyrochlore oxides, and Mn double perovskites. In particular, we show that the manganese pyrochlore oxide In$_2$Mn$_2$O$_7$, hitherto unknown to spintronic applications, is a promising candidate for spin transport as it combines low electron effective mass ($0.29 m_0$), a large exchange splitting of the conduction band (1.1 eV), good stability in air, and a Curie temperature (about 130 K) which is among the highest of concentrated ferromagnetic semiconductors. We rationalize the high performance of In$_2$Mn$_2$O$_7$ by the unique combination of a pyrochlore lattice favoring ferromagnetism with an adequate alignment of O-2p, Mn-3d, and In-5s, forming a dispersive conduction band and enhancing the Curie temperature. We further find that Sn and Mo can be incorporated on the In site while acting as shallow donors, suggesting that In$_2$Mn$_2$O$_7$ can be effectively n-doped.

Cognitive Materials Discovery and Onset of the New Discovery Paradigm Dmitry Zubarev; IBM Almaden Research Center, United States

The discovery of novel materials can generate immense technological, economic, and social benefits. However, these are slow, challenging, expert-intensive efforts. Our thesis is that new capabilities of cognitive computing – particularly natural language processing, knowledge representation, and automated reasoning – are poised to transform the process of materials discovery and take us from our current discovery paradigm driven by data science and machine learning to the next stage where cognitive systems seamlessly integrate information from human experts, experimental data, physics-based models, and data-driven models to speed discovery. We discuss the key bottlenecks to discovery that need to be removed to enable this new approach and illustrate progress towards this cognitive future with examples from IBM research efforts in Accelerated Materials Discovery.

Bridging the Electronic, Atomic and Mesoscopic Scales Using Machine Learning Subramanian Sankaranarayanan$^{1,2}$; $^1$Argonne National Laboratory, United States; $^2$University of Illinois at Chicago, United States

The ever-increasing power of modern supercomputers, along with the availability of highly scalable atomistic simulation codes, has begun to revolutionize predictive modeling of materials. Molecular dynamics (MD), in particular, has led to breakthrough advances in diverse fields, including tribology, energy storage, catalysis, sensing. Furthermore, recent integration of MD simulations with X-ray characterization has demonstrated promise in real-time 3-D atomistic characterization of materials. The popularity of MD is driven by its applicability at disparate length/time-scales, ranging from ab initio MD (hundreds of atoms and tens of picoseconds) to all-atom classical MD (millions of atoms and tens of nanoseconds), and coarse-grained (CG) models (microns and tens of micro-seconds). Nevertheless, a substantial gap persists between AIMD, which is highly accurate but restricted to extremely small sizes, and those based on classical force fields (atomistic and CG) with limited accuracy but access to larger length/time scales. The accuracy and predictive power of classical MD is dictated by the empirical force fields, and their capability to capture the relevant physics.

In this talk, I will present some of our recent work on the use of machine learning (ML) to seamlessly bridge the electronic, atomistic and mesoscopic scales for materials modeling. Our automated ML framework aims to bridge the significant gulf that exists between the handful of research groups that develop new interatomic potential models (often requiring several years of effort) and the increasingly large user community from academia and industry that applies these models. Our ML approach showed marked success in developing force fields for a wide range of materials from metals, oxides, nitrides, hetero-interfaces to two-dimensional (2-D) materials and even water (arguably the most difficult system to capture from a molecular perspective). This talk will also briefly discuss our
ongoing efforts to integrate such cheap yet accurate atomistic models with (a) AI techniques to perform inverse design and construct metastable phase diagrams of materials (b) Deep learning to improve spatiotemporal resolutions of ultrafast X-ray imaging.

11:00 AM *MT03.05.02
Accelerating Development of Materials for Industrial and High-Tech Applications with Data-Driven Analysis and Simulations Sergey V. Barabash; Intermolecular Inc, United States

The development of advanced materials via high-throughput experimentation at Intermolecular is accelerated using guidance from modeling and machine learning (ML). Rapid materials development at a reasonable cost implies that a large number of parameters describing the deposition outcome and materials performance (including composition, phase, texture, defects, stability/degradation) and the knobs that directly and indirectly affect those outcomes (including deposition method, precursors and ambients, temperature and other conditions, film thickness, and the identity of other materials included in the stack) form a vast space that needs to be efficiently navigated. This talk primarily focuses on methods, with a few examples of specific findings from our internal R&D.

Accessing external DFT databases (such as MaterialsProject) together with high-performance computing (HPC) resources for new DFT simulations and pymatgen-enabled workflows permits rapid on-demand theoretical modeling and thermodynamic analysis. This can be used to screen materials in a stack based on compatibility, allowed chemical potentials, possibility of templating, and wetting, so as to identify most promising combinations of material layers that make up the device stack, together with desired deposition conditions. For instance, additional material layers can be identified, deposition of which ensures high quality (e.g. low vacancy concentration) of preceding layers despite the use of aggressive chemistries in depositing subsequent layers. One can further theoretically pre-screen “dopants” that help stabilizing a given phase of a given material. While relatively straightforward in the case of stabilization of TiO2 phases, such a theoretical pre-screening needs be more involved in the case of HfO2. We compare different approaches to identifying regions of thermodynamic stability in multicomponent systems, including CALPHAD, theoretical models of disordered alloys used together with DFT database queries, phenomenological selection rules and recursive partitioning based on experimental data. Unexpected phases such as alloys between ordered compounds can be predicted using thermodynamic modeling with effective Hamiltonians such as cluster expansions (CEs).

HPC-enabled, DFT-driven search for novel material phases can help building a better reference set for phase identification in thin films; e.g. our analysis during development of ferroelectric HfO2 films accounts for the novel rhombohedral phase, predicted by our DFT study[1] and independently demonstrated in recent experiments[2]. Combining DFT simulations with phenomenological modeling and data-driven search allows us to identify materials with better intrinsic properties, such as materials combining high band gap $E_g$ with high dielectric constant $\kappa$. Some materials identified by our workflows combine attractive ($\kappa, E_g$) values with possibility of synthesis at ambient conditions, even though showing smaller improvement over the common high-$\kappa$ materials than the exotic materials such as the high-pressure BeO phase predicted in literature[3] (that is yet to be stabilized at the ambient conditions). We discuss practical considerations that limit materials development based on such predictive workflows.

Finally, we illustrate co-optimization of multiple target material properties using ML based on experimental data. We discuss issues that may arise due to human pre-selection of promising phase space regions: ML algorithms readily pick up pre-detected trends, but may draw unjustified conclusions, particularly in the presence of noise/measurement errors. Use of physically meaningful descriptors, including those obtained using DFT simulations and data mining, leads to detecting important trends, improving predictions, and identifying optimal compositions.

11:30 AM MT03.05.03
Exploring Large Scale ToF-SIMS Data Matrices Using Artificial Neural Networks: Polymers and Biointerfaces Paul Pigram1, Robert Madiona1,2, Wil Gardner1,2, Nicholas Welch2, David Winkler1,2,3 and Benjamin Muir2; 1La Trobe University, Australia; 2CSIRO Manufacturing, Australia; 3University of Nottingham, United
Time-of-flight secondary ion mass spectrometry (ToF-SIMS) is continuously advancing. The data sets now being generated are growing dramatically in complexity and size. More sophisticated data analytical tools are required urgently for the efficient and effective analysis of these large, rich data sets. Standard approaches to multivariate analysis are being customised to decrease the human and computational resources required and provide a user-friendly identification of trends and features in large ToF-SIMS datasets.

We demonstrate the generation of very large ToF-SIMS data matrices using mass segmentation of spectral data in the range 0 – 500 m/z in intervals ranging from 0.01 m/z to 1 m/z. No peaks are selected and no peak overlaps are resolved. Sets of spectra are calibrated and normalized then segmented and assembled into data matrices. Manual processing is greatly reduced and the segmentation process is universal, avoiding the need to refine peak lists for different sample types or variants.

ToF-SIMS data for standard polymers (PET, PTFE, PMMA and LDPE) and for a group of polyamides are used to demonstrate the efficacy of this approach. The polymer types of differing composition are discriminated to a moderate extent using PCA. PCA fails for polymers of similar composition and for data sets incorporating significant random variance.

In contrast, artificial neural networks, in the form of self organising maps (SOMs), deliver an excellent outcome in classifying and clustering different and similar polymer types and for spectra from a single polymer type generated using different primary ions. This method offers great promise for the investigation of more complex bio-oriented systems.

We compare the analysis of large scale mass segmented matrices with those formed using conventional selection of ToF-SIMS peak lists. SOMs are used to cluster and discriminate antibody fragments bound at surfaces and to demonstrate antibody orientation in optimised ELISA format assays.

Integrate Machine Learning in Describing Radiation-Assisted Microstructural Evolution Miaomiao Jin¹², Penghui Cao³ and Michael P. Short¹; ¹Massachusetts Institute of Technology, United States; ²Idaho National Laboratory, United States; ³University of California Irvine, United States

The evolution of materials microstructure driven by radiation in nuclear applications poses an imminent need to describe the behavior for system reliability, safety and economics. Radiation effects on materials such as void swelling and embrittlement have been long standing complex phenomena yet to be well characterized under different conditions. Specifically, radiation-induced void swelling is a unique mode of degradation in nuclear materials. Serious efforts have been spent to increase radiation tolerance, which is to postpone the consequence of radiation damage. However, the behavioral sensitivity to a number of parameters such as chemical compositions and the irradiation environment makes the conventional trial-and-error experimental approach highly inefficient. Meanwhile, the physics-based computational models are also subject to inefficiency and critique of fidelity due to the complex underlying defect dynamics on multi-scales. In the era of increasing data resources from resource-consuming nuclear materials experiments, machine learning (ML) as an alternative could prove useful in more efficiently and accurately predicting macroscale materials response and guiding experiment testing. It is then applied to perform prediction of the incubation period of void swelling based on manually collected experimental data. By training decision tree based ensemble models, it delivers very good performance in prediction, and the identified main contributing factors such as temperature, Fe and Cr content, and dose rate are fairly consistent with established understandings. Ultimately, establishing a well-performed ML model is a promising route to radiation resistant material design. It is thus our plan to construct a public web platform to crowdsource more data for nuclear materials exploration. And from the methodology point of view, ML can be utilized as a subroutine in a physics-based modeling technique for acceleration. Such types of reduced-order model can constitute a future research direction, by exploring a hybrid of ML methodology and physical framework to alleviate current computational constraints in characterizing radiation-induced microstructural evolution.
1:45 PM **MT03.06.01**
*Towards Automated Information Extraction from High Resolution Transmission Electron Microscopy Images*  
Mary Scott1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Transmission electron microscopy (TEM) is the characterization method of choice to observe the atomic-scale and microstructural local features within materials that play a critical role in material performance. Current TEM capabilities include a wide variety of imaging modalities to probe a material’s structure. It is possible to resolve structures with 0.39 angstrom resolution [1], to perform rapid nanodiffraction experiments to characterize the microstructure of hard and soft materials [2], to resolve local chemistry and bonding [3], and much more. Furthermore, recent advances in fast electron detection enable imaging at nearly 100 KHz rates, enabling extremely rapid data acquisition. Directly incorporating these TEM capabilities for structural validation into a high throughput materials prediction, design and synthesis routine would profoundly speed up the materials discovery process.

However, a bottleneck exists between image acquisition and the extraction of relevant information that can be used in a materials design feedback loop. While image analysis of individual images can easily identify regions of interest and determine whether they contain defects, it is prohibitively time-consuming to manually perform this analysis on large numbers of images. This means that, for example, in a given nanoparticle synthetic optimization process, only a small number of successful end products are studied in detail. Failure cases are typically not characterized, and population heterogeneity statistics are not captured. Therefore, to automatically identify and quantify defects, size and shape statistics, and other key structural features which can dominate a material’s mechanical, electronic, and catalytic properties, a new approach is required.

Advances in machine learning and computer vision have made high accuracy automated image interpretation possible. While widely applied in the life sciences, this approach is only recently being applied to atomic resolution TEM images. Here, we present application of machine learning and other high-throughput methods to TEM images for nanoparticle identification and microstructural characterization. When combined with existing automatic image acquisition protocols, this approach is a viable option to close the materials design loop and incorporate TEM into high-throughput materials design and synthesis in a way not currently possible.

2:15 PM **MT03.06.03**
*Feature Extraction from SEM Images to Predict Materials Performance Using Computer Vision and Deep Learning Methods*  
T. Yong-Jin Han; Lawrence Livermore National Laboratory, United States

Visualization techniques, such as scanning and transmission electron microscopy, electron diffraction, X-ray computed tomography and magnetic resonance imaging, among others, are widely used providing high spatial resolution images of atomic arrangements, crystallographic information, material’s shapes, sizes and other microstructure information including defects and voids within materials. Significant advancements in materials characterization methods are providing higher resolutions images, complex information and faster data collection capabilities. With these breakthroughs in visualization techniques, the bottleneck in advancements in materials characterization will no longer be the capability limitations of the characterization tools themselves, but rather, the ability to rapidly analyze and interpret the large amount of complicated (high dimensional), high-quality data. To address this challenge, we are implementing machine learning approaches to accelerate image analysis process,
extracting images features to correlate to mechanical performance.

Breakthroughs in machine learning have shown us that deep learning (DL) has significant advantages over traditional machine learning (ML) and computer vision (CV) techniques for a variety of applications, most notably: improved predictive performance and automated learning of feature representations with minimal human guidance. However, important limitations remain. In particular, DL typically requires more labeled training examples than traditional ML approaches, and it is often difficult to explain model performance. In order to assess application of computational tools for materials science, we chose to compare the two approaches: (1) a traditional ML approach (random forest) using state-of-the-art computer vision features and (2) an end-to-end deep learning approach. In this presentation, approaches taken to extract image features from SEM images of molecular solid crystals and using these features to predict materials performance will be discussed. We show that our image-based ML approach reduces root mean square error (RMSE) by an average of 51% over a non-image-based baseline.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and was supported by the LLNL-LDRD Program under Project No. 19-SI-001.

2:30 PM OPEN DISCUSSION

2:45 PM MT03.06.05
High Throughput Transmission Electron Microscopy—Closing the High Throughout Material Discovery Paradigm Catherine Groschner1 and Mary Scott1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

The past decade has seen a rise in the concept of automated materials discovery. A large majority of the work in this area has focused around computation of intrinsic material characteristics and the creation of material property libraries1. This has been paired with methods to search for suitable candidates from these libraries. However, these predictions still require experimental validation. To this end, high throughput synthetic methods have followed both in the area of organic and inorganic materials2. The missing piece to automated materials discovery is then in high throughput characterization of materials. High throughput materials characterization represents the final feedback step to both computational predictions and high throughput syntheses.

High resolution transmission electron microscopy (HR-TEM) is particularly suited to the materials discovery pipeline because of its high resolution and local information. Most computational libraries are based on DFT calculations which are directly tied to atomic structure. By providing atomic structural information, TEM could be used to verify structural information in computation. This information is also critical to the synthesis of materials to verify the intended atomic structure is being created.

Since nanomaterials are particularly suited to analysis by HR-TEM characterization, in this talk we will address the current state of high throughput HR-TEM characterization of nanomaterials. The first fundamental problem which must be solved to allow for automation is segmentation of nanoparticle regions from the micrograph background. This is particularly challenging since the signal to noise of the particle above the background is extremely low in HRTEM micrographs. However, we have developed a convolutional neural network (CNN) which is able to segment nanoparticles with a 94% pixel-wise accuracy. The neural network is shown to be robust to changes in contrast and is sensitive to the presence of lattice fringes. We will also discuss automated detection of crystal structure and defects.

How Do We ESCALATE Lab Automation and Data Collection for RAPID Discovery of Perovskites? Joshua Schrier; Fordham University, United States

Laboratory data collection should be comprehensive but adaptable. An ideal system should provide a mechanism for specifying unambiguous machine-readable experiment that enable remote operation and replicability, presenting these as instructions to human operators and machines, capturing comprehensive data and metadata during experiment, and performing extraction, transformation, and loading (ETL) to facilitate machine learning. Yet, existing tools require significant development time that is incompatible with rapidly evolving scientific needs.

In this talk, I will describe ESCALATE (Experiment Specification, Capture and Laboratory Automation Technology) an adaptable open source package for experiment description and data collection. As a specific example, I will describe its application to Robotic-Accelerated Perovskite Investigation and Discovery (RAPID). The first generation of RAPID uses inverse temperature crystallization (ITC) to grow halide perovskite single crystals for x-ray structure determination and bulk characterization using commercial liquid handling robots. All experiment plans for the syntheses are contributed remotely, by both human scientists and algorithms trained on the reaction data. More >25 compounds have been produced by the RAPID:ITC (compared to only 4 known ITC-grown halide perovskites prior to our work), including >10 new compounds or polymorphs. Incoming data collected by ESCALATE is used to automatically train machine learning models, evaluate model performance and feature influence, and quantify reproducibility. A live web dashboard communicates these insights to the scientist and management in visual form. I will conclude by describing case studies about new scientific insights extracted from the comprehensive RAPID dataset, and discuss ongoing deployments of ESCALATE to perovskite thin film and vapor diffusion experiments.

AI–Based Learning Machines to Accelerate Discovery of New Materials Apurva Mehta; Stanford Synchrotron Radiation Lightsource, United States

With over a hundred elements in the periodic table, there exists a large number of potential new materials. Some of these new materials and rational optimization of devices based on them can provide solution to many of the growing and daunting challenges we face today, from climate change to water shortage and from faster internet to longer-lasting orthopedic implants. However, in spite of major investments in the last two decades resulting in dramatic advancement in performance of the material science tools, rate of discovery of new materials is still sluggish; it still takes over 20 years for development of a new technological material. The rate of new material discovery lags the performance enhancement of material synthesis and characterization tools because the traditional material discovery approaches based on human curation and perception are unable to cope with the revolution in data generation. They are unable to fully harness accelerating rate of data (both computational and experimental) into discovery of new materials.

Another way of looking at the problem is that the three stages of the discovery cycle, starting with predicting new experiments, performing measurements efficiently, and ending with finding new insights and discoveries in the measurements, are performed sub-optimally. Furthermore, these three stages are isolated from each other halting the discovery cycle. Suboptimal performance and broken links between the stages delay discoveries. The first stage is suboptimal because human curators are finding it increasingly difficult to find trends hidden in rapidly growing and increasingly complex materials data. Overwhelmed researchers are unable to make accurate predictions of experimental conditions (and or compositions) where new desired material may be located. Absence of reliable prior hypotheses, combined with the inability of a human curator to keep pace with information contained in high throughput measurements in real-time, forces a strategy of rapid, but blind searches of vast experimental space, resulting in increasingly large fraction of data of poor quality and of little scientific value. In a blindly cast search, even when the grid catches evidence for a new material, it often takes human researcher weeks of frustrating work wading through large number of poor quality measurements to find it. It is like searching for a needle in a
haystack in a lightless barn. The performance of the final stage of the discovery cycling is becoming worse as materials become more complex and role of processing becomes more significant, making experimental search space too complex (multi-dimensional) for a human curators, using traditional approaches, to find subtle but significant signatures of new discoveries even after prolonged data analysis.

Here, we use the search for new compositional complex alloys, to illustrate a new material discovery approach that leverages recent advances in big-data analytics, machine-learning, and artificial intelligence to link and accelerate performance of each of the three stages of the discovery cycle. The approach is based on two key learning machines: the first makes extraction of new knowledge from large and complex dataset fast, sophisticated, and independent of human curation; and the second engine then uses rapidly extracted information in a Bayesian approach to make decision-making smarter and automated. Data-driven decision-making can not only accurately predict the next experiment to perform, but optimize the experimental data collection measurement-by-measurement so only high quality measurements of with higher scientific content are collected. Close coupling of these two learning machines will bridge gaps that stall discovery cycle, and rapid iteration of one to the other will accelerate discoveries of new technological materials and devices.

4:30 PM MT03.07.03
Accurate and Explainable Machine Learning of Chemical Reactivity in Transition Metal Complexes

Pascal Friederich1,2, Gabriel dos Passos Gomes1, Riccardo De Bin3, David Balcells3 and Alan Aspuru-Guzik1,4; 1University of Toronto, Canada; 2Karlsruhe Institute of Technology, Germany; 3University of Oslo, Norway; 4Vector Institute for Artificial Intelligence, Canada

Homogeneous catalysis using transition metal complexes is ubiquitously used for organic synthesis, as well as technologically relevant in applications such as water splitting and CO2 reduction. The key steps underlying homogeneous catalysis require a specific combination of electronic and steric effects from the ligands bound to the transition metal atom. Finding the optimal combination is a challenging task due to the exceedingly large number of possibilities and the non-trivial ligand-ligand interactions. In this work, we show how high-throughput density functional theory (DFT) and machine learning methods can be combined to accurately predict activation energies for H2 splitting within large chemical spaces containing thousands of derivatives of the Vaska’s complex (trans-[Ir(PPh3)2(CO)(Cl)]. A hybrid approach combining Gradient Boosting Regression with Gaussian Processes allows reach high accuracies (MAE = 0.59 kcal/mol). In contrast with DFT calculations requiring several days to be completed, the machine learning models were trained and used on a laptop on a time-scale of minutes. By using interpretable representations and ranking the feature importances, our approach allows us to interpret the machine learning models and extract design rules to systematically control activation energies. We will give an outlook on how this model can be generalized to other chemical reactions and to derive non-trivial application specific design rules in a fully automated way.

4:45 PM MT03.07.04
Reliability Prediction and Diagnosis of Next-Generation Photovoltaics Using Sparse Datasets and Semi-Supervised Machine Learning

Felipe Oviedo1, Hansong Xue2, Jose D. Pereal1,2, Thomas Heumüller3, Zekun D. Ren2, Zhe Liu1, Shijing Sun1, John Fisher1, Christoph J. Brabec3 and Tonio Buonassisi1; 1Massachusetts Institute of Technology, United States; 2Solar Energy Research Institute of Singapore (SERIS), Singapore; 3Institute of Materials for Electronics and Energy Technology (i-MEET), Friedrich-Alexander University Erlangen-Nürnberg, Germany

Next-generation photovoltaics require high reliability to scale up to market applications. Although a number of promising novel solar cell materials, such as organic solar cells or perovskites, have shown promising performance, improving reliability remains a difficult and time-consuming challenge due to complex and lengthy characterization, and challenging decoupling of dominant degradation mechanisms [1]. Furthermore, common degradation mechanisms among similar samples are often difficult to identify, due to the dynamic nature of degradation and the use of sparse experimental datasets. In this context, we propose a methodology to accelerate 10X–100X the reliability characterization and improvement of solar cell materials and devices by combining a semi-supervised machine learning approach, used for prediction of degradation, and an inference approach based on a device numerical simulator, used to identify root-causes of degradation. First, we adapt the Latent Dirichlet Allocation (LDA) [2] algorithm to identify common degradation trends and regimes in a set of current–voltage (JV) measurements of various unlabeled and weakly-labeled solar cells. Second, using the common degradation regimes extracted by LDA and the initial few hours of degradation, we develop and train a recurrent machine learning model
[2] to predict the \( JV \) characteristics of the sample of interest at the 1000\(^{th} \) hour of degradation. Finally, we use the predicted \( JV \) degradation as function of time to infer, via a device model in a Bayesian setting, the degradation time–series of the intrinsic material and device properties, such as electron and hole mobility of the active layer, or the interfacial properties. By comparing the change in time of various material and device properties, the knowledge of these time–series allows us to quickly identify the main drivers of degradation and suggest improvements for solar cell reliability. To test our methodology, we synthesize, degrade and measure 300 samples of organic photovoltaic materials: established P3HT–PCBM, and next-generation PBDBT–ITIC and P3HT–IDTBR. Each sample in the dataset presents various degradation trends due to varying active layer compositions, hole and electron transport layer combinations, process variation and interfacial properties. Given, the high number of sources of variables, the dataset is inherently sparse. In this context, our methodology successfully determines the final degraded \( JV \) characteristics using less than 10\% of the degradation measurements, on average, and successfully decouples the root-causes of degradation across the sparse dataset. Based in our results, we propose and test potential reliability improvements for PBDBT–ITIC and P3HT–DTBR solar cell materials and architectures.

Reference:

systematic means to identify the shortest path toward a material with some desired properties or the experiments that maximize knowledge of the explored space. In many materials science tasks, however, the goal is to obtain a mapping between two or more experimentally measured quantities. Standard active learning algorithms may not be optimal for such complex scientific problems. Reducing the experimental effort to obtain such mappings can be optimized not by independently running several active learning tasks but rather by a strategy coordinating different experiments performed simultaneously. In this talk I will present the idea of cooperative learning, and illustrate it with examples from several different high-throughput studies.

8:45 AM MT03.08.03/MT02.07.03
Exploring Catalyst Chemistries beyond Scaling Laws using Statistical Learning Scott Broderick, Aparajita Dasgupta, Thaicia Stona and Krishna Rajan; University at Buffalo, United States

We have significantly expanded the knowledge-base of metal catalysts through a unique combination of manifold learning, Gaussian process regression and clustering approaches. Given the complexity in performing catalytic measurements, the amount of data available for selecting ‘optimal’ catalysts for specific reactions is limited. The work described here develops an analysis framework suitable to the small number of measurements available, while also developing a large relevant descriptor-base. We have performed the foundational work needed to develop a catalyst discovery toolkit. Using volcano plots as a platform, we have fused manifold learning methods and graph network methods from which one can rapidly explore new chemistries for single atom alloy (SAA) catalysts. We use single atom systems for testing our robustness, with the added benefit that prior work on single atom systems has not utilized machine learning. Using SAAs allows for a rapid screening of the combinatorial design space. We developed a machine learning logic for screening chemistries to define necessary detailed DFT calculations and have identified 28 alloys which are most promising for further exploration.

9:00 AM MT03.08.04/MT02.07.04
Graph Theory and Machine Learning Uncover Zeolite Transformation Pathways Daniel Schwalbe Koda, Wujie Wang and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Zeolites are inorganic nanoporous materials with broad industrial applications as catalysts, ion exchangers, and separators. Despite sustained research, controlling polymorphism is still a critical challenge in their design, relying mostly on trial-and-error. First-principles calculations could aid the search for new frameworks, but the number of theoretically accessible topologies and the complexity of their kinetic mechanisms render this approach computationally prohibitive. Here, we employ a suite of computational tools such as big-data, graph theory, structural kernels, density functional theory (DFT), and machine learning to explain and predict zeolite transformations. We first relate solid-state transformations to materials descriptors by combining crystallography with a graph-theoretical metric. Supported by exhaustive literature, we then show that interzeolite diffusionless transformations occur only between graph-similar pairs. Moreover, all known instances of intergrowth take place between either structurally- or topologically-similar structures. Our metric suggests hundreds of low-distance pairs between known frameworks and thousands of hypothetical frameworks for realizing novel transformations and intergrown crystals. Such insights are further refined by atomistic simulations. Building on millions of DFT calculations, we parameterize interatomic interactions in pure-silica zeolites using neural network models and active learning. The method enables accurate structural optimizations and off-equilibrium energy sampling with low computational cost, allowing the selection of favorable graph-driven phase transitions between frameworks and uncovering new synthetic pathways for zeolites.

9:15 AM MT03.08.05/MT02.07.05
Automatic Processing of the Scientific Literature to Accelerate Nanomaterials Design and Discovery Anna M. Hiszpanski, Brian Gallagher, Karthik Chellappan, Peggy Pk Li, Shusen Liu, Hyojin Kim, Jinkyu Han, Bhavya Kailkhura, David Butler and T. Yong-Jin Han; Lawrence Livermore National Laboratory, United States

A significant challenge in utilizing machine learning approaches to accelerate materials development is the lack of large and structured data sets. While there are ongoing community efforts to create collaborative materials databases and repositories for this purpose, the diversity and breadth of data types, length scales, and applications still makes it challenging to create such all-encompassing materials databases that are of broad practical use. However, if tools are developed to automatically process the vast scientific literature and extract and structure information of interest to a
given user, then such tools can enable the easy creation of personalized databases with user-specified relevant information to which data mining approaches can then be applied.

We developed such tools for the automated extraction of a suite of information from the text of articles pertaining to nanomaterials synthesis and demonstrate their utility for nanomaterials synthesis. Attaining nanomaterials of desired composition, dimension, and morphology is critical for end-use applications but challenging to do, often requiring time-consuming iterations of synthesis and characterization. Using a corpus of 35k nanomaterials-related articles, we first use a simple unsupervised classification algorithm based on the frequency of occurring terms to identify the primary nanomaterial composition and morphology in each article. Classifying and analyzing articles based on their targeted nanomaterial composition and morphology by itself provides a bird’s eye view and can help identify “hot topics” in the field or alternatively under-studied or challenge-to-synthesize nanomaterials. Next, we apply a supervised machine learning approach to our corpus to identify and extract from articles’ text the sentences related to the nanomaterials’ synthesis protocols, thereby yielding a useful synthesis reference library. Interestingly, we find that function words (i.e., to, in, for, of, at) commonly omitted in natural language processing of non-scientific text are in fact a characteristic trait in discriminating between synthesis- and non-synthesis-related sentences in scientific text. With synthesis protocols in-hand, we further process these via chemical entity recognition (CER) to identify and extract the chemicals used in various nanomaterials’ syntheses. We evaluate a variety of open-access CER tools, as well as our own in-house developed CER tool, that each utilize different tokenizers for parsing the text and techniques for identifying chemicals, and we find that, despite the variety of approaches undertaken, most tools have comparable performance with a peak F1 score of 87%. Normalizing the chemicals names extracted from articles, we then have the opportunity to compare the frequency of use of chemicals for various nanomaterial morphologies. We demonstrate how such analysis provides useful insights as to the importance of chemicals in directing the growth of nanoparticles during synthesis to desired morphologies, like for example nanowires versus nanospheres versus nanocubes. We package this database created entirely by extracting information from existing nanomaterials literature into a browser-based visualization tool we developed that enables easy exploration of the data, thereby helping guide hypothesis generation and reduce the potential parameter space during experimental design.

10:00 AM *MT03.08.07/MT02.07.07
High Throughput Experimental Materials Research Methods at NREL Andriy Zakutayev; National Renewable Energy Laboratory, United States

Bridging the gap between computational predictions and industrial applications requires acceleration and automation of experimental synthesis, characterization and data analysis. High Throughput Experimentation (HTE), also known as combinatorial experiments, is one possible approach to accelerate materials research. Thus, HTE combinatorial methods have been regarded as a promising approach to fulfill the promise of the materials genome initiative (MGI)[1], complementary to high throughput computations and industrial research and development. This presentation will focus on the state of high throughput experimental materials research methods at National Renewable Energy Laboratory (NREL). First, I will discuss methods for creating later gradients of thin film sample properties, in particular going beyond chemical composition of metals [1]. Then, I will talk about spatially-resolved characterization methods, including interlaboratory exchange of samples [2]. Finally, I will highlight our efforts in streamlining data analysis in combinatorial materials science, including a recently published COMBigor software package [3]. These methods will be illustrated by a broad range of materials examples, including oxides, chalcogenides, and nitrides.

10:30 AM MT03.08.08/MT02.07.08
Machine Learning-Assisted High Throughput Synthesis and Characterization of Hybrid Polymer-Carbon Nanotubes Composites for Thermoelectric Application Daniil Bash1,2, Anas I. Abutaha3, Yang Xu2, Yee Fun Lim2, Vijila Chellappan2, Zekun D. Ren1, Isaac S. Tian1,1, Pawan Kumar2, Swee Liang Wong2, Jose Recatala
The so-called 4th revolution in science began with the advent of machine learning (ML), as well as high-throughput (HT) experimentation and robotization. Herein, we describe a workflow that enables rapid screening of a parameter space of hybrid composites, comprised by carbon nanotubes and poly-3-hexylthiophene (CNTs:P3HT) for thermoelectric (TE) applications, with Bayesian optimization embedded in the feedback loop in order to explore the space in a more efficient fashion.

The parameter space under scrutiny includes 4 types of nanotubes (both single- and multiwall), 16 CNTs:P3HT ratios, 2 solvents (o-DCB, and chloroform) and 3 doping conditions, which result in 384 unique synthetic parameters. The setup used involves a robotic pipettor and the microfluidic flow reactor with XY stage for automatic drop casting. We synthesize more than 150 samples per hour, as compared to 4 samples per hour with traditional manual procedures. Characterization was done with means of hyperspectral imaging and 4-point-probe measurements to ascertain optical properties and electrical conductivity.

The conductivity data of the initial experiments was used to train the ML algorithm. After training, the algorithm inferred new experimental conditions for achieving highest possible conductivity, closing the feedback loop. In the end, 3 iterations of the experiments yielded the value of conductivity higher than 150 S cm⁻¹.

Further work includes the optimization of the experimental setup as well as the ongoing effort to use hyperspectral imaging to bypass the bottleneck step i.e. profilometry, as it is the main source of error.

Data-driven Materials Design of Halide Perovskites for Photovoltaic Applications

Shijing Sun¹, Noor Titan Putri Hartono¹, Felipe Oviedo¹, Zekun D. Ren¹, Janak Thapa¹, Zhe Liu¹, Arni Tiihonen¹, Ian Marius Peters¹, Juan Pablo Correa Baena¹, Tonio Buonassisi¹ and Savitha Ramasamy¹; ¹Massachusetts Institute of Technology, United States; ²Georgia Institute of Technology, United States; ³Institute of Infocomm Research, Singapore

To meet increasing global energy demand, it is critical yet challenging to explore new methods to accelerate the development of novel energy materials. In recent years high-throughput experimentation (HTE) and machine-learning techniques have become increasingly accessible to scientific researchers. We herein demonstrate a case study on the data-driven design of perovskite-inspired materials for photovoltaic applications, where we employed machine-learning techniques to guide the synthesis of new halide perovskites for photovoltaic applications. Halide perovskites (ABX₃, where A = Cs, methylammonium (MA), formamidinium (FA); B = Pb, Sn; and X = Cl, Br, I) have shown great promise as light absorbers. Solar cells based on perovskites have surprised the energy community as an emerging low-cost photovoltaic technology with a record power conversion efficiency (24.2%) now exceeding polycrystalline Si cells (22.3%).[1] In this study, we developed a high-throughput experimental platform for thin-film synthesis and characterization, and investigated 75 unique perovskite compositions interest for energy-harvesting applications in a two-month period. To achieve desired optoelectronic properties, we established a set of selection criteria for screening. A deep neural network is employed to classify compounds into 0D, 2D, and 3D perovskite structures via X-ray diffraction patterns analysis. [2] The combination of fast synthesis and machine-learning assisted data diagnostics achieves an acceleration of over an order of magnitude per experimental learning cycle over our laboratory baseline. Among the 41 Pb-free perovskite compositions studied, we identified the optimised doping level in a multi-site alloy series, Csₓ(Bi₁₋ₓSbx)(I₁₋ₓBrx), where a desired structural (2D) and optical properties (< 2 eV). [3] Our work contributes to the prospect of automated materials discovery and we envision an accelerated development in functional materials in the next decade aiming to provide new energy solutions.

Application of Variational Autoencoders to Create Thin Film Structure Zone Diagrams  

Lars Banko, Yury Lysogorskiy, Ralf Drautz and Alfred Ludwig; Ruhr-Universität Bochum, Germany

Structure zone diagrams (SZD) are frequently used to estimate thin film microstructures based on a few chosen synthesis parameters. Despite their usefulness, the predictive power of classical SZD is very limited due to the complexity of the synthesis-microstructure relationship of thin films. Furthermore, the complicated interplay of many synthesis parameters and compositional complexity hinders a generalisation. Classical SZD have in common that they are based on a small number of observations. Underlying trends were extracted by the scientists’ expertise and in a creative process abstracted into a diagram representation of microstructural features. Several refined SZD were proposed, which implemented more physical parameters. With emerging developments in combinatorial thin film synthesis and high-throughput characterization a fast, high-quality acquisition of microstructure data is now possible. This and progress in machine learning of images now provides tools to handle complex image data and improve SZD: We present a dataset containing > 100 samples of SEM surface images from Cr-Al-O-N material libraries, each featuring a different chemical composition and synthesis condition such as deposition temperature, ion energy and sputter frequency of high power impulse magnetron sputtering (HiPIMS). We train convolutional variational autoencoders (VAE) on this dataset of augmented SEM surface image data. Results show that VAEs can cluster microstructure data through latent space representations. The performance of different neural network architectures is discussed. The VAEs generative capabilities to predict SEM surface images from chemical composition and synthesis parameters are investigated. By sampling of the latent representation, we are able to generate SZDs for different variations and combinations of input parameters like temperature, ion energy and chemical composition. The qualitative trends which we observe demonstrate the prediction of microstructure by generative deep learning models.

Generative Adversarial Networks with Molecular Graph Convolution for Learning Secondary Structures of Functional Biomolecules  

Siddharth S. Rath1,1,1, Oliver Nakano-Baker1,1, Jonathan Francis-Landau1,1, Ximing Lu1,1, Kevin Jamieson1,1, Burak B. Ustundag1,2 and Mehmet Sarikaya1,1,1; 1University of Washington, United States; 2Istanbul Teknik Universitesi, Turkey

Generative models, a recent paradigm in machine learning has revolutionized the industry by generating ‘natural looking’ data. While such models have found limited applications in the domain sciences, they display untapped potential in generating materials or molecular structures commensurate with target properties and desired functionalities. While the protein folding problem has been addressed previously by multilevel computational methods and various deep convolutional neural networks, unfortunately, the key step of encoding atomic structures for computational treatment is a challenge. Historical efforts have focused on pre-process featurization that relies upon traditional string representation without any structural information, expert-designed heuristics-based inputs, or on volumetric modeling that presumes a specific predetermined conformation without associated functionality. Here we demonstrate the first implementation of generative models, more precisely, generative adversarial networks with graph encoding of atomic connectivity within the biomolecules, for data-driven prediction of peptide and protein conformations associated with particular functionalities such as binding to atomically flat surfaces and biomineralization. In the graph input, atoms are considered as nodes and the bonds are considered edges, while angles in the molecule are encoded as a third order tensor between any three nodes. The generator tries to output secondary structures in terms of the bond edges and angle tensors while the discriminator network learns from existing sequences and their secondary structures from pdb files and MD simulations. We test the predicted results with MD simulations as well as circular dichroism experiments. Results show that the generative model developed herein is generalizable to any functionality and more accurate than existing methodologies for predicting functionality-associated peptide conformations for practical implementations in disease diagnostics, drug screening, biosensing and bioelectronic devices. As part of the Materials Genome Initiative, the research is supported by NSF-DMREF program through the grant DMR-1629071.
Prediction Interpretability in Data-Driven Materials Development Julia Ling, Astha Garg, James Peerless, Erin Antono, Edward Kim, Yoolhee Kim, Nils Persson and Malcolm Davidson; Citrine Informatics, United States

Sequential learning is a data-driven workflow for accelerating materials development. In this iterative workflow, machine learning models are used to explore a “design space,” the set of possible experiments that could be performed, to surface promising candidate materials. Experimental data for those candidate materials are used to retrain the models so that they can provide successively better-informed suggestions.

For sequential learning to be effective, a relevant design space of candidate materials must first be constructed. These design spaces often include complex constraints, as well as a mix of continuous and categorical variables. The machine learning model can be used to sift through the design space to surface the most promising candidates. For these top candidates, it is valuable to have insights into how the model made its predictions and why it predicts high performance. Interpretability analysis can increase confidence in the model predictions, uncover sample bias in the underlying training data, and provide information on the robustness of the predicted performance. This talk will discuss approaches for constructing relevant design spaces and for interpreting model predictions, and show how these approaches fit into the overall sequential learning workflow.

Network Theory Meets Materials Science Vinay Hegde1, Muratahan Aykol2 and Christopher Wolverton1; 1Northwestern University, United States; 2Toyota Research Institute, United States

One of the holy grails of materials science, unlocking structure-property relationships, has largely been pursued via bottom-up investigations of how the arrangement of atoms and interatomic bonding in a material determine its macroscopic behavior. Here we consider a complementary approach, a top-down study of the organizational structure of networks of materials, based on the interaction between materials themselves. We demonstrate the utility of applying network theory to materials science in two applications: First, we unravel the complete “phase stability network of all inorganic materials” as a densely-connected complex network of 21,000 thermodynamically stable compounds (nodes) interlinked by 41 million tie-lines (edges) defining their two-phase equilibria, as computed by high-throughput density functional theory. We find that the node connectivity in the materials network has a lognormal distribution, and the connectivity decreases with the number of elemental constituents in a material. Analyzing the topology of this network of materials has the potential to uncover new knowledge inaccessible from traditional atoms-to-materials paradigms. Using the connectivity of nodes in this phase stability network, we derive a rational, data-driven metric for material reactivity, the “nobility index”, and quantitatively identify the noblest materials in nature. Second, we apply network theory to the problem of synthesizability of inorganic materials, a grand challenge for accelerating their discovery using computations. We combine the above phase stability network with timelines for the first experimental synthesis of each compound from literature citations. This allows us to create a time-dependent network, and from the time-evolution of the underlying network properties, we use machine-learning to predict the likelihood that hypothetical, computer generated materials will be amenable to successful experimental synthesis. **In collaboration with S. Kirklin, L. Hung, S. Suram, P. Herring, and J. Hummelshoj

A Database to Enable the Discovery and Design of Atomically Precise Nanoclusters Sukriti Manna, Peter Lile,
Alberto Hernandez and Tim Mueller; Johns Hopkins University, United States

Atomically precise nanoclusters can be used for numerous applications due to the unique properties they possess. Despite their wide range of applications, the structures and properties of many small elemental clusters remain unknown. We present the “The Quantum Cluster Database,” an open-access source containing the structures and properties of tens of thousands of cluster structures of up to 55 atoms for 55 elements. The structures are compared against previous computational and experimental data where available. We discuss the methods that are being used to accelerate the construction of the database and describe how the database can be accessed for cost-effective, data-driven materials design.

3:45 PM MT03.09.04/MT02.08.04
Data Driven Experimental Discovery of New Nitride Materials Sage Bauers¹, Elisabetta Arca¹, Wenhao Sun², Chris Bartel³, John D. Perkins¹, Aaron Holder¹, Stephan Lany¹, Gerbrand Ceder² and Andriy Zakutayev¹; ¹National Renewable Energy Laboratory, United States; ²University of California, Berkeley, United States; ³University of Colorado Boulder, United States

New materials enable new technologies, so discovery of new materials is one of the most important directions in materials research. Oxides and some other materials chemistries, which have been extensively explored in the past, yielded many spectacular properties. Other chemistries, such as nitrides, have been barely touched: for every 14 documented oxides there is only 1 known nitride.

We will present on data-driven experimental discovery of new nitride materials, focusing on experimental synthesis and characterization, while also featuring computational predictions and machine learning. The data mining efforts followed by first-principles calculations and machine learning analysis indicated that there are 93 unexplored ternary metal nitride chemical spaces, with 244 new predicted stable ternary materials, and explained the stability trends among these and other nitrides [1].

Experimental synthesis using high-throughput combinatorial methods realized 7 of these compounds, including Zn-M-N (M= Sb, Mo, W) with wurtzite-derived crystal structures and Mg-TM-N (TM = Nb, Ti, Zr, Hf) with rocksalt-derived crystal structures. Physical property characterization results of the ternary rocksalts indicate that they are semiconductors with 1.8-2.1 eV optical absorption onsets and large dielectric constants [2]. The Zn-Sb-N wurtzite is the first ever reported Sb-containing nitride, with Sb in unusually high 5+ valence state, and measured room-temperature photoluminescence near 1.6-1.7 eV solar matched band gap [3].

Overall, these results both demonstrate the power of data-driven materials discovery, and suggest that many new previously unreported nitride materials remain to be synthesized.

4:00 PM *MT03.09.05/MT02.08.05
Active Learning for Nanophotonic Design via Multi-Fidelity Physical Models Harry A. Atwater¹, Jialin Song¹, Yury S. Tokmanov¹, Yuxin Chen¹, Dagny Fleischman¹, Katherine T. Fountaine² and Yisong Yue¹; ¹California Institute of Technology, United States; ²Northrop Grumman Corporation, United States

We have explored the design of nanophotonic structures, such as subwavelength-scale spectral filters, using an advanced active machine learning algorithm that efficiently explores multiple physical models with different approximation fidelities and costs. Our method, which is applicable to a variety of nanophotonics optimization problems, employs a novel strategy consisting of a mutual information based multi-fidelity Gaussian process optimization algorithm (MF-MI-Greedy). It consists of two components: an exploratory procedure to gather information about the target (i.e., the highest fidelity) function via querying lower fidelity functions, followed by an exploitative procedure to optimize the target level fidelity with the previously gathered information. Our results on several pre-collected nanophotonics datasets demonstrate the compelling performance of the multiple-fidelity Bayesian optimization approach. These experiments suggest that there is a significant potential in utilizing cheap, multi-fidelity simulations to aid the discovery of optimal photonic nanostructures.

4:30 PM MT03.09.06/MT02.08.06
Accelerating Materials Discovery through Rapid Construction of Processing Phase Diagrams **Duncan Sutherland**, Aine Connolly, Sebastian Ament, Michael O. Thompson, Carla Gomes and Bruce van Dover; Cornell University, United States

Exhaustive experimental mapping of non-equilibrium processing phase diagrams demands a prohibitively huge allocation of resources for even a single realistic system with more than two compositional degrees of freedom, even with current state-of-the-art high-throughput techniques. Advanced data analysis methods are thus called for to accelerate such explorative efforts, focusing on multimode analysis of critical boundary points in the phase diagram where transitions are observed. Here, we present a hierarchical, prioritized data analysis structure to optimize usage of costly experimental resources. By combining data analysis methods based on optical characterization and x-ray diffraction with sophisticated active learning algorithms, we can efficiently map phase boundaries in composition-time-temperature processing phase diagrams. We demonstrate the utility of our approach by constructing processing phase diagrams for spike annealed multicomponent oxide materials.

4:45 PM MT03.09.07/MT02.08.07

**High-Throughput Screening of Perovskite-Inspire Materials Using Steady-State Photoconductivity and Bayesian Optimization** Jose D. Perea, Felipe Oviedo, Han Yin, Janak Thapa, Armi Tiihonen, Zhe Liu, Ian Marius Peters, Shijun Sun, Rafael Jaramillo and Tonio Buonassisi; Massachusetts Institute of Technology, United States

Hybrid organic-inorganic perovskites solar cells have recently increased scientific interest for their manufacturing simplicity and high performance, challenging the best thin-film photovoltaic devices. Perovskites solar cells have broad and strong light absorption along with excellent transport properties that partly explain their record power conversion efficiency above 24% [1, 2, 3]. Compositional engineering of perovskites is a time-consuming effort. Reaching high efficiency in compositions with complex and diverse dopants that usually requires significant trial and error and hundreds of measurements of full solar cells [4]. In addition to the abundance of applied research on this subject, there is great interest in understanding the fundamentals of transport and photophysical properties of various perovskites compositions [5]. High-throughput methods for screening compositions at the film level could be a potentially powerful alternative to investigate the complex perovskite composition space efficiently. Nevertheless, screening for high-efficiency perovskite compositions with high-throughput methods is not yet firmly established, in part due to the complexity of photophysical characterization experiments at the film level. In this work, we report for the first time a combination of high-throughput conventional steady-state photoconductivity method, (SS-PC) to determine diffusion lengths and Bayesian optimization methodology. This approach allows us to investigate the complex compositional space efficiently by just making films and not full solar cells. By using QSS-PC as a proxy for efficiency, we use Bayesian optimization to guide compositional changes and obtain the best solar cell efficiency for a given material, accelerating material screening by 10X.

[5] Y. Chen et al. NATURE COMMUNICATIONS | 7:12253 | DOI: 10.1038/ ncomms12253 |
Machine learning is often used in materials design nowadays. They are called as Materials Informatics [1] and Material Genome [2]. Recent progress of the technology to predict physical properties of materials is remarkable, especially in metal material [3] and small organic molecule consisting of a single raw material [4].

By contrast, in the case of thermosetting resins, mixed raw materials are often used to synthesize. In such a case, it is hard to predict the material properties due to the existence of missing data derived by the difference in the number of raw materials in each resin. Thus, we suggest a method of machine learning using explanatory variables incorporating raw material information concerning chemical structure.

First, we predicted the classification of raw materials by the random forest, where the extended circular fingerprint (ECFP) [5] was used as the explanatory variable. Then, we aggregated ECFP for each classification predicted by the random forest. After that, we constructed the prediction model by using the aggregated ECFP, feature quantities of reaction intermediates, and curing conditions of resin as explanatory variables. As a result, the model was able to predict in high accuracy ($R^2 = 0.8$), for example, the elastic modulus of thermosetting resins. Furthermore, we show the result of verification of prediction accuracy in first step, such as using the one-hot-encoding.

Therefore, we confirmed that the properties of thermosetting resins could be predicted using mixed raw materials by the proposed method.

a comprehensive quantification of its structure is necessary. In this study, through a combination of high-resolution and high-throughput imaging of the membrane, across several location and depths of the membrane, we quantitatively estimated several physical parameters such as pore area, fiber diameter, network topology, and fiber orientation of these heterogeneous membranes. Scanning Electron Microscope and atomic force microscope images were acquired to provide micron-level details of the mycelium network. These images were sampled across a range of magnifications, and image processing techniques such as statistical region mapping and axial thinning were employed for feature extraction. By obtaining a distribution of the fibers radii, Gaussian mixed models were used to identify three unique fibers indicating bifurcation as the main network growth mechanism. Additionally, unsupervised learning tools were employed to appropriately identify pores from the processed images, which showed a positively skewed data with an average pore area of 4 µm² and a mode of 0.5 µm² across the growth. These pore areas put mycelium in the magnitude for PM2.5 filtration, verifying mycelium’s potential as an air filtration membrane. The results accelerate the development of mycelium-based biofiltration products by establishing a feedback loop with Ecovative Design to optimize their growth conditions and species selection to generate optimized microstructures for filtration.

Reinforcement Learning Based 3D Molecular Structure Prediction of Aromatic Hydrocarbon Family Soo Kyung K. Kim, Youngwoo Cho, Piyush Karande, Joanne Taery Kim, Peggy Pk Li and T. Yong-Jin Han; Lawrence Livermore National Laboratory, United States

Conventional methods to predict 3D structures of the molecule are based on iterative stochastic optimization techniques by moving each atom based on energy calculation using physics-based electronic structure modeling such as DFT or MD. Therefore, computing cost of physics-based modeling of 3D molecular structure is significantly increasing with the number of iterations to calculate energy until the total energy of structure is converged, and so with the number of atoms in the target molecule. Therefore, the conventional iterative stochastic optimization may not be optimal for the molecules with a large number of atoms but relatively simple structure. Specifically, for the molecules containing multiple same substructures, such as aromatic hydrocarbon family which has derivative structures of benzene rings, the number of atoms tends to be very large compared with the simple structural pattern of aromatic hydrocarbon family.

As the cost-efficient alternatives, we propose a novel reinforcement learning algorithm to optimize 3D structure of molecules in aromatic hydrocarbon family based on DDPG (Deep Deterministic Policy Gradient) method. There are three main contributions of our proposed approach: (1) To fasten the computation, we applied novel technique to reduce the degree of freedom to move atoms by grouping repetitive substructures in aromatic hydrocarbon family as a unique entity and move them as a unit, (2) We developed the general strategy to build action space applicable to any small aromatic hydrocarbon molecules, (3) We tested whether the knowledge obtained from several aromatic hydrocarbon molecules can be transferred to new aromatic hydrocarbon molecules. To demonstrate the efficiency of our model, we predicted the 3D structure of 13 aromatic hydrocarbon molecules and compared with results from the conventional DFT calculation. Our experiments show that our model succeed to predict 3D structure of our 10 target molecules with the faster convergence than DFT calculation.

MT03.10.05
Comparison of Neural Networks Based Models and Molecular Fingerprints for the Accurate Density Prediction of Small Molecules Joanne Taery Kim, Soo Kyung K. Kim, Piyush Karande, Peggy Pk Li, Youngwoo Cho, T. Yong-Jin Han and Donald Loveland; Lawrence Livermore National Laboratory, United States

Prediction of stoichiometric properties of small molecules is an important process in developing and designing new materials having the desired properties. Specifically, fast screening to identify a promising density of the molecules is significant to develop high performance explosive and high energy molecule. To calculate the density property of molecules, sophisticated quantum level electronic structure calculations, such as DFT or MD simulation, have been employed in optimizing 3D molecular structure and find the energy minimum. However, there are two problems in employing quantum level calculation. First, it requires a significant amount of computing resources which polynomially increases as the size of the molecule. Therefore, it is computationally expensive and not scalable. Second, there are many cases the results from calculation is different with experimental value. Therefore, finding an efficient computational method to accurately predict experiment density of large number of small molecules is of great value. Recent advances in deep learning lead to rise in numerous neural networks based architectures, and they have recently been applied to various tasks in material science domain, such as small molecular design, predicting
Despite the impressive performances of previous works, there have been only a few work to predict structural properties of molecules which requires through featurization of 3D structure of the target molecule. Specifically, density prediction requires careful selection of input data and sophisticated featurization method to represent both 3D structure and physical property accordingly. In this work, we propose methods to predict experimental density value of small molecules employing various combinations of molecular featurization techniques and neural net based architectures. We used published experimental density values and 3D structure of molecules from cambridge structural database. Comparison study between different neural net architectures and different molecular fingerprint is presented and accuracy of density prediction is reported. Several preprocessing techniques including various fingerprints are also compared and discussed with the results. To the best of our knowledge, this is the first work to predict experimental density using deep learning.

**Predicting Accurate Adsorption Energies of Mono and Diatomic Gases on Transition Metal Surfaces Using Machine Learning**

Sanjay K. Nayak, Satadeep Bhattacharjee and Seung Cheol Lee; Indo-Korea Science and Technology Centre, Bengaluru, India

Finding the “ideal” catalyst is a matter of great interest in the communities of chemists and material scientists, partly because of its wide spectrum of industrial applications. Information regarding a physical parameter termed “adsorption energy”, which dictates the degrees of adhesion of an adsorbate on a substrate is a primary requirement in selecting the catalyst for catalytic reactions. Both experiments and in-silico modeling are extensively being used in estimating the adsorption energies, both of which are Edisonian approach and demands plenty of resources and are time consuming. In this work, employing a data-mining approach, we predict the adsorption energies of monoatomic and di-atomic gases on the surfaces of many transition metals (TMs) in no times. With less than set of 10 simple atomic features, our predictions of the adsorption energies are within a root-mean-squared-error (RMSE) of 0.4 eV with the quantum many-body perturbation theory estimates, a computationally expensive with good experimental agreement. We minimized the RMSE further up to 0.11 eV by using the pre-computed adsorption energies obtained with conventional exchange and correlation (XC) functional as one component of the feature vector. Based on our results, we developed a set of scaling relation between the adsorption energies computed with many-body perturbation theory and conventional DFT XC-functionals.

**Machine Learning-Directed Navigation of Synthetic Design Space—A Statistical Learning Approach to Controlling the Synthesis of Perovskite Halide Nanoplatelets in the Quantum-Confined Regime**

Erick Braham; Texas A&M University, United States

Understanding and developing maps of chemical synthesis using machine learning has the potential to revolutionize efficient synthesis. The design of a chemical synthesis often relies on a combination of chemical intuition and Edisonian trial-and-error methods which are not just inefficient but inherently limited in their ability to quantitatively predict synthetic outcomes, easily defeated by complex interplays between variables, and oftentimes based on suppositions that are limited in validity. The synthesis of nanomaterials has been especially prone to empiricism given the combination of complex chemical reactivity as well as mesoscopic nucleation and growth phenomena spanning multiple temporal and spatial dimensions. Here, utilizing the synthesis of two-dimensional CsPbBr₃ nanoplatelets as a model system, we demonstrate an efficient machine learning navigation of reaction space that allows for predictive control of layer thickness down to sub-monolayer dimensions. Support vector machine (SVM) classification and regression models are used to initially separate regions of the design space that yield quantum-confined nanoplatelets from regions yielding bulk particles and subsequently to predict the thickness of quantum-confined CsPbBr₃ nanoplatelets that can be accessed under specific reaction conditions. The SVM models are not only just predictive and efficient in sampling the available design space but also provide fundamental insight into the influence of molecular ligands in constraining the dimensions of nanocrystals. The results illustrate a quantitative approach for efficient navigation of reaction design space and pave the way to navigation of more elaborate landscapes beyond dimensional control spanning polymorphs, compositional variants, and surface chemistry.

**MT03.10.08**

**Computational Design of Iron-Based Amorphous Magnetocaloric Alloys and Exploration of Vast Material...**
Search Spaces Adam M. Krajewski\textsuperscript{1,2} and Matthew A. Willard\textsuperscript{1}; \textsuperscript{1}Case Western Reserve University, United States; \textsuperscript{2}The Pennsylvania State University, United States

Solid-state magnetic refrigeration employing the magnetocaloric effect (MCE) is a field of very active research. Compared with conventional gas compression-expansion refrigeration, magnetic refrigeration based on MCE offers improved energy efficiency, reduced environmental impact, and noise-free operation. In this study, we performed data-driven predictions of complex iron-based amorphous alloys laying in the 18-dimensional composition range: $\text{Fe}_{100-\Sigma}\text{Ni}_{0-38}\text{Co}_{0-40}\text{Cu}_{0-10}\text{Zr}_{0-11}\text{B}_{0-29}\text{Cr}_{0-10}\text{Nb}_{0-10}\text{Gd}_{0-22}\text{Mo}_{0-10}\text{Si}_{0-10}\text{Nd}_{0-15}\text{Ce}_{0-13}\text{Sm}_{0-3}\text{Mn}_{0-24}\text{Ti}_{0-8}\text{V}_{0-14}$. To design alloys that would achieve higher-than-ever reported performance in refrigeration at a desired operating temperature, we employed a combination of Machine Learning and Search Algorithms. The framework aims to maximize the magnitude of peak magnetic entropy change $|\Delta S_M|_{\text{peak}}$ and tune Curie temperature $T_C$ to value the granting of the highest performance. Based on the contents of the database we collected, our predictive tool is expected to be useful when designing alloys for applications requiring any $T_C$ between 200K and 500K. This temperature range includes room temperature (298K), which is considered to be the most important, as it would allow the creation of MCE-based household refrigerators.

Since April, we have been experimentally validating our predictions, first by testing a state-of-the-art alloy reported in the literature and then testing novel alloys designed with our predictive framework based on that alloy. Results obtained so far show excellent agreement between our predictions and experimental results. In our MRS presentation, we pay particular attention to the design of Search Algorithms. Based on our experience, this step is by far the most challenging due to the considerable dimensionality of composition and vast search space, which in our case included up to $10^{34}$ possible alloys. It is also the most crucial step to the prediction of alloys that are reasonable and are feasible to be made in the lab. We not only report our final method of search but also elaborate on challenges we overcame along the way. This knowledge should be useful to any group working on the design of high-entropy amorphous metals.

MT03.10.09
Modeling Transport Current in Polycrystalline Superconducting Materials Akiyasu Yamamoto and Takuya Obara; Tokyo University of Agriculture and Technology, Japan

Transport current is one of the critical parameters for practical applications of superconducting materials, such as transmission cables and strong magnets. On the other hand, early studies have shown that there is a large gap between the intrinsic physical properties and the macroscopic transport properties obtained as a material due to “weak-link” effects at grain-boundaries, vortex pinning performance and microstructural defects [1,2]. Establishing the prediction model of transport properties is an important issue for the utilization of automated and/or data-driven approaches to superconducting materials research and development. Connectivity is a useful parameter that represents the effective cross-sectional area of the transport current [3]. Matsushita \textit{et al}. has proposed a mean-field model that quantitatively links connectivity and microstructural defects [4]. In this study, we studied transport property prediction method based on numerical modeling. The transport mechanism of polycrystalline materials composed of crystals with electrical anisotropy and containing voids as microstructural defects was investigated by means of a random resistance network based on a three-dimensional cubic site percolation model. The local current distribution and the macroscopic connectivity of the system were obtained by numerical simulation using the finite element method. In addition, the simulated result was compared with the measured electrical resistivity of the synthesized samples.

MT03.10.10
High-Throughput Computation and Evaluation of Raman Spectra Qiaohao Liang\textsuperscript{1}, Shyam Dwaraknath\textsuperscript{2} and Kristin A. Persson\textsuperscript{1,2}; \textsuperscript{1}University of California, Berkeley, United States; \textsuperscript{2}Lawrence Berkeley National Laboratory, United States

Raman spectroscopy is used ubiquitously in the characterization of condensed materials, spanning from minerals, polymers, to biomaterials, as it provides a unique fingerprint of local bonding and environment. In this work, we demonstrate a robust and automatic computational workflow for Raman spectra that employs first-principle
calculations based on density functional perturbation theory. Sets of calculated Raman spectra peaks was compared to those obtained from established experimental databases to estimate the accuracy of the calculated properties across chemical systems and structures. Our work, consisting 55 mineral compounds and 205 pairs of matched peaks, shows that the mean wavenumber deviation is -9.66 cm\(^{-1}\) with a standard deviation of 18.58 cm\(^{-1}\), indicating our calculations tend to slightly underestimate the Raman peak locations. With a mean absolute relative error (MARE) of -2 % for wavenumbers and the low bias exhibited by the intensities, we conclude that our computational data set is in reasonably good agreement with the experimental data and have explored potential reasons for the deviations.

Alkyltin Keggin Clusters as Photoresist Material for Extreme Ultraviolet Lithography

Rebecca Stern\(^1\), Danielle Hutchinson\(^2\), Morgan Olsen\(^2\), Lev Zakharov\(^2\), Kristin A. Persson\(^1,3\) and May Nyman\(^2\); \(^1\)University of California, Berkeley, United States; \(^2\)Oregon State University, United States; \(^3\)Lawrence Berkeley National Laboratory, United States

With integrated circuit manufacturers aiming to produce sub-10nm feature sizes, extreme ultraviolet lithography (EUV) is the next developing technology for the job. The challenges with using polymer-based photoresists for EUV can be eliminated by using oxohydroxo metal nanoparticle photoresists instead. Oxohydroxo metal clusters have the potential to provide faster writing speeds, higher resolutions, and better etch resistance than chemically amplified polymer resists. In a joint computational-experimental effort we examine the stability of organotin Keggin clusters for use as sensitive high-resolution photolithographic resists. A one-step synthesis obtained the β-isomer (β-NaSn12), the γ-isomer (γ-NaSn12), and a γ-isomer capped with a butyltin (γ-NaSn13). The Sn Keggin ions crystallized readily without counterions which increased the simplicity of the synthesis as well as improved the yield, purity, and reproducibility. Solution characterization (SAXS, NMR, ESI-MS) verified that solutions contained only the Na-centered dodecamers. Computational modeling was used to determine the ground state electronic structure of the three butyltin Keggin structures, as well as the capped β-isomer (β-NaSn13), and the hypothetical α-isomers (α-NaSn12 and α-NaSn13). The computed hydrolysis Gibbs free energy and HOMO-LUMO gap provided the stability ranking: β-NaSn12 > γ-NaSn12 > α-NaSn12 which was consistent which experimental observations. The uncapped isomers were computationally evaluated to be more stable than their respective capped analogues. In-depth structure-energy analysis reveals a balance between corner-linking to minimize cation-cation repulsion, and edge-lining to maximize stability via bond formation. Therefore, this sodium centered tin Keggin ion represents the only Keggin ion family so far, that favors the isomers of lower symmetry. Finally, the system’s neutral charge makes it a valuable model system for understanding the fundamental patterning mechanisms at play.

Symmetry in *Ab Initio* Prediction of Metal Organic Frameworks

James Darby\(^1\), Mihails Arhangelskis\(^2\), Athanassios Katsenis\(^2\), Joseph Marrett\(^2\), Tomislav Fričić\(^2\) and Andrew J. Morris\(^3\); \(^1\)University of Cambridge, United Kingdom; \(^2\)McGill University, Canada; \(^3\)University of Birmingham, United Kingdom

First-principles crystal structure prediction (CSP) is a well established technique which is routinely used to predict crystal structure in a diverse range of systems such as periodic solids, interfaces, encapsulated nanowires etc. However, one downside of CSP is that the number of minima in the potential energy surface scales exponentially with system size. As such, it rapidly becomes computationally unfeasible to search for more complex structures with larger unit cells. Here we discuss how ligand symmetries can be exploited to accelerate the prediction of Metal Organic Frameworks (MOFs).

Symmetry is often imposed during CSP to reduce the dimension of the search space and expedite energy evaluations. When atoms are used as the constituent units of the structure it is simple to apply symmetry constraints. However, if, as with MOFs, we start with extended units then imposing symmetry constraints is not trivial. Our method, Wyckoff Allowed Molecules (WAM), makes use of molecule symmetries to generate trial structures with molecules on special Wyckoff sites, as well as on the general site.

To test our approach we searched for a variety of Zinc based MOFs \(^1\) using the *ab initio* random structure searching method with WAM and the CASTEP plane wave DFT code. These results will be presented and used to highlight strengths and weaknesses of the approach.

**MT03.10.13**

**Development of Machine Learning Potential for Si Clusters**

Minkyu Park1, Seokmin Lim1,2, Seungchul Kim1,2 and Yong-Sung Kim3,2; 1Korea Institute of Science and Technology, Korea (the Republic of); 2University of Science and Technology, Korea (the Republic of); 3Korea Research Institute of Standards and Science, Korea (the Republic of)

Recently, the breakthrough developments of artificial neural network (ANN) accelerate the in the field of materials science. In the last few years, J. Behler and M. Parrinello introduced a method, which is a new kind of neural-network representation of density functional theory potential-energy surfaces, called “symmetry function (SF)”.

Here, we calculate the total energies and atomic forces of variety Si clusters, which is fundamental and significant material in modern semiconductor industry, by using ANN. More than 11,000 training set data are generated by carrying out trajectories of ab initio molecular dynamic simulations with canonical ensembles at 300 and 700 K, and the static calculations of randomly positioned coordination of Si clusters. To describe chemical atomic environment properly, we carefully determined number of radial and angular SFs with different parameters. The hyper-parameters in ANN have been tuned by random search and grid search method. To evaluate accuracy of ANN models, we addressed root mean square errors between value of the DFT calculations and ANN calculations through decent-gradient algorithm. The calculated error of total energy for training and test data-sets are less than 0.08, 0.18 eV/atom, and error of atomic force for training and test-sets are less than 0.10 and 0.74 eV/A, respectively. For applications of machine learning based potential, we compared the mechanical and crystallographic properties with density functional theory calculations.

**Model-Based Optimization of Laser-reduced Graphene with Sparse Datasets**

Hud Wahab, Alexander Tyrrell, Vivek Jain, Lars Kotthoff and Patrick Johnson; University of Wyoming, United States

A major challenge towards efficient materials discovery is the reliance on human intuition in the experimental design. Currently, the navigation in the search space for targeted material properties using high-throughput experiments and computations often necessitates large resources. Here, we investigate how machine learning accelerates the search and discovery of new materials using sparse datasets. In particular, model-based search explores iteratively key parameters to guide the experiments and computations. The approach utilizes uncertainties and makes predictions from a surrogate model together with a utility function that prioritizes the decision making process on unexplored data in multidimensional space. We demonstrate this approach on the fabrication of laser-reduced graphene circuits on flexible substrates. The surrogate model is fed with surface characterizations with a view to automate the manufacturing process in a closed-loop. We demonstrate effective explorations and rapid optimizations even with sparse data and discuss the integration of machine learning in advanced manufacturing.

**MT03.10.15**

**High-Throughput Data Generation and Analysis with the Signac Software Framework**

Carl Simon Adorf, Vyas Ramasubramani, Bradley D. Dice and Sharon C. Glotzer; University of Michigan, United States

Computational resources for high-throughput data generation offer incredible potential for accelerating scientific discovery, especially if used in conjunction with well-managed computational workflows. The open-source signac data management framework enables researchers to maintain well-formed, sharable, and reusable data spaces from early exploration through production runs on supercomputers. This is achieved through a transparent, application-agnostic data and workflow model, as well as a simple and unobtrusive programmatic interface. The framework has been applied to molecular simulations, quantum chemistry, photonics, computational fluid dynamics, machine learning, graph mining, and even the management of experimental data. Implemented in Python, signac interoperates organically with other well-established libraries within the scientific software ecosystem such as NumPy and pandas, and it integrates naturally into Jupyter notebooks for data presentation and exploration. The framework readily supports the use of HDF5 files for the storage of large hierarchical numerical data. With special emphasis on enabling rapid prototyping, workflows implemented with signac are easily executed both on local...
resources and powerful supercomputing clusters like OLCF’s Summit. We will present representative examples of scientific applications that demonstrate the efficacy and versatility of signac across a range of materials research domains.

Autonomous Research Systems ARES™ for Materials Development

Benji Maruyama1, J. Daniel Berrigan1, Rahul Rao2, Ahmad E. Islam2, Jennifer Carpena2, Michael A. Susner2, Thomas J. Hardin2, Megan Creighton3, Kristofer Reyes4, Jay Myung5 and Mark Pitt5; 1Air Force Research Laboratory, United States; 2UES Inc., United States; 3National Research Council, United States; 4University at Buffalo, The State University of New York, United States; 5The Ohio State University, United States

Autonomous Research Systems like ARES™ are disrupting the research process by using AI and Machine Learning to drive closed-loop iterative research. ARES™ is our autonomous research robot capable of designing, executing and evaluating its own experiments at a rate of up to 100 iterations per day. Previously ARES taught itself to grow carbon nanotubes at controlled rates (NPJ Comp Mat 2016). Here we discuss recent research campaigns on maximizing carbon nanotube growth rates using a Bayesian optimization planner. We also use HOLMES and knowledge gradient descent to introduce advanced decision policies with local parametric models to control nanotube diameter. Implications for nanotube materials development will be discussed. Finally, we have developed a new research robot for additive manufacturing, AM ARES™, which is at the early stages of teaching itself to print structures with unknown inks. We plan to make the AM ARES™ Robot available online so that a broad community of researchers can test concepts and approaches for AI/ML and experimental design as applied to 3D printing, thus building to the larger goal of enhancing citizen science.

MT03.10.17
A New Cure Kinetic Model of Polymeric Sealants and Its Application to Simulating their Mechanical Behaviour in Industrial Processes

Jae-Hyuk Choi1, Wonbo Shim1, Doyoung Kim1, Chul Hong Rhie2 and Woong-Ryeol Yu1; 1Seoul National University, Korea (the Republic of); 2Hyundai Motor Company, Korea (the Republic of)

Accurate cure kinetic model of polymeric sealants is essential to determine processing conditions of industrial processes, e.g., an automotive painting process involving a body sealant because their mechanical behaviour is highly dependent on their degree of cure during processes. Sourour-Kamal model with seven kinetic parameters is the most widely used cure kinetic model, but it cannot describe the degree of cure in both isothermal and dynamic process conditions. In this study, additional parameters related with the temperature rate were introduced and its validity was proved by carrying out a series of cure experiments of an epoxy-base automotive sealant using a differential scanning calorimetry, finally demonstrating that the degree of cure can be calculated under arbitrary time and temperature profile. Later, the thermal expansion, the cure shrinkage, and the rheological and viscoelastic properties of the sealant were characterized with a function of the degree of cure using a thermomechanical analysis, rheometry and dynamic mechanical analysis, respectively. The developed cure kinetic model and the four properties were incorporated into ABAQUS through a user material subroutine. Finally, the mechanical behavior of the sealant under various time-varying temperatures in automotive heating and coating processes was simulated to determine whether the sealant fails or not during and after the process.

MT03.10.18
PDPep: Protein-Derived-Peptides for Materials Science and Biomedical Device Applications—a Machine Learning Approach

Siddharth S. Rath, Jonathan Francis-Landau, Chris Pecunies, Jacob Rodriguez, Deniz T. Yucesoy, Rene Overney, Sami Dogan and Mehmet Sarikaya; University of Washington, United States

Manipulating physicochemical and structural properties of materials by customizing their microstructures has been the pivotal element in materials science. However, where purely artificial efforts, e.g., heat-and-beat, usually involve complicated materials processing, nature’s design process, evolution, achieves similar functionality for materials at ambient conditions. While enantioselective directed evolution of enzymes has become recently popular in chemistry, the potential for directed-evolution in manipulating materials’ microstructure has been largely untapped. Here we demonstrate how millions of peptide sequences collected from combinatorial libraries and next-generation-sequencing paradigms, can not only be used to de-novo predict materials science relevant peptide sequences (for example, biomineralization), but also be used to scan naturally occurring pan-functional proteins for deriving
peptides with targeted functionalities (e.g., target binding). As examples to PDpep approach, we derive hydroxyapatite biomineralizing peptides from Amelogenin and use these *Amelogenin-Derived-Peptides* for developing formulations towards a utility in repairing defective dental tissues; ice-inhibiting peptides, *AFpep* (antifreeze peptides), from antifreeze proteins for controlling ice nucleation and growth; and magneto-receptive peptides, *MRpep*, from crytochrome-4 for biosensing applications, we demonstrate here that the methodology can be used to mineralize tailored microstructures with predictable materials phases as well as interface these structures with biology and materials science at the molecular level towards genetic design of functional materials in practical technological systems. As part of the Materials Genome Initiative, the research is supported by NSF-DMREF program through the grant DMR-1629071.

**Computational Design of Solid-State Electrolytes for All-Solid-State Li Batteries** Wonseok Jeong¹, Youngho Kang² and Seungwu Han¹; ¹Seoul National University, Korea (the Republic of); ²Korea Institute of Materials Science, Korea (the Republic of)

The growing research efforts have been put into developing solid-state electrolytes (SSEs) that can alleviate many of the issues of Li-ion batteries arising from the utilization of the organic liquid electrolytes. Up to date, several SSEs such as Li₁₀GeP₂S₁₂, Li₃La₂Zr₂O₁₂, and Li₁₁₃Al₀₃Ti₁₇(PO₄)₃ have been proposed as candidates in previous experiments. However, none of those SSEs are fully satisfactory due to the insufficient ionic conductivity or chemical and mechanical stability or high electronic conductivity. Nevertheless, the capability of numerous materials for SSE has been unexplored, and thus we might be able to discover new interesting candidates by a systematic investigation of relevant properties of thousands of materials. In particular, owing to the high accuracy of first-principles calculations as well as recent advances in computing power, computational screening approaches have been applied to searching publicly available materials databases for a new type of SSEs.[1,2] In this work, we take one step further toward discovering potential SSEs; in addition to simply exploring a pre-existing materials database, we try to design new materials with aliovalent substitution of cations. This aliovalent substitution is known to facilitate kinetics of Li diffusion.[3,4] We first screen potential materials, which maybe be useful in themselves or become mother materials for generating new ones by aliovalent substitution, considering fundamental properties such as the presence of transition metals, thermodynamic stability, and band gap. Afterward, we crudely examine the potential energy surface (PES) around the Li ion at interstitial sites. The materials with the most smooth PES are then chosen for the further studies. Starting from 42,337 structures from the Materials Project database, we find and design a number of new[i] Li ionic conductors, some of them are predicted to exceed the Li ionic conductivity of the state-of-the-art Li₁₀GeP₂S₁₂.

Niobium Oxide Dihalides NbOX2—A New Family of Two-Dimensional van der Waals Layered Materials with Intrinsic Ferroelectricity and Antiferroelectricity Yinglu Jia1,2, Min Zhao1, Gaoyang Gou1, Xiao C. Zeng2 and Ju Li3; 1Xi’an Jiaotong University, China; 2University of Nebraska-Lincoln, United States; 3Massachusetts Institute of Technology, United States

Two-dimensional (2D) ferroelectric (FE) materials displaying spontaneous polarizations are promising candidates for miniaturized electronic and memory devices. However, stable FE orderings are only found in a small number of 2D materials by experiment so far. In the current work, based on high-throughput screening of a 2D van der Waals layered materials database and first-principles calculations, we demonstrate niobium oxide dihalides NbOX2 (X = Cl, Br and I), a group of experimentally synthesized yet underexplored van der Waals layered compounds, as a new family of 2D materials that simultaneously exhibit intrinsic in-plane ferroelectricity and antiferroelectricity. Similar to FE perovskite oxides, polar displacement of Nb cations relative to the center of the anion octahedral cage can lead to experimentally measurable FE polarizations up to 27 μC cm−2 in layered NbOCl2. The presence of low-lying antiferroelectric (AFE) phases can effectively reduce the energy barrier associated with polarization switching, suggesting switchable ferroelectricity is experimentally achievable. In addition, the mechanism driving FE phase transitions in NbOX2 monolayers around Curie temperature $T_C$ is clearly revealed by our finite-temperature simulations. NbOCl2 monolayer is predicted to be a stable ferroelectric with $T_C$ above room temperature. Moreover, application of NbOBr2 and NbOI2 monolayers as 2D dielectric capacitors is further developed, where electrostatic energy storage of nearly 100% efficiency can be achieved in the 2D single-layer regime.

Virtual High-Throughput Screening of Photoactive Quaternary Oxides Daniel W. Davies1, Keith Butler2 and Aron Walsh1; 1Imperial College London, United Kingdom; 2STFC, United Kingdom

The discovery of earth abundant, functional materials is critical for sustainable technological advancement. There is a concerted global effort to reduce the time it takes to realize such materials via databases, high-throughput screening and informatics,[1] but forming a four-component compound from the first 103 elements results in excess of $10^{12}$ potential compositions.[2] Such a search space is intractable to high-throughput experiment or first principles calculations.

In this work, we present a low-cost, virtual high-throughput materials design workflow and use it to identify earth-abundant materials for solar energy applications from the quaternary oxide chemical space. A statistical model that predicts bandgap from chemical composition is built using supervised machine learning and the trained model forms the first in a hierarchy of screening steps. Further data-driven algorithms are used to assign crystal structures and to discard unlikely chemistries based on oxidation state information.[3]

We demonstrate the utility of this process by screening over 1 million oxide compositions generated using the open-source SMACT package.[4] We find that, despite the difficulties inherent to identifying stable multi-component oxides, several compounds produced by our workflow are calculated to be thermodynamically stable or metastable and have desirable optoelectronic properties according to first-principles calculations. The predicted phases are Li₂MnSiO₅, MnAg(SeO₃)₂ and two polymorphs of MnCdGe₂O₆, all four of which are found to have direct electronic bandgaps in the visible range of the solar spectrum.

One of the conventional approaches of materials informatics (MI) is on the basis of supervised learning, which expects a property of unknown materials from known materials. In other words, the learning process is appropriate for accurate and broad prediction within a search space where a supervised dataset covers. In this study, to discover truly new materials by a MI approach, we present a search system to explore outside of what we have known so far. Recently, Yang and Tsuda group proposed an automatic-design framework for organic materials, by using Monte-Carlo tree search (MCTS) to select a prospective molecular fragment. This search process is driven by iterative evaluations in optimization of a target property. However, long-simulation time to evaluate the property is a major bottleneck in MCTS. In the case of engine oils, for example, a molecular dynamics (MD) method using Green-Kubo formalism is a proper evaluator for viscosity property. This MD-based evaluation of viscosity requires a large number of MD time steps, which is the bottleneck of the search system.

We present an ultra-fast MD evaluation method of viscosity, which realizes the automatic oil-molecular design. This acceleration is achieved by an idea from a theoretical model of glass transition, in which viscosity can be represented by Arrhenius-type equation. This model states that viscosity can be estimated by a small number of MD steps compared to a direct evaluation methodology. We combine this fast MD evaluation with the MCTS, and examine this search system, by setting viscosity index (VI) as a target property. The VI is an indicator of viscosity susceptible to temperature; typically, high VI oil is regarded to high quality in machinery equipment. In this closed-loop search, the total number of the evaluated molecules is 55,000, which is done in the “K” super computer. We select one prospective molecule as a motif, and make it modified so as to synthesis. This MI-designed oil molecule is experimentally confirmed that it indicates high VI essentially comparable to high-VI base oils in the commercial market.

Metal oxide semiconductors, which support equilibrium populations of electron and hole charge carriers, have widespread applications including batteries, solar cells, and display technologies. It is often difficult to predict in advance if a redox process will result in localized or delocalized charge carriers; the former is associated with polaron transport and the latter with band transport. Determining polaron ground states directly within the density functional theory (DFT) framework is a formidable task and invariably requires careful parameter control of multiple expensive calculation runs[1].

Thanks to the existence of extensive databases covering calculated properties of known and hypothetical systems[2], we are able to utilize data from routine DFT calculations to predict the energetic driving force for carrier localization. By considering the competition between the loss in kinetic energy (from wavefunction localization) and gain in potential energy (from dielectric polarization), the net polaron binding energy can be determined in line with the early work of Pekar[2] and Frölich[3]. We demonstrate how this data can parameterise a simple screening metric for predicting the nature of charge carriers, circumventing the need for explicit polaron modelling in high-throughput studies. Our results are consistent with observations regarding carrier dynamics and lifetimes. We apply our screening metric to identifying p-type metal oxides (targeting low hole polaron binding energy) yielding a number of promising candidates including LiAg3O2 and Ca4Bi2O, in addition to recovering known p-type oxides such as the Delafossite structure CuRhO2.

This study highlights the utility of modern materials datasets to facilitate rapid screening of hard-to-access properties. By comparison with new data generated from hybrid DFT calculations, we explore current limitations in
terms of data quality and availability of necessary properties.

What Does “Cheap” Materials Property Prediction Enable? Shyue Ping Ong, Chi Chen, Xiangguo Li, Zhi Deng and Yunxing Zuo; University of California, San Diego, United States

In the recent decade, materials science has seen a huge growth in available data from combinatorial experiments as well as high-throughput first principles calculations. With this data explosion, we now stand at the cusp where machine learning techniques can make meaningful predictions of many properties of materials almost instantaneously. In this talk, I will discuss the potentially transformative impact that this “instant” materials property prediction can have on materials research, from providing new chemistry insights that will greatly improve our ability to “guess” new materials with superior properties to accessing large length / time scales at near DFT accuracy. I will highlight some of the most promising machine learning approaches thus far, focusing, in particular, on techniques to address fundamental data size and diversity limitations in materials science. Finally, I will outline some of the key obstacles that still remain to ML-enabled materials science.

Solid State Materials Discovery Using Computational and Data-Driven Approaches Yousung Jung; KAIST, Korea (the Republic of)

Discovery of a new material with desired properties is the ultimate goal of materials research. To date, a generally successful strategy has been to use chemical intuition and empirical rules to design new materials, but these conventional approaches require a significant amount of time and cost due to almost unlimited combinatorial possibilities of materials to explore in chemical space. A promising way to significantly accelerate the latter process is to incorporate all available knowledge and data to plan the synthesis of the next material. In this talk, I will present a few initial frameworks we have developed along this line to perform machine-learned density functional calculations, to predict the properties of a material using simple representations, and to generate new materials for a given property using materials deep generative model.

11:00 AM MT03.12.02
Pawpyseed—Post-Processing Tools for PAW Wavefunctions Kyle W. Bystrom¹, Danny Broberg², Shyam Dwaraknath¹, Kristin A. Persson¹² and Mark Asta²¹; ¹Lawrence Berkeley National Laboratory, United States; ²University of California, Berkeley, United States

Post-processing tools for PAW wavefunctions are important for the automation of DFT studies. For example, calculating the overlap operator between wavefunctions from different structures is critical for electron-phonon coupling calculations as well as new formation energy correction methods being developed for point defect calculations. PAW augments plane-wave pseudo wavefunctions with atom-centered orbitals on a radial grid to minimize the size of the plane-wave basis set needed for accurate calculations. This also makes calculating these
overlap operators nontrivial. To overcome this difficulty and enable arbitrary overlap calculations, we developed a general formalism for doing so and implemented it in an open-source code called Pawpyseed. Pawpyseed provides a powerful, parallelized C backend for handling large systems and a flexible Python front-end that takes advantage of cutting-edge research tools like the Python Materials Genomics (pymatgen) package. This performance-usability balance is ideal for automated post-processing of DFT calculations. We demonstrate one potential use of pawpyseed by implementing a perturbation theory-inspired formation energy correction for point defect calculations that improves upon previously proposed band edge shifting techniques.

11:15 AM MT03.12.03
ARTEMIS—Ab Initio Restructuring Tool Enabling the Modelling of Interface Structures Ned T. Taylor, Francis H. Davies, Shane G. Davies, Conor J. Price and Steven P. Hepplestone; University of Exeter, United Kingdom

From metal contacts to batteries, interfaces dominate the physics of devices. Whilst modelling of the individual components of such systems is well understood, the modelling of interfaces is limited due to the structure of the interface being relatively unknown. Prediction of these interfaces is driven by human intuition and computational ease, which is fraught with problems. We have developed a structural prediction approach for exploring interface structures with the goal of eliminating human bias. Here, using two test cases; 1) metal contacts of 2D systems, and 2) oxide-graphite batteries, we show how we can produce interface structures for these complicated systems in order to find the lowest energy interface.

Here, we present our software package, ARTEMIS (Ab initio Restructuring Tool Enabling the Modelling of Interface Structures), developed to ease the generation and modelling of interfaces in order to explore the energy space of interfaces and find the lowest energy interface. We model various metal contacts on a set of transition metal dichalcogenides, investigating different termination planes and surface stoichiometries. The software also enables the exploration of intermixing and plane shifting in order to find the lowest energy interface between any two materials. Hence, by using ARTEMIS, we show how a variety of metal contacts for 2D systems could be explored, as well as understanding electronic properties of graphitic/oxide mixtures for applications such as batteries.

11:30 AM *MT03.12.04
Design Strategies for the Construction of Metal-Organic Frameworks Mohamed Eddaoudi; King Abdullah University of Science and Technology, Saudi Arabia

Demand for functional materials targeted for specific applications is ever increasing as societal needs and demands mount with advancing technology. One class of inorganic-organic hybrid materials, metal-organic frameworks (MOFs), has burgeoned in recent years due, in part, to effective design strategies (i.e. reticular chemistry) for their synthesis and their inherent [and readily interchangeable] hybrid, highly functional character. Metal-organic materials, specifically metal-organic frameworks (MOFs), have emerged as a unique class of materials amenable to design and manipulation for desired function and application. Several design strategies have been utilized and developed to target viable MOF platforms, from the single-metal-ion molecular building block (MBB) approach to the hierarchical supermolecular building block and supermolecular building layer approaches (SBB and SBL, respectively) to our newly introduced merged net approach allowing for the construction of intricate MOFs with multiple ligands, . This inherent built-in information allows access to highly stable and made-to-order porous materials toward applications pertaining to energy and environmental sustainability.
Designing energy conversion materials with simultaneous satisfying activity and stability properties is a challenge especially for electrochemical reaction such as the water splitting reaction. Often, high electrocatalytic activity of a catalyst material is accompanied by structural instability. In this presentation, I will discuss a core-shell oxide catalyst material design, where an active core catalyst is covered with a stable shell, as an attractive solution to the problem of catalyst instability. So far, the influence of the core during electrocatalytic reactions on the surface of the shell of oxide systems is not well understood. In this contribution, we demonstrate how ultrathin heterostructures composed of unstable active and stable inactive layers can be used for studies of model core–shell oxide architectures. In particular, we show that as little as a one unit cell subsurface layer of an active perovskite SrRuO$_3$ “core” can activate a SrTiO$_3$ “shell” surface layer towards oxygen evolution reaction (OER). While, as little as a two unit cell shell layer is enough to completely protect the inherently unstable catalyst against corrosion during OER. Using density functional theory calculations and a simplified electronic structure model, we unravel the mechanism for the subsurface activation for a class of oxide heterostructures and rationalize the choice of the SrTiO$_3$-SrRuO$_3$ system, which is realized experimentally.$^{1}$

Data-Driven Approach for Core-Loss Spectroscopy—Prediction of Spectra and Quantification of Properties
Shin Kiyohara$^1$, Masashi Tsubaki$^2$ and Teruyasu Mizoguchi$^1$; $^1$The University of Tokyo, Japan; $^2$Artificial Intelligence Research Center, Japan

In materials development, a structural analysis of materials is indispensable to understand the structure property relationships. Especially, with increasing demand for nanoscale devices, in which peculiar atomic arrangements influence the material properties more than those in bulk, the importance of the local structure analysis is rapidly increasing. Among a variety of analytical techniques, core-loss spectroscopy, that is, electron energy loss near edge structure (ELNES) and X-ray absorption near edge structure (XANES), is strongly authentic with nano- or sub nanoscaled spatial resolution and nano- or femto-scaled time resolution, enabling to analyze the lattice defects and chemical reaction. Due to their superior spatial- and time-resolutions, huge number of spectra, several thousands and million, can be observed in one experiment.

On the other hand, interpreting the core-loss spectra is not straightforward. Although theoretical simulations of ELNES/XANES have been performed to interpret the spectra, calculating just single spectrum requires huge computational time, such as tens hours and days. The one-by-one simulation is quite difficult for the large spectrum data-set.

In this situation, we need an alternative approach to analyze a thousand of spectra. Here, we developed new data-driven approaches to predict the core-loss spectra and quantify the material properties by the machine learning [1-3]. First, we have used the machine learning to predict the core-loss spectra. A spectral database of O-K edges of silicon dioxides, including 1,171 spectra, was constructed by the theoretical calculation. Then, we constructed a neural network model, whose input layer is the partial density of states (PDOS) at the ground state and output layer is the core-loss spectra. After training, the prediction model can produce the core-loss spectra only by the PDOS. Different from the core-loss spectrum, the PDOS at the ground state can be obtained within a few minutes.

Furthermore, the prediction model constructed by the "crystalline" silicon dioxides was applied to predict the O-K edge spectra of "amorphous" silicon dioxides. Based on this investigation, we revealed the critical difference between the crystalline and amorphous silicon dioxides [2].

In addition to the spectrum prediction, we used the machine learning to find the connections between the ELNES/XANES and the materials structures and properties. The same database as above was used and considered mean bond length, bond angle and Voronoi volume as geometrical features, and bond overlap population, Mulliken charge and excitation energy as chemical bonding features. As the results, we achieved to predict the geometrical properties and the chemical bonding properties correctly. Furthermore, our prediction model constructed by the simulation was applied to an experimental spectrum, and we found that our model could predict the properties correctly from the experimental spectrum even though it had large noise.

The details of the two studies will be discussed in my presentation.

Rapid Inference of Optical Constants and Thickness of Thin Films by Supervised Machine Learning

Siyu I. Tian1,2, Zhe Liu1, Vijila Chellappan4, Yee Fun Lim4, Felipe Oviedo3, Benjamin P. MacLeod3, Fraser G. Parlane5, Curtis P. Berlinguette5 and Tonio Buonassisi3; 1Singapore-MIT Alliance for Research and Technology, Singapore; 2National University of Singapore, Singapore; 3Massachusetts Institute of Technology, United States; 4Agency for Science, Technology and Research, Singapore; 5The University of British Columbia, Canada

The use of machine learning (ML) and automation has recently emerged to accelerate material development and optimization. This automated closed-loop cycle of material development requires accurate and rapid characterization to provide feedback for the optimization of subsequent syntheses. In this study, we propose an ML-based method to rapidly extract optical constants and thickness of thin films from transmittance and reflectance (TR) spectra. The TR spectra of a thin film capture convoluted information of its optical constants (i.e., refractive index $n$ and extinction coefficient $k$) and thickness $t$. Today, a trained expert fits measured TR spectra with a material-specific parametric model and optical model to indirectly extract optical constants and thickness, and validates with low-throughput measurements (e.g., profilometry or scanning electron microscopy). Hence, the extraction of $n$, $k$, and $t$ from TR spectra becomes a bottleneck for a high-throughput experiment loop.

This study demonstrates semi-automatic extraction of $n$, $k$, and $t$ from TR spectra. First, we generate our training dataset using optics simulations. Values for $n$ and $k$ are simulated by combining several optical oscillator models (e.g., Tauc-Lorentz model); then, transfer matrix formulation of Fresnel equations are used to simulate TR spectra. The simulated data are augmented to reflect the noise and imperfection of experimental measurements, following the strategy in [1]. Second, we use a variational autoencoder (VAE) to reduce the dimension of the dataset, and then we feed the dimensionally-reduced latent variables into a deep neural network (NN) to estimate the optical parameters and thickness of the film. We found a 95% confidence interval is within ±30 nm for the whole range of 100-nm- and 2000-nm-thick films. Third, after training of the machine learning model is complete, we apply the pre-trained ML model to simulated and experimental TR spectra of organic and inorganic metal-oxides. The NN-predicted parameters are further used as the inputs to a forward-fitting Bayesian inference model to accurately extract $n$, $k$, and $t$. Lastly, we discuss how this approach might generalize to other material systems and characterization methods.

Act Locally—Tuning PV Materials to Local Climate
Erin Looney, Tonio Buonassisi and Ian Marius Peters; Massachusetts Institute of Technology, United States

Recently, machine learning (ML) has emerged as a useful tool for photovoltaics (PV) system design and performance evaluation [1]. However, many PV materials have been demonstrated, with different sensitivities to the solar spectrum and operating temperatures. In this contribution, we seek to demonstrate how ML can accelerate the adoption of PV technology, by customizing it to the local environment, leveraging a technology-dependent energy-yield model that uses open-source satellite information [2]. First, we apply ML to classify PV operating conditions (spectra + temperature) globally, using an unsupervised clustering approach with embedded physics domain knowledge. Then, on the basis of this classification, we envision a way to more accurately determine power ratings and predict energy yield for PV modules made from different materials in each climate zone, identifying opportunities for R&D innovation with strong future market pull.

Beyond-Expert-Level Prediction of Battery Performance by Feature-Engineering-Free Machine Learning
Xi Chen and Xin Li; Harvard University, United States

Predicting the performance of functional materials systems such as rechargeable batteries in real-time is of great importance to both scientific research and industry. Due to the large capacity and power needed for batteries in electric vehicles and the relatively closed environment of cars, the safety of Li-ion batteries has become the paramount concern, since failure due to short circuit or leakage of chemicals can easily catch fire. Also, a typical battery test in battery research and development can be quite time-consuming. For example, up to thousands of charge/discharge cycles are needed for a cycling performance test. Thus, there is strong interest across both the academic and industrial community in predicting the cycling performance, life and critical failure event based only on the first cycle, the initial cycles, or the few cycles before battery failure, which holds great potential of accelerating the research and development of battery materials and improving the safety control procedures of electric vehicles. Previously, sophisticated apparatus is required in order to measure indicator properties of performance, while machine learning approaches based on feature engineering procedures require a priori expertise, which impedes the application in the complicated real-world environment. Here we show a novel end-to-end machine learning approach, free of feature engineering, toward effective real-time prediction of the battery life and failure, using just the raw images of the charge-discharge voltage profiles. Our method can make unsupervised real-time automatic extraction of latent physical factors that control the battery performance beyond human expertise. We demonstrated the real-time classification of cyclability using just the first cycle, and the real-time prediction of battery malfunction up to 20 cycles prior to the catastrophic failure. Our results show significant effectiveness even for just a proof-of-concept level dataset, which paves the way toward the real-world application.

Enabling Data Science Methods for Catalyst Design and Discovery
Zachary W. Ulissi; Carnegie Mellon University, United States

Increasing computational sophistication and resources can enable a larger and more integrated role of theory in the discovery and understanding of new materials. Most materials studies start in a data-poor regime where the material of interest is unrelated to previous to studies (new structure, composition etc) or the computational methods are incompatible with previous studies (different exchange-correlation functionals, methods, etc). Efficient methods to quickly define, schedule, and organize necessary simulations are thus important and enable the application of online design of experiments approaches. I will discuss on-going work and software development to enable data science methods in catalysis including open datasets for the community. I will describe applications of our approach to ordered bimetallic alloy catalysts, with applications to several electrochemical catalyst discovery efforts including CO2 reduction, oxygen reduction, and water splitting chemistry. I will also discuss the methods and approaches we use to share data among group members and educate new students with the necessary skills to pursue these research directions (including statistics, machine learning, computer science, etc). Finally, I will discuss the transition from data-poor to data-rich regimes and our experiences when data-intensive deep-learning methods become more appropriate than simpler models based on chemical intuition.

4:00 PM MT03.13.07
Estimating Carrier Injection Barriers at Metal-Polymer Interfaces Using Multi-Fidelity Information-Fusion Method
Deepak Kamal1, Lihua Chen1, Rohit Batra1, Yifei Wang2, Zongze Li2, Yang Cao2 and Rampi Ramprasad1; 1Georgia Institute of Technology, United States; 2University of Connecticut, United States

The long term electric insulating behavior of polymers critically depends on the electronic structure at polymer-metal interfaces. Particularly, injection of charged particles (electrons/holes), from the electrodes (metals) to the dielectric (polymer) at these interfaces are known precursors to dielectric aging which culminates in the breakdown of the dielectric. In the absence of defect states on the interface, the probability of this charge injection is decided by the energy difference between the Fermi level of the electrode and the edges of valence and conduction bands of the dielectric. Conventionally, to bypass the need for laborious experimental measurements, computational schemes based on density functional theory (DFT) are employed to calculate these properties. But, computing these properties to match experimental observations requires calculations to be performed on large metal-polymer interfacial structures containing hundreds of atoms. This is computationally expensive and limits the chemical space.
one can explore to find a suitable combination for a given application. Here, we try to overcome this limitation by using a Multi-Fidelity Information-Fusion approach \[1\] to create a model that can predict the charge injection barrier, given a metal-polymer pair. To develop this model, we use charge injection barriers calculated at three different levels of fidelity. In the lowest level of fidelity, band edges positions of isolated single-chain of polymers and Fermi level of isolated metal slabs are computed to obtain the charge injection barriers. These calculations are cheap and hence a database of these values are created from quick calculations performed on a large number of metal-polymer systems. Further, property values obtained from expensive computations, considering large polymer-metal interfaces, are performed on a subset of these systems and are used as data for the second level of fidelity. Finally, the experimentally observed values of the property are used as the highest fidelity data. A co-kriging method is then used to model the relationship between a numerical representation of the metal-polymer system and values of the property at different fidelities. This approach provides an accurate, inexpensive and flexible alternative to expensive DFT calculations to obtain reliable values of charge injection barriers. These models can be readily used for screening metal-polymer systems for insulating applications.

### 4:15 PM MT03.13.08
**Data Mining of Layered Crystalline Perovskites—Structure, Energetic and Electronic Properties and a Comparison with the ABC3 Counterparts**

**Yaoding Lou\(^1\), Junkai Deng\(^2\) and Zhe (Jefferson) Liu\(^1\); \(^1\)The University of Melbourne, Australia; \(^2\)Xi’an Jiaotong University, China**

Perovskite is a classic class of materials that have been studied for a long time. Their interesting properties, such as ferroelectricity, have been enabled a wide range of applications. Recently, the Ruddlesden-Popper (RP) phase of perovskites is becoming an exciting research topic, owing to the interesting properties like superconductivity and optoelectronics. The RP perovskite has layered crystalline structure, consisting of alternated ABC\(_3\) and AC layers with a compound formula of A\(_{n+1}\)B\(_n\)C\(_{3n+1}\) where \(n = 1, 2, \ldots\) (Note that the conventional ABC\(_3\) can be seen as \(n = \infty\)). However, our understanding of RP perovskite is limited. It is highly desirable to gain an overall picture of the structure, energetic, and electronic structures of RP perovskites, particularly how the size confinement effect (i.e., the finite \(n\)) could differentiate their physical properties from the conventional ABC\(_3\). In this work, we did data-mining for the RP perovskites based on the Materials Project database (including over 100 000 inorganic compounds). It is well recognised that octahedra rotation plays a critical role in the electronic, ferroelectric, and magnetic properties of perovskites. We, therefore, carried out in-depth structure and energy analysis of octahedra rotation of RP perovskite and compared them with the conventional ABC\(_3\). Some physical insights are obtained to understand the physical origins of octahedra rotation. The detailed observations and conclusions are listed below.

1. 254 RP perovskite or inverse perovskite crystal structures are identified.
2. The RP perovskites cover diverse chemical species, such as oxide, halide, hydride, and have a wide composition range.
3. The majority of RP perovskite compounds with \(n=1\), i.e., 38 out of 56, have a larger band gap than ABC\(_3\) counterparts. There are 12 semiconductor RP compounds whose ABC\(_3\) counterparts are metallic.
4. Most of the RP perovskites inherit the octahedra rotation patterns of the ABC\(_3\) counterparts.
5. Five RP perovskites have multiple stable octahedra rotation patterns.
6. For most RP perovskites, there is a clear trend that the total energy difference between the rotated and non-rotated configurations are reduced. For some RP perovskites, the non-rotated configurations even become the ground states.
7. Our in-depth analysis suggests that the pseudo-Jahn-Teller effect could be the driving force of octahedra rotation and the relative A-site ion size (concerning B-site as expressed by tolerance factor) could serve as a resistance force for the octahedra rotation.
8. As for RP perovskites, the existence of interface moves the d-orbital of B-site ion to lower energy levels, weakening the pseudo-Jahn-Teller effect and thus the tendency of octahedra rotation.

Our work provides an overview of the structure, energetic, and electronic properties of RP perovskites, which could lay the ground for further investigation of properties of novel two-dimensional perovskites exfoliated from RP phase.

### 4:30 PM MT03.13.09
**Automated Coarse Graining Procedure for Molecular Dynamics, Preserving Rare Events**

**Blake Duschatko, Jonathan Vandermause, Nicola Molinari and Boris Kozinsky; Harvard University, United States**

Molecular dynamics is an essential computational tool for the development and discovery of new materials. However, large length and time scale systems can be computationally intractable. In particular, integration times must be small enough to capture the most rapid motions in the system. In addition, computational expense increases with system size, making it impossible to observe the dynamics of protein folding events, for example. In light of
this, coarse graining procedures to explicitly replace atoms with coarser “beads” are often needed to simulate
dynamics even at millisecond timescales.

While predominantly guided by chemical and physical intuition, recent works have been aimed at designing
automated procedures for determining coarse grained units [1,2,3]. To this end, we demonstrate the efficacy of
spectral clustering algorithms in coarse graining a variety of systems that have not been previously explored with
these methods. Alternative metrics for comparing atomic trajectories are considered that can preserve rare-events at
the coarse grained level, and we explore the physical intuition of the latent space that is afforded by these procedures
as opposed to other machine learning methods.

In addition, we consider the coupled problem of finding a force model for the coarse grained units along with that of
“fine graining” - given a latent space representation of the atomic system, how do the units interact, and how can we
go back to the atomic representation despite the dramatic loss of information? Recent work using Gaussian process
regression for \textit{ab initio} molecular dynamics [4] has demonstrated the advantage of Bayesian methods for force field
construction, and we extend these ideas to the dynamics of latent space force fields. The variance of force
predictions provides a natural indicator of when the coarse grained system is insufficient for capturing the system
dynamics, from which we consider a method for going between the atomic and coarse grained representations.

reduction approach for identifying dynamical domains in protein complexes from limited structural datasets,”
Bayesian Active Learning of Interpretable Force-Fields for Atomistic Rare Events,” arXiv preprints

\textbf{Molecular Design Strategy of $\lambda^{5}\sigma^{6}$-Phosphorous Compounds for OLED Applications} Jonas Köhling, Gerd-Volker Röschenthaler and Veit Wagner; Jacobs University Bremen, Germany

Organic light emitting diodes (OLEDs) are one of the leading technologies used as active optoelectronic device in
displays. Currently, in OLED displays the most challenging quest is to synthesize and design efficient and new
stable blue emitters or improve already existing emitters. To achieve this goal it is of great interest to evaluate a
large number of possible molecules prior to synthesis and to optimize their molecular design.

In this study a large amount, i.e. 151 derivatives, of phosphorous fluorescent compounds were evaluated with first
principle simulations regarding their light emitting properties and molecular orbital alignment. As basic structure the
central phosphorous atom is bound to one derivative of 8-Quinolinol as well as 4 fluorine atoms. 8-Quinolinol was
systematically varied by introduction of substituents from strong electron withdrawing groups (EWG) towards
strong electron donating groups (EDG). Besides the mesomeric and inductive electron withdrawing and donating
effects also the position of the substituent has a crucial influence on the calculated emitting wavelength of these
fluorophores. To determine the emitting wavelength of an isolated molecule time-dependent density functional
theory (B3LYP/6-31+G(d,p)) was employed. EWGs tend to increase the bandgap if placed on the benzene ring of
the ligand, where EDGs show the same effect when substituted on the pyridine ring of the ligand. This allows to
tune the calculated bandgap between 3.2 - 4.1 eV and to choose configurations with energetically aligned molecular
orbitals.
TUTORIAL: Advanced Materials Exploration with Neutrons
December 1 - December 1, 2019

* Invited Paper

TUTORIAL
Advanced Materials Exploration with Neutrons

Sunday Morning, December 1, 2019
Hynes, Level 2, Room 207

This tutorial will give an overview/introduction of a few commonly-used materials characterization techniques using neutrons, such as SANS, NSE, BS/TOF, PDF, etc. In the Topical Outlines, we have detailed the contents of the lectures. Prevailing materials development requires detailed structural and dynamic information down to the atomic or molecular level. Neutron scattering includes a collection of techniques, both elastic and inelastic, complimentary to X-rays, which are unique in providing the ensemble-averaged information of the atomic spatial distributions and movements with sub-angstrom spatial and sub-picosecond temporal resolution. Compared to in-house materials characterization techniques, neutron scattering requires high intensity neutron beams, which are only available at large accelerators or research reactors hosted at the national labs. We hope to give an overview of this technique for the materials scientists who do not have ready access to it.

8:30 AM
Welcome Yang Zhang, University of Illinois at Urbana-Champaign

Small Angle Neutron Scattering Yun Liu, National Institute of Standards and Technology

The lecture will discuss the applications of small angle neutron scattering to study a wide range of soft matter materials such as biological and polymeric materials.

9:10 AM
SASView Wojciech Potrzebowski, European Spallation Source

An introduction to the SAS data analysis capabilities of the community developed SASView package with information on how to contribute to its further enhancement.

9:45 AM BREAK

10:15 AM
Neutron Reflectometer John Ankner, Spallation Neutron Source Oak Ridge National Laboratory

The lecture will cover the fundamental principles underlying neutron reflectivity measurements and how the technique can be applied to the study thin films of soft matter, energy materials, biomaterials, and magnetic systems.

10:50 AM
Neutron Pair Distribution Function Katharine L. Page, University of Tennessee
This lecture will give an introduction to the technique and applications of pair distribution function (PDF) analysis, with an emphasis on nanostructure and disorder in bulk functional materials.

1:30 PM
**Time-of-Flight and Backscattering Spectroscopy** Madhusudan Tyagi, National Institute of Standards and Technology

The lecture will cover basics of backscattering and time of flight spectroscopy. Some scientific examples from backscattering and time of flight will be presented to illustrate data analysis and its interpretation.

2:10 PM
**Neutron Spin Echo** Antonio Faraone, National Institute of Standards and Technology

This lecture will cover the basic principle of operation of NSE as well as data reduction. Some relevant scientific examples of NSE work will be covered and will be used to exemplify the basic ideas of data analysis and interpretation.

2:45 PM BREAK

3:15 PM
**Simulation and Software** Anibal (Timmy) Ramirez-Cuesta, Oak Ridge National Laboratory

This lecture will cover simulations of inelastic neutron scattering spectra from atomistic models.

3:50 PM
**How to Write Winning Neutron Scattering Proposals** Victoria Garcia-Sakai, Science and Technology Facilities Council

This lecture will cover basic skills of writing successful neutron scattering proposals.

4:25 PM
**Conclusion**

Quantum Spin-Nematic State in Layered Vanadophosphates Andrey Zheludev; ETHZ, Switzerland

Conventional magnetic order spontaneously produces a static periodically modulated magnetization in the sample. It thus breaks rotational and time-reversal symmetries of the underlying spin Hamiltonian. A spin nematic is an exotic state that only breaks rotational but not time reversal symmetries. The spins remain disordered and fluctuating, but these fluctuations are spontaneously anisotropic. Theory predicts a spin nematic ground state for quantum spin systems with competing ferromagnetic (FM) and antiferromagnetic (AFM) interactions in high magnetic fields. The simplest model is a FM-AFM S=1/2 square lattice. To date there seems to be only one family of materials that approximate this scenario, namely the layered vanadophosphate. Unfortunately, our understanding of these compounds has been severely limited by a lack of single crystal samples. This is particularly problematic for experiments in magnetic fields where any features or phase transitions are smeared out by the powder averaging of the material's anisotropic properties.

In my talk I will present breakthrough magnetic, thermodynamic, ESR, NMR and neutron scattering studies on single crystals of two vanadophosphate species, namely BaCdVO(PO₄)₂ and Pb₂VO(PO₄)₂. Neither turned out to be quite the proximate FM-AFM square lattice that it was advertised to be. Nevertheless, in both systems we find clear indications of "hidden" nematic order, just below saturation in high magnetic fields.

9:30 AM *MT04.01.02
Emergent Quantum Phenomena in Frustrated Quantum Magnets—Application of External Tuning Parameters Sara Haravifard; Duke University, United States

What are the experimental signatures of exotic Spin Liquid states? What is the best approach in solving the Hamiltonian of the systems with disordered ground states? What is the role of chemical disorder and how can it be addressed? What part can the external tuning parameters play in shedding light on the mystery of long-sought Quantum Spin Liquid state and other emergent phases of matter in real materials? These are some of the pressing questions intriguing the researchers for the past decades, creating a rich and diverse arena in the field of Quantum Materials. In this talk, I will discuss how chemical composition, external pressure, and application of magnetic field, can regulate the underlying electronic and magnetic interactions in frustrated quantum magnets, ultimately driving the ground state across the phase diagram, and providing key information. As examples, I will present our recent results for neutron scattering studies performed under extreme sample environments on 2D and 3D rare-earth based geometrically frustrated antiferromagnets.

Overview of the Neutron Scattering Program at DOE’s Office of Basic Energy Sciences Pappannan Thiyagarajan; Department of Energy, United States

The presentation will provide an overview of the DOE’s Office of Basic Energy Sciences (BES) Neutron scattering programs for the fundamental materials research. The programs support basic research on the unique interactions of neutrons with matter to achieve a fundamental understanding of the atomic, electronic, and magnetic structures and excitations of materials and their relationship to macroscopic properties. Major focus is on the transformative research that uniquely requires neutron scattering as a major tool and serves as a driver for the concomitant advancement of neutron scattering techniques and capabilities for materials research at the two BES world-leading neutron scattering facilities. Research opportunities identified by the recent BES workshops and roundtables will be discussed. The application process and opportunities for white papers will be overviewed, as well as the on-line resources for principal investigators.

For additional information, visit the BES Web page at: https://science.energy.gov/bes/
Identification and Control of Domain Wall Patterning in Spinel Ferrimagnets
Gregory J. MacDougall
University of Illinois at Urbana-Champaign, United States

Spinel antiferromagnets have long been at the center of research into strong spin-lattice coupling and orbital effects. Among other properties, these materials frequently demonstrate concomitant magnetic and structural phase transitions, heightened magneto-elastic or dielectric response functions, and low-temperature multiferroism. There is very little agreement on the microscopic picture to be associated with these effects, but recent work has shown that mesoscale inhomogeneity can play a key role in raising the susceptibilities of complex materials to external perturbations.

In this talk, I will be discussing recent work at the University of Illinois which establishes the importance of mesoscale heterogeneity in determining bulk magnetic properties of spinel ferrimagnets Mn₃O₄ and MnV₂O₄. This will first include a review of Raman scattering, magnetic force microscopy and muon spin rotation data from our group, which reveal the existence of stripe-like magnetic domains in these materials that include ordered and disordered regions. The majority of the talk will then focus on our recent work performed using small angle neutron scattering (SANS), with which we observe Bragg signatures of the same domain wall patterning in the bulk with a typical length scale of ~100nm. Variation with temperature associate these domains with known low-temperature magnetostructural transitions, and measurements taken in applied field reveal a highly anisotropic response associated with domain wall motion. I will correlate key features of our SANS data with observations of nonequilibrium behavior in our magnetization data, and discuss the implications for the properties of other magnetic materials.

Research was supported by the National Science Foundation under Grant NSF DMR 1455264.

Anharmonic Effects on Phonon Eigenvectors and S(Q,E) in Quantum Paraelectric SrTiO₃
Xing He¹, Dipanshu Bansal², Barry Winn³, Songxue Chi³ and Olivier Delaire¹; ¹Duke University, United States; ²Indian Institute of Technology Bombay, India; ³Oak Ridge National Laboratory, United States

The quantum paraelectric behavior and strongly anharmonic lattice dynamics of SrTiO₃ have attracted interest for decades [1]. Reflecting the incipient ferroelectric instability near the quantum critical point and anharmonic couplings between acoustic and optic phonons, anomalous temperature-dependent phonon intensities were observed in multiple Brillouin zones (BZs) from inelastic neutron scattering (INS) experiments on SrTiO₃. The Hybrid Spectrometer (HYSPEC) and HB3 triple-axis spectrometer at Oak Ridge National Laboratory (ORNL) were used to track phonon intensities over a wide temperature range and for a large volume in reciprocal space. The $S(Q,E)$ data reveal a strong softening of the zone-center transverse optic (TO) mode, congruent with ferroelectric (FE) incipient, and simultaneously a strongly anomalous evolution of the intensity of transverse acoustic (TA) modes, which decreases dramatically on cooling. The experimentally observed trends are confirmed and rationalized using ab initio molecular dynamics (AIMD) and anharmonically renormalized phonon methods [2], which achieve quantitative agreement with the INS experiments. By analyzing the simulated temperature-dependent force constants (FC) and eigenvectors, it is found that the structure factors $|F|^2$ of TA and TO modes change dramatically with temperature, as a direct consequence of the strong anharmonicity in this system. Moreover, we identify that the changes of Ti and O eigenvectors are responsible for these striking observations, which originates from Ti-O interatomic FC changes on cooling. These results explain the long-standing question of the origin of the phenomenon first observed by Yamada and Shirane [1]. Our results also systematically extend this observation to multiple BZs and different high-symmetry directions ([1,0,0] and [1,1,0]). These results establish how temperature-dependencies of phonon intensities beyond the harmonic picture can be quantitatively measured through INS mapping of $S(Q,E)$ volumes, providing direct insights into the behavior of phonon eigenvectors in real space, and also show how first-principles simulations including anharmonic effects can reproduce and rationalize such anharmonic effects. These findings are also valuable to understand other perovskite materials with a variety of phase transitions, such as KTaO₃ and EuTiO₃, and related ferroelectricity/paraelectricity and quantum effects [3-6].

Phonons are the main source of total entropy, thermal expansion, and thermophysical properties of most materials, so it is essential to know the temperature-dependent lattice dynamics. We measured phonon dispersions in silicon by inelastic neutron scattering at elevated temperatures. We determined the thermal shifts of phonon frequencies and broadenings of phonon linewidths throughout the Brillouin zone from these experiments. Large phonon anharmonicities manifested through shifts and broadenings go beyond the quasiharmonic model even at low temperatures. Although the quasiharmonic model (harmonic phonons renormalized by volume) predicts the experimental thermal expansion of silicon well, it does not correctly depict the temperature-dependent lattice dynamics. The necessity to include anharmonicities and nuclear quantum effects to describe the lattice dynamics throughout the temperature range was verified by state-of-the-art ab-initio calculations using the stochastically initialized temperature-dependent effective potential method. The quasiharmonic model correctly predicts the macroscopic values due to a cancelation of phonon shifts, but its validity should not be assumed because it predicts average quantities. The pure anharmonicity included ab-initio calculated phonon lifetime changes and thermal conductivity correctly predict the experimentally determined lifetimes and thermal conductivity as well as previously reported values.

SESSION MT04.02: Quantum Materials II

Nature of Magnetic Excitations in 2D and 3D Spin Liquids Martin Mourigal; Georgia Institute of Technology, United States

Magnetism is a fascinating phenomenon: it is rooted in relativistic quantum mechanics and yet an integral component of the technologies we use every day. In magnetic insulators, where atomic-scale magnetic dipoles carried by electrons are closely bound to a crystal lattice, novel phases of matter with no classical analogues are possible. Chief among these phases are spin-liquids, in which strong fluctuations of magnetic dipoles preclude conventional magnetic order even for temperatures low compared to the average interaction between spins. Such exotic magnetic matter is of great fundamental interest because it features a wealth of coherence and entanglement phenomena – the hallmarks of the quantum world – and is often amenable to theoretical and computational predictions. In this talk, I will present experimental research that brings together materials chemistry, neutron scattering and computer modeling to understand the magnetic excitations in a range of frustrated oxide compounds with triangular, kagome and pyrochlore lattice structures. My talk will emphasize the importance of neutron scattering instrumentation to probe complex materials behavior in which chemical disorder, geometrical frustration

2:00 PM *MT04.02.02
Neutron Scattering of Molecular Nanomagnets Tatiana Guidi1, Stefano Carretta2, Elena Garlatti2, Alessandro Chiesa2, Paolo Santini2, Giuseppe Amoretti2, Béatrice Gillon3, Grigore Timco4 and Richard Winpenny4; 1ISIS STFC, United Kingdom; 2Università’ di Parma, Italy; 3LLB-CEA, France; 4University of Manchester, United Kingdom

Molecular nanomagnets (MNMs) are clusters made of a finite number of magnetic ions coupled by a strong exchange interaction within the clusters and with a negligible magnetic interaction between adjacent clusters in the crystal lattice. They are promising systems for technological applications in the fields of high-density magnetic memory devices, quantum information processing and spintronics. They are also model systems to study the fundamentals of quantum mechanics as they display quantum mechanics effects at the macroscopic level. The advances in the chemical engineering of these molecules have allowed the synthesis of tailor-made systems displaying several interesting quantum phenomena and to improve their properties to bring them closer to technological applications. Neutron scattering techniques have been intensively and successfully used to study the microscopic properties of molecular magnets and have enabled to reveal the signatures of their quantum behaviour. I will show how advanced neutron scattering experiments have been pivotal for the understanding of the magnetic properties and quantum behaviour of a selection of molecular magnets model systems. The new generation of neutron instruments equipped with position sensitive detectors together with the availability of large single crystals has allowed us to reveal the microscopic details of prototypical MNMs unambiguously characterising their Spin Hamiltonian [1,2], to reveal finite size effects on the magnetic properties of linear antiferromagnetic chains [3] and the entanglement between complex spin systems [4].

2:30 PM MT04.02.03
Observation of Near-Surface Diffusion of Isotopically Labelled Iron in Magnetite Steffen Tober1,2, Marcus Creutzburg1,2, Björn Arndt1,2, Konstantin Krausert1,2, Stefan Mattauch3, Sabine Pütter1, Alexandros Koutsioubas3, Amir Syed Mohd3, Lukas Volgger4, Herbert Hutter4, Heshmat Noei1, Vedran Vonk1, Dieter Lott5 and Andreas Stierle1,2; 1Deutsches Elektronen-Synchrotron DESY, Germany; 2Universität Hamburg, Germany; 3Forschungszentrum Jülich GmbH, Germany; 4TU Wien, Austria; 5Helmholtz-Zentrum Geesthacht, Germany

The defect structure in the near surface region of magnetite (Fe3O4) is particularly important for a better understanding of the material’s electronic properties and catalytic activity. Hence, the mobility of Fe in Fe3O4 is a key ingredient towards a better understanding of near surface processes. Recent scanning tunneling microscopy (STM) and low energy electron diffraction (LEED) studies of the (√2×√2)R45° reconstructed (001) surface suggested a subsurface vacancy stabilisation model for this surface, later proved by surface x-ray diffraction (SXRD) [1,2]. The surface reconstruction is reported to get lifted by formic acid adsorption at room temperature [3]. Low energy electron microscopy (LEEM) experiments under oxidising conditions showed a regrowth process of Fe3O4-layers on (001) surfaces [4]. These observations indicate an interesting interplay between cation vacancy formation and diffusion processes. The role of near surface cations was investigated by neutron scattering using 57Fe as a marker. A 25 nm thick 57Fe3O4 marker layer was homoepitaxially grown on top of a (001) polished natural Fe3O4 single crystal substrate by reactive molecular beam epitaxy (MBE). The interdiffusion of iron ions across the film-substrate interface was followed by neutron reflectivity (NR) [5]. Due to the lower scattering length of 57Fe:FeO compared to natural Fe3O4, Kiessing fringes were observed by NR. Comparison with NR simulations assuming a perfectly smooth interface between the film and the substrate showed that a notable intermixing of the iron isotopes already occurred during the growth of the marker layer at only 420 K. The diffusion process was followed by successive annealing steps in ultra-high vacuum (UHV) and the subsequent acquisition of NR curves. In the course
of the annealing, the Kiessing fringes faded out due to interfacial diffusion. The diffusion process is already observed to take place in the temperature range of 500 K-600 K over the probed depth of several tens of nanometers, which shows that substantial mass transport happens in the near-surface region at much lower temperatures as previously observed by bulk diffusion experiments [6]. Diffusion lengths and the respective diffusion constants obtained from fitted scattering length density (SLD) profiles will be compared to the results of earlier studies on bulk Fe₃O₄ at 800 K-1600 K [6,7]. The NR results are complemented by time of flight secondary ion mass spectroscopy (TOF-SIMS) data and x-ray data characterising the structural changes of the samples during the diffusion experiments.

2:45 PM MT04.02.04
Characterization of Local Atomic Structure and Dynamics in Pb-Free Relaxor Ferroelectrics Abhijit Pramanick; City Univ of Hong Kong, Hong Kong

Relaxor ferroelectrics are of great importance in many modern technologies, including high energy density capacitors, electrocaloric cooling and energy harvesting. Due to environmental concerns regarding the current Pb-based relaxors, it is necessary to develop new Pb-free alternatives. Characterization of composition-structure-property relationships is a prerequisite first step towards rational and efficient design of new materials. Nevertheless, structural understanding of relaxor ferroelectrics is challenging because of their highly disordered nature. For the new Pb-free relaxors, the polar atomic displacements are correlated over only nanometer length scales and THz frequencies, although the details of such nanoscale correlations are yet to be fully resolved. In this talk, I will present our recent findings on the nanoscale orderings of polar atomic displacements in the newly designed Pb-free relaxors, which are measured using pair distribution function analysis of neutron and X-ray total scattering patterns. In addition, I will show that while conventional pair distribution function study offer insights into the instantaneous snapshots of local atomic correlations, they do not inform about the timescales over which such correlations become stable. I will demonstrate the application of the dynamic pair distribution function (DyPDF) method to elucidate the timescales over which such nanoscale atomic orderings become stable in some Pb-free relaxor systems. The implication of nanoscale atomic ordering and dynamics towards the dielectric, ferroelectric and electrothermal properties of Pb-free relaxors will be discussed.

3:30 PM *MT04.02.05
Field-Tunable Quantum Disordered Ground State in NaYbO₂ and Related Compounds Stephen Wilson; University of California, Santa Barbara, United States

In this talk, I will present our recent results exploring the magnetic ground state and field-induced phase behavior in the triangular lattice compound NaYbO₂. The triangular lattice decorated with J_{eff}=1/2 moments has enjoyed renewed interest due to recent reports of quantum spin liquid formation in YbMgGaO₄ and related materials. One ambiguity however remains the role played by structural/exchange disorder in generating this behavior, which motivates the exploration of alternate lattice types hosting the same equilateral triangles of J_{eff}=1/2 moments. Here we establish NaYbO₂ as one such alternative with an ideal R-3m structure and minimal lattice disorder. Yb moments experience an enhanced exchange field due to smaller Yb-Yb distances, yet they fail to order at temperatures as low as 20 mK and demonstrate a frustration parameter f>400. The resulting quantum disordered state can be quenched via the application of a magnetic field that drives the formation of a fluctuation stabilized up-up-down spin state. Interlayer frustration of the native, zero-field 120 deg antiferromagnetic order on the triangular lattice is proposed as a critical ingredient for realizing this phase behavior. If time permits, recent results on related materials will also be presented.

4:00 PM *MT04.02.06
Origin of Long Lifetime of Band-Edge Charge Carriers in Organic-Inorganic Lead Iodide Perovskites
Tianran Chen; National Institute of Standards and Technology, United States

Long carrier lifetime is what makes hybrid organic-inorganic perovskites high performance photovoltaic materials. Several microscopic mechanisms behind the unusually long carrier lifetime have been proposed, such as formation of large polarons, Rashba effect, ferroelectric domains, and photon recycling. Here, we show that the screening of band-edge charge carriers by rotation of organic cation molecules can be a major contribution to the prolonged carrier lifetime. Our results reveal that the band-edge carrier lifetime increases when the system enters from a phase with lower rotational entropy to another phase with higher entropy. These results imply that the recombination of the photo-excited electrons and holes is suppressed by the screening, leading to the formation of polarons and thereby extending the lifetime. Thus, searching for organic-inorganic perovskites with high rotational entropy over a wide range of temperature may be a key to achieve superior solar cell performance.

4:30 PM *MT04.02.07
Neutron Scattering Studies of Strong Anharmonicity and Phonon Breakdown Near Phase Transitions
Olivier Delaire; Duke University, United States

Anharmonic phonon-phonon interactions are critical to rationalize and design both ferroelectrics and thermoelectrics, in which strong anharmonicity may be found near lattice instabilities. Large deviations from harmonic potential energy surfaces, as in the Landau double-well picture, give rise to interesting phonon properties characterized by extensive interactions between phonon quasiparticles and pronounced renormalization effects. Similarly, in superionic crystals, where ionic mobilities are comparable to those of liquids, the atomic dynamics are strongly anomalous but remain debated. A central question is whether phonon quasiparticles -which conduct heat in regular solids- can survive in the superionic state, where a large fraction of the system exhibits liquid-like behavior. I will present results from inelastic neutron scattering (INS) measurements of lattice dynamics in strongly anharmonic materials. Combined with large-scale first-principles simulations, such as ab-initio molecular dynamics, these INS experiments enable a detailed understanding of how peculiar atomic dynamics give rise to useful material properties. In thermoelectrics PbTe and SnSe near soft-mode transitions, large thermal conductivity suppressions are achieved by anharmonic scattering [1,2]. In superionics CuCrSe2 [3] and Na/Li solid-state electrolytes, our studies show how anharmonic phonon dynamics are at the origin of low thermal conductivity and superionicity. Yet, long-wavelength acoustic phonons capable of heat conduction remain in the superionic regime. Our studies of lattice dynamics and diffusion will help rationalize the emergence of ultralow thermal conductivity for thermoelectrics and facilitate the design of high-performance solid-state electrolytes for next-generation batteries.

The plasticity of Zr-Cu-Al bulk metallic glasses (BMGs) can be significantly improved by introducing nanoscale heterogeneous structure with the addition of Fe. However, the crystallization pathways of the phase-separated Zr-Cu-Fe-Al BMG is still unclear. The neutron and synchrotron pair distribution function (PDF) analysis illustrates that the phase-separated Zr-Cu-Fe-Al BMG behaves two-step crystallization behavior. Compared with the homogenous Zr-Cu-Al BMG with a single crystalline product tetragonal \( \text{Zr}_2\text{Cu} \), the crystalline products of the phase-separated BMG are more complicated. Upon heating the phase-separated BMGs above the crystallization temperatures, the first crystalline products of the phase separated BMG, i.e., the cubic \( \text{Zr}_2\text{Cu} \) and \( \text{Zr}_2\text{Fe} \) with \( \text{Fd}-3m \) space group, form firstly, and then transform to simpler tetragonal \( \text{Zr}_2\text{Cu} \) phase with \( \text{I}4/m \text{mm} \) space group and orthorhombic \( \text{Zr}_3\text{Fe} \) phase with \( \text{Cmcm} \) space group. Our experiments, by taking advantage of the phase contrast difference of the neutron and synchrotron PDF, reveal that there is a specific sequence of the appearance of the copper-rich and iron-rich crystalline phases during each stage. Our study would shed light on developing BMGs of a controllable heterogeneous structure with potentially tunable mechanical properties.

DYNASOR—A Tool for Extracting Dynamical Structure Factors and Current Correlation Functions from Molecular Dynamics Simulations

Diffraction techniques provide access to dynamical structure factors, which contain detailed information about dynamic processes in materials. The extraction and decoding of this information is, however, non trivial and can greatly benefit from atomic scale simulations. To this end, we here present a flexible and powerful tool that enables the calculation of static and dynamical structure factors from trajectories from molecular dynamics (MD) simulations. The DYNASOR software can readily handle input from several major open source MD packages and thanks to its C/Python structure can be readily extended to support additional software. DYNASOR is hosted as open source on gitlab [1] and can easily be installed via PIP. In addition to dynamical structure factors the code enables computation of current correlation functions and separating contributions in the form of partial correlation functions. The performance and potential of DYNASOR is demonstrated for both solids and liquids, in particular focusing on the possibility to extract the full temperature dependence of both phonon frequencies and lifetimes.

Neutron Powder Diffraction and Inelastic Scattering Studies of Different Types of H\(_2\) Coordination in Molecular Organic Framework Materials

Variable temperature neutron diffraction studies of certain molecular organic framework (MOF) materials reveal that different types of H\(_2\) can be coordinated based on the temperature of first exposure. Both neutron powder diffraction (NPD) and inelastic neutron scattering (INS) have been implemented to best describe this phenomenon. Rietveld refinements of the NPD data provides crystallographic evidence of the adsorbed H\(_2\) locations, and INS provides descriptions of the dynamics of the H\(_2\). Temperature dependent data indicates that a pseudo-chemisorbed state can transform into a physisorbed state upon warming. Furthermore, certain materials studied display NTE that can be modulated based on the different types of H\(_2\) adsorbed.

A Mass-Selective View of Local Binding and Nuclear Dynamics in a BaZr\(_{0.7}\)Ce\(_{0.2}\)Y\(_{0.1}\)O\(_{3+\delta}\) Proton Conductor as Observed by Neutron Diffraction and Compton Scattering

Concurrent neutron Compton scattering and neutron diffraction experiments at temperatures between 70 K and 300 K have been performed on proton conducting hydrated BaZr\(_{0.7}\)Ce\(_{0.2}\)Y\(_{0.1}\)O\(_{3+\delta}\) (BZCY72) fabricated by spark plasma sintering. A combined neutron data analysis, augmented with density functional theory modelling of lattice
dynamics, has enabled, for the first time in this technologically important family of proton conducting perovskite oxides, a mass-selective view of the combined thermal and nuclear quantum effect on local effective binding. The emerging picture is the one of increased anharmonic character of the lattice dynamics and local binding of the framework atoms above the orthorhombic to rhombohedral phase transition at 85 K, whereby a subtle interplay between mode hardening and softening with increased temperature tunes the effective local binding of nuclear species. Importantly, these anharmonic effects seem to be most pronounced in the case of oxygen and cerium. For the latter, the obtained results may shed more light on the origins of high sensitivity of the mixed conductivity observed in $\text{BaZr}_0.7\text{Ce}_{0.2}\text{Y}_{0.1}\text{O}_{3-δ}$. With increased Ce doping level. For the former, together with the neutron data on protons, our analysis strongly suggests the existence of a single type of trapped protons and trap proton sites in the room-temperature non-conducting phase of $\text{BZCY72}$. The protons at room temperature possess insufficiently high kinetic energy to overcome the local barrier for long-range diffusion but enough to perform transfer between different trap sites. A plausible explanation of the origins of the onset of ionic conduction would then involve distinct proton types, the ones trapped around the edges of YO6 octahedra, and the remainder formed of protons located near the ZrO6 and CeO6 octahedral edges, the sites that would favour mobile protons. The apparent proton conductivity would then result from a subtle interplay between the population size and mobility of the trapped and free proton fraction as a function of temperature.

MT04.03.05
Quantifying Doping Concentrations in Neutron Transmutation Doped GaN
Richard T. Barber¹, Quang Nguyen¹, Jae Kwon¹, John Brockman¹,² and John Gahl¹,²; ¹University of Missouri, United States; ²University of Missouri Research Reactor Facility, United States

Doping of gallium nitride (GaN) has become an important topic in the field of wide bandgap semiconductors. We have recently introduced a method for uniform doping of GaN using neutron transmutation doping (NTD). In NTD, gallium inside GaN is transformed into germanium through the use of neutron irradiation. Because of radioactivity after irradiation, measurement of doping concentration has been very challenging. Thus, we employed gamma-ray spectroscopy to accurately measure concentrations of the germanium doping in NTD GaN. This method relies on the gamma-rays outputted by decaying Ga-72 atoms before they beta decay into Ge-72. However, due to a difference in half life, the Ga-70 activity cannot be safely measured this way. An estimate of Ga-70 activity was calculated based on the theoretical amount of Ga-72 and the measured amount of Ga-72. We have confirmed the accuracy of the measurement by comparing data from inductively coupled mass spectroscopy (ICP-MS) and secondary ion mass spectroscopy (SIMS). We have successfully confirmed that our gamma-ray spectroscopy measurements turn out to be a highly accurate method for doping concentration measurement of NTD GaN.

MT04.03.06
Melanin and Neutrons—Towards Simulating Vibrational Spectra of Disordered Macromolecules
Hamish Cavaye¹, Jose Martinez-Gonzalez¹ and Albertus B. Mostert²; ¹Science and Technology Facilities Council, United Kingdom; ²Swansea University, United Kingdom

Melanin is a common and naturally occurring pigment that plays a number of important roles in the human body. Due to its biocompatibility and proton-conducting properties, melanin is a material of great interest in the field of electroceuticals; electronic devices that can interface with biological systems. Development of such devices would pave the way for personalised healthcare and for advanced health informatics, which was listed among the grand challenges for the 21st century by the National Academy of Engineering in the USA. However, there is still much that is unknown about melanin and it remains an area of active research in particular for its conducting properties and associated proton dynamics in the solid state.

Inelastic neutron scattering (INS) is a technique that is uniquely suited to investigating proton dynamics within materials, as the vibrational spectra obtained from INS are particularly sensitive to modes involving hydrogen. Unlike optical methods such as Raman and IR spectroscopies, there are no selection rules for INS and so all modes are allowed. Additionally, as melanin lacks long-range order, it is not amenable to study by diffraction techniques and INS can indirectly offer structural information by virtue of comparison with theoretical spectra produced from calculations.

Peak intensities in INS can be wholly described by the neutron scattering cross-sections and absolute quantities of the atoms involved. This means that predicting INS spectra is often a much more reliable process than for other techniques. For small, isolated molecular species or materials with well-characterised crystal structures, agreement between predicted and experimental spectra can be very good, thus leading to full assignment of the features in the
spectra. However, for larger and less well-characterised macromolecular materials such as melanin, performing the
theoretical calculations necessary to predict the associated INS spectrum is non-trivial and in most cases the
computational cost is prohibitively expensive.
We present our recent work towards a method by which the experimental INS spectrum of a melanin sample can be
analysed by the combination of several short and simple first-principles calculations to gain insight into the system
for a reasonable computational cost.
In the first stage we perform density functional theory (DFT) calculations for a range of expected monomeric
moieties, which are used to obtain vibrational frequencies and atomic displacements for each of their vibrational
modes. These calculations can then be interpreted by AbINS, a module within Mantid which was developed to
generate predicted INS spectra from such calculation outputs. Lastly, we create a linear combination of these
“monomer spectra” in order to replicate the experimentally measured spectrum of melanin itself. From here, the
main features of the spectrum can be identified and characterised, leading to insight into its structure.

Abstract: Neutron radiography is a non-destructive non-invasive technique capable of characterizing materials in-
situ. At reactor facilities, this method is capable of measuring defects such as porosity or cracks in advanced alloys
and engineering components, water movement in geomaterials and plant roots, lithium transport in functioning
batteries, etc. At these facilities, novel techniques such as grating interferometry have recently been developed as a
mean to change contrast and to increase sensitivity to smaller features. Spatial resolutions of tens of µm can be
achieved over a field-of-view of several cm². Moreover, in the past decade, the development of time-of-flight (TOF)
imaging capabilities at spallation neutron sources have enabled the characterization of microstructures and isotope
mapping using Bragg edge and resonance imaging, respectively. Spalled neutrons offer novel imaging contrast
mechanisms in both the thermal/cold and epithermal range that are not easily attainable at reactors. This presentation
aims at giving an overview of neutron radiography and computed tomography techniques at both reactor and
spallation sources, followed by selected research examples such as lithium transport in batteries, hydrogen content in
engineering materials, 3D mapping of additively manufactured (AM) components, microstructure evolution in AM
samples as a function on temperature and stress, isotope mapping in nuclear materials, etc. A brief overview of the
VENUS project, a TOF imaging beamline in construction at the Spallation Neutron Source of Oak Ridge National
Laboratory, will also be given.

Advances in Neutron Imaging Nikolay Kardjilov1, Ingo Manke1, Robin Woracek2, Henning Markoetter1, André Hilger1, Tobias Arlt1, Robert Bradbury1 and John Banhart1; 1Helmholtz-Zentrum Berlin, Germany; 2European Spallation Source (ESS), Sweden

Imaging techniques based on neutron beams are rapidly developing and have become versatile non-destructive analysing tools in many research fields. Due to their intrinsic properties, neutrons differ strongly from electrons, protons or X-rays in terms of their interaction with matter: they penetrate deeply into most common metallic materials while they have a high sensitivity to light elements such as hydrogen, hydrogenous substances or lithium. This makes neutrons perfectly suited probes for research on materials that are used for energy storage and conversion, e.g. batteries, hydrogen storage, fuel cells, etc. Moreover, their wave properties can be exploited to perform diffraction, phase-contrast and dark-field imaging experiments. Their magnetic moment allows for resolving magnetic properties in bulk samples. This presentation will focus on recent applications of neutron imaging techniques in both materials research and fundamental science illustrated by examples selected from different areas.

Application of Advanced Neutron Scattering Techniques to Study Hydrogen Behavior in LWR Nuclear Fuel Cladding Brent Heuser1, Jun-Li Lin1, Timothy Prisk2, Tanya J. Dax2, Alexander Kolesnikov3, Changwoo Do4, Hassina Z. Bilheux1, Brianne J. Heisinger1, Yongfeng Zhang4 and Garrett Granroth3; 1University of Illinois at Urbana-Champaign, United States; 2National Institute of Standards and Technology, United States; 3Oak Ridge National Laboratory, United States; 4Idaho National Laboratory, United States

Light water nuclear reactor (LWR) technology and the development of advanced nuclear reactors depend on materials innovation and mitigating deleterious environmental effects. This talk will focus on the utility of neutron scattering techniques to interrogate LWR structural materials. Emphasis will be placed on the study of hydrogen behavior in LWR cladding. We use the newest generation of neutron sources and instruments to study hydrogen at low concentration; novel experiment results will be presented that demonstrate the utility of neutron scattering as applied to nuclear materials.

11:00 AM MT04.04.04
Advanced Characterization of Nuclear Materials Using Neutron Imaging Yuxuan Zhang1, Hassina Z. Bilheux1, Kristian Myhre1, Jean-Christophe Bilheux1, Jiao Lin1, Jared Johnson1, Andrew Miskowiec1, Rodney Hunt1, Louis J. Santodonato2, Jamie Molaison1, Paris Cornwell1 and Erik Stringfellow1; 1Oak Ridge National Laboratory, United States; 2Advanced Research Systems, Inc., United States

Advanced fuel materials for nuclear energy systems are being investigated using neutron imaging at both the High Flux Isotope Reactor (HFIR) and the Spallation Neutron Source (SNS) at Oak Ridge National Laboratory (ORNL). Research efforts have specifically focused on understanding how production processes impact elemental distributions within the tristructural-isotropic (TRISO) fuel kernels. Conventional characterization techniques (i.e. scanning electron microscopy with energy dispersive spectroscopy, optical microscopy, etc.) often require significant and destructive sample preparations, are greatly limited by the penetration depth, and thus are unable to extract bulk information. In our work, attenuation-based neutron computed tomography at CG-1D beamline at HFIR was performed on TRISO fuel kernels to evaluate the presence of carbon agglomerates in 3 dimensions. Additionally, at the SNAP beamline at SNS, neutron resonance computed tomography was performed to map the isotopic content of the kernels contain uranium and gadolinium. Neutrons with energies higher than 1 eV are absorbed by the nucleus of an atom. Absorption as a function of neutron energy can be mapped from the radiographs and display isotope-specific peaks that can be fitted to quantify the amount of isotope present in the material in 3 dimensions. This presentation presents the characterization of nuclear fuel materials using both the attenuation-based and resonance computed tomography techniques. These two techniques can be utilized in unison to provide unique insight on the material’s manufacturing processes.

Neutron Characterization of Boron-Containing PDMS Composites for Space and Nuclear Applications

Joseph H. Dumont¹, Samantha J. Talley¹, Eamonn C. Murphy¹, Zachary Brounstein¹, Alexander M. Long¹, Tom Robison², Kwan-Soo Lee¹ and Andrea Labouriau¹; ¹Los Alamos National Laboratory, United States; ²National Security Campus, United States

Polydimethylsiloxane (PDMS) or silicone, is widely used in both industrial applications and academic research area due to its low cost, easy manufacturability, backbone flexibility, low surface energy, and chemical and thermal stability. PDMS elastomers are typically prepared by a hydrosilylation reaction between the hydride groups and the vinyl groups in PDMS. Alternatively, it has been used to synthesize foams vulcanized at room temperature for cushioning applications by reacting a hydride-functional PDMS with a hydroxyl-terminated PDMS at room temperature.¹⁻³

There is an increased demand in aerospace, nuclear reactors, and other neutron-producing sources for neutron shielding materials to mitigate ionizing radiation damage.⁴⁻⁵ The attenuation from neutrons radiation in space and nuclear applications can be performed using isotopically-enriched boron (¹⁰B) because of its large neutron cross-section.¹⁰B has previously been successfully incorporated in a PDMS and other polymer matrices for these types of applications.³,⁶ However, compliant PDMS composites with high concentrations of ¹⁰B (≥ 70 wt%) have not been proposed.

The Energy-Resolved Neutron Imaging (ERNI) Flight Path at the Los Alamos Neutron Science Center (LANSCE) allows to probe boron-containing materials and obtain an energy resolved transmission spectra on a pixel-by-pixel bases. This allows 3D reconstructions via Computed Tomography (CT) of the samples and verifies the filler distribution.

In this work, we study the neutron attenuation and boron distribution of highly-filled boron-containing PDMS composites (50-70% by weight) using the capabilities at LANSCE and CT. Additionally, the chemical, thermal and mechanical properties will be studied using a wide range of experimental techniques are used including Fourier transform infrared spectroscopy, mass spectroscopy, differential scanning calorimetry, thermogravimetric analysis, nuclear magnetic resonance spectroscopy, and mechanical testing. The resistance of the composite materials to solvents will be investigated through solvent swelling experiments and exposure to high humidity. The presented work lays the foundation for highly-filled composite polymer foams to be considered for space and nuclear applications.

Mapping Porosity, Crystal Phases and Material Phases with Multi-Scale and Multi-Modal Imaging D.S. Hussey¹, V. DiStefano¹, J.M. LaManna¹, L.G. Butler², L.M. Anovitz³ and D.L. Jacobson¹; ¹National Institute of Standards and Technology, United States; ²Louisiana State University, United States; ³Oak Ridge National Laboratory, United States

Neutron imaging has seen rapid development in new methods. These methods exploit neutron diffraction, refraction, and magnetic precession, to generate novel image contrasts. Dark field image acquired over a broad range of autocorrelation lengths (nm to µm) provides a quantitative measure of the porosity in the sample and in 3 dimensions. By acquiring images as a function of wavelength, and determining the wavelength at which a particular lattice plane no longer contributes to scattering (so-called Bragg edges), one can infer crystal phase. If the scan is made with sufficiently fine wavelength resolution, one can measure the average strain along the beam direction. Another recent advance comes from combining neutron and X-ray tomography (NeXT) in a simultaneous fashion. NeXT provides researchers with a unique tool to study complex structures, as the bivariate histogram of attenuation values makes the problem of segmentation slightly easier. Because the two probes interact differently for a broad range of materials that are difficult to separate with one probe alone. As an example, in fluid flow in geological specimens, water and void space can be difficult to distinguish in an X-ray tomogram, while the matrix and void space can be difficult to distinguish in neutron tomograms. By combining both views simultaneously, the problem of segmenting flow is straightforward. This presentation will discuss dark field imaging in geology and additive manufacturing, the Bragg edge imaging system at NIST using the analysis of austenite vs martensite in TRIP steel, as well as introduce the NIST-NeXT system highlighting the analysis of concrete and shale rocks.

11:45 AM MT04.04.07
In Situ Neutron Diffraction of Strain Path Change Effects in Cold-Rolled MgAZ31B Sheet Karl Sofinowski¹,², Steven Van Petegem¹, Jan Capek¹, Tobias Panzner¹ and Helena Van Swygenhoven-Moens¹,²; ¹Paul Scherrer Institute, Switzerland; ²École Polytechnique Fédérale de Lausanne, Switzerland

There has been growing interest in wrought magnesium alloys (most commonly, AZ31) for strong, lightweight structural components in cars, aircraft, and electronics. These components are subjected to non-linear loading conditions during cold-forming and use, which is known to have significant effects on the mechanical properties of metals. It is therefore important to study the microstructural evolution during strain path changes in these alloys to understand their macroscopic response under such conditions.

In situ neutron diffraction has been used extensively to investigate the evolution of intergranular strain during loading to provide insight on the relative behavior of different magnesium alloy deformation modes during uniaxial tension/compression tests. In this work, we report on the results from in situ neutron diffraction experiments combined with in situ acoustic emission of strain path changes of cold-rolled Mg AZ31B sheets. It is found that, while dislocation slip prevails as the main deformation mechanism, the twinning activity strongly depends on the nature of the strain path change. Post mortem EBSD is also presented to characterize the twin variant selection, which depends heavily on the strain path change angle as well.

This research is performed within the ERC Advanced Grant MULTIAX (339245).
Complex hydrides have been found to exhibit variety of functionalities that can be utilized for many applications. One of the important applications of hydrides is for energy storage such as hydrogen storage due to the high hydrogen capacities of the light weight complex hydrides and superionic battery application due to the fast ionic mobility in some small ion-containing hydride systems. In this talk, I will present some of our recent work on rational development of novel complex hydrides, e.g. inorganic-organic combined complex hydride systems for hydrogen storage, including metal guanidinates, borohydride guanidinium complexes, and novel salts comprised of alkali cations and large polyhedral boron-hydrogen-based anions for superionic conduction. I will focus on the structural studies of these materials with aspects of crystal structure determination of novel hydrides using the combined x-ray/neutron powder diffraction and neutron vibrational spectroscopy. The rich information obtained from the structural and dynamic analysis and their implications for hydrogen storage and ionic conductivity will be discussed.

2:00 PM *MT04.05.02
A View into Adsorption and Separations Processes within Metal-Organic Frameworks through Neutron Scattering Craig Brown1,2; 1National Institute of Standards and Technology, United States; 2University of Delaware, United States

Adsorption of molecules in functionalized and high surface area metal-organic frameworks (MOFs) is of emergent technological importance in a multitude of areas ranging from chemical separations to energy storage. We have been studying the properties of MOFs for storage and separations of industrially important small molecules such as hydrogen, oxygen, carbon dioxide, noble gases, and short chain organics. Besides the geometrical and porosity control available in MOF chemistry, the properties of the frameworks can be tweaked to elevate electrostatic interactions by exposing open metal cation sites or functionalizing ligands. Here, we discuss the information accessible from neutron scattering experiments on a selection of nominally rigid MOFs. The results illustrate the power, and limitations, of diffraction and spectroscopy in elucidating the governing characteristics of these material properties and the interactions with the guest molecules.

2:30 PM MT04.05.03
Determining Electron/Phonon Interactions in Organic Semiconductors Using Inelastic Neutron Scattering Harrelson F. Thomas1, Varuni Dantanarayana1, Makena Dettmann1, Luke Daemen2, John Anthony3, Enrique D. Gomez4, Alessandro Troisi5, Nir Goldman6, Roland Faller1 and Adam J. Moule1; 1University of California, Davis, United States; 2Oak Ridge National Laboratory, United States; 3University of Kentucky, United States; 4The Pennsylvania State University, United States; 5University of Liverpool, United Kingdom; 6Lawrence Livermore National Laboratory, United States

Organic semiconductors (OSCs) provide the unprecedented ability to tailor properties like electronic band gap, mechanical flexibility, processability, and biocompatibility. Recent theories suggest that low frequency dynamic intra- and intermolecular motions are critical to determining localization of the charge carrier, and thus, control the hole mobility. We used inelastic neutron scattering (INS) to probe thermal disorder directly by measuring the high resolution phonon spectrum in multiple small molecule OSCs. We achieved near perfect agreement between the INS spectra of OSC crystals and first principle electronic simulations. This simulation is used to generate a set of electron-phonon coupling parameters, which are used to compute hole mobility using transient localization theory. The charge mobility, calculated from first principles, is in excellent quantitative agreement with macroscopic measurements.

We note however, that most OSCs are not extended crystals. Instead most OSCs are a mixture of multi-crystalline and amorphous domains. The electronic simulation method used in our first study (plane-wave DFT) is much too computationally expensive to include chemical, structural, or even orientational disorder. So even though it is possible to measure a low energy phonon spectrum using INS in a polymeric or multi-crystalline sample, it was until now not possible to model the spectrum. We developed two multi-scale modeling techniques to model phonons in disordered samples and allow us to quantitatively validate the models using INS spectra. For modeling disordered crystals we developed the use of density functional tight binding to model phonons and INS spectra. For fully amorphous samples we developed the use of molecular dynamics to model INS spectra in amorphous small molecules and polymers. This presentation will detail the use of these modeling techniques.
Advanced Neutron Scattering in the Service of Advanced Manufacturing Technology
Markus Strobl\textsuperscript{1,2}, Efthymios Polatidis\textsuperscript{1}, Pavel Trtik\textsuperscript{1}, Jan Capek\textsuperscript{1}, Jacopo Valsecchi\textsuperscript{1}, Roland Loge\textsuperscript{1}, Kilian Wasmer\textsuperscript{1}, Nikola Kalentics\textsuperscript{3}, Rita Drissi Daoudi\textsuperscript{3}, Manuel Morgano\textsuperscript{1} and Hossein Tabasi\textsuperscript{3}; \textsuperscript{1}Paul Scherrer Institut, Switzerland; \textsuperscript{2}Copenhagen University, Switzerland; \textsuperscript{3}EPFL, Switzerland; \textsuperscript{4}EMPA, Switzerland

The Neutron Imaging and Applied materials Group at the Paul Scherrer Institut (PSI) in Switzerland has a long tradition of supporting industry and industrial R&D with neutron imaging and diffraction investigations. Often results have an impact on advancing and improving manufacturing. In particular also the development of metal additive manufacturing (AM) can profit from the ability of neutrons to penetrate deep into and to hence non-destructively assess bulk metal materials.

Conventional neutron imaging is applied at the imaging beamlines NEUTRA and ICON to provide insight into produced porosities and geometric integrity of required structures inside a built part. The results are to validate predictions and build strategies and to guide e.g. sensor developments for in-situ AM process control. While neutron imaging at PSI provide spatial resolutions down to below 5 micrometers, with novel advanced methods structural variations on sub-micrometer length scales can be resolved.

The fact that in additive manufacturing the material is established simultaneously together with the geometry of a specific part, enables to tune the material properties with respect to loading states it undergoes during service. At POLDI, a neutron diffractometer for engineering materials research, the mechanical behavior of TRIP and TWIP steels is investigated, in order to determine the crystallographic textures to be locally produced by AM for either promoting or suppressing the TWIP or TRIP effects with respect to the applied loading.

While neutron diffraction is routinely applied to study local residual stresses generated during the build process, respectively their relief during post build treatments, also advanced neutron imaging techniques provide sensitivity to local crystallographic features such as microstructure and residual stresses. For example, the residual stress variations in the critical surface regions achieved through laser shock peening (LSP), displaying a strong gradient towards the bulk reaching to depths of millimeters, have been shown to be best probed by Bragg edge imaging. The method provides sufficient spatial and crystallographic resolution while being able to provide large area views of treated specimen.

A number of recent examples of neutron measurements in the service of advanced manufacturing technology shall be presented and discussed.
coupled. Therefore we use several incident energies and combine the data to obtain \( S(Q, E) \) with high resolution. We plan to apply this approach to the study of local dynamics of liquids with important applications, such as aqueous solution of salts and liquid electrolytes for energy storage and as insulator in field-effect-transistors. The knowledge garnered shall contribute to the bottom-up design of better functional liquids.

Capturing Functional Nanostructures and Their Interfaces with Neutron Total Scattering Katharine Page\(^1,2\);
\(^1\)The University of Tennessee, Knoxville, United States; \(^2\)Oak Ridge National Laboratory, United States

It is widely recognized in catalysis, fuel cell and battery chemistry, bio- and geochemical processes, and a host of additional functional materials areas that unique properties and characteristics are governed by intricate structural-chemical relationships. Uncovering the identity and role of locally ordered motifs, including those of surface species and interfaces, remains a challenge because experimental tools to observe materials at atomic length-scales, in relevant operating conditions, or within sufficiently fine time scales are limited. We present our efforts to apply and extend neutron total scattering and related probes towards capturing the interplay of crystal chemistry and functionality in nano- and nanostructured materials. Examples include: (1) exploration of internal dipole-dipole ordering in ferroelectric nanocrystals, demonstrating the enhancing effects of cubic particle shape and polar surface termination; (2) investigation of layered manganese oxide structures, where interlayer water molecules, hydrogen bonding, and the nature of vacancies/intercalants strongly impact electrochemically active variants; and (3) demonstrated abilities to probe the structure and dynamics of gas-solid interfaces in catalytic materials, where the signatures of interfacial species are enhanced through the use of neutron isotope contrast techniques. These examples improve understanding of technologically significant materials and highlight a broader theme of our research aimed at extracting crystal structure models from experimental data with the detail needed to guide and validate modern nanoscale theories, and design new and improved functional materials. Current challenges and future opportunities in this arena will be discussed.

4:30 PM MT04.05.07
Local Structure Analysis and Modeling of Lignin-Based Carbon Composite Anodes through the Hierarchical Decomposition of the Radial Distribution Function Software – HDRDF Dayton G. Kizzire, Valerie García-Negrón, David Harper and David Keffer; The University of Tennessee, Knoxville, United States

High performance Li-ion batteries manufactured with bio-based and renewable materials are a necessity in a market focused on efficiency, sustainability and cleaner energy. Previous studies have suggested a solution through lignin, a low-cost, renewable bio-feedstock with a high carbon content. Processing and pyrolysis of the lignin produces a graphitic composite composed of nanoscale crystallite spheres dispersed in an amorphous matrix and have shown success in uses as high-performance anodes in Li-ion batteries. These bio-based composite structures have proven to have superior charge capacity, high reversible capacity, low irreversible capacity loss, and high cycle life when compared to traditional intercalated Li-ion anodes. Understanding the structure of the bio-based anode is critical to explaining the exceptional anode properties. The local atomic environment is often characterized via a radial distribution function calculated from neutron and x-ray scattering experiments, but when studying complex materials, interpretation of the RDF can present a significant challenge due to the nature of scattering from the amorphous phase. Traditionally, large scale molecular dynamics (MD) simulations are used to form a hypothetical structure and generate a corresponding RDF to be compared to experiment. Alterations to the material’s structure and constituent particle size in MD simulations is an expensive and time-consuming process. A significantly more efficient approach for the interpretation of RDFs of complex materials is the Hierarchical Decomposition of the RDF (HDRDF), in which the total RDF is decomposed into components, some of which are modeled with static atomic structures and others of which are modeled as continuous mesoscale objects. The HDRDF software generates a real-space model of the complex nanomaterial and correlates the RDF to a set of material descriptors, such as crystalline domain size, crystalline volume fraction, total density, etc. and compares its RDF to experiment. The HDRDF approach has been shown to use roughly one million times less computational resources compared to MD simulation. We report progress on the development of a second generation of the HDRDF software, which extends the capability to arbitrary domain geometries and we apply the HDRDF technique to the interpretation of neutron and x-ray scattering of lignin-based nanostructured carbon composites. This work implements HDRDF to quantitatively determine how choice of lignin feedstock and pyrolysis temperature impacts the nano- and mesoscale structures of the resulting graphitic composites. Initial results have shown crystallite radius increases and crystalline
volume fraction decreases as pyrolysis temperature increases.

4:45 PM MT04.05.08
Creepy Concrete—Understanding Concrete Creep In Situ Using Neutron Scattering Nishant Garg; University of Illinois Urbana Champaign, United States

The phenomenon of creep in concrete, even after 40 years of experimental and theoretical research, is not fully understood. While it is commonly agreed that the viscoelastic nature of the primary hydration product, calcium-silicate-hydrate (C-S-H) gel, is largely responsible for concrete creep, the physical, nano-scale origin behind this viscoelastic nature is not clear. In order to determine if atomic-scale structural reorganization of C-S-H occurs during creep, in situ neutron scattering was used to continuously examine cementitious samples subject to uniaxial compression over a period of 9 months. For this in situ study, a custom load-frame was designed and implemented at the Nanoscale Ordered Materials Diffractometer (NOMAD) beamline at the Spallation Neutron Source (SNS), Oak Ridge National Lab. Pair distribution function (PDF) analysis of total neutron scattering was performed to follow the evolution of changes in the local structure of C-S-H, resulting in novel insights for the mechanism of concrete creep.

9:00 AM *MT04.06.01
A Novel Strongly Spin-Orbit Coupled Quantum Dimer Magnet: Yb2Si2O7 Kate A. Ross; Colorado State University, United States

The quantum dimer magnet (QDM) is the canonical example of "quantum magnetism". This state consists of entangled nearest-neighbor spin dimers and often exhibits a field-induced "triplon" Bose-Einstein condensate (BEC) phase. We report on a new QDM in the strongly spin-orbit coupled, distorted honeycomb-lattice material Yb2Si2O7 [1]. Our single crystal neutron scattering, specific heat, and ultrasound velocity measurements reveal a gapped singlet zero field ground state with sharp, dispersive excitations. We find a field-induced magnetically ordered phase reminiscent of a BEC phase, with exceptionally low critical fields of Hc1 ~0.4 T and Hc2 ~1.4 T. Using inelastic neutron scattering we observe a Goldstone mode (gapless to within = 0.037 meV) that persists throughout the entire field-induced magnetically ordered phase, suggestive of the spontaneous breaking of U(1) symmetry expected for a triplon BEC. However, in contrast to other well-known cases of this phase, the high-field (H > 1.2T) part of the phase diagram in Yb2Si2O7 is interrupted by an unusual regime signaled by a change in the field dependence of the ultrasound velocity and magnetization, as well as the disappearance of a sharp anomaly in the specific heat. These measurements raise the question of how anisotropy in strongly spin-orbit coupled materials modifies the field induced phases of QDMs.

9:30 AM *MT04.06.02
Perspectives of the European Spallation Source—The Next-Generation Neutron Facility Ken Andersen; European Spallation Source ERIC, Sweden

The European Spallation Source is currently under construction in Lund, Sweden. It is designed to provide world-leading performance, with instruments optimized for the long-pulse time structure of the facility, making full use of what will be the world’s brightest neutron beams for the study of materials ranging from biological systems and soft matter to engineering materials, structural chemistry and magnetism.

An overview will be given of the state of the construction project, as well as key design features of the facility,
allowing an unprecedented degree of flexibility and performance for the instruments. 15 instruments are under construction, covering SANS, reflectometry, imaging, engineering diffraction, powder and single-crystal diffraction, chopper spectrometers, and crystal-analysyer spectrometers. Highlights of instrument design aspects will be raised, which further enhance the scientific impact of the instruments.

10:00 AM BREAK

10:30 AM *MT04.06.03
First Experiments at the Second Target Station of the Spallation Neutron Source Paul Langan; Oak Ridge National Laboratory, United States

Neutron scattering has become a vital tool for studying materials across many scientific fields and applications, including automotive engines, batteries, data storage, geology, polymers, and biomedicine. In the United States, the Office of Science of the US Department of Energy (DOE) supports two major neutron scattering user facilities at Oak Ridge National Laboratory (ORNL): the High Flux Isotope Reactor (HFIR) and the Spallation Neutron Source (SNS). SNS is currently undergoing a proton power upgrade (PPU) to double its power capability to 2.8 MW. This upgrade, which will be completed in 2024, will deliver 2 MW of proton beam to the existing First Target Station (FTS) at the SNS, resulting in a significant increase in thermal neutron brightness to enable new capabilities for materials research in the thermal energy (shorter wavelength) range. The PPU project will also provide the addition power required to operate a planned Second Target Station (STS) for SNS. STS will provide pulsed beams of cold (longer wavelength) neutrons with unprecedented peak brightness and containing broad ranges of neutron energies. These beams will provide wholly new capabilities for the study of a broad range of materials using neutron scattering and support users in many fields of research—materials science, physics, chemistry, geology, biology, and engineering, among others—and in industry. When it is fully built out, the capabilities offered by the twenty-two instruments planned for the STS will complement those of HFIR and the FTS. The STS has a pivotal role to play in extending the reach of neutron scattering to new transformative opportunities for discovery science and applications that require time-resolved examination of nonequilibrium processes in dynamic hierarchical systems over greatly increased length, energy, and time scales. To illustrate the extraordinary potential of the STS to impact a broad spectrum of scientific fields, examples of first experiments to be conducted at the STS will be described.

11:00 AM *MT04.06.04
WASP the Wide Angle Neutron Spin Echo Instrument Peter Falus and Bela Farago; Inst Laue Langevin, France

The first Neutron Spin Echo (NSE) instrument has been in user operation for 40 years now and the newest one: WASP at ILL has just started commissioning. I will use this occasion to review how the basic design of the NSE spectrometers have developed during these years. The technical and scientific capabilities of the new instrument will be presented as well.

All functioning Neutron Spin Echo spectrometers use the basic IN11A design where the precession field is generated by long solenoids along the neutron beam. This construction limits the angular coverage and count rate of the instruments. Last century there have been two tries to make a wide angle coverage neutron spin echo instrument. IN11C at ILL is equipped with a flattened solenoid and has been in use since its creation. It has a 30 degree-wide angular coverage but a very limited resolution. This instrument was practically trading intensity for resolution. The SPAN instrument at HZB used a pair of coils in the anti Helmholtz configuration creating an azimuthally symmetric magnetic field; which, in theory, could allow a nearly 360 degree detector coverage. WASP uses an improved SPAN construction, and it aims to have a 500 times higher detected intensity than IN11A while the resolution remains the same.

The long construction has finished in 2018, and the three weeks of commissioning were promising. We have echo in all detectors up to one third nominal field integral, and the detected intensity is 500x of IN11A. By the time of the conference we hope to present detailed characterisation of the instrument.

11:30 AM *MT04.06.05
Examples of Materials Research at ESS Using Neutrons—From Construction towards Operation Monika Hartl¹, Luke Daemen² and Yongjoong Lee¹; ¹European Spallation Source ERIC, Sweden; ²Oak Ridge National Laboratory, United States
The European Spallation Source ESS in Sweden is currently in construction and will receive first neutrons in 2021. The start of the user program will be in 2023. Even now, during construction of the facility, we are encountering interesting material problems, some of which can be solved best using neutron scattering. This presentation will show examples for ESS material research that supports construction and leads towards operation. The data shown throughout the contribution has been recorded at currently operating spallation sources such as SNS, ISIS and JPARC.

Material degradation due to radiation is a limiting factor for the lifetime of high power spallation sources. This well-recognized fact leads to increased research efforts in finding the best materials for construction of ESS and understanding what happens with the materials on the atomic scale when exposed to a radiation field. These material investigations are greatly aided by the use of neutrons. Examples given are connected to understanding the radiation hardness of greases and oils, investigating the effect of purity and grain size of beryllium on its effectiveness as neutron reflector as well as solving issues related to the ortho- to parahydrogen conversion in the cold moderators. With ESS moving towards the start of the user program in 2023, we are beginning to collaborate with local scientists and small local industry on scientific projects using neutron scattering as main analysis tool. This helps to educate the local user community in the usefulness of neutrons and us in preparing the user laboratory infrastructure for the future. We will show an example using neutron vibrational spectroscopy to observe bisphenol A adsorbed on sand and clay. This is currently an area of great interest to the water industry as these materials are part of water filters potentially suitable to remove bisphenol A from sewage water. This project benefited from the use of neutrons as the bisphenol A adsorbed on clay and sand cannot easily be detected using optical spectroscopy or X-ray methods.

SESSION MT04.07: Soft Materials I
Session Chairs: Mark Dadmun and Changwoo Do
Wednesday Afternoon, December 4, 2019
Hynes, Level 2, Room 207

1:30 PM *MT04.07.01
**Measuring and Modeling In Situ SANS from Complex Fluids Under Programmable Flow Histories** Patrick T. Corona¹, Nino Ruocco¹, Kathleen M. Weigandt², L. Gary Leal¹ and Matthew Helgeson¹; ¹University of California, Santa Barbara, United States; ²National Institute of Standards and Technology, United States

In situ small angle neutron scattering under flow (flow-SANS) has become a critical tool for developing processing-structure-property relationships of complex fluids and soft matter. However, sample environments and associated measurement methods for flow-SANS have largely limited these measurements to steady state flows and simple rheometric deformations (pure shearing or elongation) that fail to capture the complex nonlinear and time-varying deformations encountered during processing. To bridge this gap, we have developed a novel fluidic four-roll mill (FFoRM) that, in combination with recent capabilities for spatiotemporal measurements, enables in situ SANS measurements under programmable quasi-two dimensional flows within a single device.[1] Here, we highlight the unique capabilities of “FFoRM-SANS” by its application to understand flow-induced ordering during the processing of rod-like polymeric and colloidal fluids. Interpretation of the rich data sets obtained are interpreted using a new, general framework for model-free estimation of orientation probability distribution functions (OPDFs) from scattering of orientable particles. Doing so enables parameter-free quantification of the effective structure factor that captures the dominant contributions of flow-interaction coupling on orientational order. We find that the effective structure factor depends significantly on the flow history of the fluid, and thus provides rational criteria for designing processing flows for improved or controlled ordering.

2:00 PM MT04.07.02
**Identifying the Conformational Characteristics of Sheared Wormlike Micelles from Anisotropic Scattering Profiles** Yuva Shinohara¹, Wei-Ren Chen¹, Guan-Rong Huang¹, Changwoo Do¹, Yun Liu², Lionel Porcar² and Takeshi Egami³; ¹Oak Ridge National Laboratory, United States; ²National Institute of Standards and Technology, United States; ³Institut Laue-Langevin, France; ⁴The University of Tennessee, Knoxville, United States
Wormlike micelles (WLMs) are self-assembly systems formed by amphiphilic surfactants immersed in water. Understanding the structural origin of their rheological properties is important for scientific as well as technological reasons. Small-angle neutron scattering (SANS) has been used to investigate the conformational characteristics of WLMs under macroscopic deformations. Upon increasing the applied stress, the angular dependence of SANS intensities develops progressively due to the flow-induced alignment at a molecular level. In existing analysis schemes, an assumption of the angular distribution function is often required to extract the orientation of aligned WLMs from their anisotropic SANS spectra. The validity of the assumption is, however, not known a priori.

To bypass this intrinsic constraint, we have developed a rigorous approach based on the spherical harmonics expansion (SHE); this approach allows us to extract the conformational information of the aligned WLMs from their scattering intensity profiles without any model fitting. The feasibility of this approach is verified theoretically. Based on a case study of the hexadecyltrimethylammonium bromide (CTAB)/sodium salicylate WLM system, we demonstrate that our method not only facilitates the quantitative scattering studies of deforming materials but also provides insightful information regarding their deformation behavior at the molecular level based on the symmetric properties of real spherical harmonics.

Theoretical Framework for Determining the Structural Characteristics of Deforming Objects from Their Scattering Signature
Guan-Rong Huang1, Yangyang Wang2, Yuya Shinohara2, Changwoo Do1, Takeshi Egami2,3 and Wei-Ren Chen1,2; 1Neutron Scattering Division, Oak Ridge National Laboratory, United States; 2Oak Ridge National Laboratory, United States; 3The University of Tennessee, Knoxville, United States

There has been much interest in understanding the structural characteristics of deforming materials that are manifest on different length scales. In the context of scattering investigation, the domain of interest can be decomposed into a microscopic region within which the local configurational translation and rotation can be treated in detail, and a larger regime where the description of global shape envelope is appropriate. From a perspective of geometric interpretation at either the microscopic or the macroscopic level, a central issue is how to quantitatively determine the structural characteristics from the anisotropic scattering intensity in a model-free manner.

We present a general approach to deal with this problem, which is valid to different deformation conditions and mathematically rigorous. In the mean-field limit, we first demonstrate that the radius of gyration is indeed the source term of intra-particle structure factor. By expanding the spectral anisotropy using the real spherical harmonic expansion (RSHE), we derive the exact mathematical expression of 2nd order gyration tensor in terms of the anisotropic spatial correlation functions. Based on the same RSHE scheme, we derive the orientational distribution functions to describe the local configurational alignment. Theoretical benchmark studies demonstrate that our developed approach not only facilitates quantitative scattering studies of flowing materials based on the symmetric properties of real spherical harmonics, but also provides insightful information regarding the deformation behavior of materials at the molecular level.

Advancing Neutron Scattering to Explore Nano-Scale Physics in Energy Systems and Engineering Materials
Li Liu, Kemal Ramic and Jinghua Feng; Rensselaer Polytechnic Institute, United States

We look into methodology development based on neutron scattering techniques to “visualize” complex phenomena. This visualization must integrate scattering experimental analysis, simulation, and theory to provide real space images of such phenomena. And their potential use in exploring energy and engineering processes is highly promising. Exploratory neutron scattering methodology development for the fields of Nuclear Data and Concentrating Solar Power will be discussed in the presentation.

In Nuclear Data, improvements in determination of the thermal scattering law of moderator materials (measuring, calculating, and validating) are important for accurate prediction of neutron thermalization in nuclear systems. In
this work a new methodology for producing thermal scattering libraries from the experimental data for polyethylene (C2H4)n is discussed and expanded to other systems such as Lucite and water. Double differential scattering cross section (DDSCS) experiments were performed at the Spallation Neutron Source of Oak Ridge National Laboratory (SNS ORNL). New scattering kernel evaluations, based on phonon spectrum for (C2H4)n, are created using the NJOY2016 code. Two different methods were used: direct and indirect geometry neutron scattering at ARCS and SEQUOIA, and VISION instruments, respectively, where the phonon spectrum was derived from the dynamical structure factor S(Q,ω) obtained from the measured DDSCS. In order to compare and validate the newly created library, the experimental setup was simulated using MCNP6.1. Compared with the current ENDF/B-VII.1, the resulting Rensselaer Polytechnic Institute (RPI) (C2H4)n libraries improved both double differential scattering and total scattering cross sections. A set of criticality benchmarks containing (C2H4)n from HEU-MET-THERM resulted in an overall improved calculation of Keff, although the libraries should be tested against benchmarks more sensitive to (C2H4)n. The Density Functional Theory (DFT)+oClimax (a package provided by ORNL) method is used and is shown to be most comprehensive method for analysis of moderator materials. The importance of DFT+oClimax method lies in the fact that it can be validated against all data measured at VISION, ARCS and SEQUOIA, and experimental total scattering cross section measurements.

In Concentrating Solar Power, we are developing neutron measurements for in-situ interface corrosion kinetics and molten salt properties. This research will provide fundamental data for material selection including the molten salt systems for both nuclear and solar applications. The presentation will focus on the development of in-situ neutron techniques for fundamental understanding of the mechanisms of molten salt corrosion, and the micro-structural response of containment alloys thereto, to measure the surface corrosion kinetics. We are working on realization and initial application of in-situ techniques for measuring molten salt fundamental properties including molten salt structure, dynamics, and salt density, etc. and the micro-structural and -chemical response of containment alloys to corrosive molten salt environments. The two neutron techniques involved are Vibrational Spectroscopy and Neutron Reflectometry. They both have unique characteristics for complex liquids at high temperatures. Moreover, while we are designing and manufacturing sample environments for harsh environments (high temperature and corrosive), they will provide great first-of-the-kind experimental data for molten salt systems.

4:00 PM *MT04.07.05
Neutron Optics to Enable Polychromatic Neutron Imaging and Powder and Stress-Strain Diffraction Boris Khaykovich1, Alexandru D. Stoica2, J. T. Cremer3, Muhammad Abir1 and D.S. Hussey4; 1Massachusetts Institute of Technology, United States; 2Oak Ridge National Laboratory, United States; 3Adelphi Technology, Inc., United States; 4National Institute of Standards and Technology, United States

We are developing neutron optical devices whose task is to increase the throughput of neutron instruments. For neutron imaging, we demonstrate designs of two types of neutron microscopes. Like an optical microscope, the neutron microscope consists of a condenser and an image forming optics. Neutrons are focused on the sample by the condenser mirrors while the image forming mirrors focus transmitted neutrons on the detector [1]. The condenser is designed to maximize the neutron flux and to obtain desired beam divergence at the sample. The condenser consists of axisymmetric confocal paraboloid and a hyperboloid mirrors, which are concentrically nested. The image-forming optics are designed using different combinations of the confocal nested ellipsoid and hyperboloid mirrors called Wolter mirrors. Both optics are being manufactured for installation at NIST. The design of magnification-10 mirrors should achieve the spatial resolution of about 10 μm. Importantly, the resolution of the microscope is determined by the mirrors rather than by the beam collimation as in conventional pinhole imaging, leading to possible dramatic improvements in the signal rate and resolution. Also, in contrast with pinhole imaging, in the microscope, the samples are placed far from the detector to allow for bulky sample environment. For diffraction, we are developing analyzers for polychromatic cold and thermal diffractometers. Polychromatic incident beam allows for multiplexing analyzer crystals in order to cover relatively large solid angles. Specifically, we optimized axisymmetric PG analyzers inspired by the very first neutron-diffraction experiment by Mitchell and Powers [2]. In addition, we are adopting bent single-crystal wafers following the developments of the so-called “thickness focusing” [3,4]. The combination of the polychromatic beam [5] and focusing geometry allows increasing both the signal rate and resolution. The proposed instruments will have much higher throughput than existing instruments and thus enable diffractometers at compact neutron sources.

Characterization of Colloidal Nanocrystal Surface Structure Using Small Angle Neutron Scattering and Efficient Bayesian Parameter Estimation
Samuel W. Winslow¹, Wenbi Sheherbakov-Wu¹, Yun Liu², William Tisdale¹ and James W. Swan¹; ¹Massachusetts Institute of Technology, United States; ²University of Delaware, United States

Complete structural characterization of colloidal nanocrystals is challenging due to rapid variation in the electronic, vibrational, and elemental properties across the nanocrystal surface. While traditional characterization techniques such as electron microscopy and X-ray scattering can provide detailed information about the inorganic nanocrystal core, these techniques provide little information about the molecular ligands coating the nanocrystal surface. Moreover, because most models for scattering data are parametrically nonlinear, uncertainty estimates for parameters are challenging to formulate robustly. Using both PbO- and PbCl₂-derived, oleate-capped PbS quantum dots as a model system, we demonstrate the capability of small angle neutron scattering (SANS) in resolving core, surface layer, ligand-shell, and solvent structure for well-dispersed nanocrystals using a single technique. We quantify a ~0.3 nm thick surface PbClₓ layer on the PbCl₂-derived quantum dots, previously only hypothesized. Global fitting of the SANS data across a solvent deuteration series enables unique determination of the spatial distribution of each material. Molecular dynamics simulations were used to develop a coarse-grained form factor describing the scattering length density profile of ligand-stabilized nanocrystals in solution. We introduce an affine invariant Markov chain Monte Carlo method to efficiently perform nonlinear parameter estimation for the form factor describing such dilute solutions. This technique yields robust uncertainty estimates. This experimental design is broadly applicable across colloidal nanocrystal material systems including emergent perovskite nanocrystals and the parameter estimation protocol significantly accelerates characterization and provides new insights into the atomic and molecular structure of colloidal nanocrystals.

4:45 PM MT04.07.07
Understanding Formation of Chitosan-Gold Gels using Small Angle Neutron Scattering
Radha Perumal Ramasamy¹ and Vinod K. Aswal²; ¹Anna University Chennai, India; ²Bhabha Atomic Research Centre, India

Biopolymers are very important class of materials as they are environmentally friendly. Chitosan is a very popular biopolymer and it has several advantages such as excellent film forming capacity, biodegradability and nanoparticle forming capability as it has reducing and stabilizing effect on metal ions. Understanding the interactions between ions and chitosan can help us make better membranes that can be potentially used in battery technology. Here, the use of Small Angle Neutron Scattering (SANS) in chitosan gels is explored. SANS is a useful technique for the characterization of biological materials. SANS experiments involve scattering of a monochromatic neutron beam from the sample and measures the scattered neutron intensity as a function of scattering vector. The wavelength of the neutron beam used was 5.2 Å with a resolution (Δλ/λ) of about 15%. All of the data were collected in the accessible Q range of 0.017–0.35 Å⁻¹. All of the SANS data were corrected for the background, the empty cell contribution, and solvent contribution, and were normalized using standard procedure. Chitosan solution was prepared by adding 1% (w/v) of chitosan powder, 1.5% (w/v) of acetic acid to D₂O. Previous study by us has shown that we can use neutron scattering to determine the radius of gyration (Rg) of chitosan and the size of the gold nanoparticles. Using SANS and SEM images we could show that the size of the gold nanoparticles templated on chitosan is comparable to that of the Rg of chitosan when the chitosan solution contained 1Mm HAuCl₄ and was heated to form red colored solution. Also, we have shown that increasing the concentration of gold in chitosan solution to 3mM and more resulted in the formation of gels. When the gels where heated it resulted in the formation
of rose red colored liquid. When chitosan-HAuCl₄ gels where incubated at 25° C the gels collapsed in time. After ten days when the samples where imaged it was observed that micron sized gold particles had formed. The particles where mostly hexagonal in shape. The size of these particles are much larger than the Rg of the chitosan and therefore this result implies that chitosan acts as a template for the gold ions to nucleate and form micron sized particles. The formation and the collapse of the gels was attributed to the electrostatic interactions between the gold ions and the chitosan unit with the gold ions acting as bridges. This in turn made the liquid viscous thus forming gels. SANS was used to study the formation of the gels. SANS results showed that the Rg for chitosan film is lesser than that for chitosan in solution. Also, the Rg for chitosan-gold gels was the same as that of chitosan in solution. There was no correlation length observed in chitosan solution, however it was present in chitosan-gold gels. This result indicates that the chitosan units are localized in the gel phase. These gels have potential applications in detectors.

SESSION MT04.08: Soft Materials II
Session Chairs: Antonio Faraone and Victoria Garcia Sakai
Thursday Morning, December 5, 2019
Hynes, Level 2, Room 207

8:45 AM MT04.08.01
Insights into the Structural Dynamics of Polyfluorene β Phase Using Neutron Spectroscopy Nicholas D. Siemons¹,², Anne Guilbert², Jenny Nelson², Mohamed Zbiri¹ and Christian Nielsen³; ¹Institut Laue-Langevin, France; ²Imperial College London, United Kingdom; ³Queen Mary University, London, United Kingdom

Within the polymer semiconductor family, poly(9,9-dioctylfluorene) (PFO) has attracted interest for applications such as light emitting diodes and lasers due to its efficient pure-blue electroluminescence. It has been shown that PFO can adopt a unique and interesting conformer termed as ‘β phase’.¹,² This conformer exhibits efficient light emission and spontaneous emission.³–⁵ However it also emits light at different wavelengths to the other blue emitting material conformers, and therefore can pose challenges in the creation of polymer LED’s. It has also been shown to act as a charge transport trap,⁶ therefore electron-phonon coupling and slower dynamics are likely to impact photoemission. We look to provide insight into the β phase dynamics to help with characterisation. We use temperature-resolved neutron diffraction and spectroscopy techniques to study β phase and to propose a crystal structure for it. We explore the dynamics using quasi-elastic and inelastic neutron spectroscopy in combination with molecular dynamics simulations and quantum chemical calculations. Combining the neutron data with computational methods allows us to test various polymer-solvent compound/co-crystal structures as candidates for β phase and explore its dynamical features.

9:00 AM *MT04.08.02
Impact of Encapsulated Species on Block Copolymer Micelle Self-Assembly and Dynamics Megan Robertson¹, Tyler Cooksey¹, Xiuli Li², Bryce Kidd² and Louis Madsen²; ¹University of Houston, United States; ²Virginia Tech, United States

Block copolymer micelles enable the formation of widely tunable self-assembled structures in liquid phases, with applications ranging from drug delivery to personal care products to nanoreactors. In order to understand fundamental aspects of micelle assembly and dynamics, the structural properties and solvent uptake of biocompatible poly(ethylene oxide-b-ε-caprolactone) (PEO-PCL) diblock copolymers in deuterated water (D₂O) / tetrahydrofuran (THF₈) mixtures were investigated with a combination of small-angle neutron scattering (SANS), nuclear magnetic resonance (NMR), and transmission electron microscopy. PEO-PCL block copolymers, of varying molecular weight yet constant block ratio, formed spherical micelles through a wide range of solvent compositions. We investigated the effect of solvent composition on the unimer content, aggregation number, degree of solvent swelling of the micelle core, and micelle size parameters. Furthermore, we explored the impact of guest molecules, such as model drug compounds, on the micelle self-assembly. Finally, we are developing a time-resolved NMR technique, complemented by existing time-resolved SANS methods, to quantify chain exchange dynamics in these systems.
**Small Angle Scattering Studies of Hierarchically Self-Assembled Binary Nanoparticle Superlattices** Sung-Min Choi; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

The nanoparticle superlattices (NPSLs) can provide new emerging properties through collective coupling between nanoparticles, which are strongly dependent on the lattice symmetry of NPSLs as well as nanoparticle composition. Various methods have been developed for the synthesis of NPSLs, which include slow solvent evaporation, DNA-mediation, electrostatic interaction and others. In our group, we developed for the first time a micelle-assisted method for forming exceptionally ordered NPSLs which are inherently sensitive to environmental conditions, and used it to demonstrate the thermally reversible structural symmetry transitions of NPSLs. We applied this method for one-dimensional [1] and spherical [2] nanoparticles, respectively, which show a spectrum of lattice symmetries depending on particle size ratio, composition, and temperature. The structural details and phase transitions are investigated by neutron and x-ray small scattering techniques. The maximization of free volume entropy is considered as the main driving force for the formation of superlattices, which is well supported by theoretical free energy calculations.

**Elucidation of Buried Polymer Interfaces through Contrast Variations** Wei Chen1,2, Zhang Jiang1 and Matthew V. Tirrell2,1; 1Argonne National Laboratory, United States; 2The University of Chicago, United States

Soft interface characteristic of a strong response to external stimuli represents a grand challenge central to many technical applications, ranging from electrochemistry to colloidal science, heterogeneous catalysis, nanoscience, corrosion, tribology, surface science, biology, and energy production. However, there is a dearth of techniques capable of probing both spatial arrangement and chemical property at interfaces, especially if the solution contains a mixture of ions and organic and biomolecules. As complementary to contrast variation neutron scattering, resonant x-ray scattering (RXS) by merging x-ray scattering and x-ray absorption spectroscopy in a single experiment has developed into an important technique, which yields orders of magnitude more contrast between materials than non-resonant x-ray scattering and provides the unique sensitivity to chemical configurations and spatial relationships of organic functional groups (resonant scattering centers) at important 1–1000 nm length scales. This added resonant sensitivity represents a qualitatively different scattering mechanism than those active in non-resonant x-ray, neutron, and electron scattering.

Here we applied RXS to investigate a breadth of interfaces from Hard-Soft to Soft-Soft: solid-solid interfaces of polystyrene (PS) films on the silicon substrate, solid-liquid interfaces of silica nanoparticles surface grafted poly (2-methacryloyloxyethyl phosphorylcholine) (PMPG) zwitterionic polymer brushes (SiO2-PMPG) in solutions, and polymer interfaces of symmetric polystyrene-block-poly(methyl methacrylate) (PS-b-P(MMA)) diblock copolymers. It is found that the chemical interfacial width of PS thin film at the substrate interface arising from the preferential orientation is about one order of magnitude of the polymer radius of gyration (Rg). Moreover, although the ion-induced changes of PMPC thickness are not apparent in aqueous solutions, their chain conformations like zwitterion distribution and correlation varied, dependent on salt types, ionic strengths and ion valences. As each monomer has no net charge, the chains are not in extended configurations at low salt concentrations. In contrast to simple polyelectrolytes, they expand when salt is added since the local attractions between positive and negative ions are screened, thereby producing a rich science base in understanding the configurations, ionic distribution, and in interfacial interactions of zwitterionic polymer brushes in a variety of relevant and important ionic environments. Regarding the PS-b-P(MMA) diblock polymers with lamellar microdomains normal to the substrate, their even order scatterings should be significantly reduced or extinct as a result of symmetric extinction. By adjusting beam energies
close to the absorption edge of the constituent atoms, the intensity of odd order scatterings remains intact, while that of even order scatterings changes as a function of beam energies. Quantitative analyses on these RXS data around the individual absorption edge of constituent components allow us to determine electron density profiles at interfaces, independent of the models. This, in turn, establishes the relationships of interfacial structures and physical properties of polymers and soft condensed matter, which can be strongly influenced by inherent structural disorder ranging over length scales from molecular functional groups to characteristic conformation and crystallization scales up to sample dimensions.

11:00 AM MT04.08.05
**Exploring Protein-Polymer Interactions with Neutron Scattering** Bradley Olsen¹, Helen Yao¹, Chris Lam², Aaron Huang¹ and Wei-Ren Chen²; ¹Massachusetts Institute of Technology, United States; ²Oak Ridge National Laboratory, United States

Proteins form the basis for important materials in today’s society, including a wide variety of biocatalysts and biosensors that are critical to the production of chemicals, medicine, and national defense. In many of these materials as well as in other applications such as antifouling coatings, self-assembled biomaterials, and protein crystallization, the interactions between proteins and polymers are critical to the functioning of the device. However, measurement of these interactions has traditionally been quite difficult, requiring arduous thermodynamic measurements to estimate interaction parameters in a variety of different competing theoretical frameworks.

Here, we explore several approaches to better understand protein-polymer interactions through the use of neutron scattering methods. First, we explore measurements of the form factor of protein-polymer bioconjugates, where the shape of the flexible polymer coil attached to the protein can provide information on the protein-polymer interaction. Measurements on a series of different polymers are performed, and data fitting allows the general behavior of these molecules in solution to be understood. Measurements are interpreted in the light of coarse-grained molecular simulations of the bioconjugate materials.

Second, cross structure factors are measured for protein-polymer blends at relatively high concentration in order to provide insight into the physics under more strongly interacting conditions. Measurements were performed for three different model systems using contrast variation small-angle neutron scattering (CV-SANS), and cross structure factors were extracted from the data. These were analyzed through systematic comparison to the dilute solutions of protein and polymer as well as through inverse Fourier transforms to provide real space information.

Finally, several experiments suggest that hydration plays a key role in governing interactions between proteins and polymers, especially at high concentration where there is a competition for water. SANS measurements of high concentration solution, combined with a new analysis method, enable estimation of hydration numbers from the traditional dilute regime through the semidilute and into a relatively concentrated regime, allowing an understanding of how hydration number changes with concentration to be gained. Comparison of this neutron data with other spectroscopic data and self-assembly measurements provides insight into how hydration governs the molecular interactions that drive these processes.

11:30 AM MT04.08.06
**Mapping Structural Dynamics of Conjugated Polymers** Anne Guilbert¹, Mohamed Zbiri², Peter Finn³, Christian Nielsen² and Jenny Nelson¹; ¹Imperial College London, United Kingdom; ²Institut Laue-Langevin, France; ³Queen Mary University of London, United Kingdom

Conjugated polymers have attracted a keen interest over the past decade for their potential applications as semiconductors in various types of devices: organic light emitting diodes, organic solar-cells, organic field-effect transistors, etc. One of the potential advantages of polymeric semiconductors over their inorganic counterpart is the possibility of processing them from solution. To increase solubility, alkyl side chains are added to the conjugated backbones of the polymers. The side chains are therefore not involved in the frontier molecular orbitals. Thus, they do not impact directly optoelectronic properties. However, they do impact the polymer conformation and the polymer packing, which in turn impact the optoelectronic processes and the subsequent emergent macroscopic properties of the material. Recently, the side chains have also been engineered to transport ions in the solid-state, opening a new range of applications such as batteries or bio-sensors. Because polymers are soft materials, a range of
dynamics occurs over an extended time scale, from femtosecond to millisecond, and are likely to modulate the impact of microstructure on the optoelectronic properties of the material. Vibrational dynamics have been evidenced to impact absorption, inner reorganization energy, charge transfer between similar molecules and between different molecules at an heterojunction, delocalization, and so more generally charge transport and charge separation processes. Slower dynamics on the picosecond to nanosecond time-scale include side-chain reorientation and backbone torsion. These dynamics are impacted the conformation of the chains and thus, modulates the efficiency of the opto-electronic processes. It has been shown for instance that the global charge transport network changes over timescale competing with charge carrier lifetime. Furthermore, these slow dynamics are temperature-dependent and therefore, can be activated during device operation. For instance, molecular diffusion becomes predominant above the glass transition of the material and is a known degradation mechanism.

We present a detailed microscopic study of the structure-dynamics relationship of both regio-regular (RR) and regio-random (RRa) poly(3-hexylthiophene) (P3HT) using elastic, quasielastic, spin-echo and inelastic neutron scattering techniques. We use deuteration to modulate the coherent and incoherent cross-sections of the materials, beyond a contrast variation purpose, allowing particularly to access both self-motions and collective dynamics of the materials. Measurements are underpinned by quantitative numerical simulations using classical molecular dynamics (MD) simulations, as well as molecular and periodic density functional theory based quantum chemical (QC) calculations. MD simulations reproduced well the large structural features and slow motions, but provided a limited description of molecular vibrations. MD shed light on differences in collective dynamics between Q-values linked with the π-π stacking and the lamellar stacking of the polymer, with the crystalline phase being the most impacted. Molecular QC described well the high-energy vibrational features, while periodic QC allowed to describe the mid-energy vibrational range. We show that this extensive combined approach of neutron-based measurements and multi-computational calculations allows to fully map the structural dynamics of conjugated polymers such as P3HT.

11:45 AM MT04.08.07
Composition of Polyimide Aerogels Saturated with Ionic Liquids by SANS Samantha Rinehart1, Rocco Viggiano2, Baochau Nguyen2, Maryann Meador2 and Mark Dadmun1; 1University of Tennessee, United States; 2NASA Glenn, United States

Polymeric aerogels, more specifically polyimide aerogels (PIA), provide excellent mechanical properties relative to traditional silica aerogels while maintaining thermal stability. NASA has investigated PIA paired with ionic liquids as novel mechanically robust electrolyte systems for next generation batteries. Common laboratory techniques provide insight into the relationship between polyimide structure and surface area, porosity, and pore volume of the aerogel; however, these measurements are traditionally conducted sans solvent. Because of this, the impact of the ionic liquid on the nanoscale structure of PIA is unclear. To determine the impact of solvent presence, we use small angle neutron scattering to determine the skeletal size and composition of solvated PIA. Careful analysis of SANS data from PIA/ionic liquid constructs surprisingly shows that the ionic liquid penetrates the polyimide skeleton. This unexpected structure clearly impacts charge transport and therefore performance of the aerogel as a battery component. This mixing behavior must be more fully understood to rationally utilize these promising materials in devices and further experiments are planned to elucidate the impact of polyimide and ionic liquid structure, as well as fabrication procedure on the pore size, structure, and mixing behavior in PIA/ionic liquid aerogels. These results therefore broaden the characterization tools of polymeric aerogels and provide pathways to correlate a broad range of their structural characteristics to their performance.
Experimentally exploring the molecular exchange in polyelectrolyte complexes is crucial to understanding the kinetic behaviors of many ionic systems. Polyelectrolyte complex (PEC) micelles are a type of nanoscale assemblies whose core is usually composed of ionic complexes and corona is constituted by neutral and hydrophilic polymers. Here, we present the employment of time-resolved small-angle neutron scattering (TR-SANS) technique to assess the chain exchange rate in polyelectrolyte complex micelles in aqueous solutions. The aim is to explore the dependency of the molecular exchange rate on polymer block length, system temperature, and solution salinity. We investigate two micelle systems that are prepared through the ionic complexation between poly (styrene sulfonate) (PSS) and a polypeptide, poly (ethylene oxide)-block-poly (L-lysine) (PEO-b-PLL), or a synthetic diblock polyelectrolyte, poly (ethylene oxide)-block-poly (vinyl benzyl trimethyl ammonium chloride) (PEO-b-PVBTMA). Neutron contrast is obtained by deuterium labeling the PVBTMA block and PSS block. Measurements performed up to 34 hours after the mixing of deuterium-rich micelles and hydrogen-rich micelles imply that the PEC micelles may not exchange molecules with their surroundings due to the strong ionic interaction between oppositely charged groups. Neither the elevation of system temperature nor increase of solution salinity, two common ways to weakening the strength of electrostatic interactions, seem to unlock the molecular exchange at the experimented time scale. We postulate that it is the large energy barrier stemming from the breakup of ionic pairs in polyelectrolyte complexes that prevents the chain expulsion or micelle fusion from happening. We anticipate these findings would provide fundamental insights on the origin of morphological complexities and nonequilibrium phenomena in polyelectrolyte-based self-assemblies.

2:00 PM MT04.09.02
QENS Insights on the Nanoscopic Origin of Rheological Properties in Some Well-Dispersed Polymer Nanocomposites
Antonio Faraone1 and Erkan Senses2; 1National Institute of Standards and Technology, United States; 2KOÇ University, Turkey

Polymer nanocomposites (PNCs) with attractive polymer–nanoparticle (NP) interactions, are often reported to disperse individually, enabling the investigation of interfacial effects on the rheological properties without contribution from particle percolation. By taking advantage of selective isotope labeling of the chains, neutron scattering techniques uniquely allow the possibility of investigating the structural and dynamical properties of the polymers in the matrix. In particular, high-resolution QuasiElastic Neutron Scattering (QENS) techniques, such as backscattering and Neutron Spin Echo, allow directly observing the chain motions at the nanoscale by simultaneously accessing a broad range of time-scale (from sub-nanoseconds to hundred nanoseconds), and length-scales (from monomer size to entanglement mesh sizes); specifically important for polymers are the localized fast dynamics on sub-monomer level, the segmental dynamics at the monomer level and the entangled/collective dynamics at larger scales. These information, as well as those obtained using X-ray Photon Correlation Spectroscopy (X-PCS), provide microscopic insight relevant for the understanding of the rheological properties of the PNC.

Here, I will present results on the nanoscale dynamics of polymer chains in composites with dynamically asymmetric interphases, [1] with NPs of sizes comparable to that of the polymer coils in the matrix, [2] and which have been subject to large deformation. [3]

2:15 PM MT04.09.03
Neutron Scattering Investigations on Structure and Dynamics of Architecturally-Engineered All-Polymer Nanocomposites
Erkan Senses1, Madhusudan Tyagi2 and Antonio Faraone2; 1Koc University, Turkey; 2National Institute of Standards and Technology, United States

Recent advances in synthetic chemistry made it possible to precisely control the topology of polymers that determines many of their physical properties. Ring, star, comb, bottlebrush and hyperbranched polymers exhibit structural relaxation that is not observed in their linear chain counterparts. In particular, star shaped polymers in which many linear chains share a common center are particularly interesting as the monomer density towards the center increases dramatically at high functionalities, making a portion of a star macromolecule dense and impenetrable, akin to hard-spheres. Thus, depending on the number and the length of arms, these polymers can
display both soft and hard nanoparticle character, making them ideal to study the effect of interphases in polymer nanocomposites. In our work [1], we used high-glass transition temperature (\( T_g \)) deuterated star shaped polymers as nanofillers and dispersed them in miscible low-\( T_g \) hydrogenated linear matrices to create a new kind of polymer nanocomposites in which the interpenetration between the fillers and the matrix, and therefore, the bulk rheological properties, are systematically varied via filler architecture at the same particle concentration. The resulting ‘architecturally engineered’ nanocomposites transition from the well-known simple linear blends to conventional hard sphere-polymer nanocomposites. We investigated these nanocomposites using static (SANS) and quasielastic neutron scattering (backscattering and spin-echo) measurements over a wide range of time and length scales in the glassy and melt state of the composites. The localized and segmental dynamics as well as chain-chain entanglements are all modified by compactness of star-shaped fillers. The observed microscopic changes manifest at the macroscopic level as softening and stiffening depending on the functionality and sizes of the macromolecules, thus offers a novel approach for tuning the physical properties of polymer based nanocomposites for advanced materials applications.

2:30 PM MT04.09.04
Bicontinuous Structure Gel from Binary Solvent Spinodal Decomposition Stabilized by Nanoparticles Jamming within One Liquid Phase Yuyn Xi\(^1,2\) and Yun Liu\(^1,2\); \(^1\)National Institute of Standards and Technology, United States; \(^2\)University of Delaware, United States

In this work, nanoparticles with preferential wetting to one of the liquid phases are demonstrated to arrest the spinodal decomposition of binary solvent mixture. A physical gel is formed and thus termed as solvent segregation driven gel (SeedGel). Small angle neutron scattering (SANS) experiments are conducted to identify the partition of particles by contrast matching the scattering length density of one liquid component to that of the nanoparticles. During the solvent phase separation, nanoparticles are found to be jammed within the phase that is rich in one of the liquid components. Compared to bicontinuous interfacially jammed emulsion gel (Bijel), SeedGel greatly relaxes the rigid restriction on the neutral wettability of the nanoparticles to the two solvents. Additionally, SeedGel shows reversible thermal response to quasi-static temperature ramping. The multi-length scale characterizaton by SANS and ultra-small angle neutron scattering (USANS) reveal that both the particle-particle distance and the domain size can be directly manipulated by temperature change and are strongly correlated with the gel transition. The SeedGel formation mechanism is also applicable to sub-10 nm particles, which possesses a great potential to link the self-assembled structure with the unique properties of small particles, such as quantum dots. Moreover, SeedGel can be molded to various shapes due to the enhanced mechanical strength. Subsequent drying of the solvents results in nano-porous medium up to centimeter size with neither nanometer nor micrometer cracking. In conclusion, a new mechanism of arresting liquid-liquid spinodal decomposition with colloidal particles is proposed. The strategy for preparing SeedGel can serve as a versatile, yet simple method to assemble particles to porous materials that can be implemented to various applications that favor high surface area.

2:45 PM MT04.09.05
Application of Artificial Intelligence and Machine Learning for Accelerated Data Collection and Analysis of Small Angle Neutron Scattering Changwoo Do\(^1\), Ming-Ching Chang\(^2\), Yi Wei\(^2\) and Wei-Ren Chen\(^2\); \(^1\)Oak Ridge National Laboratory, United States; \(^2\)University at Albany, State University of New York, United States

Pursuing hardware upgrades to provide brighter beams for material studies has been the paramount goal of every neutron scattering facility. Here, we present an alternative route to circumvent the limitation of neutron flux using recent advancements in artificial intelligence (AI), namely image super-resolution deep convolutional neural network (CNN). The feasibility of accelerating data collection has been demonstrated by using small angle neutron scattering data collected from the Extended Q-range Small Angle Neutron Scattering (EQ-SANS) instrument at Spallation Neutron Source (SNS). Data collection time can be reduced by increasing the size of binning of the detector pixels at the sacrifice of resolution. High-resolution scattering data is then reconstructed by using AI deep super-resolution learning method. This technique can not only improve the productivity of neutron scattering instruments by speeding up the experimental workflow but also enable capturing kinetic changes and transient phenomenon of materials that are currently inaccessible by existing neutron scattering techniques. Then, we will show how Machine Learning can be used to assist users in selecting appropriate scattering models.

Towards Understanding the Role of Lipid Complexity in Tuning Biomembrane Properties
Elizabeth Kelley; National Institute of Standards and Technology, United States

A 5 nm thick membrane separates the cell from its surrounding environment. Life places extreme demands on the material properties of these thin membranes by requiring that they are both rigid enough to define the cell structure yet flexible enough to undergo dramatic changes in cell shape during processes like endocytosis and cell division. In turn, the properties of the biomembranes are determined by the unique characteristics of the thousands of chemically distinct lipid molecules that make up the membrane. A long-standing challenge in biophysics is to link the complex and highly regulated lipid diversity to the membrane properties and ultimately cell function. This talk will highlight new insights from neutron scattering towards understanding the role of lipid diversity in tuning the properties of model biomembranes. We will demonstrate how subtle changes in lipid composition, such as mixing hydrophobic tail lengths or adding charged headgroups, can have significant and unexpected effects on the membrane elastic properties. The results reveal the complex and interwoven relationship between lipid membrane composition, structure and dynamics.

4:00 PM *MT04.10.02
Biomimetic Lipid Membranes—A Neutron Scattering and Simulations Perspective
Rana Ashkar1,1, Milka Doktorova2,3, Haden Scott4, Frederick Heberle4, Elizabeth Kelley5, Michihiro Nagao5,6, Jan-Michael Carrillo5, Bobby Sumpter7, Francisco Barrera4, George Khelashvili3 and John Katsaras7; 1Virginia Tech, United States; 2University of Texas Health Center at Houston, United States; 3Weill Cornell Medical College, United States; 4The University of Tennessee, United States; 5National Institute of Standards and Technology, United States; 6Indiana University, Bloomington, United States; 7Oak Ridge National Laboratory, United States

Lipid bilayers, the main matrix of cell membranes, host a wide range of vital biological processes and are ubiquitous in a variety of research areas at the interface of biophysics, health care, and biotechnology. In order to understand the function of lipid membranes and fully utilize their potential in pharmaceutical and biotechnological applications, it is imperative to understand the phenomena that control key membrane functions, such as domain formation and protein recruitment. Among such phenomena, membrane dynamics, manifested in mechanical and diffusive membrane properties, remain poorly understood despite evidence of their active role in various cellular processes. This talk will focus on recent advances in neutron scattering characterization and MD simulations for interrogating molecular and collective dynamics in lipid membranes and their response to cholesterol content, lateral rearrangement, and protein binding events. The synergistic integration of neutron scattering and simulations, and the inherent capabilities of both techniques to probe selective dynamics, is offering significant insights into the delicate spatiotemporal functions of biomimetic lipid membranes.

4:30 PM MT04.10.03
Tuning Interactions between Modular Coiled Coil Bundles via Computational Sequence Design—A Small Angle Neutron Scattering (SANS) Study
Nairiti J. Sinha1,2, Rajkumar Misra1, Rui Guo3, Christopher J. Kloxin1, Jeffery G. Saven1, Grethe V. Jensen1 and Darrin J. Pochan1; 1University of Delaware, United States; 2National Institute of Standards and Technology, United States; 3University of Pennsylvania, United States

Computational sequence prediction is a powerful design tool that has enabled discovery of non-natural peptide sequences that can assemble into coiled coil bundles that are antiparallel homotetramers containing strategically-placed solvent-exposed amino-acid side groups and chemically-reactive complementary functional groups. By taking advantage of the tunable interaction landscape coupled with orthogonal chemical-assembly pathways, the
artificial coiled coils can be utilized as tunable anisotropic *Molecular Legos* or modular building-blocks to construct artificial biomaterials that display a rich hierarchical nanostructure. In this talk, we will discuss the design and construction of new sequences of robust 4 nm x 2 nm cylindrical coiled coil forming peptides that have been computationally designed to carry different net charge as a result of the dissociable amino-acid side-groups in the peptide sequence. Thus, an entire spectrum of charged bundles has been studied, consisting of bundles that carry a high net positive charge (+32) to those with a high net negative charge (-32) in order to systematically investigate the impact of the net charge and also local charge distribution on inter-bundle interactions as a function of solution conditions such as pH and ionic strength. We have employed Small Angle Neutron Scattering (SANS) extensively to characterize the computationally designed bundle dimensions and inter-bundle interactions since SANS is uniquely suited to studying soft-matter systems in their native solution state in a non-intrusive and non-destructive manner. SANS along with Small Angle X-ray scattering (SAXS) has yielded insight into the rich interaction landscape of charged bundles at the nanoscale. We show that all bundles at dilute concentrations yield a form-factor scattering profile that can be fit using a cylinder model to extract the bundle dimensions. The experimentally measured dimensions are directly compared to the expected dimensions calculated using the bundle PDB file. As the bundle concentration increases, a correlation peak or ‘ionomer peak’ is observed in the scattering profile, the strength of which increases with net charge and bundle concentration and is responsive to the presence of salt. The electrostatic repulsion interactions between bundles resulting in the correlation peak are modeled using both Effective Hard-Sphere (EHS) and the Hayter-Penfold (HP) structure factor, with the latter giving better fit results especially for highly charged bundles at higher concentrations. Lastly, we will show that the coiled coil bundle stability and solubility in water, i.e. the formation of stable coiled coil homotetramers in aqueous solution is dependent on a number of factors such as the net charge on the bundle, type of charge (negative versus positive), temperature and ionic strength, which is characterized for a specific peptide sequence via contrast-matching SANS measurements.

4:45 PM MT04.10.04
Internal Dynamics and Hydrodynamics of the NISTmAb 8670 and Its Comparison with Industrial Monoclonal Antibodies Jannatun Nayem1,2, José R. Villanueva-Valencia3, Norman Wagner1 and Yun Liu2,1; 1University of Delaware, United States; 2National Institute of Standards and Technology, United States; 3University of Guanajuato, Mexico

Internal dynamics such as the movements of hinge-bending domain motions of therapeutic monoclonal antibodies (mAb) are crucial for important bio-functionalities during targeted immune therapies. However, determining these functional dynamics via traditional spectroscopic techniques (e.g. NMR) at the spatial and temporal scales pertinent to a mAb is highly nontrivial primarily due to their anisotropic shape and large molecular weight. Currently, the commonly used theories have inaccurate assumptions and often do not apply to anisotropic proteins at high concentrations. Here, we have established a substantiated methodology using a unique combination of the neutron spin echo spectroscopy, an accurate dynamic decoupling theory, and the semi analytic colloidal theories for dilute suspensions to probe the internal dynamics of NISTmAb, RM 8670. Our findings show that at the short time limit when the contribution of the rotational motion is negligible, the effective diffusion coefficients obtained by NSE is intrinsically different from the long-time diffusion coefficient obtained by the dynamic light scattering, which is primarily due to the anisotropic shape of a mAb. A prominent difference between a rigid-body mAb diffusion and the overall effective diffusion of a NISTmAb at 3-5 nm length scales is observed. This concludes that the intra-particle domain motions contribute ~15% to the total effective diffusion of a NISTmAb within the NSE correlation time window. Our analysis also provides a theoretical description of the hydrodynamic parameter. The hydrodynamic effects of many different mAbs were evaluated and a universal method was established that describes the concentration dependence of the diffusion coefficients with different types of solution interactions. To our surprise, when the hydrodynamic volume fraction is considered, the hydrodynamic parameters collapses from values ranging from 7.6 to 11.2 to that of 2.5 to 3.3 approaching the hard sphere (HS) value, 1.83. This elucidates the importance of hydration and shapes in solution stability. Though a qualitative agreement is achieved between NSE experiments and atomistic molecular dynamic simulations, their intra-particle dynamics are overestimated. We attribute the difference to the force fields and water models used in the simulation. The findings of this work provide foundation for future theoretical and simulation work for predicting diffusion properties and their related macroscopic solution properties for proteins with various shapes, sizes, and interactions.
Segregational Behavior of d-Transition Elements at Different Grain Boundaries in Tungsten—First-Principles Study

Ahmed Tamer A. AlAsqalani1,2 and Tomas Polcar1; 1University of Southampton, United Kingdom; 2Assiut University, Egypt

Owing to their excellent physical properties such high melting temperature, significant high-temperature strength and good thermal conductivity, tungsten and tungsten-based alloys are promising candidates in various applications. They are commonly used as potential plasma-facing material in fusion reactors and electrical contacts. In literature, several experimental observations by TEM revealed the improved thermal stability of W-based binary alloys upon addition of Ti, Ag and Ta atoms [1,2]. These observations have been attributed to the segregation of solute atoms to grain boundaries (GB). The propensity for segregation of these alloying elements is different as indicated by formation of enrichment/depletion regions around GBs. However, the segregants behavior, enhanced stability and its underlying mechanisms are not fully understood. In this work, an extensive DFT calculations have been performed to explore the GB morphological effects on the segregation behavior of Ti, Ag and Ta as examples of 3d, 4d and 5d elements, respectively. Six different GB structures consisting of low/high-angle symmetric tilt [001] GBs are considered. It is found that Ag atoms exhibit substantial tendency of segregation to both types of GBs. In contrast, both Ta and Ti atoms exhibit preferential propensity to segregate to high-angle STGB. The highest segregation energy values obtained for Ti, Ag and Ta are -0.017, -1.53 and -0.2, respectively. The change of metallic bond nature between solute and W atoms are responsible for the variation of the segregation energy for each element. Furthermore, segregation energy results indicate that while Ag atoms tend to segregate within and around the GBs plane, whereas Ti and Ta atoms energetically prefer to reside within the GB core. This behavior was explained using density of states (DOS) and charge transfer analysis. We found that d-d hybridization and charge transfer between solute and host atoms play important role in determining segregation/anti-segregation character for each GB site. A comparison of our DFT results with existing thermodynamical and atomistic models have been made and some improvements should be included for further development.

10:30 AM *MT05.01.01
Unravelling the Origins of Functionality through Correlative Multimodal Chemical Imaging Olga S. Ovchinnikova, Anton V. Ievlev and Alex Belianinov; Oak Ridge National Laboratory, United States

The key to advancing energy materials and biological systems is to understand and control the structure and chemistry at interfaces. While much of the dynamic chemistry can be studied on macro-scale systems, there is a lack of means to localize chemical measurements and correlate them to nanoscale structure of the material. Through a unique merger of advanced scanning probe and ion microscopy with mass spectrometry techniques rooted in innovative data processing and control algorithms, we are now able to understand the interplay between chemical and physical functionality at the fundamental length scales using multimodal chemical imaging. This multimodal imaging transcends existing techniques by providing nanoscale structural imaging with simultaneous chemical analysis. Here, I will discuss how we have developed and used this capability to visualize dynamic material transformations at interfaces, to correlate these changes with chemical composition, and to distill key performance-centric material parameters. One exciting capability is to drive materials away from equilibrium at the nanoscale with highly localized fields. This allows field confinement effects on localized chemistry in materials to be locally probed, especially at interfaces. This in turn yields direct information on key energy related questions such as electron and ion motion distribution and transport at and between interfaces. Overall, I will focus on ways to unlock the mystery of active interface formation through intertwining data analytics, nanoscale elemental and molecular characterization, with imaging; to better grasp the physical properties of materials and the mechanistic physics-chemistry interplay behind their properties.

11:00 AM *MT05.01.02
Exploring a FIB-SEM Research Data Ecosystem Keana Scott, Alline Myers and Peter Bajcsy; National Institute of Standards and Technology, United States

In the past decade, focused ion beam scanning electron microscopy (FIB-SEM) has transformed from a niche technique for semiconductor and materials science research into a broadly useful processing, analysis and characterization technique of choice for many disciplines. Although, Ga+ FIB-SEM instruments are the most commonly used FIB-SEMs, plasma FIB-SEMs have enabled routine 3D structural analysis of (relatively) large volumes. And the availability of multiple ion species is enabling application specific uses of different FIB instruments and renewing interests in techniques such as FIB-SIMS (Secondary Ion Mass Spectrometry). Additionally, advances in the instrument hardware and software have resulted in increased system stability and robustness, as well as ease of use and maintenance that have significantly lowered the barrier to entry into FIB-SEM techniques. However, as the FIB-SEM instrumentation becomes increasingly automated and complex, the challenges associated with the resulting data volume and complexity are increasing. The current trend towards open
and re-usable data also requires added effort to provide necessary meta data and curate the research data into a consumable format.

In this presentation, examples of materials characterization applications that are uniquely enabled by FIB-SEM are described, and how the resulting data fits into various overlapping research data ecosystems is explored [1]. For example, a material characterizations study such as carbon fiber ultrastructure analysis can generate a large number of images. These image data sets can be used and re-used by materials scientists to explore structure property relationships while the same set of data, with an appropriate meta data, can be re-purposed as test data sets by computational imaging scientists for their algorithm development. We will explore some of the currently available data infrastructures supporting the findable, accessible, interchangeable, and reusable (FAIR)[2] data ecosystems and how the FIB-SEM community can effectively adapt these.

11:30 AM *MT05.01.03
Ultra-High Precision Engineering of 2D Nanomaterials Using Energetic Focused Ion Beam Technologies
Songkil Kim; Pusan National University, Korea (the Republic of)

An emerging paradigm in engineering is the design of materials to act as simple building blocks in order to achieve complex functionality at multiple scales. The discovery of new nanomaterials such as low-dimensional nanomaterials, new metal alloys and functional polymers, has been leading these developments, and more material and engineering design options have been given to scientific and engineering societies, with demands to overcome the challenges of the current existing technologies. However, challenges persist in integration of nanomaterials to device architectures, control of material properties, and realization of functional devices, for practical applications. To tackle these challenges, it is crucial to develop multidisciplinary, integrated approaches, to enable precise manipulation of these materials compatible with integrating them into existing engineering systems as well as for the development of new concepts of device architectures.

Developments of cutting edge technologies in manufacturing enabled to programmatically transform materials into real engineering components by ‘direct digital printing’ with high degree of controls, making it possible to manufacture complex multi-dimensional components on demand in micro- and macro-scales. As the similar concept of manufacturing, directing matter on atomic-to-nanoscales, termed as ‘focused electron or ion beam induced processing’, is being developed to achieve atomically precise manufacturing of nanomaterials and 3D structures in solids, liquids and at interfaces. Focused electron or ion beam induced processing is a resist-free advanced nanomanufacturing technique for ‘direct-write’ processing of a wide range of structural and functional nanomaterials. Focused charged particle beam-based techniques involve in electron-matter or ion-matter interaction, enabling additive/subtractive nanofabrication as well as doping and functionalization of nanomaterials, along with the in-situ nanoscale imaging in the scanning or transmission electron/ion microscope environments. Thus, these techniques provide unique opportunities in materials design to address many challenges in nanoengineered systems. In this research presentation, recent advancements of energetic focused ion beam technologies will be introduced, especially for their applications to direct manipulation of 2D nanomaterials such as graphene and molybdenum disulfide (MoS2). Among the several technological developments, the synergistic theoretical and experimental research work will be presented to introduce the promise of the focused helium ion beam and argon molecular cluster ion beam technologies in atomic manipulation, multi-mode nanofabrication, defect engineering and chemical imaging as a next-generation nanofabrication tool.

SESSION MT05.02: Novel FIB Sources and Nano-Fabrication
Session Chairs: Frances Allen, Alex Belianinov and Shane Cybart
Monday Afternoon, December 2, 2019
Hynes, Level 2, Room 204

1:30 PM *MT05.02.01
New Light and Heavy Ion Beams from Liquid Metal Alloy Ion Sources for Advanced Nanofabrication and Ion Implantation Paul Mazarov, Lars Bruchhaus, Fabian Meyer, Achim Nadzeyka, Torsten Richter, Ralf Jede, Yang Yu, Jason E. Sanabia, Lothar Bischoff, Wolfgang Pilz, Nico Klinger, Gregor Hlawacek and Jacques
Focused Ion Beam (FIB) processing has been developed into a well-established and still promising technique for direct patterning and prototyping on the nm scale, high resolution imaging or high resolution ion lithography\(^1\). Exploring the Liquid Metal Alloy Ion Sources (LMAIS) potential represents a promising alternative to expand the global FIB application fields. Thanks to this, nearly half of the elements of the periodic table are made available in the FIB technology as a result of continuous research in this area during the last fifty years\(^2\). Recent developments could make these sources an alternative technology feasible for nanopatterning challenges.

Concerning ion beam resolution and minimization of unwanted damage, light ions like He or Li are preferred candidates. Liquid metal alloy ion sources (LMAIS) with a lifetime of more than 1000 µAh on the basis of Ga\(_{35}\)Bi\(_{60}\)Li\(_{5}\) and Sn\(_{95}\)Li\(_{5}\) alloys were developed, characterized and tested in a commercial mass-separated VELION FIB-SEM system (Raith GmbH)\(^3\). In the case of Li ions from the mass separated FIB a lateral resolution of 5.6 nm could be obtained in first experiments and the sputter yield was determined to 0.4 for 35 keV Li ions on Au. For reference, the helium ion microscope (HIM) has a lateral resolution of about 0.5 nm and 1.8 nm, for He and Ne respectively, He has a sputter yield of 0.1\(^4\). For sub-10 nm focused ion beam fabrication and microscopy, the GaBiLi-FIB or the SnLi-FIB could therefore be considered as alternatives to the HIM with the benefit of providing additional ion species in a mass separated FIB without changing the ion source.

In this contribution the operation principle, the preparation and testing process as well as prospective domains for modern FIB applications will be presented\(^1,5\). As an example we will introduce a GaBiLi LMAIS in detail. It enables high resolution imaging with light Li ions and sample modification with Ga or heavy polyatomic Bi clusters, all coming from one ion source. Moreover we will discuss the main properties of a modern LMAIS like long life-time, high brightness and stable ion current. The physical basics and experimental results of LMAIS, their physical properties (I-V characteristics, energy spread) and questions of the preparation technology using elementary as well as binary and ternary alloys as source material will be covered.

2:00 PM *MT05.02.02*  
**Gas Assisted Plasma FIB—A Delaying Tool** Anne Delobbe\(^{1,2}\), Gregory Goupil\(^2\), Sharang Sharang\(^3\) and Pascal Gounet\(^4\); \(^1\)Tescan Orsay Holding, Czechia; \(^2\)Orsay Physics, France; \(^3\)TESCAN Brno s.r.o., Czechia; \(^4\)ST Microelectronics, France

Initially launched in 2011 by Orsay Physics, Xe Plasma FIB-SEM is currently used to save operation time for many applications which were up to now realized by Ga FIB. Ga FIB and Xe FIB instruments are the go-to tools for chip material analysis in the semiconductor industry for applications like TEM lamella preparation, circuit editing, and physical inspection by sample preparation.

With the downscaling of the technologies, delaying, which consists of perfect layers by layer de-processing, is one particular very demanding application which was developed using the plasma FIB. The goal is to localize a failure in a fully integrated circuit included in a few hundreds of nanometers thick area. The demand for suitable and nano-accurate polishing techniques are in growing demand to reveal buried interest areas with the assurance of matching to the reference sample with no modification due to the preparation technique used. Many trials have been attempted to use a FIB to remove homogeneously different metal/insulator layers. A solution is to work on ion species, ion energies, spot size, scanning strategy… But ion beam etching alone is not able to achieve planar surface on interconnect technologies. The milling rate of different materials is too unequal and their architecture is too tricky to reach deep layers with the minimum roughness on the sample. Thus, due to a constant evolution of the material used in the semiconductors and their intrinsic tangle at the nanometric level, it becomes an increasingly pressing demand to reach, without alteration, a specific area in such complex structures. To overcome these artifacts, a solution is to control FIB milling rates of all the different as-constitutive elements of the SC’s surface by adding a specific chemistry near the area of interest during operation. In this perspective, we developed a new reliable, fast and accurate Gas Injection System (OptiGIS) and its devoted precursors. The chemistry used for homogeneous milling needs also to overcome the production of residues and particulates.
which are undesirable for electrical characterization and are caused by milling of surface materials such as the case of plasma FIB delayering. Conductive residues can redeposit on sample surface, shorting metal lines to one another and creating false electrical signals, while non-conductive residues may cover metal lines and result in bad electrical contact. To mitigate this issue, gases etchant are used in delayering process to produce volatile by-products when reacting with the surface easily removed by the vacuum pump instead of redepositing on sample surface. A successful Xe FIB delayering on sub-14 nm technology from metal 8 to transistor contacts in combination with special gas chemistry will first be presented.

In a second part, this case will be compared to the performance of this process with a Ga FIB. The differences between the two use cases will then be exposed for comparison.

Experimentally, top-down delayering of sub-14 nm technology nodes were performed with both Ga and Xe FIBs using special gas precursor. GIS was inserted to inject gas on to the area of interest. Suitable current density, beam shape and gas delivery was prepared to conduct planarity and the process was monitored using end point detection based on the SE signal being generated during the etching process. The parameters will be discussed.

In a third part the focus will be on the end pointing. This end pointing recognizes each peak as the metal layer and the trough as via layer which gives full control to the operator to start and stop the process in any layer of interest. A final fine polishing is performed once the specific layer is entered to get rid of residual precursor or carbonated compounds before the final analysis such as probing.

2:30 PM MT05.02.03
Comparison of Gallium and Neon Ion Beam Milling on GaAs Deving Xia\textsuperscript{1}, John A. Notte\textsuperscript{1}, Ying-Bing Jiang\textsuperscript{2} and Brett Lewis\textsuperscript{1}; \textsuperscript{1}Carl Zeiss, United States; \textsuperscript{2}The University of New Mexico, United States

Microscale and nanoscale structuring are important processing steps for prototyping advanced semiconductor devices from III-V materials such as GaAs and GaN. For example, the self-assembly of group III metallic nanodots and other nanostructures of III-V compound semiconductors has become a topic of much interest \cite{1}. Also, the controlled growth of III-V materials shows interesting optical qualities with the prospect of negative index of refraction materials \cite{2}. Traditionally, ion beam milling with a gallium focused ion beam instrument (Ga-FIB) has been used to structure these materials. The same Ga-FIB is also routinely used for sample preparation for subsequent transmission electron microscopy (TEM) imaging or analysis steps. However, the use of the Ga-FIB can significantly alter these materials through ion beam induced damage effects, including the implantation of gallium. In some cases, there is evidence of Ga-rich “droplets” that seem to form on the surface of these materials.

The ZEISS ORION NanoFab serves as a useful platform for the prototyping of advanced III-V materials for semiconductor, optical, and other device researches. This instrument provides a traditional Ga-FIB, but helium and neon focused ion beams with 0.5 and 2.0 nm probe sizes (respectively). Together these ion beams can offer sub-nanometer imaging resolution, as well as device fabrication with no artifacts associated with gallium residue. The same platform also offers secondary ion mass spectrometry (SIMS) based elemental analysis with a magnetic mass spectrometer, and a lateral resolution on the order of 15 nm.

In this talk, we compare the effects of Ga and Ne ion beam milling into a GaAs substrate. These two ion beams are used over a range of areal dosages (ions/cm\textsuperscript{2}) to explore the milling rate, milling artifacts, and pattern formation. On the same platform, the helium focused ion beam is used to assess the milling rate, and for detailed examination of the milled patterns and surface morphology. As expected, experimental results show that the milling rate with a 30 keV Ga-FIB is much faster than that with a Ne ion beam. However, the gallium beam tends to induce a progressive formation of Ga-rich nanodots or nanodroplets on the bottom and sidewalls of the milled pits. In contrast, when using a Ne beam with the same 30 keV energy, the bottom surfaces of the milled pits show a porous texture. With a lower Ne ion beam energy, such as 10 keV, the bottom surface appears to be much less porous without any significant decrease of milling rate. The neon beam with its small probe size and easy operation at low probe currents, enables high fidelity patterning of the GaAs. We further examine the milled samples using TEM to assess damage, implantation, and structural changes below the surface. Further investigations include the effects of an etchant gas (XeF\textsubscript{2}) for material removal using both the Ga and Ne beams. Additional experimental results include the milling of GaN substrates with both Ga and Ne ion beams.

Ne-FIB Fabrication of Tips for Atom Probe Tomography
Frances I. Allen\textsuperscript{1,2}, John A. Notte\textsuperscript{3}, Paul T. Blanchard\textsuperscript{4}, Norman A. Sanford\textsuperscript{4}, Ruopeng Zhang\textsuperscript{1,2}, Andrew M. Minor\textsuperscript{1,2} and Soeren Eyhusen\textsuperscript{3}; \textsuperscript{1}University of California, Berkeley, United States; \textsuperscript{2}Lawrence Berkeley National Laboratory, United States; \textsuperscript{3}Carl Zeiss Microscopy, United States; \textsuperscript{4}National Institute of Standards and Technology, United States

Focused ion beam (FIB) milling using gallium ions is routinely used for the site-specific preparation of sharp tips for Atom Probe Tomography (APT), in which atoms are evaporated from the tip and detected using a mass spectrometer to enable 3D reconstruction of the needle-shaped volume atom by atom. Artifacts from the Ga-FIB milling process include near-surface implantation of gallium and the accumulation of gallium along grain boundaries and between phases. With the advent of novel FIB sources, alternative ion species for precision milling are now available. For example, Ne-FIB-milling as the final polishing step in the preparation of electron-transparent samples for Transmission Electron Microscopy (TEM) has been demonstrated as an alternative approach for samples in which contamination effects from gallium cannot be tolerated \cite{1}.

Here we use the neon beam generated by the gas field-ionization source of a Helium/Neon Ion Microscope (HIM/NIM) for the final trimming of APT tips that have been extracted from bulk samples by Ga-FIB lift-out. Materials investigated include a titanium alloy and a sample comprising aluminum/aluminum oxide layers on a silicon substrate. High-resolution TEM analysis of Ne-FIB-milled tips reveals that implanted gallium from the pre-milling steps is successfully removed. A thin amorphous layer of < 5 nm is observed, beneath which the crystallinity of the tip is well-preserved. The experimental workflows for the Ne-FIB technique will be discussed and the 3D reconstructions from the APT measurements presented.

Electro-Hydro Dynamic Ion Sources and Focused Ion Beam Machines
Jacques Gierak\textsuperscript{1}, Paul Mazarov\textsuperscript{2} and Lothar Bischoff\textsuperscript{3}; \textsuperscript{1}Centre de Nanosciences et de Nanotechnologies, France; \textsuperscript{2}Raith GmbH, Germany; \textsuperscript{3}Helmholtz-Zentrum Dresden-Rossendorf, Germany

In this talk we will review and detail the current status of EHD ion sources, also commonly referred as Liquid Metal Ion Sources, their development perspectives and their ever present expanding applicative domains. We will review the roots of this technology born in the early 70’s, deriving from space propulsion research, when physicists applied EHD phenomena onto liquid metal meniscus to create high brightness ion sources. Since then the LMIS qualities based on a remarkable brightness, excellent emission stabilities (current emission and emitting area invariance), ease of operation, lifespan and compactness small size were at the origin of the focused ion beam (FIB).

As a deeply involved team in the pursuing quest aiming at investigating the full applied potential of the direct-write Focused Ion Beams technology since the mid-80’s, we will analyze and comment the never interrupted major effort invested around the world aiming at developing alternative ion sources. As a complement to the development of high current sources or atomic-sized emitters, we will show that high performance Liquid Metal Ion Sources and Liquid Metal Alloys Ion Sources exhibit definitive advantages at the prototyping level.

We will analyze, quantify and describe the potential gains still to be expected from the widely used gallium LMIS and other alloy ion sources, that add a large number of ion species and patterning schemes.

In conclusion we will summarize our vision on the future of FIB technology based on electro-Hydro Dynamically (EHD) driven emitters operating in the cone-jet mode, both in terms of performances, versatility and on the science frontiers these might help to push. My presentation will be an attempt to provide an overview on this FIB continuous evolution and future capabilities.

**4:00 PM MT05.02.06**
Focused Ion Beam Preparation of Strain Microscopy Samples for Coherent X-Ray Imaging of 3D Nano-Scale
Structure and Lattice Strain Felix Hofmann1, Nicholas Phillips1, Gareth Hughes1, James Douglas1, Ross Harder2 and Wenjun Liu2; 1University of Oxford, United Kingdom; 2Argonne National Laboratory, United States

Focused Ion Beam (FIB) machining has emerged as a transformational tool for microscopy, making it possible to extract samples of particular features of interest with high spatial specificity. A challenge in this context is the damage FIB inevitably causes and the consequences this damage has for subsequent microscopy. Multi-reflection Bragg Coherent Diffraction Imaging (MBCDI) is an exciting, new coherent X-ray diffraction technique that allows the imaging of 3D structure and lattice strain in crystalline materials with 10s of nanometers 3D spatial resolution. However, to function, MBCDI requires samples less than one micron in size. This constraint has thus far limited MBCDI to materials that naturally form isolated micro-crystals of this size. The vast majority of technologically important materials have thus remained out of reach.

Here we present a new FIB-based fabrication approach that allows the manufacture of micron-sized strain microscopy samples for MBCDI. Importantly these can be manufactured with high spatial specificity, such that they contain specific defects or microstructural features of interest. A very important challenge is how to manage the damage cause by FIB milling. Our previous MBCDI work on initially pristine gold micro-crystals showed that milling with 30 keV Ga ions can cause large lattice strains that extend up to hundreds of nanometers into the sample. While these strains can be reliably probed using MBCDI, they obscure the subtle strain fields associated e.g. with crystal defects of interest. Using MBCDI we demonstrate that the strains from high energy FIB milling can be reliably removed by low energy FIB polishing. This is a key aspect of the new FIB-based strain microscopy sample preparation.

Several examples of strain-microscopy sample preparation using FIB will be presented, concentrating on materials not normally suited to coherent X-ray diffraction imaging. We show that, using the new approach, the full, 3D resolved strain fields of specific, pre-selected dislocation structures can be probed. We can also study in detail irradiation-induced lattice strains in samples extracted from macroscopic armor for future fusion reactors, or local strains in a nickel superalloy. These examples highlight the general applicability of the new FIB preparation routine, transforming MBCDI to a nano-scale microscopy tool for real-world engineering materials.

4:15 PM MT05.02.07
Comparison of Several Focused Ion Beam Fabrication Methods for Quantitative In Situ Small-Scale Mechanical Testing Yang Yang1, Frances I. Allen1,2 and Andrew M. Minor1,2; 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States

Quantitative in situ TEM small-scale mechanical testing has attracted broad interest over the past 20 years. Through these techniques, one can not only directly visualize the microstructure/defects evolution during mechanical deformation, but also measure the mechanical properties of nanostructured materials. Typically, the small-scale coupons for these tests are fabricated by Gallium focused gallium ion beam (Ga-FIB). It is well-known that Ga-FIB may introduce radiation damage and gallium contamination at the sample surface. Although these artifacts may only exist at the surface layer which is usually less than 30 nm, their effects on the mechanical behavior may be significant. In addition, the sample geometry may also impact the measured mechanical properties. For example, it is difficult to control the length of the cylinder-shape pillar; thus, measuring strain accurately can be difficult. In this presentation, we will systematically compare several focused ion beam fabrication methods for quantitative in-situ small-scale mechanical testing, with an emphasis on the ion type (Ga, Ne, or Ar) and sample geometry (round-/square- shaped cross-section). We hope to provide insights into choosing appropriate FIB fabrication methods that enable more reliable quantitative in-situ small-scale mechanical testing.

Beam Exit Cross-Sectional Polishing (BEXP) and Functional SPM—New Approach for 3D Mapping of Physical Properties of Nanostructures Marta Mucientes1, Leonardo Forcieri1, Pamela Jurczak2, Mingchu Tang2, Huiyun Liu2, Yipin Gong3, Tao Wang3, Samuel Jarvis1, Kunal Lulla1 and Oleg V. Kolosov1; 1Lancaster University, United Kingdom; 2University College London, United Kingdom; 3The University of Sheffield, United Kingdom

The modern technology demands the miniaturization of devices and the discovery of novel materials, both requiring matching characterization methods possessing nanoscale resolution and able to the three-dimensional physical properties of these devices and structures. Scanning Probe Microscopies (SPM), could allow the nanoscale mapping
of the sample morphology, as well as local mechanical, electrical and thermal properties being a relatively easy to use and efficient tool for exploration of inorganic surfaces. However, studying 3D structures in SPM provides significant challenge, with mechanical sectioning of the samples ruled out as it creates too rough surface, focused ion beam (FIB) creates cuts that are usually too narrow for the SPM probing tip, as well as implanting Ga ions strongly modify the properties of the materials studied and damage the surface, with mechanical cleavage can only be applied to the narrow subset of epitaxial layers with minimal defects.

Here, we present the novel Beam Exit Cross-sectional Polishing (BEXP) approach, creating nanoscale near-atomically flat sections of layers from few nm to the surface down to several micrometres deep, and minimal damage to the sections device or material. BEXP uses triple broad 1 mm wide Ar-ion beams intersecting in the cut area and shaped by the edge mask to define a cut plane. This plane oriented in such a way that it intersects the sample surface at small negative angle, with beam exiting the sample (hence the BEXP name) keeping intact the sample surface. The glancing angle and inert nature of Ar results in minimal Ar-ions implantation and modification of the sample as well as fairly flat surfaces (roughness ~1nm RMS)\(^1\), providing optimal geometry for accessed via the material sensitive SPM\(^2,3\).

The BEXP has been implemented in the nanomechanical and electrical studies of III-V compound semiconductor structures commonly employed in the manufacturing of optoelectronic devices – photovoltaics, LED and lasers.\(^4\) Due to the shallow angle of the BEXP section, the projection of the multi-layered structures increases approximately 1 to 10 the thickness of the layers, facilitating the visualization of the material defects, such as, the propagation of the antiphase domains across the structure, creating a charge separation in multiple quantum wells - one of the key problems in the efficiency of the devices. SPM maps of nanoscale sections of GaN NWs on Si revealed the electron affinity dependence with the material thickness and unexpected domain reversal in individual NW. In summary, tandem of BEXP with materials sensitive SPM provide a very efficient tool for exploring 3D structure and physical properties of solid state materials with true nanoscale resolution.

4:45 PM MT05.02.09
Transfer of Sub-10 nm Patterns to Substrate Using Helium Ion Beam Lithography and Reactive-Ion Etch
Matthew Hunt\(^1\), S. Lewis\(^{1,2,1}\), N. Lee\(^1\), H. Alty\(^2\), J. Yang\(^{1,3}\), A. Wertheim\(^1\), G. DeRose\(^1\), Stephen Yeates\(^2\), Richard Winpenny\(^2\) and A. Scherer\(^{1,1}\), California Institute of Technology, United States; \(^2\)The University of Manchester, United Kingdom; \(^3\)Stanford University, United States

While focused ion beams (FIB) of light ion species such as He\(^+\) and Ne\(^+\) are often pursued for high-resolution, direct-etch patterning, their low sputtering rates – relative to heavier ion species like Ga\(^+\), Xe\(^+\) and Cs\(^+\) – limit such uses to low-volume-removal applications. In this work, we present two light ion FIB techniques that are useful for etched patterning on orders-of-magnitude larger scales than typical, while still maintaining the high-resolution capability (e.g. sub-10 nm for He-FIB and sub-20 nm for Ne-FIB) that is most attractive about them. In the first, helium ion beam lithography (HIBL) is used to create structures as small as 6 nm wide and 20 nm tall in silicon, spaced less than 20 nm apart, which represents a new lowest published benchmark for creating Si fins for e.g. FinFET technology. This is done by exposing a novel, metal–organic resist material with 35 keV HIBL, then transferring the pattern to the substrate with a pseudo-Bosch reactive-ion etch (RIE). Requisite exposure times are on the same order of magnitude as those needed in conventional 100 keV electron beam lithography (EBL), which makes producing sub-10 nm structures as scalable with HIBL as any other process is with EBL. The second technique involves the use of He- or Ne-FIB to create nanowires as thin as 20 nm, 60 nm tall, and as long as several millimeters. To do so, a sub-10 nm thick atomic layer deposition (ALD) hard mask is patterned by direct-etch FIB, followed by the transfer of the pattern through the underlying, thicker substrate material via RIE. Patterning times by this technique can be two orders of magnitude lower than are necessary to remove the same volume of material by direct-etch only. The benefits and drawbacks to these two nanofabrication techniques are discussed, as are their underlying mechanisms and potential applications.

Local and Macroscale Property Control of Ferroic Thin-Film Materials with Ion Beams Lane W. Martin1,2;
1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Ferroic materials including oxide ferroelectrics, magnets, and multiferroics are of great interest for a range of modern applications. What’s more, these materials stand poised to revolutionize next-generation applications, if we can determine ways to overcome inherent limitations in their function. Because of their complex chemistry, propensity for defect formation, etc. these materials – especially in the thin-film form required for many advanced applications – often have performance that lags behind that of their bulk counterparts. In turn, researchers working on advanced thin-film synthesis approaches have attempted to treat these ternary, quaternary, and more complex systems more-and-more like semiconductor systems. Efforts to make cleaner, more precise versions of these materials were envisioned to produce ever better properties – but alas, these efforts have not always play out as desired.

In recent years, however, it has been seen that we can borrow other lessons from the semiconductor community to control and improve the properties of these complex, functional materials. Namely, ion bombardment approaches are seeing a renewed interest as researchers better understand how ion beams can be used to manipulate the electronic and defect structures of materials and, in turn, how this affects the evolution of the physical properties. In this talk, we will explore recent efforts focused on the use of both low- (~30 keV) and high- (~3 MeV) energy ion beams can enable control of the concentration and type of defects in ferroic oxides and, in turn, how these beams can be used to enhance material properties. Using systems like helium-ion microscopes and pelletron accelerators, we are afforded access to a range of species and bombardment conditions. Specifically we will highlight examples of work done on materials such as the canonical ferroelectrics PbTiO3 and PbZr1-xTixO3, relaxor ferroelectrics such as (1-x)PbMg1/3Mg2/3O3-(x)PbTiO3, and the multiferroic BiFeO3. Here, among other things, we will show how the controlled introduction of ion-beam-induced knock-damage creates intrinsic defects that can, in surprising fashion, improve the electrical resistance (by orders of magnitudes) of these materials, how implantation and ion-beam-induced damage can provide a pathway to control local switching enabling emergent function like multi-state functionality, and how ion-beam-induced damage can even tune the competition of energies such that one can alter the ferroic nature of these materials. To end, we will discuss where these ideas could lead us next in using ion beams to manipulate properties in materials.

9:30 AM *MT05.03.02
Fabrication of Single Atom Devices by Direct Write Nanofabrication Edward Bielejec; Sandia National Laboratories, United States

We will present our results on the fabricate of single atom devices via direct write nanofabrication using Sandia National Laboratories nanolmplanter. This focused ion beam (FIB) implantation capability is part of Sandia’s Ion Beam Laboratory and is a multi-species 10-100 kV FIB system with a minimum spot size of 10 nm with both mass resolution using an ExB filter and single ion implantation capability using fast blanking and chopping. The combination of high spatial resolution, variable energy and the ability to implant a range of elements from the periodic table makes this a versatile machine for a range of topics from deterministic seeding of TaOx memristor devices, high resolution ion beam induced charge collection (IBIC) for probing the structure of defect cascades, deterministic single donor devices for quantum computing research, to the formation of individual defect centers in wide bandgap substrates including diamond, SiC, hBN, etc… using in-situ detectors. Here we concentrate on FIB implantation into diamond nano-structures for the creation of color centers.

Color centers in diamond including NV, SiV and GeV are used for a range of applications from metrology to single
photon sources. We demonstrate the ability to deterministically implant ions into diamond photonic nanostructures with high spatial resolution, <40 nm. This enables high resolution arrays for yield testing as well as the development of strong coupling between the resulting color center and the nanophotonic cavities. Separately, we have demonstrated single ion detection using an in-situ diamond detector with signal-to-noise-ratio approaching 10.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA-0003525.

10:30 AM *MT05.03.03
Neuromorphic MoS2 Memtransistors Fabricated by Localised Helium Ion Beam Irradiation Jakub P. Jadwiszczak¹, Darragh Keane¹, Gregor Hlawacek², Hongzhou Zhang¹ and Shane Cybart¹; ¹Trinity College, Ireland; ²Institute of Ion Beam Physics and Materials Research, Germany; ³University of California, United States

Two-dimensional layered semiconductors have recently emerged as attractive building blocks for next-generation low-power non-volatile memories. However, challenges remain in the controllable sub-micron fabrication of bipolar resistively switching circuit components from these novel materials. In this work, we demonstrate lateral on-dielectric memtransistors from monolayer single-crystal molybdenum disulfide (MoS2) utilizing a focused helium ion beam. The site-specific irradiation with the probe of a helium ion microscope (HIM) allows for the creation of charged defects in the MoS2 lattice. The reversible drift of these locally seeded defects in the applied electric field modulates the resistance of the semiconducting channel, enabling versatile memristive functionality on the nanoscale. The asymmetric nature of the ion irradiation plays a crucial role in controlling the resistive switching behaviour and hence optimising the device performance. This work has potential to advance the down-scaling of memristive devices with low power consumption and applicability for synaptic emulation in next-generation flexible electronic applications.

11:00 AM MT05.03.04
Large Scale Automated Fabrication Using a Helium Ion Microscope Ethan Cho, Jay C. LeFebvre, Hao Li and Shane Cybart; University of California, Riverside, United States

We have fabricated a variety of high-transition temperature superconducting (HTS) Josephson devices with properties that exceed prior-art devices using a focused helium ion beam (FHB). These FHB Josephson junctions have exceptional qualities such as a resistance greater than 1 kohms as well as superconducting quantum interference devices with voltage close to 1 mV. These high figures of merit make HTS devices appealing for many applications. Unfortunately, these demonstrations are small scale devices with few junctions contained in small 100 micron areas due to the field of view of the FHB at high resolution. To bring this technology to the next level, innovations are needed for large area patterning such as those implemented in commercial electron beam lithography equipment. We present our efforts in bringing this to fruition using our Orion plus microscope equipped with a Raith ELPHY pattern generator system. We developed an automated direct-write Josephson junction process where large-scale areas are broken into smaller write fields that are compatible with the field of view of the FHB. The smaller areas are individually written and stitched together. Since the FHB is not equipped with a laser interferometer stage, it is necessary to account for stage backlash and other sources of stitching error using auto-alignment marks in the circuit design. Using the Raith ELPHY pattern generator we maintain a small field of view for high resolution patterning and control the stage to stitch the device with errors less than a few micrometers per movement. Additionally, while setting up the coordinate system to match the design and the patterned device, a focal plan is fitted in the coordinate system to keep the beam in focus even after long stage movements. This further reduces the action needed by a human operator. To test the automation process, we designed a large area wide-bandwidth, high-dynamic range sensor which consists of a large number of long Josephson junctions in an array. The array, typically several millimeters long, is much larger than common lithography write fields (typically a hundred micrometers) making the fabrication process excessively long and tedious. The signal voltage output scales with the number of junctions contained in the series array which is an important metric for determining the device performance. Previous designs were limited to a few hundred junctions with output voltage of less than 5 mV. By automating the process, we are
now capable of making arrays with over 2600 junctions in series with voltage output over 100 mV! This circuit was installed into a prototype receiver for signals intelligence research and is one of the first FHIB Josephson circuits to be transferred out of the university.

11:15 AM MT05.03.05
Pulsed Laser-Assisted Helium Ion Nanomachining of Monolayer Graphene—Direct-Write Kirigami Patterns
Cheng Zhang1,2, Ondrej Dyck2, David A. Garfinkel1, Michael Stanford1,2, Alex Belianinov2, Jason D. Fowlkes2, Stephen Jesse2 and Philip Rack1,2; 1The University of Tennessee, Knoxville, United States; 2Oak Ridge National Laboratory, United States; 3Rice University, United States

A helium gas field ion source has been demonstrated to be capable of realizing higher milling resolution relative to liquid gallium ion sources. One drawback, however, is that the helium ion mass is prohibitively low for reasonable sputtering rates of bulk materials, requiring a dosage that may lead to significant subsurface damage. Manipulation of suspended graphene is, therefore, a logical application for He⁺ milling. We demonstrate that competitive ion beam-induced deposition from residual carbonaceous contamination can be thermally mitigated via a pulsed laser-assisted He⁺ milling. By optimizing pulsed laser power density, frequency, and pulse width, we reduce the carbonaceous byproducts and mill graphene gaps down to sub 10 nm in highly complex kirigami patterns. The experimental observation is qualitatively in line with the Finite Element Method simulation results. This technique enables complex features to be direct written on suspended membranes, opening the gate to a variety of applications such as fabricating heterostructure carbon-based devices.

11:30 AM MT05.03.06
Phase Transitions in He⁺ FIB-Irradiated VO₂ Observed with 4D-STEM Imaging
Steven Zeltmann1, Lei Jin1, Frances I. Allen1, Junqiao Wu1 and Andrew M. Minor1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

The metal-insulator transformation in vanadium dioxide (VO₂) at ~340K is accompanied by a spontaneous strain of ~1%, which can be used to create nano-scale sensors and actuators. The ability to grow homogeneous single-crystal nanostructures, the large change in lattice parameters (orders of magnitude greater than typical thermal expansion), and low transition temperature are advantageous in applications, and highly sensitive nano-thermometers and microscale solid engines have been previously demonstrated. In this work, we demonstrate nano-scale local patterning of the transition temperature of 100 nm thick VO₂ nanowires by 30 kV He⁺ focused ion beam irradiation. Doses in the range of 10¹⁵-10¹⁶ ions/cm² do not evidently disturb the VO₂ lattice, but rather are believed to introduce oxygen vacancies that modify the transformation behavior. Spatially resolved measurement of the transition temperature is accomplished using four-dimensional scanning transmission electron microscopy (4D-STEM), a technique where a convergent electron probe is rastered across an electron-transparent sample and the full diffraction pattern is acquired at every probe position. In each of the diffraction patterns we find the position of the Bragg scattered electrons, which are used to determine the local lattice parameters.

We performed 4D-STEM scans of VO₂ nanowires with different patterned He⁺ doses using an in situ heating stage to reveal the monoclinic-rutile transformation as a function of space and temperature. We found that the transition temperatures measured by the structural distortion match those separately measured by electrical resistivity on homogenously irradiated nanowires with the same He⁺ doses. We also observe sharp interfaces between the rutile and monoclinic phases at the boundaries between different He⁺ doses. These results demonstrate the possibility of fine-tuning of the transformation temperature for precisely controlled actuation, as well as graded structures that allow for smooth onset of the actuation or sensing signal, by local irradiation with the He⁺ FIB.

11:45 AM MT05.03.07
Use of Helium-FIB to Study Helium Ion Irradiation Effects for a Tungsten Target
Mehdi Balooch, Frances I. Allen and Peter Hosemann; University of California, Berkeley, United States

The interactions of 25 keV helium ions with a tungsten (100) single crystal target at room temperature for doses ranging from 1x10¹⁵ to 1x10¹⁸ ions/cm² are investigated using a helium Focused Ion Beam (FIB) microscope to perform the irradiations in a site-specific dose-controlled manner. The swelling and surface topographic changes of the exposed surfaces are initially observed using Helium Ion Microscopy (HIM) and Atomic Force Microscopy
At a dose of about $5 \times 10^{17}$ ions/cm$^2$, blisters abruptly appear and randomly rupture. Channeling phenomena along 110 orientations becomes evident on W(100) blisters in the HIM micrographs. Blisters are found to grow to a maximum of 1 micron in diameter before rupture. Cross-sections through blisters prepared by gallium FIB milling and imaged by Transmission Electron Microscopy (TEM) reveal the formation of a blister cavity with helium nanobubbles of around 1 nm in diameter found in the material above and below the cavity. The formation of nano-cracks connecting nanobubbles is also observed, in agreement with the mechanism of blister formation involving the inter-bubble fracture of highly over-pressurized helium bubbles proposed decades ago by Evans [1], which until now, to the best of our knowledge, had not been experimentally verified. We also apply nanoindentation to measure the reduced modulus and hardness values versus indentation depth for areas implanted to different doses and propose a phenomenological equation to describe the experimentally-determined hardness and swelling values.

**Nanoscale Superconducting Quantum Devices Based on High Transition Temperature Superconductor Materials Fabricated by Focused Helium Ion Beam** Hao Li, Ethan Cho and Shane Cybart; University of California, Riverside, United States

Focused helium ion beam (FHIB) fabrication of high transition temperature superconductor (high-$T_c$) Josephson junctions has opened up new opportunities in both basic science and applications due to the much smaller critical dimensions afforded by the process. The displacement of critical element atoms such as oxygen or amorphization of the polycrystalline film directly introduced by FHIB can change the electrical property of high-$T_c$ superconductor to normal metal, even insulator at low temperature. The controllable changes of the electrical properties within nanometers provides the basis to investigate the quasiparticle tunneling density of states at different angles, which is highly related to the cooper pairing mechanism where scientist are expecting breakthrough for decades. Versatile nanoscale quantum devices by combining the nanoscale functional features, such as very narrow barrier (at the order of the coherence length in a-b plane, ~2 nm), sub-10 nm insulating lines and area have also been designed and made. Scaling down the size of the features of basic also benefits the superconducting electronics technology for higher detector sensitivity, higher circuit integration density, and higher circuit performance. In this presentation, we show how helium ion junctions can be used for spectroscopic studies of the superconducting energy gap and its anisotropy in the a-b plane. In addition, we demonstrate applications of nanojunctions in high-frequency applications, digital circuits, and quantum sensing.

**Superconducting Nanoscale Detectors Fabricated Using Precision Dislocation Engineering** Ilya Charaev, Glenn Martinez, Denis Bandurin, Andrew Dane, Reza Baghdadi, Marco Colangelo and Karl K. Berggren; Massachusetts Institute of Technology, United States

We present an alternative approach to creating nanowires through local damage by a focused He ion beam (HIM). Motivated by the successful realization of Josephson junctions (JJ) after the introduction of dislocations into an otherwise orderly atomic arrangement [1], we have fabricated nanoscale detectors on superconducting films using He$^+$ ion beam irradiation < 0.5 nm diameter. The ion beam propagates through the thin film and leaves a very narrow damage track. It benefits from a reduced interaction volume compared to that of an electron beam of similar energy and archives higher resolution without needing resist. Furthermore, this He$^+$ beam technique allows for control of the atomic layer in three dimensions due to low dose and high collimation. We have performed an analysis of critical dose for different materials and have characterized patterned nanostructures. Our results suggest HIM may have advantages over e-beam lithography for some applications.

Ion Beam Induced Damage in MgB2 and Co-Doped Ba(FeAs)2 Thin Films for Josephson Junctions

Leila Kasaei1, Hussein Hijazi1, Mengjun Li1, Ryan Thorpe1, Hongbin Yang1, Philip E. Batson1, Ke Chen2, Torgny Gustafsson1, Xiaoxing Xi2 and Leonard C. Feldman1; 1Rutgers University, United States; 2Temple University, United States

Josephson junctions (JJs) are widely used in many superconducting circuits. Focused He+ ion beam irradiation has the potential of direct writing JJ multi-junction circuits. We have used 30 KeV He+ focused ion beam (He-FIB) with beam diameter of less than 0.5 nm to create nano-scale “normal” barriers, fabricating planar Josephson junctions in superconducting MgB2 [1,2] and Co-doped Ba(FeAs)2 (Ba122) thin films. Results show excellent device-to-device reproducibility. Accurate descriptions of the ion beam created normal state are critical to the development of beam created JJs and superconducting devices. By exploiting TRIM, TEM, and channeling RBS analysis, we have explored several means to obtain experimental information of the final state of the irradiated materials, so as to correlate these structural results with the electronic properties of the resulting film.

Nanoscale Devices Fabricated by Focused Ion Beam Irradiation of YBa2Cu3O7 Thin Films

Max Karrer; University Tübingen, Germany

Recent advances in focused ion beam (FIB) techniques have opened new opportunities for nanoscale milling and local modification of thin film superconductors. We present various FIB-based approaches to produce devices in thin films of the cuprate superconductor YBa2Cu3O7 (YBCO). By Ga FIB milling, we fabricated YBCO nanoSQUIDs on bicrystal substrates with ultra-low flux noise in the thermal white noise limit [1]. Such devices offer detection of magnetization reversal processes in individual magnetic nanoparticles or nanowires [1-3]. By He FIB irradiation, it is possible to locally drive YBCO from the superconducting to the insulating state, with high spatial resolution, and hence to “write” Josephson barriers into thin films [4]. We present here a comprehensive analysis of the electric transport properties at 4.2 K of He-FIB produced YBCO Josephson junctions [5]. The critical current density $j_c$ can be adjusted by irradiation dose $D$, with an exponential decay of $j_c(D)$. For Josephson devices we find an approximate scaling of the characteristic voltage $V_c \propto j_c^{1/2}$, and current-voltage characteristics that are well described by the Resistively and Capacitively Shunted Junction model, without excess currents for $V_c < 1$ mV. The He-FIB technique provides the possibility to place junctions at arbitrary location, with different orientation and shape, and even with different $j_c$ on the same chip. Moreover, He-FIB irradiation with high dose produces highly resistive walls or areas. We used this feature to produce dc SQUIDs with sub-μm loop sizes and very low flux noise. As a further He-FIB application, we demonstrate the creation of ultradense tailored periodic pinning arrays for Abrikosov vortices in YBCO thin films, with lattice spacing down to 70 nm. By electric transport measurements and molecular dynamics simulations, we study unconventional commensurability effects of the vortex lattice with the fabricated quasi-Kagomé pinning lattices. Altogether, the He-FIB technique provides a promising tool for nanoscale patterning of advanced devices, e.g. Josephson junction arrays, in YBCO thin films.

Nanocluster Formation In Silica via Microbeam-Focused MeV Ion Implantation

John D. Demaree1 and Daryush Ilia2; 1CCDC Army Research Laboratory, United States; 2FSU, United States
Nanometer-scale metallic clusters of Ag and Au can be formed via implantation of 0.785 MeV Ag and 1.450 MeV Au ions into high-purity optical quality fused quartz silica (Infrasil), followed by thermal annealing at temperatures from 500-700°C (Ag nanocluster formation) or 900-1100°C (Au nanocluster formation). The optical properties of the resulting material – specifically, the intensity and wavelength of the plasmonic absorption bands from 400-530 nm, as well as the off-resonance absorption – are strongly affected by the total ion fluence, the particular metallic ion(s) implanted, and the details of the annealing process (temperature, time, and implantation/annealing processing order). In past studies, we have shown that ion beams focused to a 2mm diameter and stepped slowly in 0.5mm increments laterally across a silica surface results in significantly different nanocluster formation than when ion beams are rastered across a much larger area in a conventional way. We have speculated that the increased ionization and/or localized thermal load in a moderately-focused process can lead to the acceleration of metal atom diffusion and nucleation of metallic nanoclusters, even at relatively low overall sample temperatures. In this work, we will extend these studies to more tightly focused beams using an electrostatic quadrupole lens recently installed on a National Electrostatics 5SDH-2 accelerator. Focusing Ag and Au beams down to less than 100 micrometers in diameter, we will explore the limits of MeV ion implantation into such small areas without unacceptable damage to the silica host. The implanted surfaces will be examined with 3D wide area microscopy and 3D laser microscopy and optical absorption photo spectrometry, as well as Rutherford Backscattering Spectrometry (RBS) to confirm the implantation dose. To reach the implantation fluences needed for nanocluster formation (10^{16} atoms/cm^2 to 10^{17} atoms/cm^2) in reasonable times, it is likely that the current density in the microscopic area will be very high, which may lead to damage via melting, plastic flow, electric microdischarges, or even ablation. If, however, we can form nanoclusters with tailored optical properties in these small areas, this technique could be used to create regimented structures with interesting and useful optical properties.

Expanding the FIB/SEM Toolkit—Taking a Look at Various In Situ Sample Processing and Characterization Possibilities
Andrew J. Smith, Andreas Rummel, Klaus Schock, Matthias Kemmler and Stephan Kleindiek; Kleindiek Nanotechnik, Germany

FIB/SEM tools have become commonplace in many university, industry, and research labs and are employed for a wide range of applications in a variety of research and industrial fields. From preparing samples for Transmission Electron Microscopy (TEM) and Atom Probe Tomography (APT), to milling specific test structures for further analysis or mechanical/electrical characterization, to failure analysis and circuit edit tasks in semiconductors - FIB/SEMs are an integral part of many problem-solving and research workflows. Injecting process gases is an important part of many FIB/SEM processes. Precursor materials are introduced into the microscope's vacuum chamber and are decomposed by either the ion or electron beam. This results in material deposition, enhanced etching of specific materials, or the generation of very smooth surfaces on mixed-material substrates. A compact, flexible gas injection system will be introduced. In addition, injecting liquids (at high chamber pressures) can also be of interest for specific research topics. Another important topic is sample agility. For one, when milling into samples with the goal of preparing cross sections or large TEM lamella, so-called curtaining effects can be very bothersome. An approach for mitigating these effects will be discussed. In addition, some sample analysis methods require the ability to tilt and rotate samples to specific angles - beyond what the microscopes' stages allow by default. One such analysis is Electron Channeling Contrast Imaging (ECCI), which will be introduced briefly. Finally, there are assembly tasks which require a high degree of sample motion, not accessible with standard microscope stages. An example of such an assembly task will be provided. In addition, FIB/SEMs are often used in materials characterization. Tensile and compression tests can be performed on FIB-milled structures. Or, the FIB can be a tool that allows preparing/retrieving micro- or nano-sized objects and
Atomic Force Microscopy is popular among a wide range of research fields as it provides 3D topography information. Combining AFM with FIB/SEM tools yields the ability for multi-modal tests e.g. by combining the AFM technique with electron-based analysis methods (e.g. EDX).

**Advances in FIB Nanotomography—Towards 1 nm³ Voxel**s Michael W. Phaneuf, Alexandre Laquerre and Ken G. Lagarec; Fibics Incorporated, Canada

For about 20 years gallium FIB systems have been used to produce precise serial section datasets for the purpose of 3D analysis and reconstruction [1,2,3,4]. In this technique, volume pixels (voxels) with dimensions on the nanometer scale in x, y and z are acquired by "slicing" with a "machining beam" and detecting signals stimulated by an "imaging beam", resulting in datasets that can readily span one hundred micrometers or more in at least one dimension. In our lab, we have demonstrated 1,000,000 cubic micrometers of aluminum alloy can be analyzed (with 40 nm voxels) in about 48 hours.

While the initial published efforts typically achieved slice thicknesses on the order of 100 to 500 nm, across just a few dozen slices, more recent efforts have accomplished thicknesses (and voxels) below 5 nm in size [5] and many thousand slices in a dataset. Achieving precision, accuracy and information fidelity under these conditions has become a complex task. This presentation will outline our experiences performing precision sectioning with gallium ions and imaging with either low energy electrons (in our ZEISS Crossbeam 550) or helium ions (in our ZEISS Orion NanoFab), coupled with precise beam control and dynamic measurements of slice thickness and beam position to achieve these goals.

Recent advancements towards the goal of 1 nm³ voxels will be demonstrated in the analysis of a range of materials systems. Multi-resolution analysis encompassing high voxel resolution imaging coupled with intermediate resolution analytics using EDS and EBSD will also be presented. The trade-offs necessary between various instrument parameters in order to enable successful implementation, the challenges of the existing technologies, and the requirements for future instrumentation and analysis development will also be discussed.

During the last decade the combination of different microscopic and spectroscopic methods into one instrument gained increasing importance due to the simultaneous acquisition of complementary information. Especially highly...
localized probing of mechanical, electrical, magnetic, chemical and crystallographic properties on the nanoscale represents a key success factor for gaining new insights in the micro and nano world.

We present a unique atomic force microscope (AFM) – the AFSEM™ - designed for seamless integration into scanning electron microscopes (SEM) or FIB systems. Its open design and the use of self-sensing cantilevers with electrical readout allows for simultaneous operation of SEM, FIB and AFM inside the vacuum chamber to perform correlative in-situ AFM/SEM/FIB analysis of ion-beam treated nanostructured materials. We present correlative AFM/EBSD data of a FIB polished ZrO₂ ceramic of phase transformed regions. While EBSD allows for locally identifying areas where the phase transformation has occurred, in-situ AFM can now be utilized to analyze phase-transformation-induced topographic changes with sub-nm resolution.

In a further step, we demonstrate how in-situ correlative analysis with the AFM in an SEM and dual-beam system can be extended into the third dimension to measure nanomechanical properties of soft material. To achieve this, FIB slicing and mapping of nanomechanical properties using the AFSEM™ is performed in repetitive steps to build up a 3-dimensional elasticity map. Finally, we present, for the first time, in-situ correlative AFM results of helium treated surfaces inside the Zeiss ORION Nanofab. These experiments include the detailed study of a broad variety of samples. The dose-dependent creation of helium bubbles is shown on silicon, copper and steel surfaces. In addition, in-situ correlative MFM analysis of helium treated samples are shown. We observed the creation of magnetic domains on helium treated steel surfaces as well as the modification of multi-layered magnetic structures by ion-beam treatment.

Based on the broad variety of applications regarding the characterization of different materials and devices we anticipate the AFSEM to be one of the driving characterization tools for correlative SEM/FIB/AFM analysis in the future.

Focused Ion Beam Processing for Practical 3D Analysis of Hard and Soft Biomaterials Meltem Sezen and Busra Tugba Camic; Sabanci University, Turkey

In this study, strategical nanostructuring, patterning and characterization routes were applied to determine morphological, chemical and structural features of biomaterials, ranging from nanocomposite biocompatible ceramics and biodegradable polymer coatings to soft neural tissues. Studies concerning serial sectioning which is followed by high resolution imaging/EDS mapping were performed at Focused Ion Beam - Scanning Electron Microscope (FIB-SEM) platforms for revealing biomaterials’ inner structures (morphological and chemical distribution data e.g. porosity, dopant/matrix, networking) in three dimensions down to the nanoscale. Novel biodegradable and biocompatible polymer nanocomposites were developed by doping silver nanowires (AgNWs) and boron nitride (BN) nanoparticles inside biopolymer (e.g. PLA, PCL) matrices, and three-dimensional characteristics of these samples were investigated at the micro/nano-scale by the use of proper processing methodologies and instrumental parameters. In addition, different natural tissues and synthetic biocomposites; such as human tooth, human brain and ceramic bone-graft materials were processed and analyzed by using serial ion slicing applications provided by FIB-SEM platforms. This study showed the versatility of using case-specific strategies for instant and simple processing of a variety of both hard and soft biological samples, which can be coupled with simultaneous imaging and chemical analysis procedures.

SESSION MT05.06: Theory and Simulations

9:00 AM *MT05.06.01
Free-Standing and Supported Two-Dimensional Materials under Ion Irradiation Arkady Krasheninnikov; Helmholtz-Zentrum Dresden-Rossendorf, Germany
Ion irradiation has successfully been used for introducing impurities and creating defects in two-dimensional (2D) materials in a controllable manner. Moreover, focused ion beams, especially when combined with in-situ or post-irradiation chemical treatments, can be employed for patterning and even cutting 2D systems with a high spatial resolution. The optimization of this process requires the complete microscopic understanding of the interaction of energetic ions with the low-dimensional targets. In my presentation, I will dwell upon the multi-scale atomistic computer simulations of the impacts of ions onto free-standing (e.g., suspended on a TEM grid) and supported (deposited on various substrates) 2D materials, including graphene and transition metal dichalcogenides (TMDs), such as MoS$_2$ and WS$_2$. The theoretical results will be augmented by the experimental data obtained by the coworkers. Finally, I will touch upon the interaction of highly-charged [3] and swift heavy ions [4] with 2D systems and overview recent progress in modelling this using non-adiabatic approaches including time-dependent density functional theory and Ehrenfest dynamics [5].

9:30 AM MT05.06.02
First-Principles Study of Charge Equilibration and Electronic Stopping in Self-Irradiated Silicon Cheng-Wei Lee and Andre Schleife; University of Illinois at Urbana-Champaign, United States

Charged energetic particle radiation has technological interest in applications including nuclear energy, outer space, medicine, and fundamental research. As a result of irradiation, damage, including point defects, forms and ultimately determines the material properties. Therefore, understanding the underlying interactions between charged particles and a material is important. When using the semi-empirical SRIM model to describe the interaction of charged ions with target materials as well as defect formation, one particularly severe drawback is that the model assumes an equilibrium charge state for the projectile. However, the Lindhard-Winter model predicts that the charge state of the projectile strongly affects electronic stopping and recent experimental results show that channeling U$^{91}$ in Si indeed experiences larger stopping power than off-channeling U ion. The underlying mechanism is not fully understood.

We use first-principles simulations, based on real-time time-dependent density functional theory, to study charge equilibration and electronic stopping for projectiles in multiple initial charge states. Our simulations for heavy (silicon) projectiles traversing crystalline bulk silicon indeed showed a pronounced dependence of electronic stopping on the initial projectile charge state. This effect was not observed in computational data for light projectiles impacting metal or semiconductor targets, but is qualitatively similar to the experimental results of channeling U$^{91}$ in Si.

To provide detailed understanding, we analyze the dynamics of charge equilibration, influence of the impact parameter, and contributions of core and valence electrons to electronic stopping. We observe that the equilibrium charge state of the Si projectile primarily depends on the impact parameter and ultimately dominates electronic stopping. Our results provide insights for future application of multi-charge ion source and can be integrated with multi-scale models, e.g. two-temperature molecular dynamics, to more accurately predict the defect formation during primary knock-on events.

Interrogation of the Nano-Beam and Nano-Target Effects in Ion Radiation Using IM3D Yang Yang1,2, Yong Gang Li3, Michael P. Short1 and Ju Li1,1; 1Massachusetts Institute of Technology, United States; 2Lawrence Berkeley National Laboratory, United States; 3Institute of Solid State Physics, Chinese Academy of Sciences, China

Nanoscale ion implantation represents an expanding, interdisciplinary field that combines radiation effects with nano-engineering to control matter on the atomic level. In so doing, it offers the potential to create novel nano-devices such as quantum computers, magnetometers, nanowire pn junctions, etc. In particular, ion implantation enables more precise control of the spatial distribution and concentration of dopants/defects, making it highly desirable to fabricate nano-devices reproducibly. However, confidently taking advantage of it hinges upon the accurate and precise knowledge of the spatial distribution of dopants and defects created by ion implantation. Widely used, modern 1D simulations, such as SRIM (the Stopping Range of Ions in Matter) for example, may fail to predict this distribution because of the breakdown of key assumptions, including a large ion beam and target homogeneity in at least one dimension. Full three dimensional (3D) simulations of ion implantation are necessary in a wide range of nanoscience and nanotechnology applications to capture the increasing effect of ion leakage out of surfaces [Handbook of Materials Modeling. https://doi.org/10.1007/978-3-319-50257-1_115-2]. Using a recently developed 3D Monte Carlo simulation code IM3D [Scientific Reports 5 (2015) 18130], we first quantify the relative error of the 1D approach in three applications of nano-scale ion implantation: (1) nanobeam for nitrogen-vacancy (NV) center creation, (2) implantation of nanowires to fabricate p–n junctions, and (3) irradiation of nano-pillars for small-scale mechanical testing of irradiated materials. Because the 1D approach fails to consider the exchange and leakage of ions from boundaries, its relative error increases dramatically as the beam/target size shrinks. Lastly, the “Bragg peak” phenomenon, where the maximum radiation dose occurs at a finite depth away from the surface, relies on the assumption of broad beams. We discovered a topological transition of the point-defect or defect-cluster distribution isosurface when one varies the beam width, in agreement with a previous focused helium ion beam irradiation experiment. We conclude that full 3D simulations are necessary if either the beam or the target size is comparable or below the SRIM longitudinal ion range [Nanoscale 10 (2018) 1598].

SESSION MT05.07: FIB-SIMS I
Session Chairs: Alex Belianinov and Silke Christiansen
Wednesday Morning, December 4, 2019
Hynes, Level 2, Room 204

10:30 AM *MT05.07.01
FIB-SIMS—Recent Advances in Secondary Ion Mass Spectrometry for Analytical Dual Beam Focussed Ion Beam Instruments Lex Pillatsch, Agnieszka Priebe and Johann Michler; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Secondary ion mass spectrometry (SIMS) is a well-known technique for 3D chemical mapping at the nanoscale, with detection sensitivity in the range of ppm or even ppb. Energy dispersive X-ray spectroscopy (EDS) is the standard chemical analysis and imaging technique in modern scanning electron microscopes (SEM), and related dual-beam focused ion beam (FIB/SEM) instruments. Contrary to the use of an electron beam, in the past the ion beam in FIB/SEMs analytical instruments has predominantly been used for local milling or deposition of material. In this talk we will review the emerging FIB-SIMS technique which exploits the focused ion beam as an analytical probe, providing the capability to perform secondary ion mass spectrometry measurements within FIB/SEM instruments: secondary ions, sputtered by FIB, are collected and selected according to their mass by a mass spectrometer. In this way a complete 3D chemical analysis with high lateral resolution < 50 nm and a depth resolution < 10 nm is attainable. We first report on the historical developments of both SIMS and FIB techniques and review recent developments in both instruments. Next, the components of modern FIB-SIMS instruments, from the primary ion generation in the liquid metal source in the FIB column, the focussing optics, the sputtered ion extraction optics, to the different mass spectrometer types are all detailed. The advantages and disadvantages of parallel and serial mass selection in terms of data acquisition and interpretation are highlighted, while the effects of
pressure in the FIB/SEM, acceleration voltage, ion take-off angles and charge compensation techniques on the analysis results are then discussed. The capabilities of FIB-SIMS in terms of sensitivity, lateral resolution, depth resolution and mass resolution are reviewed including measurements conducted on standard calibration samples such as BAM and VCSEL samples and also metallic nanoparticles incorporated into an inorganic matrix. Different data acquisition strategies related to dwell time, binning and beam control strategies as well as roughness and edge effects are discussed. Application examples are then presented for the fields of thin films, polycrystalline metals, batteries, solar cells, metallic multilayers, and biological samples. These are followed by studies towards enhancing secondary ion yields, and therefore TOF-SIMS signal quality, using supplementary gases. Two approaches are presented – one using a novel Cs evaporator prototype and the other based on supplying water vapour and fluorine gas using a commercial in-situ Gas Injection System (GIS). The potential of fluorine gas for increasing the spatial resolution of TOF-SIMS data (elemental distribution images and depth profiles) and de-coupling mass interference is demonstrated. Finally, FIB-SIMS is compared to EDS, and the potential of the technique for correlative microscopy with other FIB/SEM based imaging techniques is discussed.

11:00 AM *MT05.07.02
NanoFab-SIMS—A Promising Tool for the Characterization of Nanofeatures Christelle Guillermier, Brett Lewis and Fouzia Khanom; Carl Zeiss SMT, Inc., United States

The rapid development and evolution of the nanotechnology market has triggered an increased demand for advanced characterization techniques at the nanoscale level. As of today, nanofeatures characterization requires the use of multiple ex-situ correlative techniques. For instance, Transmission Electron Microscopy (TEM) or Scanning Electron Microscopy (SEM) is often combined with Secondary Ion Mass Spectrometry (SIMS). SEM/TEM can uniquely reveal the nanofeature’s morphology, size and specific location on a sample (sub-organelles of a cell for example) while SIMS, a well-established sensitive surface analytical technique, will provide the chemical information. Although essential, ex-situ correlative techniques comes with the caveat of requiring adaptative sample preparation and the non-trivial task of identifying features of interest for the subsequent elemental characterization technique. TEM combined with Energy-Dispersive X-ray spectroscopy (EDX), on the other hand, offers in-situ characterization; but unlike SIMS, EDX cannot provide chemical information at sub-micrometric resolution and lacks the ability to detect light elements (H and Li).

A promising new technology for the characterization of nanofeatures has emerged with the configuration of the NanoFab with a SIMS detector. The ORION NanoFab is an ion microscope that allows high resolution secondary electron (SE) imaging with a He⁺ focused ion beam which can be focused to a 0.5 nm probe size. This same instrument also provides a Ne⁺ ion beam with a focused probe sizes of 2 nm. Recently, this platform has been configured with a custom-designed magnetic sector spectrometer equipped with four Channel Electron Multipliers (CEMs) positioned in the same focal plane. The accessible mass range is 1 to 250 amu and the mass resolution M/DM exceeds 400. Importantly, SIMS with neon provides elemental imaging with spatial resolution smaller than 15 nm. The combination of high resolution He⁺ secondary electromaging (0.5 nm) with Ne⁺ SIMS elemental mapping yields a direct correlative technique particularly attractive for exploring nanoparticles, as well as nanofeatures in general, in their macroscopic environment.

The NanoFab-SIMS has demonstrated recent success for the characterization of nanofeatures in the fields of perovskite materials, CIGS solar cells, nanotoxicology, batteries and nano-analytics in life science. We will present novel applications of this technology in the fields of nanomedicine, photonics and biology. More specifically we will show results on the characterization of biogenic nanoparticles (size in the 20 to 200 nm range) whose properties provide alternative treatment for bacterial resistance to antibiotics. We also investigated the elemental composition of doped phase-separated dielectric nano-particles in optical fibers and demonstrated that their composition varies with the particle size (size range 30-700 nm). Biology examples will include visualization of cells sub-organelles tagged with osmium antibodies.

11:30 AM MT05.07.03
Enhancing Sensitivity with NeFIB-SIMS—A Material and Parameter Study Brett Lewis, Fouzia Khanom and Christelle Guillermier; Carl Zeiss SMT Inc, United States

Recently, the ZEISS ORION NanoFab has been equipped with a double focusing magnetic sector secondary ion
mass spectrometer (SIMS) capable of chemically mapping features on the order of 10 nm[1-3] using a highly focused neon ion beam produced from a tuned gas field ion source. Initial results are extremely promising, already demonstrating usefulness in applications ranging from defect localization for semiconductor chips, chemical endpointing, and depth profiling to nanotoxicology[4], battery research[5], and characterizing solar cells[6, 7] and optoelectronics[8].

However, the utility of such an instrument is limited by its ability to detect trace elements which at small dimensions can be comprised of a limited number of atoms. Ultimately, the sensitivity of the SIMS is determined by the secondary ion (SI) current produced via the primary ion beam sputtering away the target material. This SI current is dependent on the sputter yield of the material, the collection efficiency of the detector, and, importantly, the ionization cross section of the species of interest.

In this study, we present a method for increasing the ionization cross section of different materials via the introduction of an in-chamber oxygen co-flow on a prototype tool, demonstrating in some cases a more than 2 order of magnitude increase in the SI useful yield. It is shown that oxygen can significantly enhance the positive ion yield of neighboring ions due to the readily forming oxide bond. When this bond is broken by the incoming primary ion, the oxygen tends to accept electrons due to its high electron affinity leaving the ion of interest more likely to be positively charged. Evidence shows that the ion yield enhancement is directly related to the surface coverage of the oxygen.

To study mechanistic effects and dependencies, we present data showing the effect of varied oxygen partial pressure, pixel dwell time, refresh time, beam current, and material type. The effect of the gas co-flow on sputter rate is also noted and presented.

Finally, we demonstrate the effect on the ultimate resolution that results from enhanced sensitivity with metallic nanoparticle contaminants on a silicon surface as well as on the BAM L200 standard. The future implications and challenges of increased sensitivity are also discussed.

11:45 AM MT05.07.04
High-Resolution Cs+ Ion Beam for FIB and SIMS Applications Brenton Knuffman, Andrew D. Schwarzkopf and Adam V. Steele; Zerok Nanotech Corporation, United States

The Low Temperature Ion Source (LoTIS) produces a beam of Cs+ ions that can be focused to nanometer spot sizes. This capability enables LoTIS to provide value in FIB applications where excellent machining acuity is required, such as circuit edit, as well as analytical applications where a high yield of secondary ions is desirable, as in secondary ion mass spectrometry (SIMS). The combination in a single beam will enable process control of nanomachining applications using simultaneous FIB machining and SIMS analysis.

We present the latest results from a prototype Cs+ Low Temperature Ion Source (LoTIS) retrofitted to a commercial FIB platform. Spot sizes as small as (2.1 ± 0.2) nm (one standard deviation) are observed with a 10 keV, 1.0 pA beam. Brightness values as high as (2.4 ± 0.1) × 107 A m-2 sr-1 eV-1 are observed near 8 pA [1]. We will also discuss plans for a new FIB+SIMS platform and examples of applications that are enabled by this unique combination.

Compared with the gallium liquid metal ion source (LMIS) utilized in most FIB systems today, LoTIS can provide a similar range of currents (pA to several nA), smaller spot sizes, and a reduced subsurface affected volume. These benefits have been utilized in the prototype system to perform circuit edits on 10 nm node chips. When compared with the standard Cs ion source used in commercial SIMS systems, LoTIS can deliver 100x more current into an
equivalent spot. Additionally, LoTIS can deliver a few pA into few nm spot sizes, enabling SIMS material analysis at the ~4nm fundamental physical limits of the technique. This also enables the use of SIMS in problem domains where x-ray dispersive spectroscopy has been used traditionally.

SESSION MT05.08: FIB-SIMS II

1:30 PM *MT05.08.01
Analytical Capabilities on FIB Instruments Using SIMS—Applications, Current Developments and Prospects
Tom Wirtz, Jean-Nicolas Audinot, Jelena Lovric, Alexander Ost and Olivier De Castro; Luxembourg Institute of Science and Technology, Luxembourg

Secondary Ion Mass Spectrometry (SIMS) is an extremely powerful technique for analyzing surfaces, owing in particular to its ability to detect all elements from H to U and to differentiate between isotopes, its excellent sensitivity and its high dynamic range. SIMS analyses can be performed in different analysis modes: acquisition of mass spectra, depth profiling, 2D and 3D imaging. Adding SIMS capability to FIB instruments offers a number of interesting possibilities, including highly sensitive analytics, in-situ process control during patterning and milling, highest resolution SIMS imaging (~10 nm), and direct correlation of SIMS data with data obtained with other analytical or imaging techniques on the same instrument, such as high resolution SE images or EDS spectra [1,2].

Past attempts of performing SIMS on FIB instruments were rather unsuccessful due to unattractive detection limits, which were due to (i) low ionization yields of sputtered particles, (ii) extraction optics with limited collection efficiency of secondary ions and (iii) mass spectrometers having low duty cycles and/or low transmission. In order to overcome these limitations, we have investigated the use of different primary ion species and of reactive gas flooding during FIB-SIMS and we have developed compact high-performance magnetic sector mass spectrometers operating in the DC mode with dedicated high-efficiency extraction optics. We installed such SIMS systems on different FIB based instruments, including the Helium Ion Microscope [3-5], a FIB-SEM DualBeam instrument and the npSCOPE instrument, which is an integrated Gas Field Ion Source enabled instrument combining SE, SIMS and STIM imaging with capabilities to analyse the sample under cryo-conditions [6].

Here, we will review the performance of the different instruments with a focus on new developments such as cryo-capabilities and new detectors allowing parallel detection of all masses, showcase methodologies for high-resolution 3D chemical imaging, present a number of examples from various fields of applications (nanoparticles, battery materials, photovoltaics, micro-electronics, tissue and sub-cellular imaging in biology, geology,...) and give an outlook on new trends and prospects.

Development of an In Situ Cryo High Resolution Instrument for Multimodal Analysis in Nano-Toxicology
Olivier De Castro1, Jelena Lovric1, Rachid Barrahma1, Olivier Bouton1, Eduardo Serralta2, Nico Klinger3, Gregor Hlawacek2, Peter Gnauck3, Serge Duarte Pinto5, Falk Lucas3 and Tom Wirtz1; 1Luxembourg Institute of Science and
Nowadays many consumer products contain nanoparticles in order for them to have certain desired properties. However, with the addition of nanoparticles these products can have potentially unknown health risks to humans, animal and plant species, and to the environment in general. The nanomaterial risk identification involves their physico-chemical characterization currently employing a variety of techniques and separate instruments. This makes the characterization an expensive and time-consuming process.

In the framework of the Horizon2020 project npSCOPE, we are developing a new integrated instrument for the characterization of nanoparticles. The aim is to improve the efficiency of the nanomaterial characterization workflow by integrating several techniques in one single instrument. The npSCOPE instrument is equipped with the ultra-high resolution Gas Field Ion Source (GFIS) technology [1] allowing the sample to be irradiated with very finely focused He+ and Ne+ ion beams at the nano-scale. Furthermore, the instrument incorporates detectors for secondary electron imaging, a secondary ion mass spectrometer (SIMS) for chemical analysis [2-4] and a detector allowing the detection of transmitted ions/atoms to obtain in-situ structural/3D visualisation data. The instrument will allow the characterization of nanoparticles in their native state as well as embedded in complex matrices (e.g. biological tissue, liquid, etc.). A further key feature of the instrument is cryo-capability, including a 5 axis cryo-stage, in order to perform analyses of biological samples in a frozen-hydrated state and thus avoid artefacts caused by classical sample preparation (e.g. chemical fixation) used for HV or UHV imaging of biological specimens at room temperature.

Beside analyses of nano-toxicological samples we are planning to use this instrument in different material science fields as well as other life science domains that require high resolution imaging in cryo-conditions (e.g. lipid research) [5].

(For further information please visit www.npscope.eu)

[5] This project has received funding from the European Union’s Horizon 2020 Research and Innovation Programme under grant agreement No. 720964.
dynamics. Thus, KPFM only detects the small remainder of the photoinduced field, suggesting that the large photoinduced chemical changes are shielded as such less visible in traditional indirect measurements like KPFM. These pieces of knowledge—which are critical for further developments of HOIPs optoelectronics—were unknown previously, suggesting the importance of the direct observation of ion dynamics in HOIPs using tr-ToF-SIMS.

SESSION MT05.09: Biological Applications of FIB
Session Chairs: Alex Belianinov and Silke Christiansen
Thursday Morning, December 5, 2019
Hynes, Level 2, Room 204

9:00 AM *MT05.09.01
Cryo-FIB Sample Preparation Methods for Tissue and Cells in Structure Biology Studies at Molecular Resolution
Miroslava Schaffer1, Stephan Kleindiek2, Benjamin D. Engel1, Stefan Pfeffer1, Michael Heymann1, Tim Laugks1, Julia Mahamid1, Andrew J. Smith2, Juergen M. Plitzko1 and Wolfgang Baumeister1; 1Max Planck Institute of Biochemistry, Germany; 2Kleindiek Nanotechnik GmbH, Germany

In situ cryo-electron tomography (cryo-ET) has become a central technique in structural biology over the last decade, facilitating studies of molecular structures directly within the native cellular environment. This progress was to a large extent driven by ground-breaking developments in sample preparation of frozen-hydrated specimen by cryo-focused-ion-beam microscopy (cryo-FIB) [1-4]. Standard FIB millings routines for homogeneously thick, electron-transparent lamellas from plunge-frozen specimen are nowadays well established and regularly carried out [5]. Lamellas are created directly on the frozen TEM grid by completely removing all material on both sides of the volume of interest.

However, this technique is limited to samples which can be vitrified in toto by plunge-freezing TEM grids, preventing a wide range of biological questions from being addressed by cryo-ET. Large specimens such as tissue samples from multicellular organisms require vitrification by high-pressure-freezing (HPF) to prevent the formation of crystalline ice. These samples are then too thick for the standard cryo-FIB lamella milling.

Overcoming this limitation is thus the next milestone for in situ cryo-ET. Several FIB techniques from materials science have been proposed for adaptation to cryo-preparation of thick biological samples, and proof of principle studies showing the feasibility of the FIB milling at cryogenic temperatures have been published. However, due to the stringent sample quality requirements of cryo-ET at molecular resolution, successful application of these techniques has so far not been demonstrated.

In this presentation we will show our recent cryo-FIB sample preparation development which enabled the first molecular resolution cryo-ET studies of HPF vitrified tissue [6]. Utilizing a cryo-adapted micromanipulator ‘gripping’ tool developed especially for this application, this novel cryo-FIB lift-out technique completely avoids localized material deposition and associated contamination issues. Fluorescently-labelled volumes of interest are selectively extracted from large HPF bulk samples and transferred onto special customized TEM grids for final thinning and subsequent use in the cryo TEM. We will discuss the optimization steps of each part of the complete workflow from HPF freezing to final cryo-ET experiment which were required to obtain meaningful tomographic data at molecular resolution.

Multimodal Analysis of Calcified Biological Materials  
Lasse M. Kling; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

In ageing societies all over the globe, the number of people suffering from bone disease, e.g. osteoporosis (OP) in the first place, has increased dramatically. OP considerably impairs patients' life quality, and results in high societal costs. However, current understanding of bone disease is still insufficient due to the lack of appropriate high resolution tools that permit a thorough analysis of scale bridging bone architectures from macro to nano with statistical significance to support the development of better treatments by drugs or surgical intervention.

Cutting-edge correlative workflows starting from X-ray microscopy (XRM) volume analysis, with voxel sizes of <1µm, over light sheet fluorescence microscopy (LSFM) and large scale scanning electron microscopy data acquisition, to dual beam microscope analysis (focused electron- and ion beams) permit the scale bridging investigation of bone architectures and thus merging the “big picture” and the underlying ultrastructure with statistical significance. Together with advanced data analysis even including machine learning approaches permit reaching the next, so far unprecedented level of understanding.

I will show an examplary correlative workflow from sample collection over sample preparation and the acquisition of bone fine structures, composed of trabecular-, vascular-networks as well as a three-dimensional arrangement of osteo-lacunae (OL) that host osteocytes and the interosteocyte lacuno-canalicular network (LCN). Blood vessel and OL volume can be assessed quantitatively with statistical significance in a new generation of lab-based XRM and LSFM. For investigation of the more delicate LCN we conduct dual beam microscope analysis (focused electron- and ion beams) in combination with additional analytical add-ons and demonstrate how this correlatation of various image modalities utilizing correlated data from electron-, ion-beam imaging and analytics, probes and focused laser light will permit to advance the current understanding of scale bridging bone architectures and their function. [ref1, ref2, ref3].

based scheme will be presented that makes it possible to compensate for heat induced deposit distortions. If left uncorrected, this type of artifact/error prevents CAD replication during deposition when using a typical organometallic precursor for deposition. The compensation strategy will be demonstrated for electron-based nanoprinting using both simulations and experiments. However, the CAD capability that will be presented is also compatible with the use of an ion beam for deposition. Select applications of functional 3D nanoprinted structures will also be presented.

11:00 AM *MT05.10.02
Direct-Writing Nanofabrication of Complex 3D Superconducting Nanostructures Rosa Córdoba1,2, Alfonso Ibarra3, Dominique Mailly4 and Jose M. De Teresa2,3; 1Molecular Science Institute (ICMol), Spain; 2Aragon Material Science Institute (ICMA), Spain; 3University of Zaragoza, INA, LMA, Spain; 4University Paris Saclay, Univ Paris Sud, CNRS, Ctr Nanosci & Nanotechnol, France

Nowadays, superconductors are commonly utilized in several applications such as energy generators and storage due to their unique capability of transferring electricity without energy losses. In some applications, their nanoscale patterning enhances their performance and gives rise to new physical phenomena. Innovative schemes have taken advantage of the third dimension (3D) for the development of advanced superconducting electronics. Thus, 3D nanosuperconductors could promote a change in the next generation of electronic components. Nevertheless, their fabrication and characterization are still challenging and only a few works addressing the growth of real 3D nanosuperconductors have been reported so far 1-4.

In this contribution, we introduce a template-free nano-lithography method to fabricate in a single-step 3D nano-elements on-demand with arbitrary geometry. The fabrication of complex 3D nano-architectures opens fascinating novel routes in the fields of material science, physics and nanotechnology. This specific technique called focused ion beam induced deposition (FIBID) is based on chemical vapour deposition process assisted by a charged particle beam focused to a few nanometers. Particularly, by using tungsten hexacarbonyl molecules with a He+ ion beam focused to 0.3 nm, complex 3D W-C nanostructures have been fabricated 5. As a proof of concept, we report for the first time the fabrication and characterization of 3D superconducting crystalline WC hollow nanowires with outer diameters down to 32 nm and inner ones down to 6 nm56. In addition, by modifying the ion beam current, hollow nanowires with controllable inner and outer diameters have been achieved 7. The growth of the vertical WC nanowire occurs around the ion beam spot, mainly due to the interaction of secondary electrons with the adsorbed precursor molecules, whereas a cavity at the center of the nanowire is created due to the He+ beam milling effect on the growing material. As shown by transmission electron microscopy, nanowires microstructure displays grains of large size fitting with face-centered cubic WC1-x phase. By studying their magnetotransport properties, we have found that nanowires exhibit 1.5 times higher superconducting critical temperatures (6.4 K) as well as 1.5 times higher upper critical magnetic fields (≈14 T) (Fig. 1(c)) when compared to nanowires grown by a Ga+ FIBID.

The fabrication of such nanomaterials with excellent properties makes this technique at the cutting edge of nanofabrication methods based on focused beams of charged particles.

A Focused Ion Beam (FIB) can be combined with precursor materials to grow deposits, the technique being referred to as Focused Ion Beam Induced Deposition (FIBID). In the standard FIBID configuration, a gas injection system delivers a precursor material in the gas phase, which becomes adsorbed to the substrate surface. The FIB irradiation decomposes the precursor molecules, creating a local deposit. The primary application of FIBID is the growth of metal lines, used to perform electrical connections during circuit edit [1] or utilized to contact nano-objects such as nanowires [2]. More recently, FIBID has found applications for the direct growth of functional materials in the fields of magnetism [3], superconductivity [4] and nano-optics [5]. Typical disadvantages when using FIBID include the long processing times and the appearance of side effects in the deposit and in the substrate: ion-induced defects, implantation, amorphization and milling [6]. New advances in FIBID aiming to lower the required ion doses would have a beneficial impact by decreasing the processing time and by minimizing the detrimental side effects caused by the ion irradiation.

In the present contribution, we will introduce FIBID under cryogenic conditions (Cryo-FIBID), which has been found to be an ultra-fast method to grow metal layers, nanowires and contacts [7]. Cryo-FIBID relies on FIB irradiation of a condensed layer of a precursor material formed on the substrate under cryogenic conditions. The technique implies cooling the substrate below the condensation temperature of the gaseous precursor material, subsequently irradiating with ions according to the wanted pattern, and posteriorly heating the substrate above the condensation temperature.

It will be shown that by using W(CO)6 as the precursor material, a Ga+ FIB, and a substrate temperature of -100 °C, W-C metal layers and nanowires with resolution down to 38 nm can be grown by Cryo-FIBID [8]. The most important advantages of Cryo-FIBID are the fast growth rate (about 600 times higher than conventional FIBID with the precursor material in gas phase) and the low ion irradiation dose required (~ 50 μC/cm2), which gives rise to very low Ga concentrations in the grown material and in the substrate (≤ 0.2 %). This approach gives solution to the typical problems of the FIB technique: ion implantation, ion milling, ion-induced creation of defects and amorphization. Electrical measurements indicate that W-C layers and nanowires grown by Cryo-FIBID exhibit metallic resistivity. These features pave the way for the use of Cryo-FIBID in circuit editing and photomask repair in the semiconductor industry and, more generally, for the local growth of metal layers, nanowires and contacts, with various applications in nanotechnology.

**Atomistic Insights into Self-Fold Process of Nanostructures Induced by Focused Ion Beam**

Cheng-Lun Wu and Chun-Wei Pao; Academia Sinica, Taiwan

Focused Ion Beams (FIB) are versatile tools with cross-disciplinary applications from the physical and life sciences to archaeology. Nevertheless, the nanoscale patterning precision of FIB is often accompanied by defect formation and sample deformation, which brings opportunities in fabricating nanostructures with complicated three-dimensional geometries, as well as challenges in controlling the degree of deformation. In this study, we revealed the fundamental mechanisms governing the self-folding of nanostructures undergoing FIB processes by a series of GPU-accelerated, large-scale molecular dynamic simulations. We revealed that the primary mechanism leading to nanostructure deformation during FIB processes is the mass transport to the free surface of nanostructures induced...
by energetic ion bombardment. We revealed a surprisingly simple linear correlation between atomic volume removed from the film interior and film deflection angle, regardless of incident ion energies and currents, by quantitatively analyzing the amount of volume removed from film interior. Hence, the present study demonstrates that it is possible to control the self-folding of nanostructures by controlling the direction of mass transport via carefully manipulating incident ion energy, and direction, thereby allowing fabricating nanostructures with complex three-dimensional geometries.

Capturing Crystal Nucleation in 4D at Atomic Resolution Jianwei Miao1, Jihan Zhou1, Yongsoo Yang1, Yao Yang1, Dennis S. Kim1, Andrew Yuan1, Xuezeng Tian1, Colin Ophus2, Fan Sun1, Andreas K. Schmidt2, Michael Nathanson3, Hendrik Heinz3, Qi An4, Hao Zeng5 and Peter Ercius2; 1University of California, Los Angeles, United States; 2Lawrence Berkeley National Laboratory, United States; 3University at Buffalo, The State University of New York, United States; 4University of Colorado Boulder, United States; 5University of Nevada, Reno, United States

Nucleation plays a critical role in many physical and biological phenomena ranging from crystallization, melting and evaporation to the formation of clouds and the initiation of neurodegenerative diseases1-3. However, nucleation is a challenging process to study in experiments especially in the early stage when several atoms/molecules start to form a new phase from its parent phase. Here, we advance atomic electron tomography to study early stage nucleation at 4D atomic resolution4,5. Using FePt nanoparticles as a model system, we reveal that early stage nuclei are irregularly shaped, each has a core of one to few atoms with the maximum order parameter, and the order parameter gradient points from the core to the boundary of the nucleus6. We capture the structure and dynamics of the same nuclei undergoing growth, fluctuation, dissolution, merging and/or division, which are regulated by the order parameter distribution and its gradient. These experimental observations differ from classical nucleation theory (CNT) and to explain them we propose the order parameter gradient (OPG) model6,7. We show the OPG
model generalizes CNT and energetically favours diffuse interfaces for small nuclei and sharp interfaces for large nuclei. We further corroborate this model using molecular dynamics simulations of heterogeneous and homogeneous nucleation in liquid-solid phase transitions of Pt. We anticipate that the OPG model is applicable to different nucleation processes and our experimental method opens the door to study the structure and dynamics of materials with 4D atomic resolution.

Recent Advances in 3-4D In Situ X-Ray Imaging of Solidification Dynamics and Microstructure Formation
Ragnvald Mathiesen; Norwegian University of Science and Technology, Norway

Over the last decade, we have seen a vast development in X-ray imaging techniques, methods and instrumentation, both at synchrotron facilities and in the home laboratory. At present, X-ray imaging experiments can be carried out with spatial resolutions < 10 nm, or with time resolutions down to ~100 ns. It is also becoming more feasible to use other channels than those typical in transmission-based imaging (attenuation, phase contrast), such as diffraction or scattering to form the image contrast, also when studying dynamic systems. In solidification science, X-ray radiography, topography and tomography are well-established methods for studies solidification dynamics and microstructure formation. The presentation will show recent advances in fast high-resolution quantitative in situ imaging in 3 and 4D, with examples on how experimental output may be used to evaluate and guide computer modelling efforts within the field. Furthermore, some recent and near-future advances within X-ray imaging will be presented, allowing to combine ultra-fast imaging with high spatial resolutions to study governing process dynamics at mesoscopic scales. These advances also include image modalities new to solidification science, that may open for novel studies. Finally, the talk will present some preliminary results from dynamical dark-field imaging studies of dendritic mushy zones and growing eutectics, demonstrating a method that can provide completely new insight into thermomechanical effects in solidification processes.

In Situ X-Ray Investigations of Thin Binary Metallic Alloys and the Interplay of Confinement and Growth
Maike Becker1,2, Jonathan Dantzig1, Laszlo Sturz2, Matthias Kolbe1, Stefan Klein1,2 and Florian Kargl1; 1German Aerospace Center (DLR), Germany; 2Aix-Marseille Univ., Université de Toulon, CNRS, IM2NP, France; 3University of Illinois at Urbana-Champaign, United States; 4Access e.V., Germany; 5Deutsche Gesellschaft für
Materialkunde (DGM), Germany

X-radiography enables the observation of the solidification process in a few hundred microns thin samples of metallic alloys in real-time. Therefore, growth characteristics like solidification velocities or concentration changes can be determined and analyzed. The choice of thin samples avoids a superposition of the solidification structures and exploits the X-ray contrast through a clear distinction between the solid and liquid phases. Another advantage of the thin sample geometry is the possibility to arrange the main surfaces of the sample horizontally in the measurement apparatus, so that large scale fluid flows are reduced. However, radiography is only a 2D representation of a 3D process in which the radiography images display a projection of the 3D sample. Hence, what happens in the thickness direction remains largely hidden. Therefore, the question remains how the confined geometry influences the solidification process and the final microstructure.

We present our results on X-radiography studies of equiaxed dendrite growth in a near-isothermal temperature field with a focus on Al-Ge alloys. We have discovered a dendrite orientation transition (DOT) with increasing Ge concentration in this alloy system. Supplementary post mortem EBSD analysis of the in situ processed samples revealed that the dendrites change their growth directions from the crystallographic <100> to the <110> direction. In addition we found that the thin sample geometry influences the selection of the primary growth directions, so that different growth morphologies develop depending on the orientation of the crystals in the sample. Indeed, confinement in one direction forces the dendrites to select in-plane growth directions. Furthermore, the detailed study of the crystal orientations helped to identify certain 3D growth structures from the transmission contrast in situ images of the dendrites, although the images only represent a projection.

Additional important growth characteristics for dendritic growth are tip growth rates and liquid concentration fields. Both parameters are accessible in our in situ experiments. Tip growth rate measurements typically show a transient, an accelerating and a decelerating regime. However, acceleration occurs only when either the dendrites nucleate far from each other so that they have sufficient time to grow, or when they nucleate in a more undercooled melt. Concentration measurements show that deceleration clearly coincides with the overlap of solute fields from neighboring dendrites. Furthermore, we determined the profile of the solute concentration in front of a dendrite tip. These observations are used to elucidate the influence of confinement on the growing microstructure. To better understand the influence of the thin sample geometry and of important material properties on microstructure formation, a comparison of our experimental data with simulations is also pursued.

Investigating Nucleation and Initial Grain Growth in the Alloy System Al-Ge Observed in Real Time with In Situ Techniques Mareike Wegener1, Paul Kamm2, Francisco Garcia-Moreno2 and Florian Kargl1; 1German Aerospace Center (DLR), Germany; 2Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany

In-situ techniques like X-ray radiography at thin samples or tomography in the bulk material has become a powerful tool to investigate solidification process in metals in real time [1-3]

We use laboratory based X-ray radiography and fast synchrotron X-ray tomography to analyze nucleation and the initial growth of the nucleated grain depending on the level of added grain refiner, alloy composition and cooling rate, for the alloy system Al-Ge.

The influence of solute segregation and nucleation undercooling is characterized and parameters for the development of dendritic or globu-dendritic morphology of the grain studied. Fast synchrotron X-ray tomography enables 3D time-resolved observation of dendritic growth. With 50 topographies per second (tps) the destabilization of the solid-liquid interface and the transition from spherical growth towards dendritic morphology, in the early stage of the grain growth, was observed and a critical radius for the transition determined.

Nickel-based superalloys are nowadays still the reference material family to produce blades for advanced turbine engines. Creep-resistant turbine blades and vanes are produced by lost-wax casting and directional solidification, enabling an accurate control of the microstructure and therefore the manufacturing of single-crystal parts. Need for a higher efficiency of turbines motivates the use of materials resistant to higher temperatures. Nevertheless, selecting materials with improved mechanical properties sometimes increases the challenges to process them. For instance, CMSX-4 single crystal superalloy is known to be sensitive to the occurrence of freckles, defects causing the affected parts to be rejected.

Understanding the impact of thermo-solutal convection during alloy solidification is of central importance in the casting industry because convective flow generated from density variations in the liquid is at the origin of many casting defects, such as chemical segregations and freckles. Direct observation of metal alloy solidification by X-ray imaging is an invaluable tool to reveal the dynamics of microstructure formation. Among the various X-ray imaging techniques available using laboratory or synchrotron sources, X-ray radiography is an attractive method that simply consists in illuminating a thin sample with X-ray radiation. The transmitted image is collected on a detector to obtain a projected image of the solidification front, in situ and in real-time.

The present communication reports observations of the solidification of CMSX-4 and binary Ni-11wt.%Al alloys by using fast synchrotron X-radiography. Experiments have been carried out at the ID19 beamline of ESRF (European Synchrotron Radiation Facility) using a new high temperature furnace allowing materials with a high melting temperature to be studied. The use of a high-temperature directional solidification furnace along with the combination of an intense monochromatic beam and a high-speed X-ray sensitive camera allowed us to carry out the direct observation of the development of solutal flow during dendritic growth for Ni-based alloys. The formation of a dendritic network will be studied for directional solidification experiments carried out at various growth velocities using two solidification configuration: (i) the power-down technique consisting of concomitantly decreasing the temperature of the heating element and (ii) by pulling allowing us to follow the solidification of the whole sample from the bottom to the top. Interaction of the dendritic network with solute plumes will be reported, along with the development of convective flow in the mushy zone. The formation of liquid pockets on the sample side lead to the formation of equiaxed structures during their solidification. The processing of images recorded during pulling experiments allowed us to reveal the segregation pattern forming at the sample scale. In addition, measurements of characteristic parameters (primary, secondary dendrite spacings) will be compared to analytical models.

Since the discovery of quasicrystals (QCs) in 1984 [1], QCs have attracted substantial interest due to their unique structure. For instance, QC patterns exhibit long range order without short range periodicity, and classically forbidden rotational symmetry (e.g. 5-, 8-, 10-, and 12- fold). There exist two classes of QCs with different dimensions of quasiperiodicity: 2D (decagonal, $d$-) and 3D (icosahedral, $i$-) QCs. In the former case, the $d$-QC is stacked periodically along a decagonal ($i.e.$, ten-fold) axis [2]. In contrast, the $i$-QC shows quasiperiodicity in all directions. While the exceptional structural aspects of QCs have been reasonably well described in the literature, there are still remaining questions in terms of why and how they form in the first place.

In our talk, by leveraging state-of-the-art dynamic imaging techniques, we present our efforts on tracking the nucleation and growth of both classes of QCs near- and far-from-equilibrium, as well as the structural relaxation of QCs upon prolonged annealing. Our research was conducted with the aid of time-resolved synchrotron-based X-ray
microscopy (XRM) and dynamic transmission electron microscopy (DTEM). By coupling these two techniques, we have investigated a broad range of length-scales (from tens of nm to hundreds of μm) and solidification pathways (1 K/s to 10^6 K/s cooling rates). The results provide a wealth of knowledge on the emergence of QCs in deeply undercooled melts; the influence of phasons on QC stability; the growth mode of the QCs from a liquid (solidification) as well as a solid phase (precipitation); and similarities and differences in the crystallization signatures between the QCs and periodic approximant phases. We anticipate that our real-time experiments can provide guidance for simulations on this exotic form of matter.

Radiographic Investigations of the Formation and Growth of Primary Intermetallic Compounds in Liquid Aluminium Alloys Shikang Feng1, Enzo Liotti1, Christoper Gourlay2, Yi Cui2 and Patrick Grant1; 1Oxford University, United Kingdom; 2Imperial College London, United Kingdom

X-ray radiography and tomography imaging studies have been applied widely to study solidifying alloys in order to understand the effect of cooling conditions, alloy composition and presence of external fields such as gravity, electromagnetic pulses, extrinsic additions, etc on crystal formation and growth. However, these studies have predominantly concerned understanding primary phase formation whereas the properties of many engineering alloy castings are more generally (and more dramatically) controlled by the size, morphology, distribution, volume fraction and nature of minority, dispersed secondary phases. These phases may be present in concentrations of only a few volume percent, and are frequently formed at temperatures close to the formation of the majority phase or at lower temperature by eutectic reaction, which makes studying the dynamics of their formation and growth more difficult. These secondary intermetallic compound (IMC) phases are also often ordered structures that exist only over a comparatively narrow range of compositions. In contrast to the disordered primary phases, such as a-Al in aluminium alloys, the way in which the formation and growth dynamics of these ordered IMCs can be affected by changes to casting conditions is much less well-understood.

This investigation applies equipment and software tools developed for the radiographic study of the dynamics of primary phase formation using synchrotron X-rays in aluminium alloys and applies them to model alloys in which normally secondary minority IMCs, known to have a controlling effect on toughness and ductility, are contrived to appear directly from the cooling liquid as primary phase, unconstrained by any prior formation of a conventional primary phase. The formation and growth of two alloy classes are studied in detail: (i) Al-3wt%Fe in order to study the important β-Fe IMCs found in may commercial aluminium alloys, and (ii) an Al-Pt-Er model alloy chosen to have similar morphology IMCs to β-Fe but where the presence of Pt and Er enable the use of a novel pixellated spectrometer detector that spatially resolves the distribution of Pt and Er in the forming IMCs, and in the surrounding liquid. In the former alloy, a technique for estimating the formation temperature of every β-Fe IMC particle directly from the radiographic image sequences is also described.

Real-time observations are combined with detailed post-solidification microscopy including high resolution electron back-scatter diffraction (EBSD) to confirm similarities of the IMCs in both alloy systems, and to identify a common twin plane re-entrant (TPRE) growth mechanism. Extrinsic additions to the alloy such as grain refiners are also investigated to show how IMC formation dynamics and temperatures can be manipulated in a manner similar to that of α-Al dendrites. Examples are given of how the different data from these experiments can be fused to improve our understanding of the factors controlling the formation and growth of IMCs. These insights may ultimately allow better exploitation of the beneficial effects of IMCs on properties such as tensile strength, while minimising their detrimental effects on toughness and ductility, and so enable the development of “tolerant” processing of alloys to enable greater metal recirculation.

11:45 AM MT06.02.06
A Joint Machine Learning and Multi-Stage Thresholding Approach to Automated Dendrite Analysis within In Situ X-Ray Videos of Isothermal Equiaxed Alloy Solidification in Microgravity Jonathan S. Mullen, Mert Celikin and David Browne; University College Dublin, Ireland
The automated assessment of growing dendrites within in situ X-ray videos of alloy solidification can be vulnerable to errors stemming from the underlying traits of the frames provided. Specifically, the high degree of image difference between the start and the end of the observed process, along with factors such as noise and the effective shutter speed used, can lead to a reduction in assessment accuracy. The approach demonstrated here seeks to address and mitigate these issues through a combination of machine learning and multi-stage thresholding, balancing the adaptability of the former with the processing capabilities of the latter. This solution was developed and tested using a video of spatially isothermal, equiaxed solidification of a thin Al-20wt%Cu alloy sample during the 2015 MASER 13 sounding rocket microgravity flight within the on-board XRMON-SOL furnace.

SESSION MT06.03: Rapid Solidification and High Undercooling

1:45 PM *MT06.03.01
Dynamic Transmission Electron Microscopy for In Situ Studies of Irreversible Materials Processes Joseph McKeown; Lawrence Livermore National Lab, United States

The dynamic transmission electron microscope (DTEM) at Lawrence Livermore National Laboratory (LLNL) was developed to enable imaging of rapidly evolving, irreversible materials processes with nanometer spatial and nanosecond temporal resolutions. DTEM uses electron pulse trains generated by UV-stimulated photoemission to provide multiple (up to 9) image acquisitions across temporal ranges from hundreds of nanoseconds to microseconds, yielding frame rates that are on the order of 10^6 times higher than conventional in situ TEM frame rates. This pulse train is accomplished with a laser based on an arbitrary waveform generator (AWG) to shape laser pulses to square temporal profiles, producing a user-defined (pulse duration and spacing) UV pulse train that is delivered to the instrument’s photocathode to generate an electron pulse train. Each electron pulse captures an image at a specified delay time, and a high-speed electrostatic deflector directs each image to a different segment of a CCD camera. A multi-frame image (i.e., a movie) is obtained at the end of the experiment. Here, an overview of the DTEM instrument and its operation will be presented.

The majority of DTEM work has focused on imaging of microstructure evolution and precise measurement of kinetics during non-equilibrium phase transformations. As a representative example, studies of rapid alloy solidification (RS), in which solid-liquid interface evolution is monitored and the solidification dynamics are determined, will be discussed. RS occurs in numerous manufacturing processes, such as laser welding and additive manufacturing (AM). Recently, the growth of metals-based AM has led to renewed interest in developing predictive modeling capabilities to describe microstructure evolution under RS conditions (i.e., large deviations from equilibrium solidification due to high interface velocities). Calibration and validation of models to describe these non-equilibrium solidification conditions has proved challenging, largely due to the difficulties associated with acquiring in situ experimental measurements. DTEM results (measured interface velocity and morphology) will be presented in conjunction with efforts to calibrate and validate phase field models to describe RS.

Finally, future directions of research using DTEM will be discussed, with particular focus on efforts to develop an experimental platform to image microstructure evolution and defect formation and propagation during in situ high-strain-rate tensile testing of metals with the goal of understanding the dynamic mechanical properties of materials.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract No. DE-AC52-07NA27344. Portions of this work were funded by the Laboratory Directed Research and Development (LDRD) Program under project tracking code 18-SI-003.

2:15 PM *MT06.03.02
In Situ High-Energy X-Ray Diffraction Studies of Undercooled Solidification Jianrong Gao; Northeastern University, China
Liquid metals can be undercooled significantly below their melting temperatures and bring about formation of a rich variety of metastable microstructure. It is of fundamental and technical interest to understand thermodynamics and kinetics of undercooled solidification. In the past twenty years, solidification velocity-undercooling relationships in pure substances and alloys have been established by means of in situ observations of a traveling thermal front on the surface of the solidifying bulk liquid using a camera or a photodiode. Those relationships have been used to test various theories on rapid solidification and provided insights into metastable microstructure formation under non-equilibrium processing conditions. However, primary solids nucleated from the undercooled liquid may differ from those predicted by an equilibrium phase diagram suggesting metastable or even new solidification pathways. They are more often than never remelted or decomposed in a late stage of solidification or through solid-state cooling leading to difficulties in identification of their crystal structure and changes of solidification pathways. In situ monitoring of undercooled solidification using the time-resolved X-ray diffraction technique can ease these difficulties and provide critical knowledge of solidification pathways, stable or metastable, as well as ripening or decomposition of primary solids. In this talk, I shall present two examples of the use of this technique in in situ monitoring of non-equilibrium solidification of undercooled Nd–Fe–B and Co–Si alloys. In both alloys, metastable solids are formed at medium bulk undercoolings but are decomposed prior to completion of solidification of a bulk liquid. With such knowledge, microstructure formation in as-solidified samples can be well understood. I shall also talk about potential of this technique in advancing current understanding of other non-equilibrium solidification phenomena or in combination with other techniques.

In Situ Observation of Crystal Orientation Effect on Lamellar-Eutectic Solidification Microstructures in Thin Al-Al2Cu Samples Sabine Bottin-Rousseau; Sorbonne University, France

We present an in situ experimental study of crystallographic effects during nonfaceted eutectic growth in thin Al-Al2Cu samples. Thin (about 10 µm thick) near-eutectic Al-Al2Cu films were prepared by plasma sputtering on flat sapphire (Al2O3) substrates. The thin-sample geometry allows one to observe lamellar-growth patterns in real time without convection in the liquid. We used a reflected-light long distance optical microscope that focuses the contact surface of the metallic film with one of the transparent walls of the sample container during directional solidification.

We recall that in bulk solidification, in brief, the Al-Al2Cu alloy usually forms lamellar microstructures. The two eutectic phases are also known to present special, or heteroepitaxy crystal orientation relationships (ORs). Marked crystallographic effects, i.e., a dependence of the growth microstructure on the OR, have been reported for a long time in Al-Al2Cu. More recently, a theory of such crystallographic effects, which takes into account the anisotropy of the surface free energy of the interphase boundaries in the solid, has been proposed, and essentially validated by experimental and numerical studies using model systems [1-3]. This analysis casted light on the distinction that exists between a « floating » dynamics, which is characteristic of an essentially isotropic system, and a « locked » dynamics, during which the lamellae follow a direction that is determined by the OR-dependent anisotropy, and thus possibly grow inclined with respect to the thermal-gradient axis.

Our observations, combined with ex situ crystallographic analysis (X-ray diffraction and EBSD), provide additional evidence for this statement. We studied 8 different eutectic grains of large (typically 4 mm) lateral extension. Most of (7 out of 8) were of the locked type. At low velocity, that is when the lamellar spacing is larger than the sample thickness, the solidification dynamics is essentially 2D. In locked grains, the interphase boundaries appear then as straight lines under the optical microscope, and follow an essentially uniform locking direction. Here are our main findings: 1-Al2Cu crystals were not arbitrarily oriented with respect to the sample walls, namely, a {001} plane and a {100} plane were both nearly perpendicular to the sapphire plate (within 10°); 2-The apparent trace of the
interphase boundaries followed a direction that was systematically belonging to the \{100\} plane in question; 3-We found some reproducible ORs, but none of them were close to the so-called Beta-6 or Alpha-4 ones that are frequently found in bulk samples [4,5]. It seems therefore that a heuristic density criterion that was successfully invoked for predicting the prevailing coincidence planes in the In-In₂Bi eutectic alloy is of poor help in the present case [6]. Our results also raise new questions about the selection dynamics of the ORs during the early stages of eutectic solidification.

3:45 PM MT06.04.02
Emergence of Faceted Spiral Patterns During Eutectic Crystallization
Saman Moniri¹, Hrishikesh Bale², Tobias Volkenandt³, Yeqing Wang⁴,¹, Jianrong Gao⁴, Tianxiang Lu¹, Kai Sun¹ and Ashwin J. Shahani¹; ¹University of Michigan, United States; ²Carl Zeiss Microscopy Inc., United States; ³Carl Zeiss Microscopy GmbH, Germany; ⁴Northeastern University of China, China

Engineered self-organization presents a future approach to manufacture multi-phase materials with superior properties. In particular, non-equilibrium routes to emergent metastable states could unveil novel functionalities not present in equilibrium states. Herein, we demonstrate the spontaneous formation of metastable, two-phase spiral microstructures during crystallization of a eutectic alloy system. Despite recent reports of spiral self-assembly in both metallic and organic systems, the underlying growth mechanism remains elusive. To reveal the origin of spiral growth, we pursue a multiscale investigation encompassing 3D measurements – X-ray nano-tomography aided by machine learning and electron backscatter diffraction – along with in situ synchrotron X-ray diffraction and atomic-resolution electron microscopy. The results show that crystallographic defects within 'hidden' polytetrahedral phases provide a template for spiral eutectic crystallization. Our findings demonstrate the ubiquity of defect-mediated growth in multi-phase materials and establish a pathway towards bottom-up synthesis of 3D chiral microstructures beyond the scope of existing approaches.

4:00 PM MT06.04.03
Diffusion Controlled Dynamics of Faceted Solidification Front Patterns
Silvere Akamatsu¹,²; ¹CNRS, France; ²INSPI-CNRS-SU, France

During solidification of a faceted alloy, the growth shape of the crystalline solid is primarily determined by the strongly anisotropic mobility of the interface between the solid and the melt. In a given system, it is not rare to observe facets that grow extremely slowly at finite undercooling, and even appear "frozen" or "blocked" on the spatial scale of the optical microscope, and other ones that grow as fast as if they were atomically rough. During solidification of a dilute alloy, the interplay between such a facet growth kinetics and the diffusion of chemical species in the liquid is then very complex, and achieving a steady-state growth regime, if possible at all, depends critically on the orientation of the crystal and boundary conditions.

Here, we present an experimental study of faceted growth patterns in dilute transparent alloys. We used thin-sample directional solidification techniques that permit to control the orientation of large single crystals with respect to the setup, and observe the evolution of the solid-liquid interface in real time with an optical microscope as a function of the growth rate. We will successively consider two cases. First, in impure biphenyl, the platelike growth shape of the monoclinic crystals includes two low-mobility (001) facets and four high-mobility (110) facets. We found that if a thin crystal is oriented with the (001) facets parallel to the sample walls, steady faceted cells and dendrites form for solidification velocities \( V \) above the threshold \( V_c \) of the Mullins-Sekerka instability. Both acute-angle [100] and obtuse-angle [010] cells are observed. As previously predicted theoretically, the presence of mobile facets on both sides of the dendritic finger does not strongly affect the regular dendritic scalings. For \( V < V_c \), large single crystals undergo a plastic deformation during growth due to long-range thermal stresses. Second, we considered a cyano-bicyclohexane molecule called CCH4 in the scientific literature. In this system, the interface between a nematic liquid and the so-called smectic B phase (a historical, but misleading name that designates a hexagonal molecular-
crystal solid with both orientational and positional long-range orders) presents a single facet plane parallel to the basal plane of the hexagonal stacking. We could bring evidence that the facets have practically no mobility at undercoolings smaller than about 0.1 K. In configurations where the CCH4 molecular layers are perpendicular to the sample walls, but tilted with respect to the main solidification axis, we observed drifting shallow cells (V>Vc) and a type of solitary wave, called faceton (V<Vc). A faceton consists of a localized traveling pattern with an asymmetric faceted shape, which propagates laterally, along the solidification front, in a stationary or oscillatory way. This dynamics casts light on the microscopic growth mechanisms of the facets in this system. It also has some striking similarities with the growth dynamics of silicon polycrystals.

4:15 PM MT06.04.04
Effect of Subgrain Boundaries on Microstructure Evolution During Directional Solidification of Binary Alloys Kaihua Ji1, Fátima Mota2, Younggil Song1, Jorge Pereda2, Bernard Billia2, Nathalie Bergeon2, Rohit Trivedi3 and Alain Karma1; 1Northeastern University, United States; 2Aix-Marseille Université and CNRS, France; 3Iowa State University, United States

Alloy microstructures formed by directional solidification are often polycrystalline, made up of several large grains of different crystallographic orientations with respect to the temperature gradient. While strongly misoriented grains are generally eliminated at early stages of growth, grains with misorientations less than about 15 degrees can persist to late stages and form subgrain boundaries (SBs), which can influence microstructure selection by mechanisms that are still not well understood. Here we combine experimental, phase-field, and analytical methods to investigate the coupled spatiotemporal evolution of SBs and cellular array structures, including the selection of the primary spacing and the lateral drift velocity induced by the grain misorientation. Experiments were carried out in the DECLIC/DSI experimental set-up aboard the International Space Station where a transparent (Succinonotriile-0.24wt%Camphor) alloy contained within a 3D crucible is solidified under purely diffusive growth regime. The in situ observations exhibit both convergent and divergent SBs, where two grains drift laterally to converge on and diverge from each other, respectively. Near a convergent SB, grains usually inter-penetrate, and the primary spacing of cells decreases in a relatively short range as cells are suppressed and eliminated at the SB. Near a divergent SB, however, a peak accompanied by a long tail is observed in the spacing distribution along the direction normal to the SB. Meanwhile, a divergent SB drifts laterally with a non-trivial velocity comprised between the drifting velocities of individual grains. State-of-the-art phase-field simulations reproduce those novel phenomena observed in the microgravity experiments.

We further develop a discrete nonlinear advection-diffusion equation to describe quantitatively the spatiotemporal evolution of the primary spacing in the presence of SBs. Our results show that advection alone, previously found to describe well the spacing evolution within a single misoriented grain, is insufficient to model quantitatively this evolution in the neighborhood of spacing extrema caused by SBs. We find that incorporation of phase diffusion, which tends to uniformize the spacing, is essential to quantitatively predict both the spacing evolution near extrema and the apparent drifting velocity of SBs that is comprised between the drifting velocities of individual grains. The non-trivial prediction of this apparent velocity directly links phase diffusivity to an experimentally observable quantity. Those insights into polycrystalline directional solidification provide an improved basis for controlling alloy microstructures.

Grain Competition in Polycrystalline Columnar Dendritic Solidification—Scale Bridging by Handshake between Phase Field and Dendritic Needle Network Methods Amir Molavi, Kaihua Ji and Alain Karma; Northeastern University, United States

Dendritic microstructures are the most frequent among cast metallic alloys. Understanding their formation has been a problem of long-standing interest because of their profound influence on mechanical properties. During columnar solidification, spatially extended dendritic grains of different misorientations with respect to the temperature gradient growth competitively. This growth competition has been recently investigated using 2D and 3D phase-field simulations. The results have highlighted the limitation of using a traditional minimum undercooling criterion to predict grain selection and the importance of considering details of grain interactions. However, results to date remain limited to moderate growth rates and large temperature gradient that form weakly branched cellular/dendritic array structures. Here we report the results of a study that combines phase-field (PF) and the dendritic needle network (DNN) methods to investigate grain competition in the well-developed dendritic regime relevant for casting.
of concentrated alloys. The PF model of alloy directional solidification exploits a novel rotationally invariant finite-difference discretization of the anti-trapping current to accurately resolve the dendrite tip operating state of misoriented grains. PF simulations are used to investigate the growth dynamics of secondary and tertiary branches, which play a key role in grain competition. In turn, DNN simulations with branching parameters calibrated by PF simulations, are used to characterize experimentally measurable grain boundary (GB) trajectories on larger length and time scales and to construct GB orientation selection maps as a function of GB bi-crystallography. The results reveal how the grain competition on the macroscale is influenced by the sidebranching dynamics on the dendrite tip scale, which is itself controlled by the magnitude of crystalline anisotropy and noise amplification. Results are compared to available experimental data.

Mechanisms of Structure Formation in Ice-Templated Materials—Experimental Observations Kaiyang Yin1, Kaishua Ji2, Moises Silva1, Louise L. Strutzenberg3, Rohit Trivedi4, Fridon Shubitidze5, Alain Karma2 and Ulrike G. Wegst1; 1Dartmouth College, United States; 2Northeastern University, United States; 3Northwestern University, United States; 4NASA Marshall Space Flight Center, United States; 5Iowa State University, United States

The basis of freeze casting is a phase-separation-induced templating of a second phase (e.g. polymers or particles, or both). The process is complex, a large number of parameters determine the structure and properties of the resulting freeze-cast material: i) the chemistry of the solution or slurry system (e.g. polymer and/or particle composition and properties such charge, size and shape), ii) additives and impurities (and their effect on either the solvent, polymer or particles), iii) processing conditions (e.g. cooling rate, temperature field), and iv) the physics of the strongly anisotropic faceted growth of ice. Empirically over the past 15-20 years, strategies have been developed to control some of these parameters in an attempt to custom-design and manufacture in a single processing step materials over several length-scales. However, while many different materials compositions have been investigated over the years — e.g. ceramic- and metal-based systems, both typically processed with the addition of polymeric dispersants and binders, and polymeric ones, both fibrillated and "smooth" — few have been analyzed with the intent to gain a better understanding of the mechanisms by which the ice crystal growth drives structure formation and self-assembly processes. The latter is what we attempt in this study.

Collating structural features found in the cell walls of freeze-cast ceramics (platelets versus particles), fibrillated biopolymers (collagen, nanocellulose), and "smooth" biopolymers (chitosan, trehalose), we can capture the ice crystal growth process and analyze it "post-mortem." Further assessment of the cell-wall structure using a variety of characterization techniques provides unique insights into the effects and their significance on cell wall assembly of anisotropic ice crystal growth, shear flow generated by the volumetric expansion of ice, and other forces, such as those exerted by the mold, for example. Combining these experimental observations with 3D Phase-field simulations of structure formation in ice-templated materials, detailed in a companion presentation, it becomes possible to gain fundamental science insights and obtain the desired structure-property-processing correlations not only at the more traditional macroscopic, but also at the meso- and microscopic scales.

Analysis of Strain Aging of Steel Sheets by In Situ Electrical Resistance Measurement Mai Nagano1, Kotaro Hayashi1 and Masato Ueda2; 1Nippon Steel Corporation, Japan; 2Kansai University, Japan

The observation of the dynamic dislocations-carbon atoms interaction is important in the steel material design. BH steel sheets are bake hardened in the manufacturing process. It is said that solute carbon atoms are segregated in dislocations after bake hardening. Solute carbon atoms are observed by atom probe method [1]. However, there are few examples observed directly including the behavior of dislocations after bake hardening. An electrical resistance measurement method is able to observe both the solute carbon atoms and the state of dislocations [2]. The electrical
resistivity measurement can not only be measured on bulk samples, but also the in-situ measurement of the process of deformation after pre-deformation, baking, and hardening after baking. In this study, we developed in-situ measurement methods of electrical resistance in the bake hardening test. And we considered the metallurgy of BH steel sheets in the process of thermomechanical treatment of BH steel sheets.

Cold rolled sheets of Fe-0.02 mass% C-0.1 mass% Mn alloy, Fe-0.002 mass% C-0.1 mass% Mn alloy, and Fe-0.002 mass% C-0.1 mass% Mn-0.03 mass% Ti alloy were prepared. The respective alloys are called carbon steel, low carbon steel and ultra-low carbon steel. These cold rolled sheets were held at 1073 K for 120 seconds and then water cooled. From the test steel, a tensile test specimen with a load axis perpendicular to the rolling direction was cut out. The length of the gauge portion was 50 mm and the width was 2 mm. In tensile deformation, the electrical resistance of each specimen was measured at room temperature. In order to measure the electrical resistance of the test piece only, the test piece was electrically isolated from the device and the electrical resistance was measured in distilled water ice water. When tensile deformation was applied, the stroke speed was 0.25 mm / min. The electrical resistance was measured at a current value of 100 mA by the four-point DC method. In addition, after pre-deformation was applied to some of the test pieces as the bake-hardening treatment, the test pieces were immersed in a bath furnace at 443 K for 20 minutes. After that, the electrical resistance of the same test piece was measured again in tensile deformation.

The structure after water cooling was observed with an optical microscope, and the carbon steel was a composite structure of pearlite and ferrite. Low carbon steel, ultra-low carbon steel has ferrite structure. The average grain sizes of carbon steel, low carbon steel and ultra-low carbon steel were 11 μm, 17 μm and 16 μm respectively.

In carbon steel, the electrical resistance was measured during tensile deformation before bake hardening. As a result, the stress increased with the increase of stroke and the electrical resistance. The gradient of electrical resistance to stress is different in elastic deformation, Lüders deformation, and uniform plastic deformation area. The gradient of the electrical resistance to stress is called a stress-electrical resistance factor. The stress-electric resistance factor is larger in the order of Luders deformation, uniform plastic deformation and elastic deformation. In addition, the electrical resistance during tensile deformation was measured for the sample that had undergone the bake hardening process. As a result, the stress-electric resistance factor after the end of elastic deformation increased more rapidly than the pre-deformation. The increase in electrical resistance may correspond to the increase in lattice defects and the solute carbon concentration.

Thus, we developed a series of methods to measure the electrical resistance in situ in the bake-hardening test, and it became possible to capture microscopic information on the structure of dislocations and solute carbon atoms.

Effect of Solid-State Diffusion on Morphological Evolution During Liquid Metal Dealloying Longhai Lai and Alain Karma; Northeastern University, United States

Liquid metal dealloying (LMD) is a novel technique to produce nano-/meso-scale composite and open nanoporous structures with ultra-high interfacial area for diverse applications. This method exploits the selective dissolution of one element of a binary alloy into a metallic melt. Previous experimental and modeling studies have revealed that the kinetics of LMD is diffusion limited and that interfacial pattern formation can be understood in the framework of interfacial spinodal decomposition and diffusion-coupled growth. However, quantitative discrepancies exist between experiment and modeling predictions. Here, we report the results of a phase-field modeling study that reveals a surprisingly strong influence of solid-state diffusion on dealloying morphologies. Even though the solid-state diffusivity is four to five orders of magnitude smaller than the liquid-state diffusivity, it is found to stabilize the diffusion-coupled growth of lamellar structures, thereby favoring the formation of this aligned structure over high-genus topologically connected structures. The results also reveal that solid-state diffusion enables the solid-liquid interface to relax to local chemical equilibrium, thereby influencing the concentrations of alloy elements on the liquid side of the interface and in turn morphological evolution. We also present long-time simulations of dealloying kinetics that shed light on the origin of existing discrepancies between modeling and experiment.

X-Ray Photon Correlation Spectroscopy Studies of Spinodal Decomposition in TiO2-VO2: Epitaxial Thin Films Jeffrey A. Eastman1, G B. Stephenson1, Carol Thompson2, Matthew J. Highland1, Jyotsana Lal2, Irene Calvo-
Almazán¹, Hoydoo You¹, Yue Cao¹ and Hua Zhou¹; ¹Argonne National Laboratory, United States; ²Northern Illinois University, United States

TiO₂-VO₂ alloys are known to undergo spinodal decomposition when cooled below 557°C at a critical composition of 34 mol % Ti.¹ Since the misfit between the rutile-structured TiO₂ and VO₂ lattices is significantly smaller along the a-axis than along the c-axis of the tetragonal unit cell, annealing samples in the spinodal region of the phase diagram results in development of a composition modulation along the [001] direction, with an average quasi-periodicity varying from 15-50 nm, depending on composition and annealing conditions.¹,² Since the VO₂-rich regions of the resulting nanostructure exhibit a metal-insulator transition and a correspondingly large change in magnetic susceptibility near room temperature, while the TiO₂-rich regions remain insulating at all temperatures and exhibit very different optical behavior than VO₂-rich regions, these alloys are of interest as possible tunable metamaterials.² Full control of the synthesis of such metamaterials requires detailed understanding of their phase separation behavior as functions of temperature, composition, epitaxial strain, and surface orientation. To obtain this information, we recently initiated an x-ray photon correlation spectroscopy (XPCS) study of epitaxial TiO₂-VO₂ alloy thin films. XPCS is a coherent x-ray technique that can provide unique insight into the dynamical behavior of materials. Films with controlled composition, thickness, and surface orientation are grown epitaxially on TiO₂ substrates. Samples are illuminated with a partially coherent monochromatic x-ray beam at Sector 12-ID-D of the Advanced Photon Source. The time- and Q-dependences of the diffuse intensity that develops along [001] directions near Bragg reflections during spinodal decomposition are monitored in situ, while annealing samples. At temperatures in close proximity to the critical temperature for phase separation we are attempting to characterize equilibrium composition fluctuations for the first time in a crystal with a conserved order parameter (Model B in the notation of Hohenberg and Halperin³). At somewhat lower temperatures, e.g., 400°C, XPCS can reveal new information on atomic-level dynamics as the sample undergoes spinodal decomposition. Closer to room temperature, the metal-insulator transition associated with a tetragonal-to-monoclinic phase transition provides another opportunity to use XPCS to observe equilibrium critical fluctuations.

In Situ TEM Investigation of the Electroplasticity Phenomenon in Metals Xiaqing Li¹,², Andrew M. Minor¹,², John Turner², Rohan Dhall² and Karen Bustillo²; ¹University of California, Berkeley, United States; ²National Center for Electron Microscopy, United States

Electroplasticity (EP) is a phenomenon in which applied pulsed electric fields during deformation result in increased formability in metals. This phenomenon has been studied since the 1950’s [1] and researchers have proposed two possible origins of this nearly-universal effect: (1) localized Joule heating at lattice defects and (2) the electron wind effect leading to vacancy migration [2]. However, there is no clear evidence of the true origin of this behavior at the level of individual defects [3]. In this work, in situ Transmission Electron Microscope (TEM) electromechanical tests were performed in order to correlate direct observations of dislocation motion with both mechanical data and applied electrical pulses in an effort to provide clarity on the true origin of this interesting phenomenon.

In this study we have systematically studied the way electrical fields alter the structure and mobility of dislocations in Ni. The controlled electromechanical experiments were performed during in situ testing in a JEOL 3010 TEM, an electrical push-to-pull device (E-PTP) and a Bruker, Inc. Picoindenter with Nanoscale Electrical Contact Resistance (nanoECR). Specific loading and observation directions were selected for the specimens, which were attached via focused ion beam (FIB) lift-out to the E-PTP device. The specimens were deformed uniaxially in tension with the motivation to correlate dislocation behavior and applied current pulses. A sequence of tests was carried out by load control and with variable electrical current pulsing during the mechanical test.
After each test, videos of the dislocation behavior could be directly compared to the electrical and mechanical data. Our initial studies resulted in two types of dislocation motion. The first type of motions happened in less than 0.1 sec where pre-existing dislocations escaped from the sample upon pulsing. The other type of motion was slower, with dislocations remaining in the sample for more than 1 second. In the latter case, dislocation motion could be observed through several consecutive steps.

Our observations found that during plastic deformation, relatively large slip traces with dislocations nucleated from the edges could be triggered by the pulses, contributing to large displacement increases in the sample. One example of dislocation motion in Al shows the motion of a dislocation could be correlated directly with the applied current when it was turned on, which can be explained by small changes in the applied electrical current that enabled the dislocation to overcome barriers. In addition, dislocations tend to move with a faster speed and a longer distance during the pulsing period, compared to the purely mechanically-triggered movement. We will also discuss results such as these in the context of local joule heating which can be measured indirectly through expansion of the lattice measured using TEM diffraction.

It is our ultimate goal to quantitatively measure the strain fields and local lattice change around dislocations to understand the external current effects in the plastic deformation of metals and alloys. Comparisons between the lattice strain fields, dislocation behavior and applied electric filed will provide valuable data to further improve atomistic models describing the dislocation motion change with electroplasticity. These experimental and theoretical frameworks will provide a scientific foundation for the design and optimization of alloys with enhanced electroformability for targeted manufacturing applications.

MT06.05.05
Laue Microdiffraction Measurements in Directionally Solidified Al-Al2Cu Eutectic Microstructures in Thin Samples Mehdi Medjkoune; Sorbonne Université, France

We present the first study by Laue microdiffraction (LMD) of the crystal orientation relationships in lamellar microstructures obtained by thin-sample directional solidification of the eutectic Al-Al2Cu alloy. The two eutectic phases are the Al-rich cubic solid solution (α) and the tetragonal intermetallic Al2Cu (θ). Thin Al-Al2Cu samples (12 µm thick) were fabricated by plasma sputtering on a clean, optically flat, sapphire single crystal. Eutectic growth was performed in our laboratory by using standard directional solidification (DS) at constant velocity in a fixed temperature gradient, and rotating directional solidification (RDS). The RDS method allows one to rotate the sample with respect to the temperature gradient, and therefore vary continuously the orientation of the eutectic solid during solidification. Both DS and RDS setups are equipped with a long-distance optical microscope for real-time observation of the growth front. Laue microdiffraction has been carried out ex situ on the BM32 beamline of the European Synchrotron Radiation Facility (ESRF) in Grenoble, France. In this technique, a thin “white” x-ray beam (typically 5 to 22 keV) of lateral extension in the 100 nm range is sent to the surface of the sample. Selected areas (typically 100X100 µm²) were investigated by using a step-wise scanning motion of the sample holder. At each position (sample pixel) the camera detector records a full Laue pattern, which includes diffracted spots emitted by the metallic film and the sapphire substrate (nondestructive method). The signal coming from the sapphire single crystal was observed to remain unchanged during a scan. The alternation of the aand q lamellae could be clearly seen, and the corresponding sets of diffraction spots univocally indexed.

We investigated 5 samples containing each 2 to 3 large eutectic grains. Here, we will mainly focus on a reference sample that has also been investigated by x-ray diffraction (XRD pole figures) and EBSD. That sample contained three distinct eutectic grains of the so-called locked type. Our XRD, EBSD and LMD results are in full quantitative agreement with each other: 1-In the three grains, the Al2Cu crystals are oriented with a(100)θ plane nearly parallel, and the (001)θ plane nearly perpendicular to the sample wall; 2-The distinct crystal orientation relationships (ORs) that we could identified in the three grains (and in the other samples) are different from those that are most commonly found in bulk Al-Al2Cu samples; 3- There are strong indications that the interphase boundaries follow a (010)θ plane, independently of the OR. As a main conclusion, we found that the structure of the Al2Cu phase dominates the determination of the free energy of the interphase boundaries, and selects the lamellar growth direction. Further investigations will be needed for elucidating the OR-selection mechanism at play (nucleation, grain competition). Finally, LMD measurements can be used to measure the mosaicity of the crystals. This work is in progress.
3D Phase-Field Simulations Explain Experimental Observations of Structure Formation in Ice-Templated Materials

Kaihua Ji¹, Kaiyang Yin², Louise L. Strutzenberg³, Rohit Trivedi⁴, Fridon Shubitidze⁵, Ulrike G. Wegst⁵ and Alain Karma¹; ¹Northeastern University, United States; ²Dartmouth College, United States; ³Marshall Space Flight Center, United States; ⁴Iowa State University, United States

Recent improvements to quantitative phase-field simulations now make it possible to model microstructure formation in three dimensions (3D) on experimentally relevant length and time scales, but quantitative modeling remains so far limited to materials that solidify with atomically rough non-faceted solid-liquid interfaces such as metallic alloys and transparent analogs. We developed a quantitative phase-field formulation for the faceted ice-water system with anisotropic solid-liquid interface energetic and kinetic properties calibrated against existing experimental observations of free dendritic growth of pure water under microgravity conditions. Using 3D phase-field simulations of directional solidification of water with a dilute impurity, we reproduce for the first time salient features of freeze-cast templated structures including the formation of lamellae and undulated ridges. The formation of ridges is shown to be caused by the breakdown of ice platelets, which grow in between lamellae in the basal plane of ice, into linear arrays of cells with rounded tips. The cell spacing determines the ridge spacing and undulations are generated by secondary oscillatory instabilities of cell growth. Our results highlight the crucial role of the anisotropy of both the solid-liquid interface free-energy and the interface kinetics in structure formation. They also demonstrate that other potentially important physical effects neglected in the phase-field model, such as fluid flow generated by the expansion of ice, may play a more secondary role in structure formation. The value of such 3D phase-field simulations is immense since they enable us to investigate little studied and not yet modeled mechanisms of hierarchical microstructure formation and cell wall material self-assembly, both of which define anisotropy, property profile, and overall performance of freeze-cast materials. A companion presentation highlights the experimental results that motivate our work.

Tracking the Initial Stages of Grain Boundary Formation in Bi₂O₃-Doped ZnO Polycrystalline Materials—Dynamics and Structures

Marcelo A. Martinho, Gabriel D. Rocha, Marco Aurelio L. Cordeiro and Edson R. Leite; Federal University of São Carlos, Brazil

Owing to the structural and chemical nature of polycrystalline materials, grain and phase boundaries play a fundamental role in these materials properties by tailoring desired material features (e.g., mechanical, electrical, optical properties). In spite of the evident importance, the basic understanding of these interfaces is still in its beginning, and lacks an essential correlation of its structure and materials properties. In order to provide fundamental insights into the structure and chemical nature of the grain boundary in oxides, grain boundaries of Bi₂O₃-doped ZnO polycrystalline materials in earlier sintering stages were analyzed by Aberration-corrected Transmission Electron Microscopy (FEI Titan Themis Cubed TEM operating at 300kV), where inelastic electrons from the beam were used as a source for mild temperature increasing in the system. Polycrystalline Bi₂O₃-doped ZnO samples were produced by solid-state synthesis route, consolidate by simple uniaxial pressure and sintered at 1100 °C for 2 hours. By using a Helios Nanolab Dualbeam 660 (Thermo Scientific), grain boundaries were identified and prepared in thin lamella form, which were studied by TEM. The first feature observed is the Bi-rich (nano)interphase region, where several atomic organizations could be identified. These structures formation was correlated to the complexions (phase-like behavior) [1,2] and their neighboring crystals orientation. Besides, during the analyses, electron beam promoted mild temperature increasing in the sample, which was enough to induce Bi migration, which was possible to observe at atomic resolution and real-time. According to the time-resolved images, the Bi diffusion followed a chemical potential gradient path over the sample, i.e. from higher (bulk) to lower (grain boundary region) chemical potential gradient, inferring it was the driven force for the phenomenon. Moreover, the temperature increasing promoted the Bi-rich phase acting as a liquid-like behavior on the sample surface, following the same chemical potential gradient path over the sample. The interface between ZnO crystals and Bi-rich interfaced also played an important role in the dynamics, where the Bi atoms could crystallize (oxide form) and then incorporated to the grain boundary region. Hence, by following the myriad of phenomena at atomic scale and real-time, this study demonstrates the complexity of grain boundary formation and provides new venues towards the development of advanced materials by grain boundary engineering.

We follow an Al-12\%at.pct Cu alloy sample from the liquid state to mechanical failure, using in situ X-ray radiography during directional solidification and tensile testing, as well as three-dimensional computed tomography of the microstructure before and after mechanical testing. The solidification processing stage is simulated with a multi-scale dendritic needle network model, and the micromechanical behavior of the solidified microstructure is simulated using voxelized tomography data and an elasto-viscoplastic fast Fourier transform model. This study demonstrates the feasibility of direct in situ monitoring of a metal alloy microstructure from the liquid processing stage up to its mechanical failure, supported by quantitative simulations of microstructure formation and its mechanical behavior.
dislocation density, texture, stress field, etc. These two in situ/operando synchrotron diffraction techniques can not only help us understand the unique microstructures of AM materials, but also enable many other exciting research opportunities. These include, but not limited to, the establishment of precise time-temperature-transition diagrams (particularly in the time domain below ms) of structural and functional alloys, and the development of kinetics-driven synthesis routes for novel metastable alloys with hierarchical microstructures and tailored functionalities.

In Situ Observation of Laser Additive Manufacturing with High-Speed X-Ray Diffraction Seunghee Oh1, Joseph Pauza1, Christopher Kantzos1, Joseph Aroh1, Rachel Lim1, Sidi Feng1, Andrew Chuang2, Niranjan Parab2, Cang Zhao2, Tao Sun2, Robert M. Suter1 and Anthony D. Rollett1; 1Carnegie Mellon University, United States; 2Argonne National Laboratory, United States

Laser powder bed fusion (LPBF) is a standard technique in additive manufacturing (AM) of metal because of its capability to build complex and precise parts. The laser-based processing is accompanied by rapid heating and cooling, and abrupt changes in phase and structure. Applying the high-speed synchrotron X-ray diffraction of the Advanced Photon Source (APS) provides essential insights into AM processing. In this study, we used high energy monochromatic X-rays and a high-speed Pilatus detector to probe the dynamics of the rapid evolution of the microstructure of AM metals under laser exposure. Various physical phenomena, including phase transformation, thermal effects, and evolving microstructure, are quantified using high-resolution x-ray diffraction. Based on the temperature and phases present, the Bragg rings expand, broaden, vanish, and re-appear. We have applied this in-situ synchrotron x-ray technique to various materials, including Al-, Ti-, Fe-, and Ni-based alloys. In Ti-6Al-4V, phase transformation between liquid, HCP α phase, and BCC β phase can be clearly identified. Movement of the (110) peak of BCC during the transformation indicates recalescence caused by the exothermic process from BCC to HCP. Although the phase composition is generally as expected from the relevant phase diagram, the kinetics often vary from typical experience. In Inconel 718, e.g., precipitate formation takes place within a few milliseconds after solidification, which conflicts with standard TTT diagrams. The in-situ analysis shows that a few milliseconds are enough for Laves and carbide phases to form. The temperature of specimens is also inferred from the coefficient of thermal expansion (CTE) and the instantaneous lattice parameter(s) value. In addition, high-speed X-ray in-situ imaging technique provides geometric information on vapor cavities, melt pools, and cracking. The coupling of these two in-situ techniques will improve our understanding of the physics underpinning metal LPBF process.

9:30 AM MT06.06.03
In Operando Direct Metal Laser Printing of Ti6Al4V During X-Ray Diffraction Samy Hocine1,2, Sin Ting Cynthia Chang2, Daniel Grolimund3, Nicola Casati4, Steven Van Petegem2 and Helena Van Swygenhoven-Moens1,2; 1École Polytechnique Fédérale de Lausanne, Switzerland; 2Paul Scherrer Institute, Switzerland; 3PSD/MicroXAS Paul Scherrer Institute, Switzerland; 4PSD/MS Paul Scherrer Institute, Switzerland

Laser based additive manufacturing allows building layer by layer a designed shape offering versatility and flexibility to many metallurgical sectors. The obtained microstructures depend however strongly on the laser and scanning parameters. Trial-and-error methods to determine the optimal SLM processing parameters for a desired microstructure are time consuming. Numerical modeling approaches can help predicting and understanding the role of individual parameters, but because of the multiple length and time scale character of the physical processes involved, the models become rapidly very complex.

To speed up the selection of parameters, to help validating computational models and to improve our understanding on the link between process parameters and microstructure in SLM, we have developed a miniaturized SLM device (MiniSLM) that allows printing 3D samples during synchrotron X-ray diffraction. The design of the SLM device was driven by specific requirements that are related to its implementation at synchrotron beam lines; the requirement to be portable and to be small and light enough to fit at various beam lines. Furthermore, the X-ray beam needs direct access to the powder bed, minimizing interference with absorbing or diffracting material. The constructed MiniSLM has all basic functionalities of commercial available SLM machines.

We report on Ti-6Al-4V samples that were manufactured in operando during X-ray diffraction at the MicroXAS and MS beamlines of the Swiss Light Source. By varying the laser power, scanning speed and hatch distance, various energy densities were obtained. The dynamics of the alpha and beta phases during fast heating and solidification are
tracked with a time resolution of 50µs. We reveal the influence of laser and scanning parameters on the temperatures reached during the process, the cooling rates of α and β phases and the duration the β phase exists during processing. By performing experiments with different scanning strategies including those required for making open lattice structures, we demonstrate that printing of short scan lines, as used in an island scanning strategy, result in coarsening of the prior β grains, lowering of the cooling rates after solidification, and therefore leading to a substantial different microstructure.

The time resolved measurements obtained from in operando xray diffraction provides information averaged over the volume probed by the x-ray beam (varied between 40µ and 200µ). We demonstrate how the in operando results can be used for validation of FEM-based models. Tuning the xray beam profile to the mesh size or vice versa, will optimize the synergetic aspect.

9:45 AM *MT06.06.04
Fast Synchrotron Imaging of Force Regime Transition in Arc Weld Pools
Fan Wu¹, Ken V. Falch¹,², Michael Drakopoulos³,⁴ and Wajira Mirihanage¹; ¹The University of Manchester, United Kingdom; ²Deutsches Elektronen-Synchrotron, Germany; ³Diamond Light Source, United Kingdom; ⁴Brookhaven National Laboratory, United States

Welding is considered as the most efficient and economical route for joining metals. In fusion welding processes, metals coalesce via extremely rapid melting and subsequent solidification. The melt pool evolution during this melting and solidification sequence determines formation of the final weld joint shape, microstructure and defects. So that scientific insight on weld pool evolution and related phenomena is vital to enhance structural integrity and resilience of the welded structures or components. However, inherent complexity with multi-physics phenomena, associated high temperatures and the rapidness of the welding processes make direct experimental investigations extremely demanding. In this contribution we report the observation of solid-liquid-solid phase transformation and related melt pool dynamics that take place during electric arc welding, obtained through in situ synchrotron imaging at millisecond scale. The analysis flow patterns along with the quantified weld pool surface dynamics revealed us to how different contributing forces dictate the flow conditions over the distinct durations of the relatively short existence of the liquid phase. Our preliminary results suggest the existence of arc, surface tension and gravity dominant regimes during the evaluation of the weld pool. Further, we present our observations on how different welding parameters influence these regimes and develop into different transient conditions.

Towards Multiscale Observations of Dynamics in Polycrystalline Microstructures—High Energy X-Ray Diffraction Microscopies
Robert M. Suter; Carnegie Mellon University, United States

High energy x-ray diffraction microscopies make possible the in-situ observation of internal microstructural evolution during processing in a wide variety of polycrystalline materials. Using distinct but compatible methods, length scales from millimeters to tens of nanometers can be accessed. Currently, crystalline grain unit cell orientations and strain fields are mapped over cubic millimeter volumes using high energy diffraction microscopy (HEDM). Bragg coherent diffractive imaging (BCDI) is sensitive to Angstrom scale atomic displacement fields that are resolved to a few tens of nanometers inside nano-particles; individual dislocations and their motions have been resolved. Dark field x-ray microscopy (DFM) also is able to image individual defects and their motions. Soon to come upgrades to synchrotron radiation facilities such as the Advanced Photon Source and the European Synchrotron Radiation Facility will accelerate and broaden the applicability of these techniques while also posing significant data volume challenges. Current efforts seek to combine these capabilities to allow mapping macroscopic volumes of a sample at micron resolution and then to zoom in on chosen regions of interest for studies of underlying
nanoscale dynamics. Such multiscale measurements have the potential to lead to development of validated multiscale models that are based on fundamental mechanisms and therefore can be predictive rather than being tailored to a specific sample. This talk will present an overview of experimental methods and their capabilities and progress towards integration. Example applications to in-situ studies of mechanically and thermally induced evolution will be demonstrated.

11:00 AM MT06.07.02

X-Ray Reflectivity with a Twist—Quantitative Time Resolved X-Ray Reflectivity Using Monochromatic Synchrotron Radiation

Howie Joress1,2, Shane Q. Arlington3, Timothy P. Weihs3, Joel D. Brock2 and Arthur R. Wolf1; 1National Institute of Standards and Technology, United States; 2Cornell University, United States; 3Johns Hopkins University, United States

We present our work on the development, demonstration, and application of a new method of quantitative time resolved specular x-ray reflectivity (XRR) for use with monochromatic synchrotron radiation. Our method utilizes a polycapillary x-ray optic to create a convergent beam, illuminating the sample surface with x-rays over a range of incident angles. An area detector collects scattered intensity over a range of exit angles. By altering the geometry, rotating the sample normal out of the plane of the incident beam, we can greatly reduce the effect of diffuse scatter, significantly improving the quality of the measured XRR compared to previous convergent beam XRR methods. We demonstrate our technique with time resolution up to 10 ms and show XRR with intensity over 5 orders of magnitude with $q_z$ resolution sufficient to measure Kiessig fringes from films as thick as 105 nm. Our optic, with a working distance of 22 cm, makes this measurement compatible with many in situ processes. After demonstrating this method, we applied it to the study of interdiffusion in metal-metal multilayers. By measuring the intensity of the first multilayer diffraction peak during rapid sample heating at up to 90 °C/s, we were able to extract the activation energy for interdiffusion in an Al/Ni multilayer system.

In Situ Thermal Cycling in TEM of an Additively Manufactured Steel

Manas V. Upadhyay1, Eva Héripré2, Alexandre Tanguy1, Sylvain Durbecq1, Lluis Y. Cardona2, Thien-Nga Lê1 and Simon Hallais1; 1LMS, CNRS, Ecole Polytechnique, Institute Polytechnique de Paris, France; 2Laboratoire MSSMat, UMR CNRS 8579 CentraleSupélec, Université Paris-Saclay, France

Additive manufacturing (AM), also known as 3D-printing, of metals and alloys involves reading a 3D part geometry from a computer-aided design file and building it in a layer-by-layer manner by locally melting the material using a moving heat-source (laser or electron beam). Based on the material feeding approach, metal AM processes can be divided into: (a) direct energy deposition (DED) and (b) powder-bed fusion methods. In DED, the feedstock material in powder/wire form is directly fed into the heat-source as it scans the build surface whereas in PBF, the powder feedstock is deposited onto a powder-bed between two successive layer scans. For both processes, the final as-built part contains surface and volumetric defects, and a heterogeneous non-equilibrium microstructure. These phenomena depend on the AM process parameters, composition of the feedstock, and the desired final part geometry which together determine the material properties, the residual stresses and the subsequent part performance. AM holds the potential to revolutionize the metal and alloy manufacturing sector through its ability to simultaneously synthesize the material from powder/wire form and manufacture the desired part geometry without the need of tooling.

In recent years, increasing number of research efforts are being dedicated to better understand, control and improve the process-microstructure-properties-performance relationship of AM metals and alloys. However, nearly all experimental and modeling efforts in this field have been directed towards studying the heat-matter interactions in the melt-pool and rapid solidification. While these are important topics to study, it is equally important to understand the microstructure evolution in the heat-affected solid zone which undergoes thermal cycling. Consider the layer-by-layer building of a single-track (one heat-source scan per layer) wall and focus on the material at a point X on a deposition layer \(L(>1)\). Immediately after the localized deposition, the material at X cools down at a very high temperature rate (ranging from \(10^3\) to \(10^6\) °C/s). Addition of more layers (i.e. \(L+1, L+2, \ldots\)) results in thermal cycling at X with varying temperature rates and amplitudes. The transient thermal gradients result in the formation of high-amplitude cyclic thermal stresses which must affect the microstructure at X, for example, through dislocation density evolution, recrystallization, precipitation, etc. At later stages of thermal cycling (i.e. during deposition of layer \(N >> L\)), a steady-state heat transfer could occur at X resulting in additional microstructural...
changes. Furthermore, material points at different locations in the as-built part are subjected to different thermal histories resulting in heterogeneous microstructural evolution. To our knowledge, there have been no coherent studies dedicated towards understanding the microstructural evolution during thermal cycling of the material. The main difficulty is tracking the microstructural changes in-situ during the AM process.

In this study, we are particularly interested in understanding the microstructural changes at the intragranular length scale due to thermal cycling during the AM processing of 316L stainless steel. Instead of following the building of this steel inside the AM processing chamber, we thermally cycle TEM lamellae inside a transmission electron microscope and follow their evolution in-situ. The lamellae are prepared from the material synthesized during the building of a wall of 316L stainless steel using a Laser Metal Deposition machine (a DED process). Once inside the TEM, the lamellae are subjected to the temperature vs time history obtained from thermal measurements at a given point-of-interest on the 316L wall during its processing. This thermal cycling results in some very interesting changes in the microstructure which will be presented during this talk.

Influence of Controlled Cooling Rates During Thermomechanical Processing of Ti 6%Al 4%V Alloys Using In Situ Scanning Electron Microscopy Genevieve A. Kane, M. David Frey, Daniel Lewis and Robert Hull; Rensselaer Polytechnic Institute, United States

We describe novel experimental approaches to examine the microstructural evolution of Ti 6%Al 4%V upon cooling from above the beta transus (~995 °C) while imaging in the scanning electron microscope. Ti 6%Al 4%V is a two phase, α+β titanium alloy with high strength and corrosion resistance. The existence of the α/β transformation gives rise to different microstructures and properties through various thermomechanical treatments. Fully lamellar microstructures, bi-modal microstructures, and equiaxed microstructures can each be obtained by accessing different cooling rates upon the final treatment above the beta temperature, each resulting in uniquely enhanced material properties.

Utilizing the capabilities of a heating/ tensile stage developed by Kammrath & Weiss Inc., that also incorporates in-situ nano-indentation capability, we are able to apply real-time imaging techniques in the scanning electron microscope to monitor and control the development of the microstructure. Annealing temperatures up to 1100 °C are attainable, with cooling rates ranging from .01 ° C per second to 4 °C per second. This has allowed us to directly observe the formation of lamellae at different annealing temperature/ cooling rate combinations to determine the lamellar microstructure width, separation, and colony size.

Applying a cooling rate (0.1 °C per second) to samples annealed to 1100 °C showed that lamellar microstructures initiate and form within alpha colonies at temperatures of ~ 920-930°C. When held at the temperature where lamellar formation initiates, the lamellae continue to propagate and lengthen by 50% from their initial length in two minutes time throughout the parent grains. Upon further cooling, the lamellae widen from 3.5- 7 µm to 8-15 µm. Extensive analysis of lamellar microstructure formation and growth will be presented, comparing different temperature regimes, cooling rates and times at temperature.

The ability to further refine thermomechanical processing conditions allows for an assessment of mechanical properties associated with the presence of both phases, and their final microstructure, particularly given the in-situ indentation capabilities available in our system. As such, the ability to deconvolute temperature and time considerations in the formation of lamellar and also bi-modal microstructure is vital, and will be discussed in detail during this presentation.

Acknowledgments: This research is sponsored through grants from the National Science Foundation, Awards CMMI-1647005, and CMMI-1729336. This work was performed with the use of clean room and characterization facilities within the Center for Materials, Devices and Integrated Systems at Rensselaer Polytechnic Institute. We also acknowledge collaborations with Dr. Antoinette Maniatty, Dr. John Wen, Arun Baskaran, Sagar Bhatt, Anant Kekre, and Michael Allahua. Additionally, we acknowledge the help and expertise of Kammrath and Weiss with equipment development.

The Synergy of Tomography and Simulation—A Method to Determine Grain Boundary Properties Jin Zhang¹, Henning Poulsen² and Peter W. Voorhees¹; ¹Northwestern University, United States; ²Technical University of Denmark, Denmark

An approach is proposed to measure grain boundary properties by comparing the evolution of experimentally determined 3D grain structures to that derived from simulation. Grain evolution in pure iron is determined in three dimensions and as a function of time using diffraction contrast tomography at a synchrotron source. The temporal evolution of over 1300 grains is quantified. This provides information on the morphology and kinetics of a large number of grain boundaries in a single experiment. Using a time step from these data as an initial condition in a phase-field simulation, the computed structure is compared to that measured experimentally at a later time. An optimization technique is then used to find the reduced grain boundary mobility that yields the best match of the simulated microstructure. We find a strong variation of the reduced mobility for a given grain boundary misorientation. A strong dependence of the reduced mobility on location in Frank-Rodrigues space is also observed.

2:00 PM MT06.08.02
The Dynamics of Abnormal Grain Growth in a Particle-Containing System—New Insights from Multimodal Three-Dimensional X-Ray Imaging Jiwoong Kang, Ning Lu, Nancy Senabulya and Ashwin J. Shahani; University of Michigan, United States

Since the intrinsic grain structure of a polycrystal has significant impact on its properties, investigators have focused intently on studying the dynamics of the grain network under various external stimuli, e.g., heat. Upon annealing the material may undergo abnormal grain growth (AGG), in which a few grains grow more rapidly compared to the others. AGG is a common grain coarsening phenomenon that has been observed in a vast array of metallic and ceramic systems. To capture AGG, past experimental studies have relied heavily on two-dimensional (2D) experiments, such as surface characterization via electron backscatter diffraction (EBSD) and optical microscopy. However, such experiments have had limited success in developing a comprehensive model of AGG due to lack of information below the sample surface. Furthermore, these characterization techniques are destructive in nature, and thus it is impossible to follow the individual grain trajectories as a function of time (in the same specimen). As a result, it is impossible to determine the sequence of events that led to AGG in the first place.

Integrating X-ray absorption- and diffraction-contrast tomography (denoted ACT and DCT, respectively) in the laboratory can provide in-depth information on microstructures that are simultaneously polycrystalline and multiphase. Here, we have harnessed this non-destructive method to gain new insights into the problem of AGG in a particle-containing system. We investigate an Al-Cu alloy as a model system. The prepared specimen was imaged through the combination of ACT and DCT on a laboratory X-ray microscope in situ and as AGG proceeds. The 3D data provided an unprecedented opportunity to uncover what determines the expansion and shrinkage of grains — including the abnormal grain — as a function of the initial grain size and topology [5, 6]. However, both of these metrics do not correlate with grain growth rate. Instead, we find a strong correlation between the locations of secondary phase particles (obtained via ACT) and grain boundaries (imaged via DCT). As the specimen is annealed, the distribution of grain boundaries becomes more closely correlated to the distribution of AlCu particles, suggesting that the abnormal grain nucleates in a relatively particle-free region of the sample volume. Meanwhile, the normal grains are pinned by a dense particle cloud. Once it has attained its size advantage, the abnormal grain persists to grow due to an exceptionally large capillary driving force. This study provides new understanding on the origin of AGG with implications for the production of single crystals.

Bulk nanocrystalline alloys possess many unique physical properties with tremendous potential for various applications. However, ultra-nano grains of sub-4 nm dimension are extremely difficult to create and stabilize. This research proposes a spontaneous and reversible approach to nanocrystallize Cu-Sn bimetallic alloy by taking advantage of the polymorphic phase transition of Cu$_6$Sn$_5$. During temperature increase, and starting from a temperature 275 °C lower than the melting point of bulk Cu$_6$Sn$_5$, ~10 nm Cu$_6$Sn$_5$ nanoparticles were coarsened to tens of nanometers, as observed by in situ TEM. The particle growth continued even during the initial cooling stage. Interestingly, when the cooling process went through the polymorphic phase transition temperature of Cu$_6$Sn$_5$, η-Cu$_6$Sn$_5$ was transformed to η$'$-Cu$_6$Sn$_5$, and massive grain refinement occurred spontaneously as confirmed by atomic level monitoring in TEM. The final grain size reached a mean value of ~2.5 nm, sufficient small to be in a regime with enhanced ductility, offering highly improved ductility because of inverse Hall-Petch phenomenon, and excellent thermal, electrical and mechanical properties. This process is also reversible, offering an unprecedented method to stabilize extremely small nanograins. Such an ultra-nano material can be technically useful for a variety of applications including as a unique circuit interconnection material which can serve at higher temperatures than its processed temperature. We successfully demonstrated using nano-Cu$_6$Sn$_5$ as the interconnection material for the packaging of SiC high-power devices. Because of the significantly depressed sintering temperature of ultra-fine Cu$_6$Sn$_5$ nanoparticles, the SiC can be successfully packaged at a temperature lower than its actual working temperature. Because of the enhanced ductility of the inverse Hall-Petch sub-4 nm nanocrystalline joints, nano-Cu$_6$Sn$_5$ has a very promising potential to be used in the packaging of flexible devices. It can offer two attractive advantages simultaneously: processing at low temperature to prevent the damage of the flexible substrate; but working at a relatively high temperature to allow the usage of high-power flexible electronics. Like Cu$_6$Sn$_5$, other alloys such as Cu-Al, Fe-Zr, Al-Ni, etc. also possess such a capability of phase transition-induced grain refinement. This work will inspire other researchers to create many additional, sub-4 nm type nanocrystalline alloys, offering unprecedented pathway to realize ultra-nano-grained alloys and more interesting functions which were difficult to gain before.

2:30 PM *MT06.08.04
Grain Growth in Metallic Films—Experiments, Simulations and Data Analytics Katayun Barmak$^1$ and Yekaterina Epshteyn$^2$; $^1$Columbia University, United States; $^2$The University of Utah, United States

Most technologically useful materials are polycrystalline microstructures composed of a myriad of small monocristalline cells/grains separated by grain boundaries/interfaces. Grain boundaries play a crucial role in determining the properties of materials across a wide range of scales. A grand challenge problem in engineering of polycrystals is to develop prescriptive process technologies capable of producing an arrangement of grains that provides for a desired set of materials properties. One method by which the grain structure is engineered is through grain growth or coarsening of a starting structure.

Grain growth can be viewed as the evolution of a large metastable network, and can be mathematically modeled by a set of deterministic local evolution laws for the growth of an individual grain combined with stochastic models to describe the interaction between grains. Thus, to develop a predictive and prescriptive theory, investigation of a broad range of statistical measures for microstructure evolution during grain growth in polycrystalline materials are needed and must be obtained using experiments, simulations, data analytics and mathematical modeling. One of the goals of our current research presented here is thus to use data-driven numerical simulations closely integrated with experiments in order to improve upon mathematical models of grain growth and guide design of new experiments.

In this talk, we will report the results of in situ experiments of grain growth in thin films of Pt conducted using a heating holder in a transmission electron microscope (TEM). Our interest here is the dynamics of grain boundary motion. In addition, we will report on ex situ experiments of grain growth in Al, Al-0.2 at% Mn and Cu thin films, with thicknesses in the range of 25-150 nm and annealing temperatures in the range of 150-600 °C. A variety of
geometric and topological metrics of the grain structure were extracted from bright-field or dark-field (TEM) images or precession electron diffraction crystal orientation maps, including not only the grain size, but also the dihedral angles, the number of neighbors (i.e., side class) and the side class of nearest neighbors of grains.

The experimental grain size distributions for the Al and Cu films were found to be remarkably similar to each other despite the many and significant differences in experimental conditions, which include sputtering target purity, presence of an alloying element, substrate type, film thickness, deposition temperature, actual as well as homologous annealing temperatures, annealing time, absolute grain size, and the twin density within the grains. This similarity argues for a universal experimental grain size distribution, which for grain diameters is lognormal as found previously for thin films at stagnation. Comparison of the experimental grain size distribution with that for two-dimensional, sharp-interface grain growth simulations with isotropic boundary energy shows the distributions to differ in two regions, termed the “ear” and the “tail”. It is shown that the excess small grains in the region of the “ear” are primarily the 3 and 4-sided grains, whereas the excess of large grains in the “tail” region are grains with more than 9 sides. The excesses in the ear and tail regions of the experimental distributions are necessarily balanced by a deficiency in the mid-sized grains with 6-8 sides. We will also present the grain boundary character distributions in the films and compare and contrast our findings with those for bulk samples with grain sizes in the micrometer range.

Unveiling Fundamentals of Ink-Based 3D Printing by Operando X-Ray Photon Correlation Spectroscopy
Maria A. Torres Arango1, Yuyang Zhang1, Gregory Doerk1, Ruipeng Li1, Chonghang Zhao2, Yu-chen Karen Chen-Wiegart1, Andrei Fluerasu1 and Lutz Wiegart1; 1Brookhaven National Laboratory, United States; 2Stony Brook University, The State University of New York, United States

Central to the advances in functional materials and their processing is the thorough understanding of the fundamentals governing the processing-properties relationships. In additive manufacturing, understanding these relationships is necessary since anisotropy is inherent to the processing techniques, compromising the components quality, performance and reliability. For continuous-flow direct writing (CDW) the materials are formulated as viscoelastic colloidal inks and extruded through a nozzle forming a component. Therefore, these inks are subjected to multiple stimuli during the deposition and post-processing stages, which affect the way these materials self-assemble, store/release stress, and subsequently form and propagate defects.

Seeking to unveil such fundamental relationships, we conduct operando synchrotron x-ray photon correlation spectroscopy (XPCS) studies to investigate the inks’ structural and dynamical evolution during the out-of-equilibrium stages associated with the 3D printing process. During the shearing and relaxation of the inks multiple phenomena take place including loss and recovery of the gel structure, solidification and jamming to name a few. Our setup combines XPCS and CDW at the Coherent Hard X-ray Scattering beamline (CHX-11ID) at the National Synchrotron Light Source II. XPCS is especially suited for investigating the nano-scale spatio-temporal evolution of materials processed by CDW, covering its relevant length and time scales, from tens to hundreds of nanometers, and milliseconds to the hundreds-of-seconds range. We observe the ink’s nanoscale structure and dynamics as a function of the spatial position within the printed filaments, which may further be related to the printed-structures’ solvent evacuation, colloid re-arrangement, and substrate properties (ink/substrate interactions). Additionally, we investigate the dependence on compositional variation, including inks from branched vs. monodisperse colloids and inks containing solvents with different vapor pressures, to expose fundamental differences in the structural and dynamic evolution. While our work serves to enlighten fundamental processes in CDW, it may be extended to other 3D printing techniques. Moreover, it constitutes the basis for the discovery of new pathways for the engineering of materials that exhibit novel properties and unprecedented performance, as well as shedding light onto solving...
relevant issues in additive manufacturing, including cracking, delamination and poor layer-to-layer adhesion.

3:45 PM MT06.09.02
“Sintering” Models and In Situ Experiments—Data Assimilation for Microstructure Prediction of Nylon Component SLS Additive Manufacturing William S. Rosenthal, Francesca C Grogan, Yulan Li, Erin I Barker, Josef Christ, Timothy Pope, Christopher Barrett, Marvin Warner and Amra Peles; Pacific Northwest National Laboratory, United States

Selective laser sintering (SLS) methods are workhorses for the additive manufacturing of polymer-based components. The ease of rapid prototyping and short-run manufacturing by anyone with a laptop and machine access also means it is easy to produce illicit or counterfeit components. It is necessary to have a data-calibrated in-situ physical model of the build process in order to predict expected and defective microstructure characteristics that inform the provenance of these components.

Toward this end, we calibrate 2D and 3D phase-field sintering models for material microstructure evolution and its kinetics during synthesis. We seek to understand and predict microstructure characteristics such as pore structure and layer interfaces in components built by a Formiga P100 SLS printer using PA 2200 Nylon 12 feedstock. This is accomplished by assimilating multiple in-situ data streams, post-hoc imaging analysis, and computational model predictions in an adaptive Bayesian parameter estimation algorithm. In-situ data sources include infrared thermal imaging, built-in printer environmental sensors, and laser pathing guidance, including experimental uncertainty estimates. These are supplemented by post-hoc conical and synchrotron X-ray computed tomography, from which we infer bulk porosity and distributions for local and global pore characteristics. Similar predictions for porosity distributions are provided by the stochastically-driven phase-field sintering model. Randomized feedstock configurations are explored by a stochastic model for Nylon particle deposition and composition, which has been calibrated to bulk particle size analyses from a laser diffractometer. Additional model parameters such as system free energy, interfacial energy, and sintering kinetics are first constrained to physically-relevant search directions by global and local sensitivity analysis, and then explored using an adaptive sampling algorithm to match predictions.

Using this feedback loop, we obtain data-constrained estimates of sintering model parameters along with uncertainty bounds. We conclude by combining these predictions with the infrared thermal maps, and quantitatively relate the in-situ build environment to the resulting microstructure in sintered nylon components.

SESSION MT06.10: Processing of Ceramics
Session Chairs: Ashwin Shahani and Tao Sun
Tuesday Afternoon, December 3, 2019
Hynes, Level 2, Room 209

4:00 PM MT06.10.01
Kinetic Pathways of Layered Oxide Formation are Templated by Low-Temperature Intermediates Wenhao Sun1, Jianming Bai2, Gerbrand Ceder1 and Feng Wang2; 1Lawrence Berkeley National Labs, United States; 2Brookhaven National Labs, United States

Solid-state ceramic synthesis is often believed to equilibrium process, as the high temperatures of calcination are expected to minimize kinetic limitations associated with nucleation and growth. Despite this intuition, non-equilibrium phases are often observed during solid-state synthesis, prompting questions regarding the mechanistic origins of these metastable intermediates. Here, we use in situ synchrotron XRD to compare the multistage phase evolution of three important Li-ion cathode materials, LiCoO2, LiNiO2 and LiNi0.8Co0.2O2, during a hydrothermal-assisted ceramic synthesis process. While all three systems ultimately crystallize in the stable Rm layered phase after heating, a metastable spinel phase is observed to form prior to LiCoO2, and disordered rocksalts prior to the Ni-based compounds. We demonstrate that these metastable intermediates are kinetically-facile lithiation products of stable binary oxides that originate during low-temperature synthetic preparation. Our findings highlight newopportunities to engineer low-temperature phases to topotactically template the ceramic synthesis of target crystalline phases.
X-Ray Synchrotron Investigations of the Away from Equilibrium Crystallization of ZrO2 under Electromagnetic Excitation

Nathan Nakamura1, Laisuo Su1, Han Wang2, Shikhar K. Jha1, Haiyan Wang2, Simon J. Billinge3, C. Stephen Hellberg4 and B. Reeja Jayan1; 1Carnegie Mellon University, United States; 2Purdue University, United States; 3Columbia University, United States; 4U.S. Naval Research Laboratory, United States

Electromagnetic (EM) fields can significantly affect crystallization and phase transitions in ceramic materials, leading to low-temperature phase transitions and compositions not observed using conventional furnace-based techniques. Specifically, the application of 2.45 GHz microwave radiation (MWR) during ceramic synthesis has been found to crystallize unexpected phases and influence local atomic ordering. However, the mechanisms underlying how EM fields impact phase stability and promote far-from-equilibrium phases are not well understood. To fully understand the role of EM fields in ceramic nucleation and growth, it is necessary to characterize the relationship between the applied field and the resultant atomic structure. Due to the away from equilibrium nature of EM field-assisted phase transitions, it is necessary to characterize effects on both long range crystalline atomic order and short range atomic order which deviates from the crystalline phase. An understanding of the local atomic distortions induced by MWR and how they impact relative phase stability and the free energy space is especially critical to understanding these processes. An improved understanding of these effects will create the opportunity to utilize EM fields as an additional thermodynamic parameter to access regions of phase space not accessible via conventional synthesis routes.

We utilize a combination of synchrotron X-ray pair distribution function (PDF) analysis, synchrotron X-ray absorption spectroscopy, and density functional theory (DFT) calculations to investigate the impact of MWR on defect formation, phase transitions, and phase stability in ZrO2 thin films. Through PDF and extended X-ray absorption fine structure (EXAFS) analysis, we demonstrate that the application of MWR promotes defects on the oxygen sublattice, leading to local structural distortions which stabilize a long-range cubic atomic structure. This defective cubic ZrO2 structure forms at 225°C in the presence of MWR, significantly lower than the temperature conventionally required to synthesize cubic ZrO2 (>2400 °C). DFT calculations reveal that point defects on the oxygen sublattice can significantly alter the free energy landscape of ZrO2, and we find that the low-energy defective atomic configurations predicted by DFT correspond well to the experimental ZrO2 atomic structure observed. This combined experimental and computational study provides direct evidence for the role of EM fields in promoting defect-mediated phase transitions which deviate from the conventional free energy space of ZrO2, and creates the opportunity to further utilize MWR-assisted synthesis as a means to access away-from-equilibrium phases in ceramic oxide materials.

Defect-Mediated Anisotropic Lattice Expansion in Ceramics as Evidence for Non-Thermal Coupling between Electromagnetic Fields and Matter

B. Reeja Jayan1, Shikhar K. Jha1, Nathan Nakamura1, Shuyan Zhang1, Laisuo Su1, Phil M. Smith1, Xin L. Phua2, Han Wang2, Haiyan Wang2, John S. Okasinski3 and Alan J. McGaughey1; 1Carnegie Mellon University, United States; 2Purdue University, United States; 3Argonne National Laboratory, United States

Electromagnetic (EM) fields have been known to stimulate a range of surprising responses in materials. Microwave radiation is a type of EM field in the frequency range of 0.3 -300 GHz that can lower the synthesis temperature required for ceramics like TiO2 and induces mixed amorphous-crystalline phase compositions. To better understand the effects of microwave radiation on matter, we study structural changes during microwave heating and microwave radiation-assisted synthesis using in-situ synchrotron X-ray diffraction. We observed anisotropic expansion-contraction of lattice parameters, ‘a’ and ‘c’ of the tetragonal anatase phase, which contradicts the results from conventional thermal heating. When the as-received anatase powders are heated with microwave radiation, an instantaneous decrease in the intensities of diffraction peaks indicates loss of long-range atomic order (decrystallization), which is supported by high-resolution electron microscopy and selected area diffraction patterns. Ex-situ Raman spectroscopy and X-ray photoemission spectroscopy of microwave-heated and microwave-synthesized anatase powders indicate increased defect-generation under microwave exposure. Molecular dynamics simulations on the anatase phase of TiO2 suggests that introducing an oxygen vacancy can lead to the formation of an interstitial-vacancy pair. So, if microwave radiation can affect defect nucleation in the structure, the generation of defect-pairs away from equilibrium can explain the anisotropic lattice expansion, crystallization at lower...
temperatures, and/or stabilization of metastable phases under electromagnetic fields. Anisotropic lattice expansion and decrystallization under externally applied fields provide direct evidence for non-thermal coupling between EM fields and matter. Understanding such non-thermal, field-driven processes has implications in engineering low temperature processes for integrating ceramics with delicate polymeric materials for flexible electronics and in tailoring ceramic properties for energy storage, photovoltaic, and catalytic applications.

4:45 PM MT06.10.04

In Situ TEM Observation of Structure Evolution During Ceramics Sintering Kai He; Clemson University, United States

In situ transmission electron microscopy (TEM) has gained rapid growth in the past decade and attracted tremendous attention in diverse scientific research because it can acquire dynamic information and allow for the mechanistic understanding of various physical and chemical processes in a broad range of materials systems. Specifically, the advancement of in situ TEM in physical and/or chemically reactive environments has enabled the direct observation of structure evolution during materials synthesis. The sintering that transforms the precursor powders into the dense solid phase is the critical fabrication process for ceramic materials. To overcome the limitation of conventional long-holding techniques, recent efforts have been put toward flash sintering, which represents a solid-state synthesis far from equilibrium and shows great technical importance relevant to additive manufacturing. In this regard, to provide an in-depth understanding of the fundamental level, we employ in situ TEM techniques to study the dynamic structure evolution during the sintering of ceramic materials.

Here, we primarily focus on simple transition metal oxides (such as TiO2, Fe2O3, etc.) to investigate their sintering behaviors under various sintering rates. We use a TEM holder capable of in situ heating via MEMS-based devices, on which pristine metal oxide nanoparticles are uniformly dispersed. By tuning the input current density, we can control the power and heating speed that is applied to the nanoparticles, and simultaneously observe their morphological and structural changes in real time. From enormous in situ TEM observations, we found distinct sintering mechanisms relating to sintering rate: the slow sintering include stages of grain rotation, agglomeration, and growth, whereas the flash sintering proceeds directly through abrupt densification and subsequent growth, which is governed by the surface diffusion at different heating load. The effect of grain size and surface orientation also plays an important role in sintering kinetics. Our findings provide valuable insights into understanding the flash sintering mechanism and also show potential implications for developing fast additive manufacturing techniques for ceramic materials.

SESSION MT06.11: Semiconductors—Solidification
Session Chairs: Sabine Bottin-Rousseau and Damien Tourret
Wednesday Morning, December 4, 2019
Hynes, Level 2, Room 209

8:45 AM MT06.11.01

Role of Evolving Interface Instabilities in the Genesis and Evolution of Extended Defects During Epitaxial Growth of Cubic SiC Giuseppe Fisicaro1, Corrado Bongiorno1, Ioannis Deretzis1, Marcin Zielinski2, Silvia Scalese1, Francesco La Via1, Massimo Zimbone1 and Antonino La Magna1; 1CNR Institute for Microelectronics and Microsystems, Italy; 2NOVASiC, Savoie Technolac, France

The growth of high-quality Silicon Carbide (SiC) substrates and nanoparticles is a topic of extreme technological interest due to the importance of this material for current and future technologies. Concurrently, such growth process is challenging due to the meta-stability of different crystal symmetries (polytypes) in the usual growth conditions. Atomic mechanisms ruling the extended defects kinetics in cubic SiC material, manifesting both stacking and anti-phase instabilities, have been investigated by means of cross correlations between simulated evolution and in-situ micro-structural characterizations of crystal growth processes. First we explored the configurational space of cleaved and defective (adatoms and vacancies) surfaces with ab-initio structure predictions algorithms at density functional theory level. Then the atomistic configurations and energetics are input of a Kinetic superlattice Monte Carlo code which simulates the growth kinetics of SiC substrates and nanoparticles. Ab-initio calibrated Kinetic Monte Carlo simulations in super lattices evidence a mutable and complex kinetic behaviour which has been
validated by transmission electron microscopy analyses of experimental samples. Both simulations and characterizations show that anti-phase boundaries generate single stacking faults with different symmetries or sequences of them. Moreover, boundaries interact with the extended defects of the stacking fault class promoting their annihilation or polarity changes. Defect-defect correlations are mediated by surface instabilities, since a clear interplay between the modifications of the growing surface morphology and the bulk defects occurs and ones cause and influence each others.

9:00 AM *MT06.11.02
In Situ Observation of Melt Growth Processes of Silicon Kozo Fujiwara; Institute for Materials Research, Tohoku University, Japan

Multicrystalline silicon (Mc-Si) ingots for solar cells are manufactured by unidirectional solidification method. In general, since semiconductor materials are not subjected to structure control by a method such as thermo-mechanical treatment after solidification, structure control must be performed in a unidirectional solidification process. However, it has not been well understood how the microstructures in Mc-Si, such as, crystal grains, grain boundaries, twin boundaries, sub-grain boundaries, etc. behave at the crystal-melt interface. We have attempted to understand the crystal growth mechanisms by directly observing the crystal-melt interface of silicon.

We have developed a lab-scale in situ observation system which is composed with a crystal growth furnace and a digital optical microscope. To date, we have successfully observed crystal-melt interfaces of materials including Si, Ge, Sb, Cu, Sn, GeSn, GaSb, and so on. This presentation will focus on dendrite growth, crystal-melt interface instability, and grain boundary dynamics of silicon. The results of other materials will also be discussed.

9:30 AM MT06.11.03
Simultaneous In Situ X-Ray Diffraction Topography and Radiography Imaging for Defect Characterization During Silicon Growth Maike Becker, Gabrielle Regula, Serge Neves Dias, Hadjer Ouaddah, Guillaume Reinhart and Nathalie Mangelinck-Noël; Aix-Marseille Univ., Université de Toulon, CNRS, IM2NP, France

A new imaging device for the characterization of silicon during high temperature processing is installed at beamline ID19 at the European Synchrotron (ESRF). We demonstrate the great potential of this imaging setup for the detailed investigation of the interaction and generation of grains and defects that influence the growth process and the final crystalline structure of silicon. Better knowledge of the formation and interaction of defects in silicon is essential in order to improve defect engineering during the manufacturing step of silicon used for photovoltaic applications. In particular, defects like dislocation bunches or sub-grain boundaries reduce the photovoltaic performance and should be therefore analyzed.

In our experiments, two individual camera system that are fully synchronized record the topography and the radiography images in real-time during silicon sample processing in a Bridgman furnace. Compared to previous studies, where the topographs were recorded on X-ray sensitive films, it significantly increases the image acquisition rate allowing a detailed analysis of defect dynamics in the sample.

Topography is the analysis of the fine internal structure of an X-ray diffraction Laue spot in real space that provides information on the crystal quality by the display of lattice distortions. As dislocations and strain fields deform the crystal structure, they can be observed in a topography image by contrast changes. In our experiments, one Laue spot (topograph) is selected and recorded with one of the cameras. The transmitted beam is recorded at the same time by a second camera constituting the radiography images. The radiography contrast originates from the density difference of the solid and the liquid silicon phases and provides information on the morphology and kinetics of the interface. This supplementary information is used to identify new grain nucleation and grain competition events. The in situ studies are complemented by ex situ methods like electron backscatter diffraction and etch pitch measurements, to get information on the grain boundary character and on the dislocation density.

The combination of all techniques allows to analyze the mechanisms responsible for grain and dislocation generation and strain formation. Our work focuses on 300 µm-thin single-crystal silicon float zone samples that contain no visible defects at the beginning of an experiment. During heating, dislocations are generated at the sample edges and their motion intensifies with increasing temperature. We measure their velocities up to the melting
point and observe their interactions. In fact, little is known on the nucleation and mobility of dislocations at temperatures beyond 1373 K. When solidification starts, dislocations initially present in the seed propagate in the regrown crystal with the solid-liquid interface. It is important to learn more about dislocation extension from the seed to the regrown crystal, to explore the role of the seed used for example in recent process developments. At the sample edges (solid-liquid-vapor triple point) twin nucleation occurs, which leads to grain competition in the center, which in turn can trigger new grain nucleation. Even dislocation multiplication by the activation of Frank-Read sources can be observed, which underlines the efficiency of the new imaging device for a thorough and comprehensive characterization of silicon processing.

Synthesis of 100 Micron Scale Single Crystals of Ge$_2$Sb$_2$Te$_5$ via Femtosecond Optical Excitation Marc Zajac$^1$, Aditya Sood$^1$, Taeho Roy Kim$^1$ and Aaron Lindenberg$^{2,1}$; $^1$Stanford University, United States; $^2$SLAC National Accelerator Laboratory, United States

Phase change materials, including Ge$_2$Sb$_2$Te$_5$ (GST), can rapidly and reversibly switch between an amorphous, or glassy, state and a crystalline, or ordered, state via electrical or optical pulses. The amorphous phase and the crystalline phase have very different electrical and optical properties, which means that they can be used in rewritable optical data storage media and in fast, non-volatile electronic memory devices. Using in-situ electron diffraction techniques, we observed that excitation above a threshold fluence with a single femtosecond, 800 nm pulse induces sharp Bragg peaks indicative of large crystalline grains on the order of the probe beam size (80-100 μm). This was confirmed by transmission electron microscopy (TEM). Further analysis with the TEM showed that these large single crystalline grains are dendrites located in the center of the laser excitation with a face-centered cubic (fcc) crystal structure. It was determined via energy dispersive X-ray spectroscopy (EDX) that the large single crystalline dendrites are the same composition as the initial amorphous phase. This eliminates constitutional undercooling as a plausible mechanism to explain the formation of the dendrites. The observation of the large grains and the fact that the composition does not change indicates a large crystal growth velocity regime and opens up new opportunities for the growth of single crystal phases of the phase-change materials.

10:30 AM MT06.12.01
Atomic-Scale Observation of Dynamic Processes of SrTiO$_3$ (001) Surface Reconstruction at High Temperatures Zhen Wang$^1$, Bumsu Park$^1$, Jong Chan Kim$^2$, Hu Young Jeong$^2$ and Sang Ho Oh$^2$; $^1$Sungkyunkwan University, Korea (the Republic of); $^2$Ulsan National Institute of Science and Technology, Korea (the Republic of)

The atomic structure of (001) SrTiO$_3$ surface has been studied for a long time by various surface sensitive diffraction and spectroscopy techniques. The exotic physical properties exhibited by this surface have been of particular interests since the discovery of a two-dimensional electron gas (2DEG) at the surface [1]. Although atomic-scale surface profile imaging using high-resolution transmission electron microscopy (HRTEM) or scanning transmission electron microscopy (STEM) techniques have been used to visualize the surface structure, assessing the dynamic atomic processes leading to the surface reconstruction still remains challenging.

Here we designed an in-situ HRTEM experiment at elevated temperatures in a Cs-corrected TEM (GRAND ARM 300 CF). TEM samples were prepared from a (001) SrTiO$_3$ single crystal along the [100] and [110] cross-sectional zone axes by using FIB and attached to a DENSsolutions MEMS heating chip. A negative spherical aberration (Cs) imaging (NCSI) HRTEM condition was applied to observe the surface structure in real-time with all atoms (including strontium, titanium, and oxygen) being clearly resolved with minimal contrast delocalization [2]. In addition to the surface profile imaging at NCSI HRTEM mode, STEM high-angle annular dark-field and annular
bright-field imaging have been carried out at room temperature, 300 °C, 500 °C, 700 °C, and 950 °C. In order to determine the chemical composition and the valence state of the outermost surface atoms, atomic-resolution STEM energy-dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS) elemental mapping have been performed, respectively.

We observed that the (001) SrTiO3 surface was terminated predominantly by SrO layer throughout all temperature ranges studied by in-situ TEM. Interestingly, the SrO surface layer showed a unique surface reconstruction largely deviating from the bulk-truncated (1×1) structure with titanium (Ti) ions in the surface SrO layer, particularly occupying the oxygen-oxygen bridge sites (i.e. corresponding to the octahedral interstitial sites in bulk SrTiO3). The presence of the Ti interstitials was confirmed directly by atomic-scale STEM EDS and EELS elemental mapping. As temperature increases, the interstitial Ti atoms were displaced increasingly upward from the surface plane and caused a pronounced rumpling of the SrO layer. When the temperature is reached 950 °C, a layer-by-layer sublimation occurred from the surface by the formation and migration of atomic step with a unit cell step height. We directly observed that the Ti atoms from the moving step edge migrate and occupy the interstitial sites immediately when the sub-surface SrO layer is exposed as free surface during sublimation. From the Ti-L2,3 and O-K EELS edges, we observed that the formal valence of the interstitial Ti is mainly +3 and the surface SrO and sub-surface TiO layers contain a significant amount of oxygen vacancies. The observed surface structure of (001) SrTiO3 with Ti interstitials in the SrO termination has not reported before and we believe this unique surface structure is closely related to the formation mechanism of surface 2DEGs by oxygen vacancies. Our real-time surface profile imaging of the dynamic processes of surface reconstruction provides new insight into the surface science and has the potential to reveal the emergent phenomena such as the formation mechanism of 2DEG at oxide surfaces.

Low-Temperature Growth of Epitaxial BaTiO3 Ultrathin Film by Molecular Beam Epitaxy and Its Structural Properties Yeongjae Shin1, Juan Jiang1, Yichen Jia2, Frederick J. Walker1 and Charles H. Ahn1,2; 1Yale University, United States; 2Yale, United States

BaTiO3 (BTO) is a promising candidate for lead-free electronic devices for applications using piezoelectric or ferroelectric thin films. To achieve large-scale integration of BTO with existing semiconductor technology, however, the synthesis of high-quality BTO films at suitably low temperatures is required to reduce the thermal budget during device fabrication. Here, we report a successful synthesis of ultrathin epitaxial BTO films on SrTiO3 (001) by molecular beam epitaxy with a substrate temperature as low as 280 °C. X-ray diffraction and in-situ reflection high-energy electron diffraction are performed to investigate the structural properties and relaxation of the BTO film during growth. This result paves the way toward the realization of novel nanoelectronic devices using epitaxial BTO films.

11:00 AM MT06.12.03
Investigating Thin Film Growth Mechanisms in Real Time Using RBS and XRD Andre R. Vantomme1, Jelle Demeulemeester1, Annelore Schrauwen1, Dries Smeets1, Koen van Stiphout1, Christopher B. Mtshali2, Christophe Detavernier1, Kristiaan Temst1 and Lino M.C. Pereira1; 1KU Leuven, Belgium; 2Materials Research Group, South Africa

Thin films formed by solid phase reaction often exhibit a complex composition of several atomic species. The (re)distribution, diffusive and reactive properties of the individual species as well as their relative motion upon thermal treatment have a distinct influence on the formation properties and thus on overall thin film properties. Rutherford backscattering spectrometry (RBS) and X-ray diffraction (XRD) measurements have proven extremely valuable in the study of thin film formation as a function of thermal treatment. RBS is an ideal technique to unravel the compositional depth profile of thin films. On the other hand, X-ray diffraction provides complementary information on the lattice structure (hence the phase!) and texture of the material.

In conventional studies, several specimens are typically subjected to different heat treatments and subsequently analyzed one by one, in order to obtain a complete overview of the reaction sequence. However, due to the discrete
character of this approach, critical stages for the understanding of the development of thin film properties (e.g., formation of transient phases) are easily overlooked. This problem is circumvented by determining the specimen properties in real time, i.e. in situ during annealing/reaction with a high sampling rate. Additionally, real-time measurements drastically decrease the workload, as kinetic parameters, redistribution properties and phase sequence during thin film reaction, for example, can be obtained from a combined ramped RBS or XRD annealing, while numerous specimens have to be analyzed in the conventional approach.

The strength and complementarity of these in situ techniques will be illustrated with a number of typical examples. These will include:
- Growth mechanism of binary and ternary silicide and germanide thin film by thermal annealing. Particular attention will be devoted to the (re)distribution of Pt or Pd during solid phase reaction of Ni<sub>x</sub>Pt<sub>1-x</sub> and Ni<sub>x</sub>Pd<sub>1-x</sub> alloys with Si, and the role of Pt/Pd on the growth kinetics.
- Determining the dominant diffusing species during nickel and palladium germanide formation, two of the most promising candidates for use as ohmic contacts when anticipating germanium-based devices. By continuously monitoring the movement of a thin (inert) marker in situ during phase formation by RBS, the relative contribution of the atomic species to diffusion can be directly deduced.
- Metallization of GeSn, a material which is used to enhance the charge transport properties in the MOSFET channel via strain engineering. Ge<sub>x</sub>Sn<sub>1-x</sub> with Sn concentrations required for device operation (of the order of 6-9 at.%) are metastable. Further treatment such as annealing, implantation or metallization often results in phase separation, i.e. Sn precipitation. Therefore, particular attention has to be paid to the Sn redistribution during metallization, for example Ni/GeSn reaction. A combination of in situ RBS and in situ XRD enables us to follow the (meta)stability and reaction kinetics during reaction.

An additional comment that should be made is that, in order to extract the compositional depth profile embedded in the RBS data, dedicated analysis of each individual spectrum, one by one, is required. Since a single real-time measurement easily contains a hundred or more spectra, analyzing a full data set can be extremely time consuming. To this end, we have implemented a novel analysis technique, i.e. artificial neural networks (ANNs), to tackle the quantitative analysis of large real-time RBS data sets. This approach, which is based on pattern recognition, allows to analyze vast amounts of data without compromising the integrity of the results, thus enabling to conduct systematic real-time RBS studies on large batches of samples or experiments.

Coherent X-Ray Measurement of Local Step-Flow Propagation During Growth on Polycrystalline Organic Semiconductor Thin-Film Surfaces
Randall Headrick<sup>1</sup>, Jeffrey Ulbrandt<sup>1</sup>, Peco Myint<sup>2</sup>, Jing Wan<sup>1</sup>, Yang Li<sup>1</sup>, Andrei Fluerasu<sup>3</sup>, Yugang Zhang<sup>4</sup>, Lutz Wiegart<sup>3</sup>, Karl Ludwig<sup>2</sup>; 1University of Vermont, United States; 2Boston University, United States; 3Brookhaven National Laboratory, United States

Vacuum physical vapor deposition of C<sub>60</sub> on a graphene-coated surface is investigated in real-time by utilizing 9.65 keV X-rays from the CHX coherent hard X-ray synchrotron beamline at NSLS-II. X-ray Photon Correlation Spectroscopy is performed in the Grazing Incidence Small Angle X-ray Scattering (GISAXS) mode to achieve surface-sensitive conditions. Local step-flow is monitored through the observation of oscillatory correlations in the GISAXS intensity. The experimental results show that the step-flow velocity is nonuniform, and we model the velocity of each step-edge as being a simple function of the lengths of the terraces above and below it. This model predicts that the steps become almost stationary near the edges of the mounds, and the average slope of the surface is large. It was not previously known that such nonuniform and disordered step arrays as we have observed would follow such a simple growth law. We also find that the sensitivity to local step-flow is increased due to coherent mixing of X-rays scattered from the average mound structure with those scattered from the step array. This effect is a version of heterodyne scattering, where the scattering from the average step array can be considered to be a quasi-static reference signal. This work shows that the use of coherent X-ray scattering provides an approach to better understand surface dynamics and fluctuations during crystal growth. We have also extended these measurements to additional materials systems, including the growth of organic semiconductor small molecules with a lower symmetry than C<sub>60</sub>, such as diindenoperylene.
The continued demand for power efficient and high-performance microelectronics components is the key driver for the increase in the density and miniaturization of transistors. The performance of these nanoscale transistors depends on their architecture and materials properties. Controlled fabrication of the nanoscale semiconductors materials tailored for microelectronics application requires detailed insight into the chemical and physical processes that take place during their fabrication. Optimization of these nanofabrication processes is currently based on trial-and-error approaches, and these structures are only characterized post processing limiting the insight into how materials evolve during the fabrication.

Here, we describe our development approach, which is based on our in situ liquid phase TEM imaging platform, to directly visualize the semiconductor fabrication related processes occurring in solutions with nanometer resolution in real-time. In my talk, I will show how we can study the etching of Si and SiGe nanowires, which will be an essential element in the next generation gate-all-around field effect transistors (GAAFET). Moreover, I will show an in situ TEM based test platform for studying the effects of anisotropic etching that is often present for many semiconductor materials and describe how different crystallographic Si planes etch.

Our results highlight the importance of visualizing the processes relevant to nanofabrication in order to understand and improve the nanofabrication related processes.

Hafnia based memristive devices are promising candidates as next generation non-volatile memory devices and are appealing because of the compatibility with back-end-of-line processes in the current semiconductor fabrication process and the good chemical and thermal stability. [1-2] One major issue with current devices is the large device-to-device variability [3] which could be resolved by highly textured hafnia where grain boundaries, interconnecting top and bottom electrode, serve as predefined pathways locally constricting the formation of the conductive filament as shown by conductive AFM [4].

In this study, a TiN/HfO2/Pt stack grown on c-cut sapphire is investigated by monitoring structural changes of the dielectric layer with automated crystal orientation mapping (ACOM) during in situ heating in the TEM. The 50 nm TiN layer has been grown by using reactive molecular beam epitaxy (RMBE) followed by in situ growing 12 nm amorphous hafnia and ex situ sputter deposition of 100 nm Pt. From one stack, a cross sectional focused ion beam (FIB) lamella has been prepared and transferred onto a Micro Electrical Mechanical System (MEMS) based heating chip. Laterally resolved structural information has been acquired by ACOM in order to track structural changes in the dielectric layer. The structural changes have been compared to another stack which has been ex situ annealed.

A temperature dependant study has been performed to monitor the growth process, thus giving insight into the growth mechanism and formation of grain boundaries in this system. Furthermore, we show, that the transformation from amorphous to the polycrystalline state lowered forming voltages and device-to-device variability serving as basis for a direct structure-property correlation.

Nanostructured Au films resulting from supersonic cluster beam deposition of bare gold clusters show a non-ohmic electrical behavior and complex and reproducible resistive switching with characteristics suitable for neuromorphic applications [1, 2]. In order to achieve a deeper understanding of the modification induced at the nanoscale by joule heating in a gold cluster-assembled film due to the flow of an electrical current, we performed an in situ HRTEM characterization of the dewetting of the nanostructured films under thermal annealing.

Gold cluster-assembled films were fabricated by supersonic beam deposition on silicon nitride membranes, with nominal thickness of 1, 3, 12 and 18 nm respectively. Their initial morphology depends on the deposited amount of gold: while the samples 1 and 3 nm-thick are constituted by isolated and branched gold nanosized polycrystals, those with the higher thickness show a quite more branched, and percolating. The TEM/HRTEM/STEM measurements showed that the samples’ in situ heating leads to the dewetting of the gold polycrystals, and to the depercolation of those initially percolated, via the retraction of all the branches constituting the Au crystals. Such an evolution, common to all samples, was studied in terms of collective behavior, by low-magnification TEM imaging, HAADF-STEM and electron diffraction (ED) pattern collection of large ensembles of gold polycrystals. In particular, the global evolution under thermal in situ stimulus of the gold polycrystals not giving rise to a percolating network was quantified investigating the change of typical features such as their sizes, the latter expressed by their maximum (length) and minimum (width) mean Feret diameter, and the area fraction of the substrate covered by them. With regards to the Feret length and width, as well as to the covered area fraction, both not percolating samples showed that, as a consequence of the branches retraction, these parameters decreased with the thermal increase, bringing to smaller, still polycrystalline but spheroidal nanoparticles, showing a log-normal distribution of their size and with the mean one increasing with the nominal thickness. The same behavior was observed even for the percolating structure, but due to the fact that they were initially connected among them, the determination of the Feret parameters was achievable only after their dewetting. As well, the concomitant thickness increase of the gold nanocrystals during their branches’ retraction was qualitatively observed by HAADF-STEM imaging. The ED diffraction patterns indicated that: i) the as-deposited gold nanostructures did not grow following any preferential crystalline direction, and that ii) while the dewetting gave rise to the size increase of the central parts of the originally branched gold nanostructures, the crystal structure of those zones did not change with the heating and then again no any preferential crystal orientation was found after their thermally-driven evolution’s completion. Finally, the spherical aberration(Cs)-corrected HRTEM allowed determining the atomically-resolved in situ thermal evolution of single gold nanocrystals in the direct space, showing that the branches retraction is accompanied by the most peripheral crystal grains’ boundary movement, bringing to the formation of final, thicker, separate and more regular gold nanocrystals, in agreement with what observed on large ensemble of nanostructures.

A Stochastic Simulation Model for Understanding the Dynamics of Au-Seeded III-V Nanowire Growth Erik Mårtensson1,2, Carina Babu Maliakkal1,2, Sebastian Lehmann1,2, Marcus Tornberg1,2, Daniel Jacobsson2,3, Axel R. Persson2,3, Reine Wallenberg2,3, Jonas Johansson1,2 and Kimberly A. Dick1,2,3; 1Solid State Physics, Lund University, Sweden; 2NanoLund, Lund University, Sweden; 3National Center for High Resolution Electron Microscopy and Centre for Analysis and Synthesis, Lund University, Sweden

Direct observation of growing Au-catalyzed III-V nanowires via in-situ transmission electron microscopy can give crucial insights into the theoretical understanding of the growth process, through monitoring the dynamic behaviour of the catalyzing seed particle as well as the resulting nanowire it gives rise to. [1,2] However, the theoretical
framework of nanowire growth is to a large extent built on physical quantities which are not directly measurable in a microscope (e.g. the supersaturation of the growth species in the seed particle), often lack the dynamic aspect of the growth process, and rely on material properties and interface energies which are not always well known. This can make it difficult to correlate observations from *in-situ* experiments with nanowire growth theory.

Here, a stochastic simulation model of III-V nanowire growth is presented, which captures the dynamic processes of nanowire growth in a theoretical framework.[3] The model is based on the material flow of the growth species through the seed particle to follow the composition of the seed over time. Knowing the composition in turn allows for the calculation of nucleation rates using classical nucleation theory. Then, the moment when nucleation occurs, as well as the type (meaning crystal structure/composition), is decided using these nucleation rates and random numbers. Nucleating a new layer in turn affects the composition of the seed which allows the model to capture the dynamics of nanowire growth.

The model is designed to have the same input parameters as those used for experimental growth, such as the flow of growth species and temperature of the system. The output of the simulation include the temporal evolution of the physical quantities used in theoretical works, but also the size and composition of the seed, the crystal structure and composition of the growing nanowire and other properties which can be directly compared with observations from *in-situ* microscopy. This makes stochastic simulations and *in-situ* microscopy mutually beneficial. The simulations can provide explanations to experimentally observed trends due to the output of additional physical quantities, while the observations provide real time correlated measurements of the growth dynamics which can be used to improve the model.

An example of this synergistic nature will be presented, where experimental *in-situ* growth of GaAs nanowires using metalorganic precursors in an environmental transmission electron microscope was combined with simulations.[4] Experiments showed that the two distinct steps in nanowire growth, meaning the incubation period and the step flow growth, occurred on similar time scales and were found to be controlled by different parameters for most of the tested parameter space. Because of this, a step flow process was added to the model, and analyzing the simulations gave insights to how these processes can be limited by one or both of the growth species in different regimes. The experimental values for the step flow times in turn allowed us to tune and improve upon some of the parameters used in the simulations which are not well known, such as the interface energy between the liquid seed particle and the GaAs nanowire.

The flexibility of the simulation framework allows for many uses beyond analyzing step flow times in GaAs nanowire growth. As an example, the input variable corresponding to the flow of growth species can be changed throughout the course of the simulation. This gives the model the freedom to theoretically evaluate growth of heterostructures with different crystal structures for binary nanowires or different compositions for ternary nanowires.

*In Situ* Observation of Surface-Diffusion-Assisted, Solid-State Oriented Attachment to Platinum-Based Nanowires

Yanling Ma\(^1\), Wenpei Gao\(^2\), Hao Shan\(^1\), Wenlong Chen\(^1\), Xiaqing Pan\(^2\) and Jianbo Wu\(^1\); \(^1\)Shanghai Jiao Tong University, China; \(^2\)University of California, Irvine, United States

One-dimensional platinum-based nanowires (NWs) have been demonstrated to possess improved activity and stability towards oxygen reduction reaction (ORR) for proton-exchange membrane fuel cells. Sufficient understanding on the growth mechanism at atomic level and seeking approaches for facile synthesis of platinum-based NWs are emerging. Here we report a novel scalable synthesis of surfactant-free thin platinum-based nanowires network electrocatalysts based on a generic solid state method. The growth stages and formation mechanism are investigated by in situ transmission electron microscopy (TEM). It reveals that the enhanced surface diffusion of Pt atoms due to the H\(_2\) adsorbate, especially on \{100\} planes, can establish a liquid-like behavior which facilitates the diffusion. Surface coalescence then prefers to occur on this specific plane, until the exposed Pt (100)
Surface is attached by other nanoparticles. In situ atomic observation demonstrated that four stages are included among this solid state orientated attachment: 1) H₂ adsorption, preferentially on Pt {100} facets, 2) higher local diffusion on Pt {100}, 3) attachment and formation of necking area between Pt nanoparticles, and 4) coalescence to form a short NW. The resulting catalysts demonstrated enhanced ORR performance: the as-prepared platinum-based NWs delivered the mass activity of 0.71 A/mgPt for Pt NWs and 1.52 A/mgPt for Pt-Ni alloy NWs, and the specific activity of 2.20 mA/cm²Pt for Pt NWs and 3.58 mA/cm²Pt for Pt-Ni alloy NWs, showing promising improvement over the commercial Pt/C catalyst. This newly developed solid state H₂-assisted method with the atomic understanding from in situ TEM observation provides an applicable path for scalable production of surfactant-free Pt-based NWs with excellent activity towards ORR. It is prone to better understand the surface adsorbate-promoted growth mechanism in gas at the atomic scale thus presents the possibility to synthesize flexible shape-controlled nanostructures in gas, similarly as in liquid phase.

2:15 PM MT06.13.04
Theory Meets Experiment to Understand the Sintering Processes of Ag Nanoparticles Edison Z. da Silva¹, Giovanni M. Faccin², Thales Machado³, Marcelo de Assis³, Nadia G. Macedo³, Elson O. Longo³, Juan Andres⁴ and Miguel A. San-Miguel⁵; ¹UNICAMP, Brazil; ²Universidade Federal da Grande Dourados, Brazil; ³Federal University of São Carlos (UFSCar), Brazil; ⁴University Jaume I (UJI), Spain; ⁵Instituto de Química, UNICAMP, Brazil

A novel process, the formation and growth of metallic Ag nanowires (NWs) and nanoparticles (NPs) on α-Ag₂WO₄ upon electron beam irradiation has been discovered and was extensively investigated by different experimental techniques including transmission electron microscopy (TEM) [1-3]. A combination of long time atomistic molecular dynamics (MD) simulations [4] and in situ transmission electron microscopy (TEM), was used to probe the coalescence of Ag nanoparticles (NPs). In the experiments we were able to observe and analyze rarely seen in situ Ag NPs growth produced by irradiation of an α–Ag₂WO₄ crystal by electrons from a TEM electron beam in vacuum, which were observed in real-time. This phenomenon can be considered as a clear example of surface plasmon resonances (SPR), in which the electron beam creates Ag NPs that become SPR electric dipoles. Nearby Ag NPs undergo coalescence processes that are controlled by dipole-dipole interactions, forming larger clusters [4]. The welding and sintering of Ag NPs analyzed with computer simulations, provided meaningful insights at atomistic level and show the role of the crystallinity and shape of the Ag NPs, lattice plane matching, and also the effect of stacking faults during these processes helping the understanding of the experiments. They uncovered an interface evolution process displaying a disorder to order transition [5] which was also verified experimentally, supporting the conclusions of this study.

Mechanisms Involved in GaAs Nanowire Formation Explored by In Situ Transmission Electron Microscopy
Jean-Christophe Harmand1, Gilles Patriarche1, Federico Panciera1, Frank Glas1, Laurent Travers1 and Vladimir Dubrovskii2; 1C2N/CNRS/Université Paris-Saclay, France; 2ITMO University, Russian Federation

We investigate several mechanisms involved in GaAs nanowire formation, using an aberration-corrected transmission electron microscope (TEM) equipped with beam sources of Ga and As4 molecules. The molecular beams are supplied to a heated SiC membrane and the GaAs nanowires form by vapor-liquid-solid growth, with or without Au catalyst particles. Growth is observed in real-time with the atomic resolution.

We adjust the As4/Ga beam flux ratio to control the geometry of the catalyst droplet. The contact angle of the droplet on the nanowire top facet has a strong influence on the stacking of the GaAs atomic layers: wurtzite (WZ) or zinc-blende (ZB) crystal structures can be obtained [1]. Both structures form layer by layer, but specific features are associated with the growth of each of these crystalline phases. WZ phase stacking systematically corresponds to nucleation events occurring at the periphery of the interface between the droplet and the nanowire. In such a case, this interface is perfectly flat and the step flow is relatively slow [2]. ZB stacking is obtained mainly at large droplet contact angles, the top facet being truncated and the step flow much faster (instantaneous at a camera acquisition rate of 10 frames per s). In this situation, the truncation volume varies periodically, at the frequency of monolayer formation as already reported in other systems [3].

We show that the previous features are not intrinsically related to the crystal structure which grows. Indeed, at contact angle below 90°, ZB monolayers can form with a slow step flow and no facet truncation at the liquid/solid interface. Moreover, we use an artifice to produce a truncation of the top facet while the droplet contact angle leads to WZ formation. In this situation, the WZ stacking is maintained but the monolayer step flow becomes fast. This shows that the truncation of the top facet acts as a reservoir of atomic species which can accelerate the completion of a monolayer, whatever the crystal structure being formed.

Finally, we will show that a fine control of the beam sources allows us to switch abruptly from one crystalline phase to another and thereby, to fabricate crystal phase superlattices.

We acknowledge the French National Research Agency (ANR) for funding the TEMPOS/NanoMAX project within the EQUIPEX "Investissements d'Avenir" programme.

Limits of III-V Nanowire Growth Based on Real-Time Observations of Droplet Dynamics Marcus Tornberg1,2, Carina Babu Maliakkal1,2, Daniel Jacobsson1,2, Kimberly A. Dick1,2, and Jonas Johansson1,2; 1Lund University, Sweden; 2NanoLund, Sweden

Crystal growth of III-V semiconductor nanowires assisted by a liquid droplet requires, apart from successful nucleation, that the particle continuously wet the top of the nanowire. Recent TEM observations have shown that with increasing droplet volume, the interface between the nanowire and the liquid may become truncated [1,2], and eventually the droplet may be displaced from the top facet [3]. While this has been observed and discussed from the nucleation point of view, it has not been addressed from the droplet dynamics perspective.

Here we compare in-situ transmission electron microscopy observations of the droplet-nanowire interface during growth of Au-assisted GaAs nanowires, with calculations of the stability of the droplet on the nanowire top facet by comparing the capillary forces. By expanding the Young’s equation for droplet on a surface to include a truncated facet, we find limits for the solid-vapor and liquid-vapor surface energy ratio with respect to the contact angle of the droplet. These limits confine an interval of surface energy rations between which the droplet remain on top of the nanowire. In addition, it is predicted that formation of a truncation of the solid-liquid interface increases the stability for having a droplet on the top of a nanowire.
From the experimental observations, based on real-time imaging of the crystal growth at ~20 frames/s, we observe the dynamic droplet-nanowire interface as the droplet is filled with Ga which results in a truncated interface from time to time. Along with these observations, we estimate the surface tension and contact angle of the droplet based on the projected droplet volume. These experimental data and observations are then combined with our theoretical calculations in order to experimentally estimate the surface energy of the GaAs wurtzite \{10-10\} solid-vapor interface. We get an experimental prediction of the surface energy for the crystal growth conditions of GaAs (pressures and temperatures) in comparison to the existing theoretical predictions made for ideal environments and reconstructions [4, 5]. The comparison can further be used to hypothesize if, or how, the surface of interest has been reconstructed.

To conclude, using high frame-rate in-situ TEM imaging in conjunction with theoretical estimations we will present a reasoning for the formation of a truncation at the droplet-nanowire interface. In addition, we will show the observed droplet dynamics and how they are used to experimentally estimate the surface energy of the wurtzite GaAs nanowire sidewall.

catalytic chemical vapor deposition (ACCVD) using Co and Ni catalysts. C K-edge, and Co and Ni L-edge XANES measurements were performed at BL-7A in KEK PF and BL-5S1 at Aichi SR, respectively. In CNT growth by thermal decomposition, CNTs are formed on SiC(000-1) surface by heating above 1200°C in a vacuum, due to the desorption of Si atoms from SiC surface. C K-edge XANES results showed that the orientation of C-C bond changed with the increase of the sample temperature. When the temperature was 1100°C, C-C bonds were parallel to the surface. However, they were aligned to perpendicular to the surface above 1300°C. Taking into account the results of first-principles density functional theory/molecular dynamics (DFT/MD) simulation [2], at the beginning, the graphene flakes were formed at ~1200°C, which were parallel to the SiC surface. As the temperature rose, they were curved by the formation of bonds with the dangling-bonds on SiC(000-1), and hemispherical structures (“carbon nanocaps”) were formed. When the temperature was above 1300°C, CNT growth was proceeded perpendicular to the surface [3]. Our results showed that the size and structure of graphene flakes formed at the initial stage would determine the structure (diameter, chirality and the number of walls) of CNTs.

Next, we performed Co and Ni XANES measurements to clarify the chemical states of these metal catalyst particles during SWCNT growth by ACCVD. Co and Ni L-edge XANES spectra showed that “as deposited” Co and Ni catalysts were both partially oxidized and they were reduced to metal particles during heating. However, after SWCNT growth started, Co catalysts were transformed to carbides, but Ni catalyst remained metallic. This indicates that, during SWCNT growth, carbon atoms dissolve into the Co catalyst particles, while carbon atoms diffused only on the surface of Ni catalyst particles. Taking into account the similarity in the bulk phase diagrams of C-Co and C-Ni, the difference in the chemical states of Co and Ni catalyst particles is due to the specific property of nano-sized particles, which is consistent with the DFT simulation [4].

This work was partially supported by the Meijo University Research Branding Project for Cultivation and Invention of New Nanomaterials under the Ministry of Education, Culture, Sports, Science and Technology (MEXT) Private University Research Branding Project (Global Development Category). The NEXAFS measurements were performed under the approval of Photon Factory Program Advisory Committee (Proposal No. 2011G539).

Using In Situ Spectroscopy Techniques to Isolate the Roles of Hydrogen Exposure and Trace Carbon Contamination on Catalyst Nucleation Success Rate for Carbon Nanotube Growth Jennifer Carpena1, Rahul Rao1, J. Anibal Boscoboinik2, Sammy Saber1, Jiang-Qiang Zhong2, Matthew R. Maschmann3, Piran Ravichandran Kidambi4, Nick T. Dee5, Dmitri Zakharov2, Anastasios J. Hart5, Eric A. Stach6 and Benji Maruyama6; 1Air Force Research Laboratory (UES Inc.), United States; 2Brookhaven National Laboratory, United States; 3University of Missouri, United States; 4Vanderbilt University, United States; 5Massachusetts Institute of Technology, United States; 6Air Force Research Laboratory, United States

Limited understanding of the factors influencing the yield of CNTs relative to the number of catalyst particles remains an important barrier to their large-scale production with high quality and to tailoring CNT properties for applications. This lack of understanding is evident in the frequent use of Edisionian approaches for achieving high-yield CNT growth, and the sometimes confusing influence of trace residues on the reactor walls. In order to grow CNTs reproducibly and enable large-scale growth, it is imperative to understand, fundamentally, how these common practices impact catalytic activity and thus nucleation success rate. Herein, we use ambient pressure-X-ray photoelectron spectroscopy (AP-XPS) and in situ Raman spectroscopy to study the influence of carbon and hydrogen on the coupling between catalyst reduction and CNT nucleation, from an iron catalyst film. The XPS results reveal a positive correlation between the degree of catalyst reduction and the density and quality of the CNTs, verifying that effective catalyst reduction is critical to CNT nucleation, and to the resulting CNT growth yield. We also show that hydrocarbon by-products from consecutive growths can facilitate catalyst reduction and increase nucleation success rates significantly. The in situ Raman studies reveal that the addition of carbon decreases the incubation time, thereby enabling a higher CNT nucleation density. Our findings suggest that common practices used in the field, such as reactor preconditioning, aid in the reduction of the catalyst population, thus improving nucleation success rates and enabling growth of dense forests.

Direct-Design Approach for Reversible Tuning of the Optoelectronic Properties of Doped Metal-Oxide Semiconductors Pragathi Darapaneni and James A. Dorman, Louisiana State University, United States

Tuning the optoelectronic responses of metal-oxide semiconductors in a stable, but reversible manner is identified as the limiting factor for their deployment in real-world flexible electronic devices. Currently, external stimuli (e.g. pressure, temperature) are applied on these inorganic semiconductors to modify their optoelectronic response, ultimately reverting to their initial state upon relaxation. Therefore, this work demonstrates the effect of polarized molecules for reversibly manipulating the optical, electrical, and magnetic transport properties of transition metal (TM) doped metal-oxides and is validated computationally. As a proof-of-concept, the electronic properties of TM dopants and their coupling with rare earths (RE) are probed using time-resolved optical spectroscopy. While these materials have applications in bio-sensors and flexible displays, the results of which have potential for quantum computing.

Functionalized Ni doped TiO$_2$ thin films were characterized to identify effect of surface dipoles (para-substituted benzoic acid ligands) on their optoelectronic and structural properties. The ligand-induced local structural and electronic changes around Ni$^{2+}$ were investigated via neutron scattering (NS) and soft x-ray absorption spectroscopy (XAS). Upon functionalization, a distinct shift in the $t_{2g}$-$e_g$ filling and energy levels were observed in the Ni L$_2$ edge XAS spectra and was attributed to a local geometry distortion. Our real time (RT) time-dependent density functional theory (TDDFT) calculations further confirm that the applied ligand field changes the 3d metal orbitals hybridization, resulting in the observed variation in the Ni L$_2$ edge XAS. Additionally, in situ ultraviolet photoelectron spectroscopy (UPS) measurements on functionalized TiO$_2$:Ni films reveal that the direction of charge transfer and band bending is reversible and proportional to the dipole moment. Next, TiO$_2$:Ni$^{2+}$ shell layer with controlled thickness, is coated on the core β-NaYF$_4$:Er$^{3+}$ nanoparticles to facilitate Ni$^{2+}$-Er$^{3+}$ energy transfer for dynamic upconversion luminescence via adaptive Ni$^{2+}$ absorption. UV-Vis and in situ photoluminescence (PL) measurements on these surface-modified RE core-TM shell phosphors indicate a clear shift in the optical absorption (~ 50 nm) and emission spectra, demonstrating the ligand-dependent luminescence of core-shell phosphor. This direct design method of combining experiments and theory will provide a robust approach for designing weak field dependent optoelectronic materials. More importantly, this ability to reversibility manipulate interfacial charge transfer processes of doped semiconductors has direct implications in the development of quantum computing type materials and memory-storage devices.

Fold 2D Woven DNA Origami to Origami+ Structures Chao Wang, Yiyang Zhang and Dongsheng Liu; Tsinghua University, China

DNA origami strategy has greatly promoted the development of DNA nanotechnology as it can construct delicate 2D/3D nanostructures. The current method to prepare DNA origami is through a woven approach to fix a long strand DNA into certain shapes. This article describes a novel strategy to fold the same 2D DNA sheet into multiple complex structures driven by introducing hydrophobic interaction. The pathway of the folding process can be adjusted by tuning the distribution and chronic order of cholesterol, resulting in different complicated structures. This method has been proved efficient for constructing variable nanostructures based on the same DNA origami sheet, and termed as origami+. This work represents a new strategy in DNA nanotechnology and will improve the ability to manipulate objects at nano-scale.

In Situ TEM Operation of a Copper-Based 3-Terminal Synaptic Cell Baoming Wang$^1$, Teodor Todorov$^2$, John
As an alternative computing architecture, neuromorphic computing has drawn enormous attention worldwide. Various analog switching devices have been demonstrated as synapses for neuromorphic computing. A particularly promising design involves an analog neural network accelerator based on a cross-point array of non-volatile memory elements. However, these devices often show non-ideal switching characteristics that will limit the accuracy in neural network training. Improved control of analog switching can be achieved by replacing each 2-terminal memory element with a 3-terminal memristor structure that has a channel with a “read” terminal on each end, plus a control electrode that is analogous to the gate in a transistor. We are particularly interested in memristor structures that do not use lithium as the diffusing species, due to its sensitivity to air and humidity. We have therefore developed a fast-switching memory element based on the use of a copper superionic conductor, Cu₁₆Rb₄Cl₁₅I₇. This unusual compound has the highest reported room temperature conductivity of any solid electrolyte, 0.34 S/cm. Ex situ measurements suggest that a voltage at the control electrode causes Cu⁺ to migrate through the solid electrolyte and deposit onto the channel, changing its resistivity, as measured using the two read terminals. However, ex situ measurements cannot directly address failure modes and the physical factors limiting reliability, even when structural and electrical characteristics are correlated before and after operation of the device. We therefore describe the use of transmission electron microscopy, with structural and analytical (EDS/EELS) capabilities, to investigate the operation mechanism and limitations of copper-based 3-terminal synaptic cells. We have fabricated electron-transparent thin film samples on commercial TEM window chips with a copper control electrode and various materials for the channel. The chips are accommodated in a Hummingbird TEM holder with biasing capability. We will describe the characteristics of these devices and correlation of their electrical performance with microstructural evolution. We will also compare the device operation with liquid cell TEM observations of the cyclic pulse deposition of copper from a liquid electrolyte, which has been proposed as an alternative synaptic cell design. For both liquid and solid electrolytes, we believe that in situ TEM techniques have a vital role to play in the material and architecture design of memristor-based 3-terminal devices.

*In Situ Gas-Cell TEM Studies of Alloyed Nanoparticles*

Boao Song¹, Yuzi Liu² and Reza Shahbazian-Yassar¹;

¹University of Illinois at Chicago, United States; ²Argonne National Laboratory, United States

Corrosion is the interaction between service materials and environments that involves chemical or electrochemical reactions at interfaces. The corrosion-induced deteriorate of proper material functions is the most common cause of the failure during service. Alloyed nanoparticles (NPs), an emerging material compound involving several elements in the form of disordered solid solutions, is attracting increased attentions since their novel properties in applications of catalysis and superior structural alloys. The corresponding service environment for such materials usually involves super critical conditions such as exposure to chloride-containing solutions, acidic, high-temperature, high oxidative gases, which requires in depth understanding of corrosion behaviors at both structural and chemical level. In contrast to alloys in bulk phase, the corrosion-resistant properties of nanoparticle phase is poorly studied due to the relatively fresh discovery of such materials system and the challenge of obtaining nanoscale information regarding to the typical few nanometer sizes of NPs. With the reduced size of alloys from bulk to NPs, it is crucial to utilize advanced characterization techniques like TEM to gain atomic resolution information during oxidation process. *In situ* TEM, with combined sub-nanometer resolution and real time observation capabilities, is essential for such study.

The oxidation behavior is specifically essential to be investigated for alloyed NPs with working conditions expose to atmospheric pressure gases at elevated temperature. To do so, an *in situ* gas-cell TEM holder is utilized to allow the alloyed NPs expose to various of gases environment. The distance between two Si microchips can be adjusted as small as 50 nm or as large as 2 μm, accommodating the major size range of synthesized NPs. Air, H₂, and water vapor gases are used to flow into the cell with a constant volumetric flow rate. A temperature controller is used to set the temperature from RT to 800 °C. The *in situ* gas-cell allows atomic resolution imaging at both room and elevated temperatures, and the structural evolution during oxidation is observed in real time. The oxidation states for various elements are evaluated by electron energy loss spectroscopy (EELS) at different temperatures. The observation is further investigated by density functional theory (DFT) calculation to gain fundamental understanding of oxidation behavior. The present study provides insights into how oxidation initiated at the surface of alloyed NPs, and help gain deeper understanding of designing anti-oxidation composition for next generation functional alloys.
Melanins are ubiquitous biopigments responsible of manifold functionalities in living organisms. Eumelanin is a hygroscopic, black-brown biomacromolecule belonging to the family of melanin biopigments. It is synthesized by the oxidative polymerization of (5,6)-dihydroxindole (DHI) and (5,6)-dihydroxindole 2-carboxyl acid (DHICA) building blocks. Different available polymerization sites, a wide variety of supramolecular arrangements and co-existing redox states, bring chemical and physical disorder to the biopigment. There is a significant interest in eumelanin physicochemical properties such as broadband optical absorption, free radical scavenging, metal-ion chelation and hydration dependent electrical response, this last mainly attributed to protonic transport. Owing to the complex structural organization, a universal theory correlating supramolecular aggregation to fundamental optical and electrical properties of eumelanin does not exist yet. Furthermore, the charge transport properties of the biopigment, object of numerous studies, are still elusive. Our group is currently investigating the solid-state polymerization of spin coated DHI and DHICA thin films at surfaces. We observe that the monomers aggregate, possibly eventually polymerizing in a time scale of 48hr at ambient condition. Images obtained by Atomic Force Microscopy (AFM) show that after a few days at ambient condition DHI thin films grow into well defined fern-like structures on certain areas of the surface. This process, attributable to a diffusion limited aggregation (DLA), is followed by the growth of crystal-like agglomerations about 400 nm-high, on the fern structures. On the other hand, DHICA thin films do not form crystal-like agglomerations. We observe, instead, that regularly shaped nano-pillar structures, uniformly coating the substrate surface, grow in about 1hr at ambient condition. The pillars gradually undergo an in-plane and out-of-plane growth, reaching average width and height of 100 nm and 300 nm. UV-Vis spectra of DHI acquired over time, show an absorption peak at 305 nm that gradually shifts to 322 nm after one month at ambient condition. We tentatively interpret this red shift as an evidence of solid-state polymerization. Interestingly, both in DHI and DHICA spectra, we observe an increase of the absorbance both in the UV and Visible regions, this latter likely due to an improved -electron delocalization of oligomeric structures over time.

Being non-toxic, abundant, solution processable and quite biodegradable, eumelanin is a promising candidate for green electronics: as such our results are of paramount importance to exploit the full technological potential of the biopigment.

References
crystalline control, it is originated from the real-time imaging function of scanning electron microscopy (SEM) and transmission electron microscopy (TEM), which allows localized crystallization (nanoscale phase change) with sub-10 nm precision. In addition, the crystallization leads to volume change, which generates stress in the thin film and triggers self-assembly of 3D nanostructures. Various complex three-dimensional (3D) functional nanostructures can be realized based on this scheme.

*In Situ* Transmission Electron Microscopy Characterization of High-Temperature Behavior of Metal Nanostructures Daan Hein Alsem, James Horwath, Khim Karki and Eric A. Stach; 1Hummingbird Scientific, United States; 2University of Pennsylvania, United States

The most common method for controlling structure through processing is through simple thermal excursions, as temperature causes atomic diffusion, and thus allows structural re-ordering. One of the primary experimental method used to determine the local internal structure of nanomaterials is that of transmission electron microscopy (TEM). Therefore, the most common dynamic *in situ* microscopy experiments revolve around the relatively simple act of heating nanomaterial samples.

Thin-film technology has allowed much more local heating of the specimen in TEM heating holders if one is studying nanomaterials, enabling more stable imaging during *in-situ* TEM heating experiments. More recently, direct temperature measurements on these thin-film heating systems have made temperature measurements at the sample become closer to becoming reality. Although double-tilt TEM heating holders have been available, they suffer from some of the same limitations as standard double-tilt TEM holders do. Specifically, backlash in the tilting mechanism and lack of repeatability of the tilt makes it difficult to get the sample in exactly the right orientation and to know the exact angle of rotation. In this work we will use an optimized double-tilt thin-film heating platform that minimizes mechanical artefacts in the tilting mechanism and provides very stable image performance when heated to temperatures up to 1000°C, where it can be run more than 150 hours. Outside of standard temperature characterization of these thin-film heating TEM systems using different high resolution optical thermal imaging techniques, we also used melting standards to confirm accurate temperature response of the on-chip temperature sensor to indicate the temperature at the sample. We can identify very local and discrete melting events of samples with known melting points and correlate this to the sensor response, where local melting happens at very discrete moments (typically within a few frames), and surface diffusion occurs in matters of seconds following that.

In addition to this, we used this new *in-situ* TEM sample heating system to characterize model nanomaterial systems. Specifically, we studied the behavior of gold nanoparticles and nanorods on SiN$_x$ substrates as function of temperature. Starting with characterizing of particle motion and stability under the beam and then the phase transformation and (rapid) shape change at the melting point. We will present rapid frame-to-frame phase transformation process of gold nanorods as we ramp the sample temperature to 1000°C and show that we can use the system to track phenomena in nanostructures over the full temperature range of the TEM heating system with good image stability. These results illustrate the optimized overall mechanical stability and temperature performance of this newly developed *in-situ* TEM double-tilt heating platform.

MT06.15.08

Acid Etching of ZnO Nanostructures—*An In Situ* TEM Study Fangyuan Liu, Xingxu Lu and Pu-Xian Gao; University of Connecticut, United States

In micromachining and nanoelectronic field, etching is an important method to selectively construct two-dimensional or three-dimensional nanostructure semiconductors by introducing etchants or sacrificing the surface with powerful force [1]. ZnO nanostructure has been one of the most popular nanomaterials being studied in the past decades due to its widespread potential applications in photovoltaics, catalysis, flexible electronics, and solid state lighting, etc. [2,3]. To improve the ZnO nanostructure based device performance, some research groups used acidic or basic wet etching to help to expose the high surface energy crystal planes such as the semipolar $\{10-11\}$ family surfaces [4]. However, it is hard to control the surface exposure regularity of the etched ZnO nanostructures. In this work, *in situ* liquid cell transmission electron microscope (LCTEM) is employed to help resolve the crystal shape change in the acid etching process and reveal the morphology transformation process. To mitigate and clarify the well-known electron beam effect in LCTEM [5], optical microscopy (OM) and scanning electron microscope (SEM) has been used in combination of the LCTEM method. By using such a combination method, the etching process of
ZnO nanostructures can be robustly and confidently analyzed from atomic to nanometer scales and the etching mechanism can be simulated. Controlling pH=1~5 and temperature from 20 °C to 60 °C, the nanostructure will be changed from pencil shape to crown shape, as well as the etching rate will be changed. And both {10-11} and {10-1-1} can be preferentially exposed. This etching study provides some insight into controllably surface etching for nanoscale crystal surfaces.

Hexagonal Palladium Hydride in Graphene Liquid Cell
Jaeyoung Hong1, Jee-Hwan Bae1, Hee-Young Park1, Sehyun Lee1, Sunjun Hong2, Hoje Chun2, Juyoung Kim1, Kyureung Lee1, Byungchan Han3, Jungwon Park3, SungJong Yoo3 and Dongwon Chun1; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Yonsei University, Korea (the Republic of); 3Seoul National University, Korea (the Republic of)

Unexpected high pressure phenomena have been reported in boron nitride, Na-Cl and water, which are not observed at ambient conditions, indicating pressure can determine the stability of crystal structure [1-3]. It is widely accepted that palladium and palladium hydride (Pd-H) have a face-centered cubic (FCC) crystal structure under environmental conditions, even at high temperature in the case of pure Pd. In this study, we firstly report hexagonal close-packed (HCP) Pd-H which is a new palladium hydride phase previously suggested by density functional theory (DFT) calculation in high pressure [4].

We synthesized hexagonal Pd-H by irradiating high energy electron beam on aqueous solution of Pd in a transmission electron microscope (TEM). We adopted graphene liquid cell (GLC) to acquire high resolution images in liquid. [5] The electron beam induced nanoparticle growth in liquid was traced by FEI Titan TEM equipped with Gatan OneView CCD camera, which can acquire a single image within 0.04 seconds. Crystal structure analysis of the Pd nanoparticles was performed by analyzing diffraction patterns generated by fast Fourier transform (FFT) of high resolution TEM images acquired during particle growth. Through the diffraction patterns obtained from various zone axis, it was revealed that synthesized Pd nanoparticles have HCP structure which is different from the structure of Pd and Pd-H at ambient conditions, FCC. From energy dispersive X-ray spectroscopy (EDS) analysis conducted with a TEM equipped with Bruker Super X-EDS system, no element except for Pd was detected, suggesting oxygen doesn’t influence on the formation of hexagonal structure. Given that EDS cannot detect elements lighter than boron and inter-planar distance of the particle is greater than that of an imaginary pure HCP Pd which has same interatomic distance with FCC Pd, created particle is assumed to be Pd-H.

Thermodynamic stability of HCP structure of Pd-H was verified with a computational study. A simulation show that Pd-H is likely to have hexagonal structure when pressure is applied and concentration of hydrogen in palladium is high. For PdH0.5, HCP is more stable than FCC only when it’s under pressure higher than a few GPa, while HCP phase is more stable even at ambient pressure in the case of PdH1. Considering the previous reports asserting that materials lying between two graphene layers experience high pressure up to a few GPa and that radiolysis of water produces hydrogen radicals, formation of hexagonal Pd-H is attributed to not only hydrogen radicals but high pressure applied by water trapped between graphene layers. [3,6] We tried to synthesize the HCP particles outside a TEM by irradiating electron on liter scale vessel under ambient atmosphere, but resulting products were mostly FCC particles, which might be due to the absence of high pressure.

Also, it was confirmed that the nanoparticle has hexagonal structure even at the beginning of the growth stage and inter-planar spacing of the particles does not change remarkably during in-situ observation, suggesting hydrogen radicals participate in both nucleation and growth reactions. It’s quite different from FCC Pd-H formation process where hydrogen is absorbed by an existing Pd matrix. In addition, we investigated thermal stability of hexagonal Pd-H by an in-situ TEM heating holder (Gatan heating holder model 652). It is known that hydrogen desorbs easily from FCC Pd-H at around 100°C even in hydrogen atmosphere [7]. Interestingly, hexagonal Pd-H maintained its crystal structure even when it’s annealed over 300°C under vacuum without noticeable lattice constant change.

References
storage and for electrocatalysis due to a combination of properties including high magneto-crystalline anisotropy, high Curie temperature, small superparamagnetic critical size and high chemical stability. Solution phase techniques provide an excellent strategy for preparing monodisperse FePt NPs with a narrow size distribution, good compositional control and well-defined shape. Traditional ex situ experiments using TEM and XRD analytic methods show that fct-FePt NPs pass through several intermediate stages during solution synthesis from Pt and Fe precursors. First, fcc-Pt and crystalline Fe3O4 (magnetite) phases appear, presumably formed by reduction of the Pt and Fe precursors, respectively, at lower temperature. Subsequently, the Fe3O4 phase disappears and the fcc-FePt phase appears. Finally, the fcc-FePt phase transforms into fct-FePt when the sample is heated to a higher temperature. Controlling these reactions is important for precise control of the resulting nanoparticles, but the mechanism of the formation of fcc-FePt from the fcc-Pt and Fe3O4 phases is difficult to characterize using only ex situ data. We have therefore used in situ liquid cell electron microscopy to explore the mechanism of the reaction between crystalline Fe3O4 NPs and Pt solution in an aqueous medium. We find that microstructural changes take place in crystalline Fe3O4 NPs upon flowing a Pt precursor solution. The size of the crystalline Fe3O4 NPs gradually decreases and they eventually disappear, followed by re-formation of small NPs. Under certain conditions we also observe the formation of unusual structures where the NPs develop hollow cores. We consider the effect of initial Fe3O4 NP size, Pt concentration and temperature on the morphological changes, and discuss a model in which the crystalline Fe3O4 NPs are reduced and alloy with Pt atoms to form fcc-FePt NPs. Understanding the intermediate reaction steps can contribute to a better control of the formation of fct-FePt NPs.

Opportunities for Imaging the Formation of Interfaces between 2D and 3D Materials Frances M. Ross;
Massachusetts Institute of Technology, United States

The interfacial structure that forms at the junction between a 2D layered material and a 3D crystal can dominate the physical phenomena exhibited by the combination of materials. In particular, epitaxial or low defect density 2D/3D interfaces minimize electrical contact resistance and allow efficient charge transfer, and are essential for achieving proximity-induced superconductivity for spintronics applications and for developing catalysts and field effect or optoelectronic devices. In situ TEM provides a unique tool for examining the structure, formation and evolution of 2D/3D interfaces by following along as 3D nanocrystals are grown on 2D substrates. The experiments require deposition capabilities as well as ultrahigh vacuum (UHV) to control the sample surface cleanliness and avoid extraneous reactions such as oxidation. We therefore use a custom TEM with base pressure in the 10⁻¹⁰ Torr range and an attached series of vacuum chambers with heating and deposition capabilities. We first transfer 2D layers or heterostructures onto substrates that can be cleaned by direct-current heating in the vacuum system. Without breaking vacuum we then deposit metals or semiconductors using evaporation or reactive gas precursors. Imaging can be carried out at the same time as, or immediately after deposition, to follow the evolution of the interfacial structure. We will illustrate the capability of TEM to analyze nanocrystal nucleation and evolution, orientation relations, interface dislocations, local strain fields and defects in several metals and semiconductors on 2D materials. We will discuss how parameters such as substrate temperature and defect density affect the morphology of deposited metals, including reactive systems such as Nb on transition metal dichalcogenides. We will show a strategy for achieving epitaxial growth of materials that show poor epitaxy, such as Ag, Ge or Si, by using a template made of another, epitaxial material such as Au. We can also measure the catalytic properties of individual metal nanocrystals as we use them to grow semiconductors using chemical vapor deposition. We finally describe the use of sequential deposition to form heterostructures and the effects of patterning the 2D material. We conclude by discussing the importance of recent developments in microscopy instrumentation in analyzing 2D/3D materials growth to help design functional nanoscale materials.
Real-Time Observations of Phase Transitions During Antimonene Epitaxial Growth
Matthieu Fortin-Deschenes1, Onur Mentes2, Andrea Locatelli2, Francesca Genuzio2 and Oussama Moutanabbir1; 1Polytechnique Montreal, Canada; 2Elettra Sincrotrone Trieste, Italy

Group V 2D materials are a new class of materials [1] which includes various allotropes of phosphorus, arsenic, antimony [2, 3] and bismuth. Amongst them, we find the α and β phases of antimonene, which display thickness dependent electronic and topological properties, including a single-layer semi-conducting phase and a quantum spin-hall state at multilayer thickness. Using Transmission Electron Microscopy (TEM) and real-time Low-Energy Electron Microscopy (LEEM) observations of the van der Waals growth of antimonene on graphene, we discuss the growth modes of α-antimonene and its transition to β-antimonene occurring at a critical thickness of ~5nm. Moreover, using synchrotron-based X-ray Photoemission Electron Microscopy (XPEEM), we discuss the environmental stability and bonding nature of both phases. These results are an important step towards developing large-scale epitaxial growth methods for group V 2D materials.

Structural Evolutions of Vertically-Aligned Two-Dimensional MoS2 Layers Revealed by In Situ Heating Transmission Electron Microscopy
Mengjing Wang1, Jung Han Kim1, SangSub Han1,2, Kyu Hwan Oh2, Hee-Suk Chung3 and Yeonwoong Jung1,1,1; 1University of Central Florida, United States; 2Seoul National University, Korea (the Republic of); 3Korea Basic Science Institute, Korea (the Republic of)

Benefited from a large density of 2D layer edges exposed on the surface, vertically-aligned 2D MoS2 layers have recently harvested excellent performances in the field of electrochemical catalysis and chemical sensing. With the increasing versatility for high-temperature demanding applications, it is vital to identify their thermal-driven structural and chemical stability as well as clarify its underlying principle. Despite various ex-situ and in-situ characterizations on horizontally-aligned 2D MoS2 layers, the direct in-situ heating of vertically-aligned 2D MoS2 layers and the real-time observation of their dynamics at the near-atomic scale have never been approached, leaving their thermal stability poorly understood. Moreover, the geometrical advantage of the surface-exposed vertically-aligned 2D MoS2 layers is anticipated to unveil the structural dynamics of interlayer van der Waals gaps and its correlation with thermal energy, unattainable with 2D MoS2 layers of any other structural forms. Herein, we report a comprehensive in-situ heating TEM study on cleanly transferred vertically-aligned 2D MoS2 layers up to 1000°C. Several previously unknown striking phenomena were observed in the course of heating; (1) formation and propagation of voids between the domains of vertical MoS2 layers with distinct grain orientations starting at about 900°C. (2) subsequent melting of 2D MoS2 layers accompanying a formation of Mo nanoparticles at about 945°C, much lower than the melting temperature of their bulk counterpart. (3) initiation of melting from the surface-exposed 2D layer vertical edge sites, congruently supported by density functional theory (DFT) prediction. These new findings obtained with vertically-aligned 2D MoS2 layers will offer critical insights into better understand the thermodynamic principle that governs the structural stability of general van der Waals 2D crystals as well as provides technological guidance for materials design and optimization in their potential high-temperature applications.

In Situ TEM of an Oxide Thin-Film Crystal Nucleation and Growth and Aberration-Corrected TEM of Oxygen Vacancy Ordering Kinetics
Robert Sinclair, Yunzhi Liu, Sangchul Lee and Kyung Hoon Min; Stanford University, United States

It is now well understood that careful in situ transmission electron microscope (TEM) experiments are required in order to reveal, at high resolution, materials phenomena which are representative of the true natural behavior. One such study, of the crystallization of high-k dielectric tantalum oxide (Ta2O5) thin films on a silicon substrate, has shown how the individual mechanisms of nucleation and growth contribute to the overall transformation and
processing behavior, and even allow in situ capacitance measurements on individual crystals. The determination of the reaction activation energy is an important component of this type of work [1]. This approach has been extended to describe the kinetics of oxygen ion-vacancy ordering in epitaxial thin films of ceria (CeO$_2$) grown on yttria stabilized zirconia single crystal substrates, as revealed by in situ aberration-corrected TEM [2].

11:45 AM MT06.17.05
*In Situ* SAXS, WAXS and Absorption Measurements on the Nucleation and Growth of CdSe Nanoplatelets

Johanna van der Bok$^1$, Paul T. Prins$^1$, Federico Montanarella$^2$, Daniel Vanmaekelbergh$^1$, Andries Meijerink$^1$, Celso de Mello Donega$^1$ and Andrei V. Petukhov$^1$; $^1$Utrecht University, Netherlands; $^2$ETH Zürich, Switzerland

A better understanding of the formation mechanism of nanoparticles is needed to control growth and fine-tune their properties for applications. SAXS, WAXS and absorption measurements are commonly used to obtain insight in the formation mechanism of nanocrystalline systems. However, these measurements are typically performed in capillaries or by taking aliquots, therefore represent particle growth under conditions that are different than the actual reaction conditions. We developed a reactor to reproduce the conditions under which nanoparticles are synthesized by using specially designed glassware. In this reactor it is possible to do in-situ SAXS, WAXS and absorption measurements in oxygen and water free environment, at high temperatures and with a time resolution on the order of milliseconds. Furthermore, we were also able to add solid reactants or inject a liquid at any time during the synthesis, while measuring.

Here we report in-situ measurements aimed at giving more insight into one of the most debated nanoparticle formation mechanisms: the formation of CdSe nanoplatelets. These platelets have a cubic crystal structure, which makes the non-isotropic growth in only two dimensions counterintuitive. Several seemingly contradicting mechanisms for the formation have been suggested, e.g. oriented attachment [1], ligand-induced two-dimensional growth [2] and nucleation on crystal facets [3]. There is a consensus that the platelets only form in solution when a mixture of short and long chain carboxylates is present. SAXS measurements show that the NPLs form after the short chain cadmium carboxylate has melted (240°C). The in-situ absorption measurements reveal a large effect of the temperature when the short chain carboxylate is introduced in the reaction mixture (190-240°C). This triggered us to investigate the effect of addition temperature and the melting point of the short chain carboxylates in more detail. The SAXS and WAXS measurements provide information on the size, shape, crystals structure and melting of the carboxylate, whereas the absorption measurements made it easier to distinguish between a mixture of quantum dots and nanoplatelets.

forces, and particle motion. Here we use in situ transmission electron microscopy and atomic force microscopy to
directly observe and measure the particle motion and interfacial forces, respectively. Integrating theoretical
calculations and simulations, we revealed the orientation dependent attachments of particles, interfacial structures,
and the factors that affect them, such as temperature, pH, ionic strength, particle shapes, and solvents, etc. In
addition, we also demonstrated that strain relaxation at the grain boundaries, induced via oriented attachments,
forming twin structures. The specific systems that we investigate are metal (Ag and Au), oxides (TiO₂), and
minerals (mica), etc. The work provides a deep understanding of mechanisms of oriented attachments and factors
control the process and thus provide a guide to design and fabricate the morphologies and structures, which are
closely related with material properties and functions.

2:00 PM MT06.18.02
X-Ray Dynamical Diffraction in Powder Samples with Time-Dependent Particle Size Distributions Adriana
Valerio, Sergio L. Morelhao, Alex J. Cabral, Marcio M. Soares, and Claudio M. Remedios; 1Institute of
Physics, University of São Paulo, Brazil; 2Universidade Federal do Oeste do Pará, Brazil; 3Instituto de Ciências
Exatas e Naturais, Federal University of Para, Brazil; 4Brazilian Synchrotron Ligth Laboratory, Brazil

Advanced synchrotron sources of high flux and detector systems capable of collecting, in just a few seconds, full X-
diffraction (XRD) patterns of powder samples create opportunities for in situ studies of a variety of processes
such as catalysis, energy storage and conversion, and crystallization of nanoparticles from amorphous precursors.
There will be thousands of XRD patterns containing information on structural changes along the processes.
Particularly in the case of crystallization, information on crystal phase, lattice strain, and particle size distribution
(PSD) as a function of time and temperature, covering the whole process from amorphous to fully crystalline phases.

Besides position of the diffraction peaks that can provide information on thermal expansion coefficients from
nanoscale to large particles with bulk properties, width and area of the diffraction peaks allow a detailed
investigation of the growth kinetics, including nucleation and coarsening processes in the time-dependent PSDs.
Particle size from diffraction peak widths stand for just one value that can be produced by an infinity of PSDs. In
situ measures of integrated intensities during growth of crystalline particles provide a direct route to access
fluctuation in the population N(t) of particles as a function of time t. Nucleation (dN/dt>0) and coarsening (dN/dt<0)
processes can be evidenced from the experimental integrated intensities when compared to theoretical values for
PSDs with constant number of particles and with imposed constraints to the determined particle sizes from
diffraction peak widths.

Coarsening (grains growing in size) under constant volume of diffraction is possible at the cost of small grains that
dissolve providing material to larger grains in a process widely known as the Ostwald ripening phenomenon. Since
first described by Wilhelm Ostwald in 1896, the phenomenon has been observed in a number of general nanocrystal
growth systems where broad spectrum of particle sizes are present [1]. This process play a fundamental role in
determining the evolution in time of the particle population, and it is crucial for controlled synthesis of nanocrystals.

For PSDs with broader distributions, particle sizes from diffraction peak widths has complex behavior with the PSD
parameters such as mode (most probable value) and standard deviation, and where dynamical diffraction corrections
can be indispensa. For strong Bragg reflections, neglecting dynamical corrections in broad PSDs with many
particles of sizes above a few hundred nanometers leads to an aberration regarding the actual mode value. Without
accounting for dynamical effects to suppress the kinematical intensity contribution of large particles, the position
and width of the PSDs would have to be much smaller than they actual are to reproduce the experimental peak
widths. In this work we developed a systematic procedure to solve time-dependent PSDs based on in situ XRD
experiments. It is based on the kinematical approach of x-ray diffraction, with proper integrated reflectivity
corrections from dynamical diffraction calculation [2]. As practical demonstration we applied this analytical
procedure to the single-phase crystallization process of bismuth ferrite [3]. In situ XRD data collection where carried
out with synchrotron x-rays of 12keV, acquisition time of 38 s per XRD pattern, and enough flux to monitor
diffracting particles as small as 20 nm.

In Operando Scanning Electron Microscopy of Growth, Etch and Alloying Kinetics of Nanomaterials

Ryo Mizuta1, Maik Simon2,3, Ye Fan1, Thomas Mikolajick2,3, Walter M. Weber2,3 and Stephan Hofmann1; 1University of Cambridge, United Kingdom; 2Namlab gGmbH, Germany; 3Center for Advancing Electronics Dresden, Germany

The potential of environmental scanning electron microscopy (ESEM) as a versatile, in-operando technique that can accommodate many length scales, substrate geometries and reactive environments has been highlighted in the context of recent in-situ studies of catalytic graphene and hexagonal boron nitride (h-BN) chemical vapour deposition [1-3]. We have set up a dedicated new ESEM system based on a modified adoption of the ZEISS NanoVP aperture technology to facilitate improved high-resolution imaging, combined with heating capabilities of up to 1000°C and a customised local gas injector system. We present here our latest results using this new in-operando capability to foster an understanding of crystal growth and phase transformations on the nano-scale specifically for 1D and 2D materials. We show in-operando ESEM of the Ni silicidation of top-down patterned Si nanochannels revealing unexpected time-dependent phenomena that contribute to inhomogeneous silicidation lengths. This silicidation process plays an important role in VLSI transistor fabrication as it allows the formation of highly conductive metal silicide contacts very close to the gate [4,5]. However, while bulk silicidation is well understood, the altered kinetics for small diameters, which are increasingly applied in highly scaled transistors, are not fully understood [6]. We introduce strategies how such silicidation on the nano-scale can be much better controlled, offering new insights for scaled contact formation. We also show an in-situ ESEM study of localised etching of 2D materials addressing key questions on the nucleation and etch kinetics specifically of graphene, h-BN and TMD materials such as WS2.

Dynamic Perturbation of the Electrical Double Layer with an Electrochemical AFM for Confined Metal Electrodeposition

Mark Aarts and Esther Alarcon-Llado; AMOLF, Netherlands

Understanding and directing electrochemical reactions below the micrometer is a long-standing challenge in electrochemistry. In this respect, electrodeposition using scanning probe microscopy provides an attractive platform, not only for additive nanoscale manufacturing, but also for the investigation of local dynamics such as mass transport and reaction kinetics.

We report on the direct writing of copper nanostructures using an oscillating nanoelectrode operated with an Atomic Force Microscope (AFM) in aqueous solutions. The nanoelectrode is used to locally initiate electrochemistry, while the AFM allows for in-situ probing of the deposited material. We demonstrate the writing of arbitrary structures beyond cluster size with lateral dimensions in the order of the tip radius. Strikingly, this local writing is only possible in highly dilute electrolytes (~ 1 µM CuSO4). Moreover, we find a profound effect of the dynamic operation of the nanoelectrode on the deposition kinetics.

We explain our results by considering the extended screening length and slow charge dynamics of the dilute electrolyte, which allows the nanoelectrode to operate inside, and disturb, the electrical double layer (EDL) at the solid-liquid interface. We visualize these (dis)charging dynamics and their effect on the reaction directly through the electrodeposited structures, and experimentally observe the Debye time of the electrolyte as a threshold value for growth. Furthermore, we show that this threshold time increases as a function of applied potential.

Our results lead us to propose a reaction mechanism based on cyclic charging and discharging of the EDL, which
facilitates local electrodeposition through direct electrostatic interaction between ions in the liquid and the nanoelectrode.

Environmental TEM Study of Size- and Shape-Selected Cobalt Nanoparticles on the External Surface of MFI Nanosheets Jennifer Carpena1, Donghun Kim2, Dmitri Zakharov3, Rahul Rao1, J. Anibal Boscoboinik4, Eric A. Stach1, Michael Tsapatsis5,6, Dario Stacchiola3 and Benji Maruyama6; 1Air Force Research Laboratory (UES Inc.), United States; 2University of Minnesota, United States; 3Brookhaven National Laboratory, United States; 4University of Pennsylvania, United States; 5Johns Hopkins University, United States; 6Air Force Research Laboratory, United States

One of the factors limiting catalytic activity of nanoparticles is the lack of control over formation and evolution processes (i.e. coalescence and coarsening) and over size and shape selectivity at high temperature. Here, we show that zeolite nanosheets of the MFI type (MFI-nanosheets or MFI-Ns), formally known as the Zeolite Socony Mobil–five (ZSM-5), can be used to keep cobalt catalyst nanoparticles docked to the support external-surface and to help retain their small size when exposed to high-temperature reducing conditions for a prolonged time. In situ environmental transmission electron microscopy (ETEM) shows that the MFI-Ns can influence not only the size of nanoparticles but also their shape via catalyst/support registry. ETEM image analysis revealed the preferential docking of nanoparticles to energetically favored configurations –namely to four or less pores consequently regulating the resulting population of nanoparticles. We ascribe the observed registry to catalyst/support interactions and to the periodic surface of the MFI-Ns with local minima, which helped stabilize nanoparticles and suppress evolution. This study elucidates how a nano-porous support surface may provide a path forward for controlling nanoparticle formation and evolution kinetics and for achieving size- and shape-selectivity at high temperature.

Optical Detection of Self-Assembly Dynamics Below the Diffraction Limit Hans Robinson, Zhixing He, Chengshuai Li and Yizheng Zhu; Virginia Tech, United States

The resolution of optical microscopy is generally limited by diffraction to approximately half a wavelength, which prevents close monitoring of the motion of nanoparticles with optical techniques. Moreover, the intensity of light scattered from a single nanoparticle scales as the square of the particle volume, making it difficult to detect the scattered light from small particles with sufficient speed to characterize particle dynamics. Various superresolution techniques exist that overcome these difficulties, but these generally require careful fluorescent labeling or else are applicable only in rather limited circumstances, and are often too slow to be of use in following the dynamics of self-assembly.

We introduce an interferometric optical technique that overcomes many of these difficulties, and therefore will allow the detailed characterization of the dynamics of self-assembly at the nanoscale. This technique measures the optical anisotropy in the scattering from individual nanoparticles or small assemblies of nanoparticles, which makes it possible to determine the three-dimensional alignment between pairs of particles or of a single anisotropic particle with time resolution on the order of a few microseconds. We will present a theoretical development of this technique, as well as experimental demonstrations on monitoring the rotational motion of individual gold nanorods and the assembly of superparamagnetic nanoclusters.

Looking forward, the technique could be straightforwardly combined with existing single-particle tracking techniques, and since it is interferometric in nature, particles as small as a few nanometers could potentially be tracked, both in position (x,y,z) and orientation (θ,φ). In addition, each measurement results in an optical spectrum, which has the added advantage that for the assembly of metal nanoparticles, the plasmon nanoruler effect could be used to determine the separation between particles with high accuracy. Taken together, these capabilities have the potential to afford in situ monitoring of nanoscale self-assembly with unprecedented detail in a straightforward, non-invasive, and affordable setup.

3:45 PM MT06.18.07
Formation of (MoO3)n Clusters and Nanoparticles in the Gas Phase Measured with Time-of-Flight and
Since the 1930s, molybdenum oxide (MoO$_3$) is in the scope of knowledge to be a very selective catalyst for the conversion of methanol to formaldehyde by oxidation [1]. It also has promising gas sensing properties and the utilization of MoO$_3$ nanorods in gas sensors exhibits a highly selective response to NO$_2$ and NH$_3$ [2]. Catalysis as well as sensing requires high surface area materials and thus a controlled formation of materials on the nanoscale. Gas phase synthesis is an established technology to produce small particles in high purity without any template. We investigated the nucleation and growth of molybdenum oxide nanoparticles in flames using time-of-flight mass spectrometry (TOF-MS) and particle mass spectrometry in combination with molecular-beam sampling. This sampling technique instantaneously interrupts all reactive gas-phase processes and thus allows a spatially resolved measurement of gas and particle-phase. TOF-MS can be used to identify the composition as well as the transient formation and growth of intermediate species such as clusters from various locations in a reactor. MoO$_3$ nanoparticles are synthesized by the decomposition of molybdenum hexafluoride (MoF$_6$) in a premixed hydrogen/oxygen flame. Due to low pressure (20–30 mbar), an almost one-dimensional, spatially extended flat flame is formed enabling spatially-resolved measurements along the reactor axis. The progress from the initial decomposition of the gaseous precursor to the formation and growth of (MoO$_3$)$_n$ clusters and nanoparticles has been studied by varying the distance between the burner head and the sampling nozzle position. The measurements show a sequential cluster formation followed by a subsequent particle nucleation. The number concentrations of differently sized clusters strongly vary indicating “magic” cluster sizes. In contrast to previously studied WO$_3$ nanoparticle formation [3], (MoO$_3$)$_n$ clusters with excess of oxygen are observed. Moreover, (MoO$_3$)$_n$ cluster and nanoparticle formation is much more prone to the flame chemistry during synthesis, which can be used to tune the nanoparticle growth process.

**In Situ Ultrafast Electron Scattering to Measure Massively Enhanced Nucleation and Growth Driven by Highly Non-Equilibrium Ultrafast Laser Assisted Diffusion** Alex Sarracino, Abdul R. Ansari, Ben Torralva and Steven M. Yalisove; University of Michigan–Ann Arbor, United States

In-situ pump probe electron scattering to study the nucleation and growth of thin films is still a technique in the early stages of development. Unlike in 4-D microscopy, where a single electron scattering event is observed $10^6$ times where reversible phenomena is interrogated, most material self-assembly at the nanoscale evolves and requires a single packet of $10^6$ electrons to probe. We will present a different approach to ultrafast pump probe electron scattering by using a laser-pumped electron gun in a reflection geometry to collect the specular beam rather than a diffracted beam which allows for lower electron loss in the material.

We have developed this technique to directly measure the ultrafast laser assisted diffusion of self-interstitials that are generated by irradiating GaAs with a 150 fs laser operating at 780nm using a fluence below the melt threshold but above the High Spatial Fluence Laser Induced Periodic Surface Structure (HSFL) formation threshold (0.04 J/cm$^2$). We have described the defect generation mechanism in the literature [1]. Self interstitials are generated via an ultrafast, athermal process in less than 600 fs after the laser pulse irradiation. Subsequent 1 kHz irradiation for one second causes the formation a self-assembled grating that eventually has a wavelength of 180 nm consisting of ~90 x 200 nm walls and ~90 x 200 nm trenches (measured with Transmission Electron Microscopy). Preliminary pump probe experiments show that the growth does not continue after the last pulse. The growth rate of the material above the original surface is at least 2000 Å/sec assuming the process takes the full millisecond between pulses. However, we have much evidence that the ultrafast laser assisted diffusion stops somewhere between 100 ps to 50 ns, hence the actual growth rate is between $10^6$ and $10^7$ Å per second.

We will present results from a nonadiabatic quantum molecular dynamics calculation where we have studied the enhancement in mass transport of a self-interstitial atom during and after irradiation. The model couples the vector potential of the laser field directly to the Hamiltonian and allows us to directly monitor the bonding and electron-ion
coupling. The method, which requires 40 attosecond time steps, has revealed additional athermal, ultrafast atomic transport mechanisms that are consistent with the extremely large growth rates we observe.

This talk will present our electron gun design and performance as well as results from our pump probe electron scattering study of the nucleation and growth of the first islands that appear after ~300 to 400 exposures. These islands are ~0.5 nm tall and ~20 nm wide and require a probe with a commensurate wavelength. Our electron pulses have a temporal width of ~2 ps after acceleration to 30KV. Results will be shown for multiple experiments where the electron beam will be delayed from 50 ps after the 400th exposure to 50 ns after the 400th exposure. By observing the reduction in the specular beam intensity we will be able to extract an arrival rate of our subsurface interstitials assisted by the optical field.

Rabouw1 and Zeger Hens2; 1Debye Institute for Nanomaterials Science, Netherlands; 2Physics and Chemistry of Nanostructures Group, Belgium

Colloidal quantum dots have recently entered the consumer market as phosphor material for television screens. Over the past 30 years of research, an enormous variety of synthesis procedures has been developed for quantum dots of different chemical compositions, sizes, and shapes. In most cases, the metal and anion precursors are mixed at temperatures of 200–350°C in the presence of coordinating ligands. The outcome of the synthesis is determined by the chemical nature and concentrations of the precursors, the reaction temperature, the presence of additives, and other parameters. While for most synthesis procedures we have a reasonable model of the underlying formation mechanisms, this model is usually supported only by indirect evidence. For example, intermediate stages in the reaction may be studied by taking aliquots from the reaction mixture and analysing them ex situ using electron microscopy. Alternatively, optical spectroscopy has allowed the study of quantum dot formation mechanisms in situ, but this method relies on reference measurements that relate properties to structure. Recently, X-ray scattering experiments have been explored as a promising route to obtain in situ data on quantum dot formation. However, X-rays penetrate poorly through the reaction mixture, so the experiments could only be performed using thin capillaries as reaction vessels, which severely hinder reactant mixing compared to conventional reaction flasks.

Here, we follow the formation of colloidal CdSe quantum dots using in situ X-ray scattering under reaction conditions comparable to typical synthesis procedures used in academic labs. To this end, we have developed a reaction-flask design that allows for proper reactant mixing while minimizing attenuation of the X-ray probe beam. We can thus track the size, size dispersion, and concentration of quantum dots during growth, without the use of calibration curves. Even for the intensively studied system of CdSe quantum dots, we show that the conventional model of separated nucleation and growth fails to provide an accurate description of the quantum dot formation. Instead, we find that the nucleation phase extends for minutes, continuing while existing quantum dots in the ensemble are growing. Although nucleation and growth are not separated, we nevertheless achieve a narrow size distribution of the final product. Based on a comparison to simulations, we propose that this seemingly counterintuitive finding is evidence for a radius-dependent quantum dot growth rate. This allows smaller quantum dots to grow faster than bigger ones, resulting in a narrow size distribution. The origin of a radius depended growth rate has most likely to do with the different faceting of larger quantum dots compared to smaller ones.

Our method has provided unexpected insights into a synthesis procedure that has been studied in depth for over 25 years. This highlights the importance of in situ measurements of nanocrystal growth under realistic reaction environments. With follow-up experiments, we will investigate the synthesis of other types of nanocrystals, including NaYF4 upconversion nanocrystals and CdSe nanoplatelets.

Real-Time Coherent X-Ray Scattering Studies of Ion Beam Nano-Patterning Peco Myint1, Mahsa Mokhtarzadeh2, Jeffrey Ulbrandt3, Suresh Narayanan3, Randall Headrick3 and Karl Ludwig1,1; 1Boston University, United States; 2Shahid Beheshti University, Iran (the Islamic Republic of); 3The University of Vermont, United...
States; 4Argonne National Laboratory, United States

Broad ion beam bombardment of solid targets leads to the spontaneous formation of nanoscale structures, such as ripples or ultrasmoothened surfaces, but complete fundamental understanding of the phenomenon is still elusive. In this work, the surface sensitive X-ray technique of Grazing-Incidence Small-Angle X-ray Scattering (GISAXS) is used to study the kinetics and dynamics of nanoscale surface evolution. While non-coherent X-rays can measure the averaged kinetics on a surface, coherent X-rays make it possible to differentiate the dynamics of fluctuations around the average kinetics. Real-time studies of ion bombarded Si, Ge, and SiO₂ surfaces have been conducted. The target materials were kept either below or above their recrystallization temperatures. In the early stage of room temperature ion bombardment, the evolution of averaged kinetics is well fit with a linear theory formalism employing a viscous relaxation term. The X-ray Photon Correlation Spectroscopy (XPCS) two-time correlation function shows a novel behavior in the early stage, with memory stretching back to the beginning of the bombardment. During the late stage where the average surface structure on a given length-scale is no longer evolving, dynamical processes exhibit compressed exponential correlation behavior. Ion bombardment experiments above the target materials’ recrystallization temperatures are ongoing and their results will also be reported.

4:45 PM MT06.18.11
In Situ and Operando X-Ray Scattering Studies of the Processing and Performance of Novel Three-Dimensional Tricontinuous Bulk Conductor/Insulator/Conductor Nanocapacitor for Ultra-High-Power Electrical Energy Storage Samuel S. Welborn1, John Corsi1,2 and Eric Detsi1,2; 1University of Pennsylvania, United States; 2Vagelos Institute for Energy Science and Technology (VIEST), United States

Three-dimensional (3D) electrostatic capacitors have the potential to outperform their conventional two-dimensional (2D) counterparts. In this talk, I will present our work on the use of real-time X-ray scattering techniques to aid the development of a novel class of 3D tricontinuous bulk conductor/insulator/conductor nanocapacitors using nanoporous gold (NP-Au), a 3D bicontinuous network synthesized by selective alloy corrosion (dealloying), as the scaffold and primary building block. These X-ray scattering experiments are performed at the University of Pennsylvania’s Dual-Source and Environmental X-ray Scattering Facility, an instrument capable of simultaneously probing the Ultra Small-Angle X-ray Scattering (USAXS) and Wide-Angle X-ray Scattering (WAXS) regimes in various experimental environments. In the first part of this talk, I will present a fundamental study on the synthesis of 3D NP-Au, the scaffold of our 3D nanocapacitor. In particular, we use in situ USAXS/WAXS to probe the evolution of microstructure, morphology, and crystal structure during electrochemical dealloying (synthesis) performed under potential control in neutral electrolyte. Our studies have revealed that both zero-dimensional (0D) Au nanoparticles and 3D NP-Au form during the dealloying process, an important and previously unknown finding. In the second part of my talk, I will present our studies on post-synthesis thermal coarsening in combination with X-ray scattering (in situ USAXS) to tailor the ligament/pore size distribution in the 3D NP-Au scaffold, which is used as the first conductor in the bulk conductor/insulator/conductor nanocapacitor. In connecting these in situ USAXS/coarsening results with in situ transmission electron microscope (TEM) observations, we have found that the abovementioned 0D Au nanoparticles play an important role in the initial stages of the coarsening process. Following the post-synthesis thermal coarsening, the insulator (alumina, Al₂O₃) and second conductor (aluminum-doped zinc oxide, AZO) are grown on the pore walls of the starting 3D NP-Au scaffold using atomic layer deposition (ALD), resulting in a 3D tricontinuous bulk NP-Au/Al₂O₃/AZO nanocapacitor. In the third part of this talk, I will discuss our use of operando Grazing Incidence SAXS (GISAXS) methods to probe the microstructural and morphological changes of the tricontinuous bulk nanocomposite during ultra-fast charge/discharge operation.
High-resolution imaging of electron beam-sensitive crystalline materials is one of the most difficult applications of transmission electron microscopy (TEM). The challenges are manifold, including the acquisition of images with an extremely low beam dose, the time-constrained search for crystal zone axes, the precise alignment of successive images, and the accurate determination of the defocus value.

We reported that using a direct-detection electron-counting camera, it is possible to acquire useful high-resolution TEM images with electron dose as low as a few electrons per square angstrom to ensure that the intact structure was captured before damage occurred [1]. In this talk, we will present a suite of new methods that we recently developed to address the rest challenges mentioned above. Our methods advance the HRTEM of extremely beam-sensitive materials from “occasionally possible” to “routine”. We demonstrate the effectiveness of our methodology by capturing atomic-resolution (~ 1.5 Å) TEM images of several metal organic frameworks (MOFs) that are generally recognized as highly sensitive to electron beams. In the case of MOF UiO-66, individual metal atomic columns, various types of surface termination, and benzene rings in the organic linkers, are clearly identified. We also successfully apply our methods to other electron beam-sensitive materials, and achieve atomic-resolution TEM imaging of the organic-inorganic hybrid perovskite CH3NH3PbBr3 for the first time [2]. More recently, we applied this new technology to prove the successful encapsulation of single molecule magnets in MOF NU-1000 [3], and to investigate the evolution and transformation of various defects in MOF UiO-66 [4]. We also found a new TEM specimen preparation technique particularly useful for beam-sensitive materials.

Controlled Manipulation of Individual Molecules on Surfaces with Advanced Scanning Probe Microscopy Techniques Omur E. Dagdeviren1, Chao Zhou1, Milica Todorovic2, Eric Altman1 and Udo Schwarz1; 1Yale University, United States; 2Aalto University, Finland

With the continued development of scanning probe microscopy techniques, manipulation of single molecules has become possible. Thereby, the manipulation path can be chosen at will and energy barriers between potential minima on that pathway can be quantified, as can the energy landscape around the molecule before and after manipulation. To explore the practicality of this novel pathway to catalysis research, we selected benzene molecules on a Cu (100) surface as a model system. We first choose a specific manipulation path and then move the tip at constant but continuously reduced heights while recording the oscillation amplitude A and phase phi with the microscope operated in our recently developed tuned-oscillator (TO) detection scheme [1]. To preserve the accuracy of recovered tip-sample interaction potentials and forces, we use oscillation amplitudes significantly larger than the decay length of the tip-sample interaction potential [2,3]. Analyzing the full (x, z, A, phi) data array then allows recovery of the potential energy U(x, z) acting between the tip and the sample, the force on the tip normal to the surface vertical tip-sample force Fz(x, z), and the force Fl(x, z) that acts on the tip along the manipulation path (i.e., lateral) with meV, pN, and pm resolution. In 54 distinct manipulation events, the molecules were either pushed, pulled, jumped to the tip, or did not move depending on the chemical surroundings of the molecule and the chemical identity of the tip. For further insight, we compared the experimentally measured energy landscapes and manipulation outcomes with computational results obtained using a Bayesian Optimization Structure Search (BOSS) protocol [4], which also delivers that the diffusion barrier evolves with the chemical identity of the tip and the surrounding of the molecule. This machine learning technique developed at Aalto University delivers the minimum energy pathways and entire energy landscapes with minimal computational effort.

Carving Pt-Based Bimetallic Nanoparticles under Electrochemical and Thermal Conditions Shu Fen Tan, Ainsley Pinkowitz, Baoming Wang and Frances M. Ross; Massachusetts Institute of Technology, United States

Pt nanoparticles (NPs) have been widely used as electrocatalysts for oxygen reduction reactions (ORR) in fuel cells of interest in the automotive industry¹ and hydrogen evolution reaction (HER) in alkaline electrolyzers.² However, the high cost as well as the high d-band center of Pt hinder its application as a cost-effective fuel cell material. Instead, Pt is combined with other metals. The resulting Pt-based bimetallic NPs are potential candidates to overcome the issues associated with pure Pt without compromising the electrochemical performance. Since the underlying electrocatalytic reactions, such as adsorption and desorption of reactants, intermediates and products, take place on the surface of the electrocatalysts, the performance is determined by the surface composition of the bimetallic NPs.³ Tremendous effort has been made in synthesizing Pt-based bimetallic NPs with precisely controlled surface structure and chemistry. In particular, chemical and electrochemical processes have both been used to tune the surface composition of bimetallic NPs.⁴ Chemical processing is often difficult to control due to random site etching, but electrochemical processing is relatively versatile and it can be straightforward to etch the non-noble metal away. However, important questions regarding this electrochemical tuning remain unresolved, regarding the interplay of kinetic etching phenomena and external parameters such as the NP shape, initial composition, surfactants, temperature and etching potential.

Here, we use in situ liquid cell electron microscopy as a direct probe of the electrochemical etching of oleylamine-capped Pt-based bimetallic NPs in aqueous sulfuric acid electrolyte solution at elevated temperatures with high temporal and spatial resolution. We have modified liquid cell chips in order to perform simultaneous electrochemical biasing and heating. We synthesize Pt-based bimetallic NPs in the shape of rhombic dodecahedra with well-defined facets.⁵ The particles contain a Pt skeleton covered by the non-noble metal, for example Ni, as well as a surface layer of Pt surrounding the entire NP. Our real-time observations reveal that the etching kinetics of these Pt-based bimetallic NPs upon application of a bias is dependent on the reaction temperature. Furthermore, the applied bias required to etch the NPs is also dependent on the reaction temperature. We will discuss the etching mechanism, taking account of the effects of the electron beam on the observations. Understanding the electrochemical behavior of these Pt-based bimetallic NPs at elevated temperatures potentially lays the foundation for rational design of desired structures for application as electrocatalysts.

Reversible Gas–Solid Reaction on Palladium Surface under an Electric Field Takehiro Tamaoka¹², Ryotaro Aso¹, Hideto Yoshida¹ and Seiji Takeda¹; ¹Osaka University, Japan; ²Kyushu University, Japan

Gas-solid reaction plays an important role in catalysis, gas sensing and gas storage. Therefore, reaction process on metal surface with gas has been extensively studied at the atomic scale. However, the reaction process on metal surface with gas under electric field remains poorly understood. In our study, we investigated the reaction process on metal surface under electric field by means of atomic-resolution in situ environmental transmission electron microscopy (ETEM), and found that an unexpected metal (Pd)-gas (N₂) compound was formed on the metal surface under an electric field.⁶

We studied Pd surface by using a pair of Pd electrode tips with nanometer separation. The reaction process on Pd surface in gases, such as O₂ and H₂, is well understood. Here, we performed systematic study on Pd surface in four typical environments (vacuum, O₂ (100 Pa), H₂ (100 Pa) and N₂ (100 Pa)) with and without an electric field. First, we studied Pd surface without an electric field.⁶ We found that the surface oxidation of Pd surface in O₂ has a
dependence of previous exposure to H₂: after prolonged exposure to H₂, the oxidation of Pd surface is suppressed. Based on the ETEM observation and electron energy loss spectroscopy (EELS) measurement, we concluded that subsurface adsorption of H atoms suppresses the oxidation of Pd surface. Then, we studied Pd surface pretreated in H₂ under an electric field. In vacuum, a tunneling current flowed across the nanogap between electrically biased Pd electrode tips. In O₂ and H₂, Pd atoms on the positive electrode tip were evaporated and then deposited to the negative electrode tip without any changes in the crystal structure.[1] In N₂, we found that a peculiar compound was formed on the positive electrode tip.[1] A PdN compound, which is predicted and confirmed only at extremely high pressure and temperature, was formed at low pressure and room temperature under an electric field. The gas-solid reaction was reversible with the change of the magnitude of an electric field. It is most likely that electrons passing through the nanogap induce the gas-solid phase transition. We will show the in situ movie of the dynamic phenomena including the gas-solid phase transition. In addition, we will show the result of ETEM observation of Pt surface. These findings obtained only by means of in situ ETEM observation have opened new route toward synthesizing nanomaterials.

Cross-Correlative X-Ray/TEM Liquid Cell Microscopy for Energy Applications Khim Karki¹, Joonsuk Park², Allen Y. Liang³, Tyler Mefford², Daan Hein Alsem¹, Eric A. Stach³, William C. Chueh² and Norman J. Salmon¹; ¹Hummingbird Scientific, United States; ²Stanford University, United States; ³University of Pennsylvania, United States

Cross-correlative techniques using transmission electron microscopy (TEM) and synchrotron transmission X-ray microscopy (STXM) are becoming more common and are used to study a wide range of electrochemical reaction-systems at the nanoscale. This approach has already started to produce new insights on the dynamics and structural changes during processes as lithium ion insertion/extraction, dendrite formation, metal nucleation, and metal corrosion. Despite the power of this approach, the challenges associated with replicating bulk-scale electrochemistry data in the environmental cell microscopy platform are well-known. First, the hardware components are not best optimized to perform in the reduced scale environment. Second, the chips configurations such as sizes and aspect ratios of different electrodes suitable for various electroanalytical measurements are poorly designed. Here, we use operando liquid cell TEM/STXM microscopy platform, validating cross-correlative electroanalytical bulk-scale measurements with model systems, to study the oxygen evolution reaction (OER) in the electrodeposited thin films of Ni(OH)₂/Co(OH)₂ for charge storage applications such as batteries and supercapacitors.

The studies presented here are performed using electrochemical cells, which consist of two microfabricated chips sandwiched with electron transparent SiNx membranes for viewing in TEM/STXM. Using a new developed hardware system with a specialized configuration of working, counter and reference electrode, we performed cyclic voltammetry studies in 0.1M CuSO₄ and 20 mM K₃Fe(CN)₆/20 mM K₄Fe(CN)₉ in 0.1M KCl solutions to validate the bulk-scale correlation between TEM and STXM. Next, we study nucleation mechanism during the electrodeposition of Ni(OH)₂/Co(OH)₂ film growth on the substrate electrode using TEM/STXM. We compare oxygen evolution on 50 μg cm⁻² geom Co(OH)₂ on glassy carbon in a macroscopic rotating disk electrode (RDE) cell at a rotation rate of ω = 1600 rpm and a scan rate of ν = 10 mV s⁻¹ and in the operando STXM cell with Co(OH)₂ on Pt at defined voltage scan rate and electrolyte flow rate. The current-potential relationship in the operando STXM cell shows similar Tafel slopes at the same potentials to the RDE tests validating the high electrochemical fidelity of the operando STXM cell. The liquid-electrochemistry hardware developed for this work can be used to study range of materials using cross-correlative imaging in TEM/SEM and X-ray microscopes.

Anisotropic Oxidation of Suspended Graphene—Etch Dynamics and Stability Beyond 1000 °C Joachim D. Thomsen¹,⁵, Jens Kling², Timothy J. Booth¹, David M. Mackenzie¹ and Peter Bøggild⁴; ¹Massachusetts Institute of Technology, United States; ²Technical University of Denmark, Denmark; ³Aalto University, Finland

We study the oxidation of clean suspended mono- and few-layer graphene in real-time by in situ environmental transmission electron microscopy [1]. In order to study the oxidative etching of suspended graphene, we have
developed a cleaning scheme that results in the near complete removal of hydrocarbon residues over the entire visible sample area (~50 µm²) [1, 2]. This etching process allows the top-down fabrication of graphene nanoribbons with lower edge roughness than can be achieved by electron beam lithography.

At pressures below 0.1 mbar we observe anisotropic oxidation and the formation of hexagonal holes with armchair-oriented edges, with an edge roughness below 1 nm. We see increasingly isotropic oxidation at higher pressures, eventually leading to irregular holes at a pressure of 6 mbar. We find that the growth rate of the initial defect is more stable than that of an extended hole. We show that this is due to re-arrangement of the edge atoms, leading to a stable defect which over time is broken by consecutive discrete and stochastic atomic removal events.

Finally, we find that few-layer suspended flakes are stable against oxidation at temperatures up to at least 1000 °C in the absence of impurities and electron beam-induced defects. These findings show (i) that the oxidation behavior of mono- and few-layer graphene depends critically on the intrinsic roughness, cleanliness and any imposed roughness or additional reactivity from a supporting substrate and (ii) that the activation energy for oxidation of pristine suspended few-layer graphene is up to 43% higher than previously reported for graphite. These results have implications for applications of graphene where edge roughness can critically affect the performance of devices, and more generally highlights the surprising (meta)stability of the basal plane of suspended bilayer and thicker graphene towards oxidative environments at high temperature.

Active and Stable Low-Platinum Catalysts—From In Situ Understanding to Rational Design Jianbo Wu and Yanling Ma; Shanghai Jiao Tong University, China

The core-shell catalysts with atomic layered surface Pt through liquid phase atomic layer deposition has been proven to be one of the most promising oxygen reduction (ORR) electrocatalysts with high activity and low consume of Pt.1-5 It is important to directly observe how the atomic layers grow via in situ technique. On the other hand, corrosion is a major and unavoidable challenge for the degradation of properties of multimetallic core-shell electrocatalysts during electrocatalysis, which restricts the practical application of this type electrocatalysts severely.6-7 Therefore, it has been an urgent issue to understand the evolution and mechanism of corrosion of Pt-based core-shell catalysts during the reaction with an aim to the effective utilization of the catalysts.8

In this presentation, we will first report a 3D growth mechanism for the formation of core−shell nanostructures involving a hybrid process with initial island growth and surface diffusion. The desired surface structure can be achieved by adjusting the competition between island deposition and surface diffusion.9 Then, we will show the corrosion behavior of Pd@Pt core-shell electrocatalysts in the etching solution, which depends on the effects of geometry and surface defect.10-11 Finally, we can demonstrate the capability of electrochemistry inside of TEM, showing both the oxidative etching and the re-deposition behaviors during the cyclic voltammetry in TEM.

*In Situ* Imaging and Characterization of the Electrochemical Nucleation and Growth of Sulfur and Bromine Microdroplets inside Liquid Electrolytes Nian Liu and Po-Wei Huang; Georgia Institute of Technology, United States

Since the first discovery of supercooling in 1724, the study of supercooled matter has been mainly limited to varying temperature or pressure. Early this year we have demonstrated an electrochemical approach to generate supercooled sulfur and observe the dynamic process in situ (see Publication 1 below). Our methodology combines dark-field optical microscopy, a transparent electrochemical cell, and a fast camera to visualize the process at single microdroplet with millisecond time resolution. This platform may open up opportunities for studying supercooled liquids as the droplets approach either homogeneous nucleation to the crystalline state or enter into the glass transition. Relevant to understanding lithium-sulfur battery chemistry, liquid sulfur is observed to form in the electrochemical cell and elucidates a long-debated reaction pathway for sulfur redox reaction in this environment. In a follow-up work (see Publication 2 below), we applied the above methodology to image in situ the electrochemical formation of polybromide droplets, which is used in zinc-bromine flow batteries, a promising technology for stationary energy storage. Using our unique platform, we reveal the liquid nature, chemical composition, and strong interaction with the electrode, which cannot be done using conventional analysis tools. The results provide insights into the role of complexing agents and guide the future design of zinc-bromine flow batteries.

This presentation is based on the following two recent publications from my lab:

*In Situ* Multimodal Characterization of Lithium/Sodium-Ion Batteries by Using Electrochemical Liquid Cell Zhiyuan Zeng; City University of Hong Kong, Hong Kong

Lithium/Sodium ion batteries have high energy density and are extremely light and inexpensive to produce, thus the success of Li/Na ion batteries may help to achieve a major leap in green energy storage technology. Advancing our understanding necessitates the development of experimental tools capable of operando characterization that can discern mechanisms of operation and degradation in the native operating environment. The most illuminating and useful characterization methods are those capable of providing detailed mechanistic information of charge/discharge dynamics of individual grains and particles. TEM investigations specialize in revealing structural and compositional information with nanoscale spatial resolution and subsecond temporal resolution. By utilizing our newly designed electrochemical liquid cells, we devoted our effort to the in situ and operando multimodal study of the dynamic Electrode-Electrolyte Interface reactions.

For lithium ion batteries, we captured dynamic electrochemical lithiation and delithiation of Au anodes in a commercial LiPF<sub>6</sub>/EC/DEC electrolyte using transmission electron microscopy (TEM). The inhomogeneous lithiation, lithium metal dendritic growth, electrolyte decomposition, and solid-electrolyte interface (SEI) formation were observed in situ. In addition, the dynamic lithiation/delithiation of MoS<sub>2</sub> nanosheets in a LiPF<sub>6</sub>/EC/DEC commercial electrolyte were also observed. Upon discharge in a voltage range of 1.8-1.2 V, MoS<sub>2</sub> on the Ti electrode underwent irreversible decomposition resulting in fragmentation of the MoS<sub>2</sub> nanosheets into 5-10 nm MoS<sub>2</sub> nanoparticles. For sodium ion batteries, we report an in situ study of Na deposition with the development of electrochemical liquid cells, in which the electrodes within a cell are patterned in different configurations to produce a flat or sharp curvature. The Na deposition shows granular growth. Variations in the SEI thickness on a Na nano-grain introduce differences in the local growth rate and disparities in the morphology. The newly formed Na grains preferentially deposit at the base of existing grains close to the electrode.

Visualising Dynamic Nanomagnetism and Magnetostructural Transitions Using Lorentz Microscopy

Trevor Almeida¹, Adrian Muxworthy², Damien McGrouther¹, Rafal E. Dunin-Borkowski³, András Kovács³, Jamie Massey⁴, Christopher Marrows⁴ and Stephen McVitie¹; ¹University of Glasgow, United Kingdom; ²Imperial College London, United Kingdom; ³Research Centre Juelich, Germany; ⁴University of Leeds, United Kingdom

In order to better understand magnetic behaviour in naturally occurring or synthetic samples, it is often necessary to investigate the underlying processes on the nano-scale. Transmission electron microscopy (TEM) allows atomic spatial resolution imaging and combining in situ TEM experiments with techniques like off-axis electron holography or differential phase contrast (DPC) imaging allows for imaging of magnetisation in nanostructures whilst under the influence of external stimuli; e.g. gas atmospheres, biasing, temperature, etc. In this context, several examples of the use of in situ TEM and magnetic imaging will be presented.

Fe₃O₄ is the most magnetic naturally occurring mineral on Earth, carrying the dominant magnetic signature in rocks and providing a critical tool in palaeomagnetism. The oxidation of Fe₃O₄ to maghemite (γ-Fe₂O₃) influences the preservation of remanence of the Earth's magnetic field by Fe₃O₄. Further, the thermomagnetic behaviour of Fe₃O₄ grains directly affects the reliability of the magnetic signal recorded by rocks. Through combining electron holography with environmental TEM, in situ heating and liquid cell TEM, the effects of oxidation [1] and temperature [2] on the magnetic behaviour of Fe₃O₄ NPs are visualised successfully, as well as the magnetism within hydrated magnetotactic bacteria [3].

Equiatomic iron-rhodium (FeRh) has attracted much interest due to its magnetostructural transition from its antiferromagnetic (AF) to ferromagnetic (FM) phase and is considered desirable for potential application in a new generation of novel nanomagnetic or spintronic devices. Several scanning TEM techniques are performed to visualise the localised chemical, structural and magnetic properties of a series of FeRh films. The quantitative evolution of the growth and co-existence of AF and FM phases in the FeRh films are observed directly during in situ heating using DPC imaging [4]. In addition, combining DPC imaging with both heating and the application of electrical current pulses in situ within the TEM provides direct visualisation of the current-driven motion of magnetic DWs within planar FeRh thin films.
The main concerns during the polarization switching in nanosize ferroelectrics are the space charges on the oxide-electrode interfaces, trapping of the charged defects and strong domain wall pinning which readily increase the required switching field. To better understand and solve these problems, dynamic experiments are needed. In situ (heating and biasing) transmission electron microscopy (TEM) offers imaging and analytical tools at the relevant length-scales.

Thin lamellae samples with optimized geometry, prepared from a single crystal BTO (100), exhibit unusually stable and ordered 180° domain walls at room temperature [1]. Heating up to ~50 °C induces highly ordered 90° walls. Further heating above the Currie temperature (Tc) and then cool-down reintroduces the 180° domain structure. The transition from 180° to the 90° domain structure could originate due to the thermal strain release as the sample is heated. The appearance of the 180° domain-state is independent of the cooling rate below the Tc.

Further to the heating studies, we applied cyclic triangle wave-shape potential with a slope of 0.035 V/s. Due to the complex geometry of the sample, the electric field at the centre of the lamella was estimated by finite element calculations. The results show a homogeneous electric field distribution within the electron transparent region of ~3.1 kV/cm per 1 V applied to the electrodes. The operando response of weakly charged domain walls on the applied electric field revealed a tail to tail configuration [2]. Theoretically, in a bulk sample this tail-to-tail configuration is hindered by the polarizing surface effect, which leads the preferable direction of the polarization to point perpendicularly to the normal of the electrode [3]. In a thin lamella sample polarization direction pointing out of the lamella surface is electrostatically highly unfavourable, which could explain the appearance of the weakly charged domain walls.

By following the dynamics of the domain walls with respect to the applied voltage, clear hysteretic and non-linear behaviour is revealed. By recording the domain growth/shrinkage and nucleation, “P-E hysteresis-like” loops can be produced by appropriate image analysis. Additionally, application of cyclic voltage with various amplitudes reveals quadratic response of the domain growth with respect to the applied maximal voltage. This direct measurement complies with Rayleigh’s law P(E)~αE² [4] and shows its fulfilment even at the local scale.

**In Situ** TEM Observation of Reversible Structural and Resistive Phase Transitions in Magnetic Perovskite Films Driven by Voltage Pulses and Strain
Lide Yao, Sampo Inkinen and Sebastiaan van Dijken; Aalto University, Finland

Oxygen defects can have a profound effect on the physical properties of transition metal oxides. In complex oxides where magnetic, ferroelectric and superconducting phases emerge from strong correlations between localized transition metal electrons, oxygen vacancies can radically alter a plurality of quantum phenomena via valence changes and structural phase transitions [1]. The ability to control the concentration and profile of oxygen vacancies in oxide nanostructures would thus open up comprehensive prospects for new functional ionic devices. Here, we use in situ transmission electron microscopy (TEM) to demonstrate reversible switching between uniform structural phases in epitaxial La2/3Sr1/3MnO3 films. In our experiments, we employ a piezo-controlled probing holder to apply short voltage pulses and local strain. Simultaneous high-resolution imaging and resistance probing under zero strain reveals reproducible voltage-induced transformations between a low-resistance perovskite phase, a high-resistance La2/3Sr1/3MnO2.5 brownmillerite structure, and an intermediate-resistance perovskite-like phase [2]. Reversible horizontal migration of oxygen vacancies within the manganite film, driven by combined effects of Joule heating
and bias voltage, predominantly triggers the structural and resistive phase transitions. Concurrent application of perpendicular strain and voltage pulses produces an entirely new structural phase whereby oxygen vacancies order in regular 3D rather than 2D patterns.

In Situ High-Resolution EELS for Probing Insulator-to-Metal Transitions in Correlated Oxide Nanostructures

Laura Bocher1,2, Xiaoyan Li1,2, Ibrahim E. K. Koita1,2, Marcel Tencé1,2, Jean Denis Blazit1,2, Luiz H. G. Tizei1,2, Mathieu Kociak1,2, Alexandre Gloter1,2 and Odile Stéphan1,2; 1Laboratoire de Physique des Solides - CNRS, France; 2Université Paris-Sud, France

Transition metal oxides (TMOs) undergo a plethora of phase transitions in response to external perturbations (temperature (T), pressure...), and vice versa outstanding physical phenomena in TMOs can be fine-tuned under controlled external stimuli (T, electrical or magnetic fields, light...). For instance, two types of insulator-to-metal transitions (IMTs) can be activated in Mott insulators or correlated systems such as (V1-xCrx)2O3 in response to external perturbations such as pressure, electronic doping or temperature [1]. V2O3 presents a T-driven IMT from an antiferromagnetic insulator (AFI) to a paramagnetic metallic (PM) state at around 160 K associated with a symmetry change. A different paramagnetic Mott insulating (PI) state can be usually destabilized by pressure or chemical doping into a correlated metallic state via the isostructural Mott transition. An out of equilibrium Mott transition can even be electrically activated in Cr-doped systems at 300K by applying short electric field pulses to induce a non-volatile ultrafast resistive switching creating conductive filaments nanodomains in the insulating matrix [2]. This electrically activated RS has revealed its potential for non-volatile memories used in high-performance resistive random-access memories. So far, the insulating/metals (I/M) domain coexistence and the electronic phase separation in such oxides have only been investigated in situ by ARPES, nano-IR and STM/STS but with 10nm spatial resolution at best and not in cross-section so as to reveal buried interfaces. Moreover, additional properties can emerge solely in nanostructured TMOs where strain engineering and interfacial mechanisms play a key role. However the local mechanisms governing I/M domain formation, percolation, and dissolution may arise at boundaries as thin as an atomic column and be due to local structural defects, chemical clustering or interfacial mechanisms – all atomic scale phenomena.

Very recently, advanced monochromated electron spectromicroscopes (UHR-STEM/EELS) emerged as real game-changers for nanomaterials characterization where the improved EELS resolution, i.e. 5meV, extending a larger range of relevant electronic excitations (from IR to soft X-ray) available at the nanometer scale and below. Combining such remarkable instrumental capabilities with in situ (tunable temperature and electrical biasing) options open an entirely new avenue of experiments for monitoring TMO’s phase transitions, and provide an unique in situ characterization tool capable of mapping the I/M nanodomains at sub-nm scale. Hence the requirement to monitor the IMT switching effect by probing and mapping in situ their electronic, atomic and chemical structures at the finest scale under thermal and/or electrical stimuli to gain a full understanding of these nanostructures’ functionalities.

Here we will first present recent variable-T UHR-STEM/EELS experiments performed on a Cs-corrector monochromated NION microscope, CHROMATEM, equipped with a HennyZ stage holder providing tuneable temperature (from liquid nitrogen to 1000°C) and biasing capabilities. New insights into nanostructured V2O3 and Cr-doped systems are unveiled by probing their PM and AFI spectroscopic features upon low-T thermal cycling through both low-loss and core-loss signatures (interband plasmon excitation and V-L2,3 and O-K fine-structures) [3]. Mapping such electronic excitations down to the nm-scale could highlight nanoscale electronic phase separation mechanisms further correlated with their structural and chemical properties down to the atomic scale. Finally, first perspectives on the electrically activated IMT in Mott insulator will be introduced.

In Situ TEM Electrical Biasing of LAO/STO Interface-Devices Revealing Charge Modulation and Associated Structural and Chemical Changes

Jinsol Seo1, Bumsu Park1, Christoph T. Koch2, Hyungwoo Lee3,4, Chang-Beom Eom4 and Sang Ho Oh1; 1Sungkyunkwan University, Korea (the Republic of); 2Humboldt-Universität zu Berlin, Germany; 3Korea Advanced Institute of Science and Technology, Korea (the Republic of); 4University of Wisconsin–Madison, United States

The recent discovery of a two-dimensional electron gas (2DEG) at the interface between insulating perovskite oxides SrTiO3 (STO) and LaAlO3 (LAO) was made possible by advances in atomic layer-controlled growth. It has been demonstrated that the 2DEG is localized within a few nm of the interface and that the carrier concentration can be altered with an electric field and/or lattice strain which allows possibility of device structures such as field effect transistor, diode and nonvolatile memory devices. Eventually, seeing such changes during the operation of devices helps us to improve our understanding and also provides a technical breakthrough for further optimization of devices.

In this study, in-situ inline electron holography biasing experiments have been carried out on the epitaxially grown LAO (10 u.c.)/STO (15 u.c.)/LAO (3 u.c.) devices to observe charge density modulation by electrostatic gating. TEM samples for in-situ biasing experiment were prepared by using focused ion beam (FIB). A thin TEM lamella prepared by FIB was attached to a MEMS biasing chip (DENSsolutionsTM) by depositing Pt to ensure electrical contact of the thin film electrodes of TEM sample to the MEMS chip. The top and bottom electrodes were electrically isolated by milling trenches. While negative/positive DC biases are applied to the SrRuO3 top electrode, inline electron holography was carried to visualize the modulation of local charge density, and STEM imaging and EELS line profile were also carried out at the same position to investigate the associated ionic displacement and change of the valence state of Ti ions using an aberration-corrected STEM operated at 300 kV (GRAND ARM 300 CF).

The in-situ TEM I-V curves of the device showed very low current level of only a few nA, indicating the leakage current through the sample surfaces has been suppressed sufficiently. The charge density maps obtained by inline electron holography clearly showed strong peaks at the interfaces of LAO/STO, which arises from both mean inner potential difference between the two materials and the interfacial space charges such as 2DEG. Therefore, to visualize the modulation of 2DEG induced by the applied bias, the charge density profiles were calibrated by subtracting that of 0 V to remove the contribution from the mean inner potential variation across the interfaces. The zero-bias calibrated charge density profiles obtained at each voltage showed an increase and decrease of 2DEG in response to negative and positive voltage, respectively. In addition to the charge density modulation, the change of valence state of Ti ion assessed by in-situ EELS and the related lattice strain by quantitative image processing of STEM images will be discussed in greater detail.

Direct Assessment of Surface Polarization of BaTiO3 (001) by In Situ Negative Cs HRTEM Imaging

Jeehun Jeong1, Zhen Wang1, Bumsu Park1, Jong Chan Kim2, Hu Young Jeong2 and Sang Ho Oh1; 1Sungkyunkwan University, Korea (the Republic of); 2Ulsan National Institute of Science and Technology, Korea (the Republic of)

BaTiO3 is one of the most promising candidate oxides for various devices due to ferroelectric polarization and/or resistive switching capability. For large data storage applications, the polarization of low dimensional material forms, especially the surface polarization, needs be characterized precisely to control its device characteristics. Recently, more attention has been paid to the (001) surface of tetragonal phase of BaTiO3 with perpendicular polarization to understand the evolution of surface deadlayer due to depolarization effects and the associated near-surface domain structure. Previously, STEM-HAADF and STEM-ABF have been used for unit-cell by unit-cell polarization mapping but for TEM study of the intrinsic surface properties a clean surface without contamination or protection should be prepared, which poses technical challenges for implementation.

Here, by means of in-situ high resolution transmission electron microscopy we observed the surface polarization of BaTiO3 (001) single crystal on the unit cell scale from 1000 °C to room temperature using a Cs-corrected TEM (Grand ARM300F). TEM samples were prepared from a (001) BaTiO3 single crystal along the [100] cross-sectional zone axis by using FIB and attached to a DENSsolutions MEMS heating chip. By using negative spherical aberration imaging (NCSI) technique, all atoms (including oxygen columns) were observed clearly with minimal contrast delocalization, so that complete and quantitative polarization maps were obtained for the BaTiO3 (001)
surface of cubic and tetragonal phases. From HRTEM surface profile imaging with minimal contrast delocalization, we found that the surface is stabilized by the BaO termination in most temperature ranges we studied. Interestingly, the surface BaO layer showed a rumpling with 4-5 unit cells period. At the peak of rumpling, the HRTEM image showed that the barium (Ba) atoms move upward from the surface plane and nearby oxygen columns are preferentially populated by oxygen vacancies. We also found that there are Ti ions in the surface BaO layer, particularly occupying the oxygen-oxygen bridge sites (i.e. corresponding to the octahedral interstitial sites in bulk BaTiO₃). The polarization maps showed that at the peak of surface rumple the polarization mostly points toward bulk region (P_{down}) and the in-plane polarization (P_{in}) dominates the neighboring unit cells with oxygen vacancies. This finding reveals that oxygen vacancies play a key role in the evolution of surface polarization. Although the surface structure and polarization observed after high temperature annealing in TEM and by using electron beam may deviate from the genuine surface properties of BaTiO₃, the observed periodic array of oxygen vacancies along in-plane direction is closely related to stabilizing mechanism of the polarization at surface. We will further show the real-time imaging of the dynamic processes of surface reconstruction occurring at various temperatures, which can be used to study how surface polarization and point defects intricately interplay with each other to result in distinct surface reconstruction, ferroelectric domain structure and ferroelectric size effects.

11:30 AM MT07.01.07
Atomic and Electronic Structures of a SrMoO₃-Based All-Oxide Epitaxial Ferroelectric Varactor Tunable at Low Voltages Leopoldo Molina-Luna, Alexander Zintler, Oscar Recalde, Patrick Salg, Phillip Komissinskiy and Lambert Alff; TU Darmstadt, Germany

In the field of oxide electronics, there has been tremendous progress in recent years in atomic engineering of functional oxide thin films with controlled interfaces at the unit cell level. The functionality of such perovskite oxides depends mostly on the electronic configuration of the B-site cations. Relevant devices such as tunable ferroelectric microwave capacitors (varactors) are based on dielectric BaₓSr_{1-x}TiO₃ and are stymied by the absence of suited compatible, very low resistive oxide electrode materials on the micrometer scale. This has been overcome by implementing highly conducting SrMoO₃ (SMO) thin-film electrodes as enabling material for all-oxide ferroelectric varactors [1]. By using scanning transmission electron microscopy (STEM) in combination with electron energy-loss spectroscopy (EELS) we were able to reveal the atomic and electronic structure in an all oxide ferroelectric epitaxial varactor heterostructure with a SMO thin-film bottom electrode. The remarkable result is that in spite of the contradicting thermodynamic oxidation conditions, the dielectric BaₓSr_{1-x}TiO₃ and the highly conducting SrMoO₃ can be effectively coupled under preservation of their physical properties in an epitaxial heterostructure with negligible cation intermixing and valence change. The resulting interface is atomically sharp down to the unit cell scale. Surprisingly, a few unit cells of SrTiO₃ are sufficient to engineer the interface, allowing the utilization of the Pt-like conducting SrMoO₃ in oxide electronics applications. Furthermore, we are currently exploring the use of microelectromechanical systems (MEMS) based in situ biasing chips to enable controlled ionic displacement studies directly inside a transmission electron microscope. We aim to link the atomic structure to the physical properties under working or so called operando conditions in electrically contacted electron transparent lamellae of the metal-insulator-metal (MIM) ferroelectric varactor structure by directly tuning the dielectric layer.

Resolving Electric Field Induced Structural Transformations in the Time Domain Using MeV Electron Diffraction Aditya Sood¹,², Xiaozhe Shen², Suhas Kumar³, Suji Park², Marc Zajac¹, Yifei Sun⁴, Shriram Ramanathan⁴, William C. Chueh¹, Xijie Wang² and Aaron Lindenberg¹; ¹Stanford University, United States; ²SLAC National Accelerator Laboratory, United States; ³Hewlett-Packard Labs, United States; ⁴Purdue University, United States

Understanding the short timescale dynamic response of materials to electric fields is essential for the development of next generation electronic & photonic devices. Specifically, in ferroelectrics, a transient measurement of lattice response to E-field encodes key information about the nucleation and growth of domains, domain wall motion, and coupling to strain. Despite its scientific and technological importance, most previous work has focused on the separate characterization of electrical transport and structure. Here, we report the development of a time-resolved technique for the simultaneous measurement of electronic
transport and atomistic structure in response to an applied E-field. This is based on in situ diffraction using ~100 fs electron pulses with energies of ~3 MeV. Our setup has demonstrated a momentum transfer range of 9 Å\(^{-1}\), q-resolution of <0.17 Å\(^{-1}\) and a temporal resolution limited only by the rise time of the E-field pulse across the device. Devices are electrically excited using short voltage pulses while structural dynamics are probed in a stroboscopic manner as a function of delay time after the pulse is turned on. As a demonstration, we use this technique to investigate the dynamics of the electrically-induced insulator-metal phase transition in VO\(_2\). Through a simultaneous measurement of structure and electrical transport, we correlate the nucleation and growth of rutile domains with metallization of the channel. These experiments provide new insights into the fundamental processes governing the switching speed of VO\(_2\) devices, and elucidate the role played by nucleation, growth and percolation of phases.

SESSION MT07.02: Imaging, Probing and Control of Domains and Domain Walls
Session Chairs: Alexei Gruverman and Dennis Meier
Wednesday Afternoon, December 4, 2019

1:30 PM MT07.02.01
Anomalous Domain Wall Motion in Copper-Chlorine Boracite—A New Opportunity in Negative Capacitance? Charlotte Cochard\(^1\), Joseph G. Guy\(^1\), Roger Whatmore\(^2\), Michele A. Conroy\(^3\), Kalani Moore\(^3\), Alan Harvey\(^3\), Ursel Bangert\(^3\), Amit Kumar\(^1\), Raymond G. McQuaid\(^1\) and Marty Gregg\(^1\); \(^1\)Queen's University Belfast, United Kingdom; \(^2\)Imperial College London, United Kingdom; \(^3\)University of Limerick, Ireland

By symmetry, all 90° domain walls in Cu-Cl boracite (Cu\(_3\)B\(_7\)O\(_{13}\)Cl) must be associated with either head-to-head or tail-to-tail polar discontinuities and are hence charged. As in other ferroelectric systems, charged walls have either enhanced or reduced electrical conductivities, compared to bulk, and so controlling their injection and movement could be of interest in the context of future domain wall nanoelectronics [1].

In this work, we show that repositioning these walls using electric fields can lead to an increase in the global electrostatic energy: changes in the microstructure can be such that regions with polarisation aligned against the field coarsen at the expense of those aligned with the field. Field-induced changes in polarisation which increase polar populations which are anti-aligned, imply a contribution to the effective permittivity from domain wall motion that is negative. This is extremely unusual and worthy of much more exploration and discussion [2].

The notion of this kind of anomalous domain wall motion seems impossible in proper ferroelectrics. However, in the case of improper ferroelectrics, such as the Cu-Cl boracites, the low spontaneous polarisation associated with strong coupling to the spontaneous strain makes the idea plausible, as local electrostatic energy increases might be offset by global strain energy decreases in the system.

After presenting evidence for the correct attribution of the nature of the domains, relying on several scanning probe techniques, the classical and anomalous motion of domain walls in Cu-Cl boracite studied through optical microscopy will be presented. The complexity of the energy landscape in this specific system will be discussed and finite element models quantifying the electrostatic work done will be presented, along with potential avenues to be pursued which could shed more light on the unique behaviour observed.

Deterministic Motion of Ferroelastic Domain Walls in Ferroelectric Bilayers Yangyang Zhang\(^1\), Myung-Geun Han\(^2\), Joseph A. Garlow\(^2\), Yueze Tan\(^3\), Fei Xue\(^3\), Long-Qing Chen\(^3\), Paul Munroe\(^1\), Nagarajan Valanoor\(^1\) and Yimei Zhu\(^2\); \(^1\)University of New South Wales, Australia; \(^2\)Brookhaven National Laboratory, United States; \(^3\)The Pennsylvania State University, United States

Efficient energy conversion and deterministic controllability are long-standing demand of novel miniaturized electromechanical devices [1]. Recent advancements in ferroelectric thin film synthesis provide a potential pathway
to apply interface engineering for favorable electrostatic and strain conditions for promotion of ideal ferroelastic domain switching and leads to enhanced electromechanical response in tetragonal PbZr$_{1-x}$Ti$_x$O$_3$ (T-PZT)/rhombohedral PbZr$_{1-x}$Ti$_x$O$_3$ (R-PZT) bilayer thin films \cite{2-3}. However, the dynamic evolution of their domain switching mechanism remains elusive.

In this work, we utilize \textit{in situ} transmission electron microscopy (TEM) to explore the interaction between two dissimilar ferroelectric layers (R-PZT and T-PZT). During the real-time domain switching process, the domain wall orientation in T-PZT can be determined by the external electric field. The interface of the PZT bilayer serves as the nucleation site for the controllable domain wall reorientation, which is revealed by both atomic resolution electron microscopy imaging and phase field simulation. Thus, the interplay between two ferroelectric polymorphs is the underlying physical mechanism for unprecedented electromechanical properties in the PZT bilayer, i.e., ferroelastic domain switching and its wall reorientation. The T-PZT/R-PZT heterostructure acts as a model system, which can stimulate further advances of electromechanical device design.

\textbf{Bulk- and Flexo-Photovoltaic Effects at Ferroelectric Domain Walls} Marin Alexe and Ming-Min Yang; University of Warwick, United Kingdom

Two years after the invention of modern prototype solar cells, it was found that BaTiO$_3$ exhibits a photovoltaic effect distinct from that of \textit{p-n} junctions, later called the bulk photovoltaic (BPV) effect. Under uniform illumination, a homogeneous ferroelectric material gives rise to a short-circuit current and produces an anomalously large photo-voltage well exceeding the bandgap energy. The microscopic origins of this effect supposed to originate from the asymmetric distribution of photoexcited non-equilibrium carriers in $k$-space, caused by absence of centrosymmetry.

The present talk will present the basics of the bulk photovoltaic effect, tip enhancement, as well as the electronic origin of the anomalous BPV in some materials such as BiFeO$_3$.I will show how the tip-enhanced effect may be used in optical switching of ferroelectric polarization. Finally, we will discuss the new flexo-photovoltaic effect which turns the BPV effect into a universal effect allowed in all semiconductors under strain gradient and how this effect does affect the local photoelectric effects at domain walls. \cite{1,2}

\textbf{3:00 PM *MT07.02.04}
\textbf{Anisotropic Polarization-Induced Conductance at a Ferroelectric Domain Walls and Heterointerfaces} Xiaoqing Pan; University of California, United States

Coupling between different degrees of freedom, i.e. charge, spin, orbital, and lattice, is responsible for emergent phenomena in complex oxide heterostructures. A notable example is formation of a two-dimensional electron gas (2DEG) at the polar/nonpolar LaAlO$_3$/SrTiO$_3$(LAO/STO) interface due to the polar discontinuity and as a means to counteract the electrostatic potential build-up across the LAO film. The polar discontinuity can also be produced by a ferroelectric polarization at the domain walls and ferroelectric/insulator interface. In this case, such a 2DEG can be controlled by switchable ferroelectric polarization, thus providing a new functionality. Depending on the polarization orientation, either electrons or holes are transferred to the interface, to form either a 2DEG or two-dimensional hole gas (2DHG). While the recent first-principles modeling predicts the formation of 2DEGs at the ferroelectric/insulator interfaces, experimental evidence of a ferroelectrically-induced interfacial 2DEG still remains elusive. Here, we report the emergence of strongly anisotropic polarization-induced conductivity at a
ferroelectric/insulator interface, which shows a strong dependence on the polarization orientation. By probing the local conductance and ferroelectric polarization over a cross-section of the BiFeO$_3$/TbScO$_3$(BFO/TSO) (001) heterostructure, we demonstrate that this interface is conducting along the 109° domain stripes in BFO, whereas it is insulating in the direction perpendicular to these domain stripes. Electron energy-loss spectroscopy (EELS) and theoretical modeling suggest that this extraordinary anisotropy of interfacial conduction is caused by alternating polarization associated with the ferroelectric domains, producing either electron or hole doping of the BFO/TSO interface. Similarly, we observed a spin-polarized 2DEG forms at the PZT/STO interface, which is strongly localized at the interfacial Ti atoms, due to the interplay between Coulomb interaction and band bending, and can be tuned by the ferroelectric polarization. Finally, we found that the intrinsic conductivity of domain walls in BiFeO$_3$ thin film grown (110) TbScO$_3$ is strongly dependent on the polarization configurations. We show that the 71° domain walls exhibit conductivity, which is about an order of magnitude larger than that of the 109° domain walls. The 71° domain wall conductivity is strongly anisotropic: more conductive along the [010] direction than along the [001] direction. High resolutions electron energy loss spectroscopy reveals that the origin of the anisotropic conductivity of the 71° walls stems from the potential discontinuity of the 71° domain walls along the [110] direction. Our findings in the ferroelectric interfaces and domain walls open a door for engineering ferroelectric/insulator interfaces toward the creation of tunable ferroic orders for magnetoelectric device applications and provide the opportunities for designing multiferroic materials in heterostructures.

Ferroelectric domain walls are spatially mobile interfaces that naturally occur in materials that develop a spontaneous electric polarization. Because of their unique electronic properties, such walls hold great promise as functional 2D systems, but the characterization of their intrinsic transport properties remains a challenging task.

Despite the significant progress in experiment and theory, most investigations on ferroelectric domain walls still fall into the basic research sector, aiming to understand their complex nano-physics and tailor their local electronic properties. One of the main challenges lies in the reliable characterization of emergent transport phenomena, which commonly is realized in terms of conductive atomic force microscopy (cAFM) measurements. However, cAFM is a two-probe measurement and, as such, susceptible to contributions from contact resistance that can obscure the data. Furthermore, as the resolution limit of cAFM ($\geq 20$ nm) is much larger than the width of typical ferroelectric domain walls ($\approx 10$ Å), it is often difficult to evaluate whether measured signals arise at the wall center, in adjacent accumulation and depletion regions, or due to displacement currents associated with domain wall movement.

In this talk, we will discuss how the physical property extraction from local conductance measurements can be improved by combining local I(V)-spectroscopy measurements with machine learning, employing a neural network autoencoder. Using the doped hexagonal manganite (Er$_{0.99}$Zr$_{0.01}$)MnO$_3$ as a model system, we conduct a comprehensive characterization, using different methods such as density functional theory (DFT), dielectric spectroscopy, piezoresponse force microscopy (PFM) and cAFM. To highlight different limitations associated with standard cAFM scans, we first discuss the observation of surprising conductance phenomena at charged head-to-head (h-t-h) and tail-to-tail (t-t-t) domain walls. We then use the neutral network autoencoder to disentangle different conductivity contributions, revealing the intrinsic electronic domain wall properties in (Er$_{0.99}$Zr$_{0.01}$)MnO$_3$.

The scaling behavior of ferroelectrics and related materials are of both fundamental and practical interest. In
particular, there has been significant progress in the understanding of scaling behavior for ferroelectrics over the past few decades. In stark contrast to ferroelectrics, understanding of size effects in relaxor ferroelectrics (relaxors), a special class of ferroelectrics, has been lacking, despite the close similarity between ferroelectrics and relaxors. In this work, we use a combination of thin-film epitaxy, X-ray diffuse scattering, scanning transmission electron microscopy, dielectric and ferroelectric characterization, and molecular-dynamics simulations to investigate the size-dependent evolution of structures and properties in the prototypical relaxor ferroelectric 0.68PbMg1/3Nb2/3O3-0.32PbTiO3. Here we demonstrate that reducing the size (i.e., thickness of the films), contrary to prior reports, first enhances relaxor behavior until a threshold thickness below which the critical temperatures that characterize various relaxor phases (i.e., dynamic, static, and frozen) collapse together, indicating destabilization of the relaxor state. Using temperature-dependent diffuse scattering, scanning transmission electron microscopy, and dielectric and ferroelectric measurements, we demonstrate that relaxors lose their defining characteristics below this threshold thickness. The mechanism for destabilization of relaxor behavior below the critical thickness is discussed in terms of faster dynamics of polarization fluctuations in ultrathin relaxor films.

In Situ Ferroelectric Domain Dynamics in PMN-PT Abinash Kumar1, Rohan Dhall2 and James M. LeBeau1; 1Massachusetts Institute of Technology, United States; 2Lawrence Berkeley National Laboratory, United States

Relaxor ferroelectrics are one of the most widely used functional materials as they exhibit low coercive field and giant piezoelectric coefficients [1]. These can be distinguished from classical ferroelectrics based on their diffuse phase transitions and dielectric properties. These properties are commonly associated with the existence of polar nanoregions in a non-polar matrix [2]. Recently, a model of slush-like response of a nanoscale multi-domain state is proposed to explain relaxor behavior, but these models are not are fully predictive [3]. In order to design relaxor ferroelectric materials, a fundamental understanding of their behavior under an applied electric field needs to be found-from the micro to atomic length scale. Recent advances in in situ microscopy and STEM detector technologies, such as 4D STEM and differential phase contrast (DPC) imaging [4], have allowed to reveal the structural information required to explain the origin of relaxor behavior.

We show that DPC provides robust imaging of the relaxor ferroelectric domain structure as a function of voltage bias. We apply the technique to Pb(Mg1/3Nb2/3)O3-28PbTiO3(PMN-PT) single crystals prepared using conventional polishing methods pair with photolithography to define the electrodes. First, influence of electron beam on the domain structure is studied by examining a series of DPC images without an applied field. The electron beam causes the domain walls to flicker in the time-resolved dataset, but large-scale changes are not observed at this field of view. A dramatic change in domains is observed at different applied electric fields. The domain structure at the start and end of a field cycle is explained in the context of remnant polarization. Effect of waveform shape on switching behavior is also determined. To quantify changes at the atomic scale, we demonstrate how in situ integrated differential phase contrast (iDPC) provides high signal-to-noise ratio imaging of oxygen atom columns, even in the presence of heavier atoms (Pb). Further, we demonstrate how the simultaneous acquisition of annular dark field (ADF) can be used to simplify the quantification and removal of drift and scan distortion from iDPC images [5]. From the drift-corrected iDPC images, the projected polarization is then quantified at different applied fields. It is observed that the polar nanoregions try to align to the electric field, but reside within a microscale ferroelectric domain that does not switch. With a combination of data across length scales for the same sample, we discuss how the resulting details provide new insights into the dynamics of relaxor ferroelectric domains.

The Domain Switching in Rhombohedral PZT Observed by In Situ X-Ray Diffraction Study by Various Frequencies Takao Shimizu1, Yoshitaka Ehara2, Takanori Mimura1, Shintaro Yasui1, Tomoaki Yamada2, Yasuhiro Imai3, Yoshio Katsuya4, Osami Sakata1 and Hiroshi Funakubo1; 1Tokyo Institute of Technology, Japan; 2Nagoya

Final Program 1/13/2020  2087
Time resolved X-ray diffraction measurement was performed for rhombohedral lead zirconate titanate (PZT) with synchrotron X-ray source for various frequencies and pulse widths. The PZT is the most widely used ferroelectric and piezoelectric material due to its outstanding electric properties. In particular, their excellent electro-mechanical responses have been attracted a great deal of interest, because they enable us to produce the various applications, such as sensors and actuators. Because of the recent increase in the demand for these devices using micro-electro-mechanical-systems, it is required to understand the nature of the piezoelectric and dielectric properties of PZT more deeply. It is well recognized that non-180° domain switching plays essential roles for the piezoelectric responses in PZT. The frequency dispersion in piezoelectric and dielectric responses often become a problem to use PZT at high frequency. Because the dispersion is known to relate with the domain switching motions, the time-resolved measurement with broadband frequency is needed to understand the piezoelectric responses. In particular, remarkable frequency dispersion is reported for rhombohedral PZT.

The PZT films prepared by metal-organic chemical vapor deposition were used for the measurements. The in-situ X-ray diffraction was performed at SPring-8 BL15XU using the focused X-ray beam on area 2 × 3 μm² in width and height using a two-dimensional focusing refractive lens. To observe the domain switching for various frequencies and duty ratios, the pulse width and repetition frequency of the electric field, were varied. The domain switching was confirmed by applying electric field irrespective of the frequencies and duty ratios. We observed marked delay of the domain switching back when removing the electric field. The high frequency of 1 MHz electric field gave rise to a small amount of domain switching motion compared to low frequencies electric field. In addition, the larger duty ratio also smaller changes in domain fraction by the electric field even with the low frequency of 10 kHz. Interestingly, the domain fraction without electric field during electric cycling (i.e. in-situ measurement) is different from the original domain fraction before starting measurements if we used at high frequencies or large duty ratios. This means that the longer time required to recover original domain structure in rhombohedral PZT, which is quite different from tetragonal PZT responding to both applying and removing the electric field.

Investigating the Strain Governing the Dynamic and Charged Nature of Ferroelastic Boracite Domain Walls by 4DSTEM
Michele A. Conroy¹, Eileen Courtney¹, Steven Zeltmann², Benjamin Savitzky², Colin Ophus², Jim Ciston², Kalani Moore¹, Charlotte Cochard³, Joseph G. Guy³, Raymond G. McQuaid³, Roger Whatmore⁴, Alexei L. Gruverman⁵, Marty Gregg³ and Ursel Bangert¹; ¹University of Limerick, Ireland; ²Lawrence Berkeley National Laboratory, United States; ³Queens University Belfast, United Kingdom; ⁴Imperial College London, United Kingdom; ⁵University of Nebraska–Lincoln, United States

Conducting ferroelectric domain walls (DWs) are an emerging research focus in nano-electronics and potential quantum technologies [1,2]. DWs have their own unique electronic properties and most excitingly can be moved by an applied stimulus.[3] However, due to the high energetic cost of creating charged DWs in conventional ferroelectrics they are not stable long term. Improper ferroelectrics circumvent this issue as their driving force is not a polar instability, but instead is the symmetry-breaking non-polar primary mode. With this in mind there has been a recent surge in improper ferroelectric DW research. In this study boracite is the material we have chosen to focus on as it has already shown very promising results in terms of charged DW injection and movement. [5] Boracite is an improper ferroelectric material where the primary order parameter is the physical quantity spontaneous shear strain. As a ferroelastic material the conductivity of the charged DWs in boracite is governed by the shear strain direction of the neighbouring domains. Thus traditional atomic resolution Scanning Transmission Electron Microscopy (STEM) polarity mapping will not give the true picture of the ferroelectric properties. In order to understand the mechanism of the DW movement and the fundamental physics governing conducting DW formation strain analysis at the DW was completed by 4D-STEM [6] strain mapping. This strain analysis was then compared to the atomic resolution STEM imaging and polarity mapping. The dynamic nature of the DWs was investigated by utilising the applied electric field of the STEM probe itself, allowing for controlled angle of the incoming applied electric field and a corresponding STEM data set.

2. Ma, J., et al., Nature nanotechnology, 2018
The secondary nature of polarization in improper ferroelectrics promotes functional properties beyond those of conventional ferroelectrics. For example, in the hexagonal manganites, the non-ferroelectric distortive origin of electric polarization enables topologically protected ferroelectric vortex domain-patterns, conducting domain walls and multiferroicity. In technologically relevant ultrathin films, however, the improper ferroelectric behavior remains largely unexplored. Here, we probe the emergence of the coupled improper polarization and primary distortive order parameter in thin films of hexagonal YMnO₃. Combining state-of-the-art in-situ characterization techniques separately addressing the improper ferroelectric state and its distortive driving force, we reveal a pronounced thickness dependence of the improper polarization, which we show originates from the strong modification of the primary order at epitaxial interfaces. Nanoscale confinement effects on the primary order parameter reduce the temperature of the phase transition, which we exploit to visualize its order-disorder character with atomic resolution. Our results lay the foundation for understanding the evolution of improper ferroelectricity within the confinement of ultrathin films – essential for the successful implementation in nanoscale applications.

SESSION MT07.03: Space- and Time-Resolved Functional Characterization by Electron and Local Probe Microscopies
Session Chair: Marin Alexe

Hynes, Level 2, Room 205

9:00 AM MT07.03.01
In Situ Chemical Studies of Functional Materials via Combined AFM/ToF-SIMS Platform Anton V. Ievlev, Yongato Liu, Sergei Kalinin and Olga S. Ovchinnikova; Oak Ridge National Laboratory, United States

For the last several decades Time-of-flight Secondary Ion Mass Spectrometry (ToF-SIMS) became a prime tool for chemical characterization of the materials at sub-micrometer and nanometer scales. However, most of the investigations published so far lacks information about physical properties of the studied samples and their time evolution. The solution can be found in combination of mass spectrometry with Atomic Force Microscopy (AFM). Such combined multimodal AFM/ToF-SIMS platform enables a nanoscale correlated studies of both chemical and physical properties of the sample. In this case, chemical phenomena characterized by the ToF-SIMS can be complemented with functional properties measured by the AFM. Furthermore, continuous data acquisition in both ToF-SIMS and AFM modes supplemented by multivariate statistical analysis allows characterization of time evolving processes. Here we utilize commercial AFM/ToF-SIMS platform to explore interplay of chemical and physical phenomena in ferroelectrics and photovoltaics. In particular, our research allowed to reveal chemical phenomena associated with polarization switching in ferroelectric thin films and study ion migration in hybrid organic-inorganic perovskites. Developed approach enables direct characterization of interplay between chemical and functional response in functional materials and aids in the development and optimization of novel functional devices. This research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility and using instrumentation within ORNL’s Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy.

Nanoscale Discharging Phenomena for Dielectric/Piezoelectric Multilayers Thomas Moran, Michael Martin, Jingfeng Song, Keigo Suzuki, Tadasu Hosokura, Nobuhiko Tanaka, Koji Murayama and Bryan D. Huey;
The ultimate dynamic electrical performance of functional ceramic devices depends on the nanoscale materials properties in 3-dimensions. Thickness effects and engineered heterogeneities are of particular interest, requiring advances in nanoscale functional measurements. Accordingly, emerging methods for micromachining and Tomographic AFM, along with Kelvin Probe Force Microscopy (KPFM), Piezo Force Microscopy (PFM), and Conductive AFM (cAFM), are used to study dielectric and ferroelectric heterostructures, including as a function of thickness. Dynamic charging and discharging processes are notably mapped with KPFM as a function of time and energy, providing novel insight into local dielectric behavior and especially the voltage dependencies of surface or grain boundary defect states. These are related to sub-surface features and thickness dependencies via tomographic PFM and cAFM, volumetrically revealing size effects, 3-dimensional heterogeneities, and charge dissipation pathways. By considering in-situ charging and discharging phenomena, the engineered performance for micro- and nano-scale electronic devices such as multi-layer-chip-capacitors can therefore be optimized.

9:30 AM *MT07.03.03
Correlated Microscopy Studies at Functional Ferroelectric Domain Walls Dennis Meier; Norwegian University of Science and Technology, Norway

Interfaces in oxide materials offer amazing opportunities for fundamental and applied research, giving a new dimension to functional properties, such as magnetism, multiferroicity and superconductivity. Ferroelectric domain walls recently emerged as a new type of interface, where the dynamic characteristics of ferroelectricity introduce the element of spatial mobility, allowing for the real-time adjustment of position, density and orientation of the walls. This mobility adds an additional degree of flexibility that enables domain walls to take an active role in future devices and hold great potential as functional 2D systems for electronics. For example, domain walls can readily be injected and deleted to control electric conductivity, enabling multi-level data storage. However, while this approach clearly achieves a step beyond conventional interfaces by utilizing the wall mobility, it does not break the mould of classical device architectures.

In this talk, I will present a conceptually different approach, utilizing ferroelectric domain walls to emulate key electronic components such as digital switches and diodes. In particular, I will discuss three experimental studies, showing how advanced microscopy strategies helped us to understand the complex nanoscale physics that give rise to the functional electronic domain wall properties. (i) The diode-like behavior that arises at electrode-wall junctions, for instance, became accessible due to innovative conductive atomic force microscopy (cAFM) studies performed under a.c. voltages in the kilo- to megahertz range [1]. (ii) By combining cAFM, transmission electron microscopy (TEM) and electron energy loss spectroscopy (EELS), we demonstrated and explained the gating of electronic currents at domain walls [2], and (iii) correlated cAFM, electrostatic force microscopy (EFM) and X-ray photoemission electron microscopy (PEEM) provided novel insight into their electrostatic properties [3]. Finally – going beyond just imaging (i-iii) – I will discuss the possibility to combine cAFM, focused ion beam (FIB) methodologies, and in-situ scanning electron microscopy (SEM) imaging to achieve domain walls with well-defined charge states. This possibility brings us an important step closer to electronic components based on individual domain walls, following the ultimate goal to achieve domain-wall based circuitry and networks.

10:30 AM *MT07.03.04
Atomic Scale Structure and Dynamics of Domain Walls in Ferro-Electrics—Determination of the Configuration of Individual Dipoles Michele A. Conroy1, Kalani Moore1, Eoghan O'Connell1, Eileen Courtney1, Alan Harvey1, Joseph G. Guy2, Charlotte Cochard2, Raymond G. McQuaig2, Lewys Jones3, Clive Downing4, Roger Whatmore4, Marty Gregg5, Alexis L. Guverman6, Quentin Ramasse6 and Ursel Bangert1; 1University of Limerick, United Kingdom; 2Queens University, United Kingdom; 3Trinity College, Ireland; 4Imperial College London, United Kingdom; 5University of Nebraska–Lincoln, United States; 6SuperSTEM Laboratory, United Kingdom
Benefits of utilising the 2-D properties and the dynamic nature of ferro-electric domain walls are increasingly being explored. The combination of their sub-nm thickness and agility permits so far un-achieved applications in nano-electronic and -photonic devices, e.g., as ultrafast electrical switches, a.o., to pump for single photon emitters, or as mobile nano-mirrors in nano-scale lasers. To achieve this a fundamental understanding of these materials and their functionalities in terms of their physical, chemical and electronic structure down to the atomic level is required. Using atomic resolution transmission electron microscopy (TEM) methods, pico-meter shifts of individual atoms were observed (e.g., in boracite and lead titanate), resulting in the formation of electric dipoles. Comparison of the contrast of the atoms in (individual) dipoles to crystal models showed the relative shifts of cations with respect to anions, revealing the dipole orientation. Maps of atom shifts, signifying the formation orientation distributions of dipoles, were obtained over 1000 nm² areas, using the Atomap[1] program. Changes of dipole orientations along certain line directions then revealed domain boundaries and walls, as well as dipole (e.g., head-to-head or tail-to-tail) constellations and angles (e.g., 90°) along these walls. The shifts of atoms as well as the orientations of individual dipoles are revealed via high angle annular dark field (Z-contrast) and annular bright field imaging, the latter method depicting also the lighter atoms (e.g., O). Positions of all atoms together with their elemental nature are disclosed with sub-Å accuracy in areas on either side of domain walls and in the domain wall itself. These measurement are accompanied by differential phase contrast imaging to reveal the local electric field directions. The relative change in the distance of cations with respect to anions along the walls can furthermore give insight into whether these walls are expected to be conducting or insulating. Moreover, the movement of the walls and control over this movement are investigated and demonstrated via atomic-scale in-situ TEM.

11:00 AM MT07.03.05
Improvement of Time Domain Performance in Atomic Force Microscopy Feedback Controlled Electromagnetic Methods by Means of Image Reconstruction Stanislav Leesment1,2; 1NT-MDT Spectrum Instruments, Russian Federation; 2NT-MDT America Inc., United States

Atomic force microscopy (AFM) provides a wide range of methods which allow mapping of electrostatic (EFM, SCM, KPFM), piezoelectric (PFM) and magnetic (MFM) properties of samples with high spatial resolution. The performance of these methods is always a trade-off between signal to noise ratio, sensitivity, and speed. The latter is limited by the parameters of the probe sensor and the bandwidth of the feedback control system [1]. Scanning speed increment is an important direction for development of in-situ studies of dynamic properties at nanoscale.

The nature of tip-sample interaction forces detected by AFM is different for various techniques. But in all cases of feedback-driven methods, the major contribution in the final result is brought by the derivative of the tracked value: surface potential in KPFM, frequency shift in MFM, etc. In the assumption of linear disturbances and taking into account that errors in trace and retrace scanning directions have odd symmetry, the following transform can be applied to AFM data:

\[
\text{pr} \quad \text{and} \quad \text{pb} \quad \text{are trace and retrace profiles of tracked parameter and} \quad \text{pr} \quad \text{is a reconstructed profile.}
\]

The example of the described approach is shown in fig. 1 representing the map of surface potential (both trace) distribution over the charged line induced by the AFM tip on Si/SiO₂ surface. Scanning was done in two-pass AM-KPFM mode consequently at maximal speed which was fitting the KPFM feedback loop response and at an order higher rate (fig. 1 a and b). Fig. 1 c represents the reconstructed surface potential map. It is seen that the reconstruction result fits well with the image taken under appropriate conditions.

The proposed image reconstruction approach can be applied to images acquired by other feedback-driven AFM methods.

**Fig. 1** AM-KPFM images of charged line on Si/SiO₂ substrate. a and b correspond to scanning speeds of 10 and 140 μm/s. c – corrected image. d introduces corresponding scan profiles. Image size: 7,7×9,7 μm. Color scale: -2,3..-7,8 V

Image was acquired by means of Ntegra AFM system, NT-MDT Spectrum Instruments Co. The authors acknowledge funding from the European Union's Horizon 2020 research and innovation program, OYSTER under grant agreement No 76082

Time-Resolved Electrical Scanning Probe Microscopy for Studying the Effect of Grain Boundaries on Ion and Carrier Dynamics in Layered Perovskite Films Rajiv Giridharagopal and David S. Ginger; University of
Layered low-dimensional perovskites have emerged as a popular system for a wide range of optoelectronic applications due to their enhanced environmental stability and tunability relative to three-dimensional hybrid organic-inorganic perovskites. However, to date there have been few studies linking the photoinduced dynamics in these layered systems with their topographic features. Here, we use two complementary “big data” electrical scanning probe microscopy methods, fast free time-resolved electrostatic force microscopy (FF-trEFM) and general mode Kelvin probe force microscopy (G-KPFM), to probe light-induced dynamics in thin films comprising Ruddlesden-Popper phases of the layered 2D perovskite (C4H9NH3)2PbI4 (BAPI) as a function of position, time, and illumination. These scanning probe techniques capture the raw AFM cantilever motion and use advanced signal processing of the large (~50 GB) four-dimensional datasets (x, y, z, t) to extract microsecond-timescale dynamics. We use G-KPFM and unsupervised clustering to show that the photovoltage equilibrates over long timescales (hundreds of microseconds) that we attribute to ion motion. Surprisingly, this effect is actually slower at boundaries between adjacent grains as opposed to grain centers. With FF-trEFM, we extract faster dynamics at grain centers but with timescales consistent with electronic motion (70 - 100 μs). We therefore propose that the slower evolution at grain boundaries is due to a combination of ion migration occurring between PbI4 planes, as well as electronic carriers moving through traps at grain boundaries, thereby changing the time-dependent band unbending even within a micron-scale perovskite grain. Beyond perovskite optoelectronics, these experiments lay the groundwork for data-driven analysis of large microscopy datasets on other dynamic systems requiring sensitive detection of transient phenomena in scanning probe microscopy.

11:30 AM MT07.03.07
Unraveling the Relationship between Layer Stacking and Magnetic Order in Nb3X8 Systems via Controlled-Temperature Cryo-STEM
Elisabeth Bianco1, Ismail El Baggari1, Berit Goodge1, Christopher Pasco2, Tyrel McQueen2 and Lena Kourkoutis1; 1Cornell University, United States; 2Johns Hopkins University, United States

Nb3X8 (X=Cl or Br) are insulating, cluster-based, layered materials that exhibit an antiferromagnetic to non-magnetic transition [1]. In Nb3Cl8, the loss of magnetic order occurs at temperatures below 90 K and has been coupled to a symmetry-lowering crystallographic distortion and layer stacking change from a 2-layer (α-phase) to a 6-layer (β-phase) unit cell [2]. The transition temperature, however, depends strongly on composition with Nb3Br8 exhibiting the β-phase at 293 K. While tuning of the magnetic ordering temperature through composition is appealing for materials design, the mechanism by which the layer stacking reorganizes is not understood, and pinpointing the emergence of such structural changes and their relationship to magnetic order necessitates atomic-resolution imaging across the transition.

Atomic-resolution, cryogenic scanning transmission electron microscopy (cryo-STEM) has enabled precise mapping of structural responses related to underpinning low-temperature physics, such as periodic lattice displacements and associated charge density waves [3-5]. Most cryo-STEM, however, is performed at the absolute temperature of the holder, precluding access to intermediate temperatures, and thus limiting the ability to track structural transformations and the emergence of correlated phases over temperature. To overcome this, we have optimized a novel approach to cryo-STEM using a liquid-N2 specimen holder equipped with a 6-pin MEMS system for local heating [6]. This has expanded the realm of cryo-STEM to any desired temperature from ~95-500 K. Thus, we can use controlled-temperature cryo-STEM to explore the effects of temperature on the layer stacking of van der Waals Nb3Br8 and its relationship to magnetic order.

Employing controlled-temperature cryo-STEM we have observed a distinct structural phase transformation in Nb3Br8 with atomic-resolution. Plan-view imaging demonstrates a clear, reversible transformation from the α-phase to β-phase at ~250 K upon cooling and β-phase to α-phase at ~425 K upon heating through a series of apparent intermediate phases. Imaging of cross-sectional specimens, however, does not show a reorganization of layer stacking. Rather, persistent stacking faults are observed, some consisting of α-phase inclusions accompanying the β-phase unit cell. The lack of an observed transition in this geometry may indicate that the transition in thin, cross-sectional STEM samples is suppressed. Coupling the plan-view results with Multislice image simulations provides a clearer picture of the temperature-induced atomic scale changes in Nb3X8 systems. Developing controlled-temperature cryo-STEM has allowed investigation into the implications of composition and temperature on layer stacking in a single materials system. Understanding the mechanism of stacking changes and their effect on magnetic ordering will afford handles for new materials with tailored transition temperatures.
Electron Transport Cathode Luminescence Microscope for the Phase-Separated Transition Metal Oxides

Hidekazu Tanaka1, Azusa N. Hattori1, Masayoshi Ichimiya2, Rupali Rakshit1 and Masaaki Ashida1; 1Osaka University, Japan; 2The University of Shiga Prefecture, Japan

Phase transitions in transition metal oxides, such as metal-Insulator transition, ferromagnetic, ferroelectric materials, are useful phenomena to realize novel electrical/magnetic/thermal switching and sensing devices. The dynamical behavior of their nano- to micro-scale domain structures play an important role for phase transitions, and their scaling behavior would create superior functionally of steep changes in resistive switching magnetoresistance in VO2, magnetite [1] and so on.

Cathodoluminescence (CL) imaging technique realizes the multi-scale from nano to several hundred micro level observation for the spatial distribution of electronic properties via the optical excitation. So far, CL mapping was not applicable for the non-fluorescent samples. Electron transport cathode luminescence microscope (ETCLM) has been developed by the energy transfer (ET) ratio visualization in the dye-assist CL technique, where ET between luminescent dye and objective materials is applied in imaging for optical conductivity dispersion over the sample based on a conventional scanning electron microscope with a CL system. This ETCLM technique enables the simple and contractless image mapping to characterize the optical conductivity, i.e., metallic/insulating area distribution based on the contrast of the ETCL intensity image. The principle of visualization for optical conductivity dispersion is derived from the radiative/nonradiative emission reflecting ET coupling between the dye and objective materials. As a proof on the principle, the ETCL mapping for the prototype Au disk patterned SrTiO3 sample was attributed to the ET process substantiated by significant ETCL change of the dye. The capability of our technique for mapping metal/insulator property distribution is demonstrated for the observation of the phase separation during insulator-metal transition process in strongly-electron correlated VO2 and Magnetoresistive manganite. Temperature dependent ETCL images adequately capture the characteristic of metal/insulator electronic domain formation across the phase transition phenomena.

data with the results of micromagnetic simulations, we are able to gain a fuller understanding of the various energy terms that contribute to the behavior that we observe.

For example in artificial spin ices, we have explored the way in which aperiodicity leads to local variations in the energy landscape and to a difference in behavior with respect to periodic ASIs. We are able to calculate the energy at each vertex motif for each possible magnetic configuration from our simulations and thus determine which vertices play the most dominant role in influencing behavior in response to magnetic fields [1, 2] and to changes in temperature. Applied to magnetic skyrmions we used in situ LTEM to observe skyrmions in a Co/Pt multilayer film as a function of applied magnetic field, and by combining with simulations we were able to determine the strength of the Dzyaloshinskii-Moriya interaction [2].

Electronic Structures of MgO/Fe Interfaces Revealed by Hard X-Ray Photoemission with an Applied Magnetic Field Shigenori Ueda1, Masaki Mizuguchi2, Masahito Tsujikawa2 and Masafumi Shirai2; 1National Institute for Materials Science, Japan; 2Tohoku University, Japan

We have newly developed hard X-ray photoelectron spectroscopy (HAXPES) under an applied magnetic field of 1 kOe to study the electronic and magnetic states of the interface-induced perpendicular magnetic anisotropy (PMA), in particular for MgO/Fe interfaces [1]. In this work, we used MgO(2 nm)/Fe(1.5 and 20 nm)/MgO(001) structures to reveal the interface-induced electronic states of the Fe film. Perpendicular magnetization of the 1.5-nm-thick Fe film without extrinsic oxidation of the Fe film was detected by the Fe 2p core-level magnetic circular dichroism (MCD) in HAXPES under a magnetic field, and easy magnetization axis perpendicular to the film plane was confirmed by ex-situ magnetic hysteresis curve measurements. The valence-band HAXPES spectrum of the 1.5-nm-thick Fe film revealed that the Fe 3d electronic states were strongly modified from the thick Fe film and a reference bulk Fe sample due to the lifting of degeneracy in the Fe 3d states near the MgO/Fe interface. We found that the tetragonal distortion of the Fe film by the MgO substrate also contributes to the lifting of degeneracy in the Fe 3d states and PMA, as well as the Fe 3d-O 2p hybridization at the MgO/Fe interface, by comparing the valence-band spectrum with density functional theory calculations for MgO/Fe multilayer structures. Thus, we can conclude that the Fe 3d-O 2p hybridization and tetragonal distortion of the Fe film play important roles in PMA at the MgO/Fe interface. HAXPES with in-situ magnetization thus represents a powerful new method for studying spintronic structures. This is a first step for HAXPES under a coexistence of electrical and magnetic fields to understand the phenomena driven by electric and magnetic fields from the electronic structures.

Coherent Soft X-Rays as a Probe for Structure and Dynamics of Materials Exhibiting Magnetic and Electronic Phenomena Andi M. Barbour, Wen Hu, Stuart Wilkins and Claudio Mazzoli; Brookhaven National Laboratory, United States

The National Synchrotron Light Source II (NSLS-II) houses the world leading coherent soft x-ray (CSX) beamline, which was designed to exploit a high coherent x-ray flux (x10^13 photons s^-1) to study structure and dynamics of novel materials and model devices using resonance elastic x-ray scattering (REXS). By selecting incident energies of x-ray absorption edges (200 - 1800 eV), researchers use the in-vacuum diffractometer and liquid helium cryostat to investigate single crystals, thin films, and engineered nano-arrays. This energy range is particularly exploited by 3d transition metal oxides, but it is not limited to these materials. The variable setup of CSX offers scientists a variety of techniques including, but not limited to, nano-diffraction, ptychography, resonant reflectivity / diffraction, and x-ray photon correlation spectroscopy (XPCS). In particular, coherent diffraction produces a signal with x-ray speckles caused by domain boundaries and defects that act as phase objects, and XPCS uses speckles to characterize dynamics of electronic and magnetic ordering on the 10s of milliseconds to hours time scale. The x-ray speckles may also be used to study phenomena like return point memory or material degradation. Our main experimental-
station also has some limited in-situ capability with permanent magnets and 4-wire measurements. This is in addition to our new holography experimental-station that is outfitted with an electromagnet (0.8 Tesla maximum) with advanced application of current/voltage to samples. We will present these capabilities, some recent science from the first 4 years of operation, and our future plans.

Optical Investigation of Magneto-Elastic Coupling in van der Waals Ferromagnet CrBr₃ Vincent Plisson; Boston College, United States

Van der Waals materials give a unique ability to explore the physics in the effective 2D regime. Due to the possibility of using mechanical exfoliation, atomically thin samples can be prepared without much difficulty. Another advantage is that exfoliatable materials can be easily strained; this can be particularly useful in observing the effect of strain on magnetism as well as determining the role of magneto-elastic effects. A key parameter to maintaining magnetism in 2D is magnetic anisotropy, a spin configuration in which the spins align in a certain crystal direction called the easy axis. Previous experiments show CrBr₃ is a ferromagnet with out-of-plane ferromagnetic ordering with Ising anisotropy. Here we report on optical measurements (Raman Scattering) done on CrBr₃ to investigate the magneto-elastic coupling and the evolution of the Raman spectra in a full temperature dependent study.

Atomic Scale Characterization of Phase Transitions by Transmission Electron Microscopy Martial Duchamp¹, Kristina M. Holsgrove², Kamble Deepak¹, Miryam Arredondo², Laszlo Forro¹ and Raju V. Ramanujan¹; ¹Nanyang Technological University, Singapore; ²Queen’s University Belfast, United Kingdom; ³Ecole Polytechnique Fédérale de Lausanne, Switzerland

Here, we present in situ and operando in a transmission electron microscope (TEM) studies where the microstructure is characterized at atomic scale across phase transitions characterized by specific temperatures, i.e., Curie temperature, critical superconductive temperature (Tc). We use a dedicated low temperature double-tilt holder able of atomic-scale characterization in a 100 K to 1,000 K temperature range while applying electrical stimulus. We will present a few cases study where the combination of low temperature and atomic resolution imaging allow to get deeper understanding on the superconductor, ferroelectric and ferromagnetic materials properties. We will present the nano-confinement effect on the Curie temperature of the (MnNiSi)₁₋ₓ(Fe₂Ge)ₓ system for magneto-caloric applications with the aim to tune the ferromagnetic transition both by a control of the composition (x) and of the crystal size. The effect of the x, accounting for MnNiSi to Fe₂Ge phase ratio have been shown to control the Curie temperature by bulk characterization techniques but so far the size effects have not been investigated. The transition is monitored both by real-space imaging techniques inside a TEM combined with phase contrast techniques that allow the measurement of magnetic moments aligned perpendicularly to the electron beam propagation direction. We will also present our recent results on the imaging of high-temperature superconductor, Bi₂Sr₂Ca₂Cu₃O₁₀, around its critical temperature (~110 K). The use of scanning (S-)TEM techniques combined with multi-slice simulations at different collection angles allowed to follow how the micro-structure affects the superconducting mechanism. We measured operando the resistivity drop inside the TEM at micro-scale using standard IV characterization techniques and electron holography for local mapping of the electrostatic potential. Multiferroic, magnetoelectric, piezoelectric and lead-free – epitaxially strained bismuth ferrite (BFO) thin films exhibits both exciting physics and fascinating characteristics for tuning their functionality. Using SEM and FIB techniques, we identified pre-written AFM regions and milled cross-sectional lamellae across distinct regions which included an area of native polymorphs, an area which was electrically written into the pure T phase and an area which was transformed back into the mixed-phase via stress. We present direct measurements of the atomic and electronic structure of the native and post-external stimuli-written phases using nano-beam electron diffraction (NBED) and electron energy-loss spectroscopy (EELS) acquired using aberration-corrected STEM, accompanied by EEL spectra calculated using the program FEFF.

Large Polarization and Susceptibilities in Artificial Morphotropic Phase Boundary PbZr₅₋ₓTiₓO₃ Superlattices Eduardo Lupi¹ and Lane W. Martin¹; ¹University of California Berkeley, United States; ²Lawrence Berkeley National Laboratory, United States
Large susceptibilities in the PbZr$_{1-x}$Ti$_x$O$_3$ system have historically been attained by selecting materials in the compositional vicinity of the morphotropic phase boundary. This typically comes as a trade-off with saturation polarization, as polarization diminishes and susceptibility rises at the phase transition. Here, we take advantage of unit-cell precise growth to introduce ferroelectric-ferroelectric interfaces as an additional design parameter wherein the material response can be tuned by both composition and superlattice periodicity. We likewise focus on heterostructures with overall chemistry near this boundary, but built from compositions far from the phase boundary itself: rhombohedral PbZr$_{0.8}$Ti$_{0.2}$O$_3$ and tetragonal PbZr$_{0.4}$Ti$_{0.6}$O$_3$. Using reflection high-energy electron diffraction (RHEED)-assisted pulsed-laser deposition, we create atomically-precise (PbZr$_{0.8}$Ti$_{0.2}$O$_3$)$_n$(PbZr$_{0.4}$Ti$_{0.6}$O$_3$)$_{2n}$ ($n = 2, 4, 6, 8, \text{and} 16$ unit cells) superlattices with overall film chemistry PbZr$_{0.53}$Ti$_{0.47}$O$_3$. As compared to uniform films of the parent materials, the superlattice structures exhibit both large saturation polarization ($P_s = 64$ µC/cm$^2$) and dielectric susceptibility ($\varepsilon_r = 776$ at 10 kHz for $n = 4$ superlattices). AC field-dependent dielectric measurements suggest the presence of both phase-boundary- and parent-like switching events. First-order reversal curve studies reveal separate switching events for each of the parent layers in addition to an emergent phase-boundary-like interfacial layer. Ultimately, this reveals that artificial superlattices can be deterministically designed as an effective pathway for enhanced responses to external biases.

**Electric Field Induced Modification of Metal/Ferroelectric Oxide Interfaces in Composite Multiferroic Systems**

Andre R. Vantomme$^1$, Sebastien Couet$^1$, Manisha Bisht$^1$, Hiwa Modarresi$^1$, Maarten Trekels$^1$, Sergey Basov$^1$, Haraldar Pall Gunnlaugsson$^1$, Mariella Menghini$^1$, Jean-Pierre Loquet$^1$, Rudolf Rüffer$^2$, Michael Lorenz$^3$, Marius Grundmann$^3$, Vera Lazenka$^1$, Margriet J. Van Bael$^1$ and Kristiaan Temst$^1$; $^1$KU Leuven, Belgium; $^2$ESRF, France; $^3$Universität Leipzig, Germany

In composite multiferroics, magneto-electric (ME) coupling – e.g., altering the magnetic properties by applying an electric field and vice versa– can be achieved by creating an interface between a ferromagnetic and a ferroelectric compound. The induced magnetoelectric coupling originates from strain transfer and strongly depends on the structural and chemical features at the interface. In order to realize structurally stable metal/oxide interfaces for electronic device applications or to realize composite multiferroics with significant ME coupling, it is therefore important to understand the interface properties and to identify how the interface is modified in the presence of an external electric field.

In our work, we have studied the evolution of the magnetic spin structure and the Fe oxidation state at the interface using Fe/LNO (LiNbO$_3$) and Fe/BTO (BaTiO$_3$) as two model systems for ferromagnetic (FM)/ferroelectric (FE) interfaces. To this end, we relied on the isotope-sensitivity of Mössbauer spectroscopy and nuclear resonant scattering (NRS) of synchrotron radiation, which allows to isolate the signal of an approx. 1 nm thin Fe layer at (or near) the FM/FE interface. Doing so, the chemistry and magnetism at the interface can be in situ probed, while an electric field is applied.

The results show that application of a large enough electric field induces the formation of a thin magnetically dead layer at the interface between the metal and the FE oxide due to ion transport across the interface. Remarkably, the final interface state depends on the polarization history of the system. In turn, this magnetically dead layer results in an irreversible decrease of the magneto-electric coupling. With recent NRS measurements, we have identified the values of the critical field above which interface mixing occurs, for both Fe/BTO and Fe/LNO systems, to be of the order of 400 kV/m [1].

Based on our experimental findings, a model was proposed [1,2] for the effect of an applied electric field on the metal/FE oxide interface. Due to the work function difference between the metal and the oxide, a built-in electric field emerges at the interface during the growth of the metal layer onto the FE oxide. Depending on the direction of this built-in field (hence, depending on the sign of the work function difference), the direction of the applied electric field either favors ion transport across the interface or opposes it until the external field overcomes the built-in field.

We recently extended and validated this model by including a wider range of oxides. Therefore, we studied by Mössbauer spectroscopy the chemistry and magnetic state of the interfaces between an Fe layer and a number of complex oxides (with a wide range of permittivity values), before and after the application of external electric fields. Besides Fe/LNO and Fe/BTO, also Fe/BiFeO$_3$, Fe/SrTiO$_3$ and Fe/MgO were investigated. This allows us to compare
metal/ferroelectric interfaces with metal/non-ferroelectric oxide interfaces to identify the effect of the ferroelectric polarization charges on the electric field induced ion transport across the interface [3]. It is found that the nature of the oxide (ferroelectric or non-ferroelectric) determines if an external electric field will induce interfacial oxidation/reduction or not.

From our investigation, it is evident that for multiferroic studies, electric fields below the threshold values should be used to avoid significant interfacial changes due to ionic diffusion, which may deteriorate the magneto-electric coupling. These findings may have important implications not only for the further development of composite multiferroics, but also for complex oxide heterostructures in general.

Scaling Effects in the Resistance-Temperature Characteristic of VO$_2$ on hBN Shingo Genchi$^1$, Mahito Yamamoto$^1$, Teruo Kanki$^1$, Kenji Watanabe$^2$, Takashi Taniguchi$^2$ and Hidekazu Tanaka$^1$; $^1$Institute of Scientific and Industrial Research, Osaka University, Japan; $^2$National Institute for Materials Science, Japan

Correlated oxide thin films often show spatial inhomogeneity in the phase states in the vicinity of the critical temperature, and consequently, the phase transitions become rather gradual. To extract the intrinsic phase transition properties of correlated oxides in device structures, therefore, spatial characterization of the phase domain sizes and the device scaling down to the domain size are necessary. Vanadium dioxide (VO$_2$) is an archetypal correlated oxide that shows a metal-insulator transition (MIT) around 340 K and of great interest for electronic device applications because the resistance changes by up-to 5 orders of magnitude across the MIT. Some studies have shown that VO$_2$ thin films consist of insulating and metallic phase domains near the critical temperature, whose sizes depend on the crystallinity determined by the growth substrates. Recently, we have demonstrated the growth of high-quality polycrystalline VO$_2$ thin films on hexagonal boron nitride (hBN) that is an insulating layered material. However, the phase domain sizes of VO$_2$/hBN have yet to be characterized. Here, we investigate the phase domain sizes and the scaling behavior of the resistance-temperature characteristics of VO$_2$/hBN. VO$_2$ thin films were grown on mechanically-exfoliated thin flakes of hBN by pulsed laser deposition. First, we employed temperature-dependent optical microscopy to characterize the domain sizes of VO$_2$/hBN, since insulating and metallic VO$_2$ are known to show different optical contrasts under visible light illumination. By optical microscopy, we found that the metallic phase domains were emerged near the critical temperature. The sizes of metallic domains were observed to range from several hundreds of nanometers up to a few micrometers, which are comparable to the grain sizes of VO$_2$/hBN measured by atomic force microscopy. Next, we measured the temperature-dependent resistances of VO$_2$/hBN of various sizes. We found that micrometer-scale VO$_2$/hBN showed a step-like behavior in the resistance-temperature characteristic, which reflects the MIT of individual domains in the thin film. The step-like resistance changes became more marked with scaling down to a few micrometers. Such step-like resistance changes can never be seen in a similar size of polycrystalline VO$_2$ on other substrates such as Al$_2$O$_3$ and is a unique feature of VO$_2$/hBN that consists of micrometer-scale domains.

Quantifying Dynamic Processes in Ferroelectrics and Multiferroics—In Situ TEM Meets Data Science Mitra L. Taheri$^{1,2}$; $^1$Drexel University, United States; $^2$Johns Hopkins University, United States

Ferroelectric materials hold great potential for a wide range of technological advances and are an actively researched class of materials. Ferroelectric switching is governed by domain nucleation and domain wall motion. These dynamic processes are difficult to measure. Although fine-scale and local probes have provided much insight and understanding of the localized switching mechanisms, exploration on a global scale, taking into account both intrinsic and extrinsic effects on switching and interfacial phenomena, remains a challenge. This talk presents results from in-situ transmission electron microscopy (TEM) that allows for the visualization of ferroelectric domain switching at high spatial and temporal resolution. In-situ TEM allows for domain dynamics to be quantified in terms of factors such as local dislocation content, charge and point defect behavior, and strain enhanced phenomena. Many of these factors occur in one experiment, however, presenting difficulties for tracking their motion or measuring.
changes. Recent developments in direct electron detection for both imaging and spectroscopy allow for rapid acquisition of time-resolved spectral data and images at rates over 1000 frames per second. At these frame rates, signal to noise ratio is not necessarily optimal. Moreover, events that occur simultaneously can easily be “missed” with conventional image processing or data analysis tools. For these reasons, machine learning approaches are implemented to glean critical information that dictates ferroelectric and multiferroic behavior in datasets deemed too “noisy” for the naked eye. These advances present the possibility of understanding multiple factors in domain dynamics simultaneously, and thus the opportunity to tune these complex materials more predictively.

Impact of Ceramic-Target Crystallinity on Metal-to-Insulator Transitions in Epitaxial LaNiO3 Thin Films Grown by Pulsed Laser Deposition Choi Jin San1, Muhammad Sheeraz2, Jong-Seong Bae2, Jun Han Lee3, Joonyuk Lee4, Jongmin Lee5, Sanghan Lee5, Hyoungjeen Jeon5, Yoon Seok Oh3, Chang Won Ahn4 and Tae Heon Kim4; 1University of Ulsan, Korea (the Republic of); 2Korea Basic Science Institute, Korea (the Republic of); 3Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); 4Pusan National University, Korea (the Republic of); 5Gwangju Institute of Science and Technology, Korea (the Republic of)

In complex oxide thin-film heterostructures, a pulsed laser deposition (PLD) technique has been widely employed for the epitaxial film growth. In PLD, we note that the plasma ions generated by the laser ablation of the ceramic target straightly move to the opposite side and then, adhere to the surface of a heated single-crystal substrate forming an epitaxial film layer eventually. Then, understanding such a dynamic process in PLD film growth is of practical interest in aspect of the high-crystalline thin-film fabrication. And, the physical properties of the as-grown films are significantly affected by the crystallinity of the initial ceramic target used for the PLD. However, the detailed studies on the relationship between the ceramic-target crystallinity and the linked physical properties have been rare. In this work, we demonstrate the effect of ceramic-target crystallinity on the metal-to-insulator transition in rare-earth nickelate thin films epitaxially grown by PLD. We first prepared two LaNiO3 ceramic targets with different crystallinity and then, visualized their surface morphology and the spatial distribution of local stoichiometry in these two LaNiO3 targets. Using various spectroscopic analyses, we microscopically examined how the target crystallinity directly affects the electrical transport properties in epitaxial LaNiO3 thin films. More details of our experimental results will be presented in conjunction with a discussion about the correlation between the observed metal-to-insulator transitions and the degree of disproportionation in the Ni charge valence state.

MT07.05.02
Structure and Electronic State of Misfit Strain Induced Morphotropic Phase Boundary Shift in Pb(Zr,Ti)O3 Epitaxial Thin Films on Various Substrate Takanori Kijuchi, Takumi Shimizu, Takahisa Shiraishi and Toyohiko J. Konno; Tohoku University, Japan

PbZr1-xTiO3 (PZT) is widely used for ferroelectric and piezoelectric applications like MEMS. PZT has a morphotropic phase boundary (MPB) where rhombohedral and tetragonal phases coexist. PZT of MPB composition leads to excellent dielectric and piezoelectric properties by free rotation of spontaneous polarization in structural gradient regions (SGR) at domain walls and phase boundaries1). The density of the SGR is expected to increase by controlling size and density of domains. We have previously elucidated that MPB compositional range of Pb(Mg1/3Nb2/3)O3-PbTiO3 (PMN-PT) and PZT thin film deposited on SrTiO3(001) (STO) single crystal was extended in comparison with PMN-PT and PZT bulk crystals, and that nano-sized domains were formed due to residual strain induced by misfit dislocations3,4). This revealed that we could control the phase stability and domain structure by utilizing elastic field. The objective of this research is to elucidate the effect of elastic field on phase stability and domain structure in MPB composition of PZT thin films from the viewpoint of microstructure. The
target of this research is to elucidate the effect of the local strain around defects on the formation of the SGR and MPB compositional range, which leads to intensify the properties of the films. XRD 2θ-ω profiles and an electron diffraction patterns of PbZr0.3Ti0.7O3 (PZT30/70) on KTaO3 (KTO) thin films prepared by CSD method using MOD solutions with excessive 10 at% Pb indicated the cube-on-cube epitaxial relationship between the film and the substrate. The film involves only a perovskite phase with no pyrochlore phase. HAADF-STEM image and the strain map by geometric phase analysis of PZT30/70 on KTO. The interface between PZT30/70 and KTO interface is coherent without misfit dislocation owing to the little lattice mismatch of about 0.01 for the rhombohedral phase and about 0.005 for the a-axis of the tetragonal phase of the film. The volume dilatation map, which means the average of the normal strain both of the in- and out-of-plane directions, showed that two phases with different volume coexisted. The normal strain map in out-of-plane direction revealed that 90°domains of tetragonal phase were formed around the interface and that two-layer structure in out-of-plane direction. The tetragonal and the rhombohedral phases were dominant at the bottom region the upper region of the film, respectively. Then, MPB composition is around Zr/Ti=30/70. From our early studies on PMN-PT and PZT epitaxial films on STO, 90°domains of tetragonal phase nucleated at misfit dislocations in the semicoherent interface. However, the result on the PZT epitaxial films on KTO shows that the growth of 90°domains needs no misfit dislocation, which is corresponding to the PTO epitaxial films on STO with little lattice mismatch of 0.01 for a-axis. The strain map of normal strain in the in-plane direction shows that tetragonal phase grew in the out-of-plane direction from the edge of 90°domains. This result suggests that the edges of 90°domains also act as the nucleation sites of phase boundaries which plays the role of the SGR, indicating that the density of two kinds of SGR, i.e. phase boundaries and domain walls, can be extended by increasing 90°domain population.

MT07.05.03 In Situ and Ex Situ Studies on the Formation of Orthorhombic Phase in HfO2-Based Thin Films Takahisa Shiraishi, Takanori Kiguchi and Toyohiko J. Konno; Tohoku University, Japan

HfO2-based fluorite-type oxides are well-known as polymorphic materials (Monoclinic, Tetragonal, and Cubic phases). In recent years, ferroelectricity has been discovered in HfO2-based thin films containing a metastable orthorhombic phase (O-phase), and these materials have attracted much attention for future ferroelectrics. Since the O-phase is obtained by rapid thermal annealing of amorphous HfO2-based films deposited at room temperature, the crystallization and formation mechanisms of the film has been of great interest. In fact, the selection of crystalline phases depends on the condition of rapid thermal annealing due to polymorphism of HfO2-based oxide family. It is, hence, important to clarify the relationship between the annealing conditions and the resultant crystalline phase, including the O-phase. In this study, we investigated the influence of the annealing conditions on the crystalline phase(s) of HfO2-based thin films, with a particular emphasis on the formation of O-phase.

20 nm-thick (Hf,Ce)O2 films were deposited on (001) yttria-stabilized zirconia (YSZ) substrates by ion-beam sputtering. The deposition was carried out at room temperature in Ar atmosphere, then as-deposited films were annealed under various conditions (annealing time and temperature) in N2 atmosphere. The crystal structure of the deposited films was investigated by X-ray diffraction (XRD) and scanning transmission electron microscope (STEM).

XRD measurement confirmed that as-deposited films are amorphous, while in-situ XRD measurement showed that as-deposited films completely crystallized at a temperature above 600 °C. The lattice constants estimated from XRD 2θ-ω patterns changed discontinuously with decreasing temperature, suggesting that a phase transition has occurred. STEM observation for the annealed films revealed that the crystallization began at the film/substrate interface. We also found that the crystalline phase of the annealed films varied with annealing temperature, and most importantly, observed that the number of O-phase domains increased with increasing annealing time. The resulting (Hf,Ce)O2 films exhibited multidomain structures composed of the O-phase. We show that the optimum microstructure can be controlled by tuning the annealing condition.

Ferroelectric Domain Switching Behavior in the (110) Orientated BFO Film Yangyang Zhang¹², Myung-Geun Han², Nagarajan Valanoor¹ and Yimei Zhu²; ¹University of New South Wales, Australia; ²Brookhaven National Laboratory, United States

Investigation of reliable or non-volatile information storage has become an irresistible attraction in the field of modern electronic technology [1,2]. As ferroelectric domain walls are one to two orders of magnitude thinner than magnetic domain walls, exploration of switching properties and stabilization of ferroelectric domains can open a way from microelectronics to nanoelectronics, that is, it can help achieve higher information storage density [3]. Here, we focus on the (110) orientated BFO film, where the compression coming from the STO substrate can suppress certain ferroelastic switching. In order to observe the real-time domain evolution, in situ electrical biasing in transmission electron microscope (TEM) is applied. During the experiment, the switching processes including nucleation at the interface, propagation and growth has been captured. Moreover, using double-spherical aberration corrected TEM, the activation of domain switching near the antiphase boundary (APB) and the stabilization of 180° domain walls at the final state maintained by flux closure are also revealed down to atomic scale. Our study sheds light on switching performance of the BFO film grown on (110) orientated substrate and is expected to provide a potential pathway for future design of information storage devices.

Ferroelectricity and Temperature Dependent Dielectric Response in Rare Earth Doped Lead Zirconate Titanate Nano Crystalline Films Mohan K. Bhattarai, Karuna K. Mishra and Ram S. Katiyar; University of Puerto Rico, Rio Piedras, United States

Rare earth doped lead zirconate titanate (PZT) nano crystalline films have excellent dielectric, ferroelectric, and piezoelectric behavior and are useful for memory and energy storage devices. Herein we report rare earth La³⁺ and Sc³⁺ cation doped PZT thin films and studied their ferroelectric properties and energy storage capacity. The nano films of (1-y)[PbZr0.53Ti0.47] y[La₁₋ₓScₓ]O₃₋δ with y = 0.10 and 0 ≤ x ≤1, were fabricated by using pulse deposition method on La₀.₆₇Sr₀.₃₃MnO₃ (LSMO) coated MgO (100) substrates employing a KrF excimer laser of wavelength 248 nm. The thickness of the grown films, measured using profilometer, was ~ 350 nm. We observed (100) oriented thin films stabilized in tetragonal perovskite phase from analysis of x-ray diffraction data. The Raman spectra of these thin films at different temperatures suggest the nucleation and evolution of the polar nano-regions dispersed in a nano polar matrix attributed to their relaxor behavior. We observed the surface roughness of films between 3 - 10 nm from analysis of Atomic force microscopy. The film capacitors fabricated as LSMO/PLZTS/Pt were investigated for its dielectric and ferroelectric behavior. The temperature dependent (100-650 K) dielectric measurement in the frequency ranges 10²-10⁶ Hz, revealed dielectric constant ε' ~ 700-2000 with a comparatively low loss. Ferroelectricity of these thin films were evident well saturated hysteresis loops at room temperature recorded at several frequencies. The high dielectric constant, low losses and excellent ferroelectricity of nanostructured film capacitors suggest their potential application in electronic devices.

Tuning Two-Photon Absorption Effect in Magnetic Nanoparticles by Employing an External Magnetic Field—Ultrafast and Magnitude Measurements Eduardo S. Goncalves¹, Jonathas Siqueira¹, Wagner Wysses¹, Kinnari Parekh², Cleber Mendonca¹, Antônio M. Figueiredo Neto¹ and Leonardo de Boni¹; ¹University of São
Colloidal dispersions of magnetic nanoparticles (NP) were synthesized at the University of São Paulo, Brazil, and at Charotar University of Science and Technology, India, based on manganese-zinc ferrites, (Mn0.5Zn0.5Fe2O4). Solutions containing nanoparticles with spherical (MZS) and cubic (MZC) nanoparticles were studied by means of the Z-Scan technique in the open-aperture configuration, allowing the determination of the two-photon absorption cross-section ($\sigma_{2PA}$). Since the nanoparticles are in the superparamagnetic state and free to rotate within the liquid carrier, external magnetic fields, with magnitudes between 0 Oe and 3100 Oe, were applied in order to orient the nanoparticles in solution, aligning the axis of easy magnetization of each NP to the external field. These experiments were performed with the incident beam polarization in the same direction to the magnetic field lines, herein called parallel configuration, and in the case in which the polarization and the magnetic field directions were orthogonal, the perpendicular configuration. To better understand the nonlinear absorption, verified during the Z-Scan measurements, the electron dynamics were investigated by a spectrally resolved femtosecond transient absorption (without the presence of external magnetic field). Samples were pumped at 390 nm (region in which the samples present a large absorption) with different pulse energy and the relaxation dynamic was probed by using an ultrashort white-light continuum pulse (450 nm to 750 nm). In addition to these measurements, the pump beam was changed for 780 nm in order to check the dynamic induced by two-photon absorption. It is important to say that in the absence of magnetic field, linear absorptions of both samples are the same, as expected since the NPs have the same constituents. The magnetic field effects on the linear absorption was also evaluated and no changes were verified regardless the field presence, indicating that the nanoparticles are being oriented but not forming bigger structures that would scatter the light. The two-photon absorption cross-section in the absence of external magnetic field was measured as $\sigma_{2PA}^0$=18.0(6) GM for spherical nanoparticles and 17.0(7) GM for the cubes. The measured values are compatible with each other within the experimental errors. For both studied nanoparticles, the 2PA cross-section measured in the parallel configuration presented an increment in the value, while in the perpendicular configuration, the measured value decreased when compared to $H=0$. In the presence of magnetic fields, nanoparticles tend to align their magnetic momentum to the external field and, in consequence, there is an alignment of crystallographic planes of the material. Thus, these experiments put in evidence the optical anisotropy in the two-photon absorption of our ferrite nanoparticles, since in the parallel configuration components of the third-order nonlinear tensor was measured alongside the magnetic momentum direction, while in the perpendicular configuration, in the two dimensions perpendicular to that direction, that are equivalent. When there is not magnetic field applied, the nanoparticles are randomly oriented and the measurements correspond to an average over the three orthogonal directions. Femtosecond transient absorption measurements revealed an ultrafast relaxation process containing at least two separated dynamical processes, one shorter than 5 picoseconds, possible related to the hot electron relaxation or exciton-exciton annihilation, and a second one, much longer, may be related to the trapped electron on the conduction band. Also, the longer lifetime may be associated to the relaxation from the conduction to the valence band. Same behavior was observed by pumping the samples with 775 nm, indicating that the electronic states excited by two-photon absorption may be the same as the ones excited by one-photon absorption.

**Nanoparticle Shape Effect on the Determination of the First-Order Hyperpolarizability Anisotropy of Magnetic Colloids**

Eduardo S. Goncalves¹, Leandro Cozza², Wagner Wysses¹, Kinnari Parekh³, Cristiano Oliveira¹, Antônio M. Figueiredo Neto¹ and Leonardo de Boni²; ¹University of São Paulo, Brazil; ²University of São Paulo, Brazil; ³Charotar University of Science & Technology, India

Colloidal dispersions of magnetic nanoparticles were synthesized at the University of São Paulo, Brazil, and at Charotar University of Science and Technology, India, based on manganese-zinc ferrites, (Mn0.5Zn0.5Fe2O4). Solutions containing nanoparticles with distinct shapes (MZS, containing spherical nanoparticles, and MZC, composed of cubic NPs) were studied by means of the hyper-Rayleigh scattering (HRS) technique, allowing the determination of the optical second harmonic generation, defined as $\beta$. The size distribution and shape of nanoparticles were determined through small angle x-rays scattering (SAXS). Since the produced nanoparticles are free to rotate within the liquid carrier, an external magnetic field was applied in order to orient the particles in solution. Experiments with applied magnetic field were performed both in the parallel configuration (when the incident laser beam polarization was parallel to the magnetic field lines) and in the perpendicular case (where the polarization and the field directions were orthogonal). Furthermore, the linear attenuation spectrum was measured in the presence and absence of external magnetic field and it shows no changes regardless the field presence, indicating that the nanoparticles are being oriented but not forming bigger structures that would scatter the light. This is
supported by the SAXS data, also measured in the presence of magnetic field, that demonstrate the formation of small linear aggregates, composed by a few nanoparticles. In the absence of magnetic field the linear attenuation spectrum of both samples is the same, as expected since the NP's have the same constituents. In this case, the hyperpolarizability was measured, for spherical nanoparticles, as \( \beta^0 = 9.5(2) \times 10^{-28} \text{cm}^5/\text{esu} \), while for cubic ones, \( \beta^\square = 7.8(1) \times 10^{-28} \text{cm}^5/\text{esu} \). For both studied nanoparticles, optical second harmonic experiments were performed in the presence of external field in the parallel configuration. In this condition, an increase in the value was verified, that is, for spherical nanoparticles (MZS), \( \beta^0 \parallel = 10.1(2) \times 10^{-28} \text{cm}^5/\text{esu} \), and for MZC sample, \( \beta^\square \parallel = 8.1(2) \times 10^{-28} \text{cm}^5/\text{esu} \). On the other hand, a slight decrease on the hyperpolarizability value was measured for experiments performed on the perpendicular configuration, \( \beta_\perp = 9.3(3) \times 10^{-28} \text{cm}^5/\text{esu} \) for MZS and \( \beta^\square \perp = 7.4(2) \times 10^{-28} \text{cm}^5/\text{esu} \) for the cubes. For cubic nanoparticles the anisotropy in the first-order hyperpolarizability \( \delta \beta = (\beta_\parallel - \beta_\perp) / \beta_\parallel \) was 8.2 while for the spherical nanoparticles, 7.6%. In the presence of magnetic fields, nanoparticles tend to align their magnetic moment to the external field, in consequence, there is the alignment of crystallographic planes of the material. Therefore, in the parallel configuration the first-order hyperpolarizability was measured alongside the magnetic momentum direction, while in the perpendicular configuration, in the two dimensions perpendicular to that direction, that are equivalent. When there is not magnetic field applied, the nanoparticles are randomly oriented and the measured hyperpolarizability corresponds to an average over the three orthogonal directions. This can be verified calculating the weighted average of the hyperpolarizability in the presence of external field, that is, \( <\beta> = 1/3(\beta_\parallel + 2\beta_\perp) \), so \( <\beta^0> = 9.6(3) \times 10^{-28} \text{cm}^5/\text{esu} \) and \( <\beta^\square> = 7.7(2) \times 10^{-28} \text{cm}^5/\text{esu} \), in both cases compatible with the measured value for the system without magnetic field. This demonstrates the shape dependent anisotropy in the second-order nonlinear properties of ferrite NP's, opening the possibility of the development of optofluidic devices, associating magnetic nanoparticles in solution and optical elements as i.e. optical fibers, as optical magnetometers, that would allow the determination of the field magnitude and direction, as well as in information propagation since there are three possible states and light intensities for a system composed by magnetic NP and an external magnetic field.

MT07.05.08

Study of the Doping Effect of Yttrium on the Electrical Properties of BaTiO3 Synthesized by Spark Plasma Sintering Adl Alshoaibi; King Faisal University, Saudi Arabia

The effect of Y2O3 doping on the structure, transport, dielectric, and relaxation properties of BT ceramics will be investigated. The possibility of formation of an extensive range of solid solution regions and the formation of a polymorphism of Y-doped BaTiO3 Will be studied. In this study, coarse-grained and nano-sized grain BT ceramics will be synthesized by spark plasma sintering. Conventional sintering is expected to produce micro-sized grained ceramics, whereas spark plasma sintering of BT nanopowder could produce nanocermics/fine grained ceramics. The structure of the BT nanocermics will be investigated by X-ray diffraction, whereas FE-SEM, Raman, and AFM will determine the grain size and the chemical composition of the ceramics. The photocurrent characteristics of BT nanocermics will be studied by using Quantum efficiency and solar systems. The transport dielectric and relaxation properties will be studied by impedance spectroscopy measurements over wide ranges of temperatures and frequencies. Thermally stimulated depolarization current (TSDC) measurements are interesting and helpful technique that will be used to study the relaxation properties due to the defects in the studied ceramics. We will also perform investigations using theoretical calculations based on density functional theory (DFT) to study the role of cation substitution on structural and electronic properties in BaTiO3.

MT07.05.09

Optical Spectroscopy, Microscopy and Structural Characterization of Monodisperse Lanthanide Doped Titanium-Containing Perovskites for Optoelectronic, Piezoelectric and Ferroelectric Applications Benard Kavey; Central Michigan University, United States

Lanthanide doped-titanium-containing perovskite nanocrystals, \( \text{M}_{1-x} \text{Ln}_x \text{TiO}_3 \) (where \( \text{Ln} = \text{La}^{3+}, \text{Nd}^{3+}, \text{Sm}^{3+}, \text{Dy}^{3+}, \text{Ho}^{3+}, \text{Er}^{3+}, \text{Ti}^{3+}, \text{Yb}^{3+} \) and \( \text{M} = \text{Ba}^{2+}, \text{Sr}^{2+} \)), have have been synthesized via a solvothermal route at relatively low temperatures, \( T < 180 \degree \text{C} \). The versatility of the synthesis route has made it possible to synthesize similar sizes (20 nm) and shapes (cuboidal) for all Ln-dopant compositions and as such, trends in their electronic and optical properties can be explored. Without the need for high temperature annealing, X-ray diffraction patterns of the as-synthesized nanocubes such as \( \text{Ba}_{0.97} \text{Ti}_0.03 \text{O}_3 \), \( \text{Ba}_{0.97} \text{Er}_0.03 \text{Ti}_0.03 \) and \( \text{Ba}_{0.97} \text{Dy}_0.03 \text{Ti}_0.03 \) powders synthesized at 150 \degree \text{C} showed highly crystalline, single phase and pure nanocrystals. Transmission electron microscope coupled with an EDS-detector was used to map and quantify the actual composition and stoichiometric ratios of the lanthanide ions.
in the crystal lattice. Also, a fluorescence emission spectroscopy of the M1,χLnχTiO3 nanocubes colloidal solution showed interesting emission spectra such as an up-conversion of the excitation wavelength for some specific Ln-dopant compositions. Temperature dependent Raman spectroscopy was used to analyze the local structural distortions within the crystal lattice as well as the tetragonality of the ferroelectric phase. We observed that for certain compositions such as Ba0.95Yb0.05TiO3, the tetragonality increases with increasing temperature but decreases sharply after the transition temperature; 80 °C. Advanced microscopy techniques such as atomic force microscopy (AFM), piezoelectric force microscopy (PFM) and magnetic field PFM were used to study the electric and magnetic field response of the nanocrystals. With increasing percent compositions of the same Ln-dopant type, we observed a general trend in the ferroelectric and piezoelectric responses of the as-synthesized M1,χLnχTiO3 nanocubes. The general trend and values of piezoelectric displacement coefficient (d33) for all sample compositions has been measured at ambient and high temperature conditions.

MT07.05.10
Probing the Dynamics of Nanoscale Thermal Transport with Ultrafast Electron Diffraction Matthew Gorfien1, Xuan Wang2 and Jianming Cao1,3; 1Florida State University, United States; 2Institute of Physics, Chinese Academy of Sciences, China; 3Shanghai Jiao Tong University, China

The fabrication of smaller, denser, and higher frequency electronic devices has resulted in the need to completely understand and control thermal transport at the nanometer scale [1, 2]. At the nanoscale shorter than the heat diffusion length, thermal transport in semiconductor devices is dominated by phonon scattering across interfaces between the semiconductor heterojunctions and is quantified by the thermal boundary conductance (TBC). We investigated the kinetics of thermal transport across a GaAs/AlGaAs epitaxial interface using timeresolved Reflection High Energy Electron Diffraction (TR-RHEED). In the experiments, the temperature imbalance is created by ultrafast heating the top GaAs nanofilm selectively with 800-nm femtosecond optical pulses and monitored by tracing its temperature evolution with TR-RHEED. The thermal transport kinetics observed with TR-RHEED was also simulated using two separate models: a heat conduction and three-temperature model, providing a method of measuring and extracting the thermal boundary conductance in semiconductor heterostructures. The TBC was found to agree well with the Diffuse Mismatch Model at lower temperature imbalance across the interface, but start showing different behavior when the temperature of the top GaAs nanofilm is higher than the Debye temperature, opening up questions about the mechanisms governing interface heat transfer under highly non-equilibrium conditions.

Modeling Shape Transforming Truss Metamaterials with a Geometrically Exact Beam Model Claire Lestringant and Dennis Kochmann; 1ETH Zurich, Switzerland; 2California Institute of Technology, United States

Slender beams undergo large deformations when subjected to moderate mechanical forces: they are therefore promising building blocks for the design of multistable, reconfigurable metamaterials. Combining these structures with active materials through advanced additive manufacturing techniques paves the way towards engineering truss metamaterials with properties tunable in time (so-called 4d-printing).

In this presentation, I use a discrete, geometrically exact beam formulation that can efficiently and accurately simulate the nonlinear deformation of slender beams featuring complex material behaviors, such as those found in the design of such metamaterials. I implement a numerical method that fully decouples the kinematics from the material behavior, and can handle finite rotations as well as a wide class of constitutive laws depending on the stretching, flexural and torsional strain and strain rates.

After presenting the underlying geometric description of framed curves, and the treatment of inelastic material models using variational constitutive updates, I will show examples covering different constitutive laws, including rate-dependent behaviors. These benchmark problems feature instabilities, nonlinear geometric couplings between bending and twist, as well as natural curvature. I will show that the convergence of the numerical method competes with classical nonlinear beam formulations.

Finally, I present an extension to beam assemblies and trusses with rigid joints, which I demonstrate on a set of examples including shape transforming structures, triggered by thermal and mechanical stimuli.

Designing Nano-Architected Materials for Extreme Mechanical Properties Lorenzo Valdevit, Jens Bauer, Cameron Crook, Anna Guell Izard, Meng-Ting Hsieh, Yunfei Zhang and Marti Sala; University of California, Irvine, United States

Architected materials have long been explored for their ability to achieve extremal combinations of mechanical and functional properties. Optimal design of the topology has allowed numerous demonstrations of mechanical metamaterials with unique combinations of high stiffness, strength, energy dissipation, low density, and many other properties. More recently, progress in additive manufacturing has enabled fabrication of nano-architected materials, which can achieve far superior properties via combined optimization of their unit cell topology and base material micro/nano-structure. This presentation will cover recent progress in the design, manufacturing and characterization of ultralight nano-architected ceramic materials with unprecedented combinations of strength, energy absorption and high temperature stability. Lattice, plate and shell-based architected materials with nanoscale topological features are fabricated by two-photon polymerization Direct Laser Writing (DLW). The polymeric preforms are subsequently pyrolyzed in vacuum, resulting in a ceramic metamaterial (carbon or silicon oxycarbide, depending on the choice of resin). The effect of the processing parameters on the microstructure and mechanical properties (ultimate strength and strain to failure) of the resulting constituent materials is discussed first. Subsequently, we present ceramic mechanical metamaterials with various topologies and relative densities, and demonstrate extremal combinations of mechanical properties. In particular we show that with proper choice of topology, ceramic nano-architected materials can exhibit progressive failure, dissipating large amounts of energy. Finally, opportunities for scalability are discussed.

9:00 AM MS01.01.03
A Next Generation Auxetic Reinforced Self-Confining Concrete Metamaterial Simos Gerasimidis, Andrew
Among the major limitations of concrete as a building material is its brittle behavior, which provides little warning prior to failure. Lateral confinement of concrete, which involves applying pressure on the concrete element perpendicular to the direction of loading, is a well-known technique that is commonly used to improve the strength, ductility and other properties of reinforced concrete members. Until today, the techniques used for applying confinement pressure in concrete can be divided into two main types based on the method of applying the confinement pressure. Passive confinement employs internal transverse steel reinforcement, external steel jackets or fiber-reinforced jackets, with which the confining pressure is generated only as a direct result of the lateral dilation of concrete under loading. Active reinforcement on the other hand has been demonstrated as a much superior confinement technique mainly because in this case, the confinement pressure is applied on the concrete before loading and is more effective in delaying the dilation of concrete structures. However, all these techniques have not really altered the concrete material itself. The focus of this work is to build upon the work already accomplished in cellular auxetic architected metamaterials and harness their auxeticity to develop a next generation high-performance self-confining concrete metamaterial.

Fundamental mechanics work has led to the creation of groundbreaking families of lattice metamaterials with mechanical properties that are unachievable without the novel architectures that form the basis of such structures. New internally structured metamaterials have been developed in the last two decades which possess unusual properties such as a negative Poisson’s ratio. These internally structured materials have also been expanded to 3D metal lattice geometries with high stiffness and strength which can be used as reinforcement in the new concrete metamaterial. When encased in concrete, the auxetic reinforcement will apply confining pressure on the concrete as soon as compression is present and therefore the volumetric expansion of the two-phase material will be controlled. This mechanism dramatically increases the strength and ductility of reinforced concrete members. The new self-confining two-phase metamaterial is different to the passively confined reinforced concrete since the confinement in the new material is not a result of the concrete volumetric expansion but a direct result of the deformation of the reinforcement under axial loading. The main difference between the new material and active confinement techniques is that with the new material there is no need for confinement of concrete prior to axial loading. The presence of axial loading alone activates lateral confinement through the auxeticity of the reinforcement.

Shape-Morphing Shells with Programmed Temporal Behaviors

Smart materials have enabled self-directed deformations of initially flat geometries into 3D shapes. However, most self-morphing structures are not capable of time-dependent actuation paths. To achieve more complex target geometries and avoid self-collisions, it is critical to locally embed target curvatures and morphing rate information in shells prior to their deployment. While some structures with intrinsic actuation capabilities have incorporated temporal programming through the sequential folding of discrete hinges, these examples do not allow for changes in Gaussian curvature. Here, we demonstrate a method for encoding temporal morphing behaviors in architected bilayer shells that assume complex shapes and doubly curved geometries. Each shell layer is a tessellation of polymeric unit cells that soften in water at rates locally prescribed by a non-periodic mesostructure. The shells contract due to the effect of a pre-stretched elastic membrane, and stiffness differentials across each of their shell layers, inducing curvature changes. Morphing is locally finalized by rigid contacts between adjacent elements, locking shells in their target geometries. Mesoscales are encoded to perform specified behaviors through an inverse design tool that is based on a data-driven model of unit cells’ temporal responses.

Phase-Transforming Metamaterials

Mechanical metamaterials are materials with micro-architectures, which give rise to unusual mechanical properties that are difficult or impossible to achieve in homogeneous materials. In this work, new types of phase-transforming metamaterials are developed to demonstrate domain switching, shape-memory effects, and energy absorption. In the first design, a metamaterial composed of an elastomer with periodic holes can undergo a phase transformation when
subjected to a compressive load, yielding a large transformation strain. We show that such phase transformations can be broadly tuned by changing the geometric parameters of the metamaterial. Examples of domain switching and shape memory effects in such a metamaterial are demonstrated. In the second design, a metamaterial composed of a compliant elastomer and rigid granular particles is proposed as a reusable energy absorber. When the metamaterial is subjected to an external load, it undergoes phase transformations between the multistable states. Correspondingly, the input energy is partially trapped as elastic energy in the elastomer, and partially dissipated by friction between the granular particles, forming hysteresis between the loading and unloading force–displacement curves. Through tuning the structural design of the metamaterial, the pretension and stiffness of the elastomer, and the size of and friction between the particles, a vast design space is achieved to program the mechanical behavior of the metamaterial. Impact tests confirm the energy-absorbing capability of the proposed metamaterial.

10:00 AM BREAK

10:30 AM *MS01.01.06
Undulating Sheets are Shape-Switching Metamaterials with Memory Martin van Hecke; Leiden University & Amolf, Netherlands

We present thin, undulating sheets that switch rapidly and reversibly between flat, rolled, helixing and crumpled shapes under loading. While these complex states are stable when the undulations are big and the sheet is slim, switching back to the rest state is easy under external forcing: an ideal starting point for multi-shape materials.

We show that the sheets' reversible shape-switching is caused by the occurrence of many local, interacting, and hysteretic pop-through defects. We classify the various stable shapes into distinct shape families, and find a transition from rolled to helixing states depending on sheet aspect ratio. We also study how mechanically trained memory arises under repeated compression of the sheets. Our work provides a novel platform for designing multi-shape metamaterials with memory.

11:00 AM MS01.01.07
Stretchable Mechanical Metamaterial Fibers with Extreme Toughness Christopher B. Cooper and Michael Dickey; North Carolina State University, United States

This talk will discuss the use of core-shell structures to create tough mechanical “metamaterial-like” fibers that stretch to large tensile strains. Tough materials have large areas under a stress-strain curve. Thus, materials that require high stress to extend to large strains have high toughness. Metals require large stress in extension but fail at low strains. Elastomers require low stress yet can extend to high strains. Here, we combined these two properties using a metal (core) and elastomer (shell) fiber structure to achieve a tough material that requires high stress to extend to large strains. The core consists of gallium, which can be injected into the fibers and then solidified at room temperature. Extending these fibers causes the metal to fracture at high stress. Rather than experiencing catastrophic failure upon fracture of the metal, the elastomer shell holds the fibers together and additional strain, counterintuitively, causes additional fracturing of the metal. Polymer “bridges” (i.e. elastomeric shell with no metal core) form between the fractured metal segments, as the metal core segments continue to fracture into smaller pieces and dissipate energy. Stress is transferred from the elastomeric shell to the metal core segments via the core-shell interface. Although there are a variety of ways to create tough materials (including chemical and physical approaches), this approach is interesting because of its simplicity and the fact that the fibers are conductive and can self-heal. These types of tough materials have applications in stretchable electronics and soft robotics because of their ability to conduct electricity, sense touch, extend to large strains (500%), and provide toughness in a manner that is reminiscent of human skin. This talk will discuss this new approach to creating tough stretchable materials for future extreme materials design.

11:15 AM MS01.01.08
Experimental Realization of a New Zero Poisson’s Ratio Structure Vladimir Gaal1, Varlei Rodrigues1, Socrates O. Dantas2, Douglas S. Galvao3 and Alexandre F. Fonseca1; 1State University of Campinas, Brazil; 2Universidade Federal de Juiz de Fora, Brazil

A structural parameter proposed almost two centuries ago, the so-called Poisson’s ratio (PR), is still a very effective
way to characterize the mechanical behaviors of materials and structural models. PR is defined as the ratio of transverse strain to longitudinal extension strain along the direction of a stretching force. The vast majority of materials present positive PR, i.e. they laterally expand (shrink) when subjected to compressive (tensile) strains. Materials with negative (the so-called auxetic materials [1]) or zero PR can be found in nature and man-made and have many technological applications, such as sensors and actuators. In particular, null PR materials, i.e. the ones that neither contract nor expand laterally due to axial strains, have received much attention towards applications in different fields as medicine and aeronautics. The most common examples of zero PR materials are gases and cork [2]. Cork has inspired the development of semi-reentrant honeycomb-like structures [3], which have become the widely used paradigm for constructing zero PR structures. In this work, we have designed and experimentally realized a new type of topological model that presents null PR under compression. Our model is not based on either reentrant honeycomb or hexagonal structures. It is composed of arbitrary planar junctions of a given structural unit cell containing two main parts: two parallel rigid bars of smooth surfaces and a soft and elastic membrane or spring connecting the rigid bars. These unit cells or blocks were printed using a homemade 3D printer and randomly distributed on a surface to form sample arrays of \( m \) by \( n \) cells. Using a homemade vise, the arrays are compressed and the strains on both transversal and longitudinal measured, the obtained PR values were almost zero. These new and very simple proposed topological models present great potential for a new paradigm in creating zero or near-zero PR structures.

11:30 AM MS01.01.09
Tunable Strain Rate-Adaptive Impact Energy Dissipation via Liquid-Crystalline Elastomers Seung-Yeol Jeon1, Zeyu Zhu1, Lichen Fang1, Nicholas Traugutt2, Christopher Yakacki2, Thao Nguyen1 and Sung H. Kang1; 1Johns Hopkins University, United States; 2University of Colorado Denver, United States

Materials that can efficiently dissipate impact energy are attractive for various lightweight applications including aerospace, automotive, and personal protection. Liquid crystal elastomers (LCEs) can exhibit remarkable energy dissipation behaviors originating from the coupling of dynamics of LC molecules (Mesogens) and polymeric networks. Here, we investigated the extreme energy dissipative behavior of LCEs over a wide range of strain rates for a fundamental understanding of their strain-rate dependent energy dissipation behaviors. We synthesized main-chain LCEs based on a two-stage thiol–acrylate reaction to examine the effect of the ordering of mesogens and chain alignment on the rate-dependent dissipation behaviors. The impact energy dissipation capability was characterized through bistable structures consisting of LCE beams to have enough time for measuring the energy dissipation by reducing the peak values of acceleration even under high impact. We found that LCEs exhibited 1 to 3 orders of magnitudes higher energy dissipation compared to conventional elastomers (Polydimethylsiloxane (PDMS)) with an increase of the energy dissipation as a function of strain rate in the tested range of \( 10^{-3} \) to \( 10^{3} \) (1/s). Moreover, the strain-rate dependency was able to be controlled by the degree of alignment of mesogens within LCEs through simple control of the applied tensile strain during crosslinking. Then, we performed finite element analysis (FEA) to find the relationship between the arrangement of mesogens and strain-rate dependent energy dissipation based on Prony series parameters obtained from dynamic mechanical analysis. The results from FEA analysis showed good agreement with data from experiments at different strain rates. We envision that our findings can contribute to rationally designing and synthesizing LCE materials and structures with desired strain rate-adaptive energy dissipating capability, which will be useful for various applications including impact mitigation for aerospace, automotive, and personal protection materials and structures.

11:45 AM MS01.01.10
Graphene-Based Nanoscale Version of Da Vinci’s Reciprocal Structures Alexandre F. Fonseca and Douglas S. Galvao; State University of Campinas, Brazil

Structural reciprocity (SR) is a concept of self-supporting of load-bearing bars that together form larger mechanical resistant structures [1]. Dating back to the Neolithic, SR was found from native tepees and tents, to old bridges like the one over the Rhine that was built in the Roman Empire by Julius Caesar, and even in the drawings of Leonardo Da Vinci [2]. Commonly seen in floors or roofs, SR is also present in art, religious symbols and decorative objects. Although SR involves a mutual exchange of action and reaction between parts of the whole structure, it is also known to rely on a perfect symmetric relationship between them [1]. A structure having SR is called reciprocal
structure (RS). The main characteristics of a RS are, first, the role of supporting and being supported should not
occur in the same part of the structure, i.e., they must be separated, not overlapping like in truss bars. Second, each
element of a RS must, at the same time, support the others and being supported by the others. These two properties
make beams and two-dimensional materials very much appropriated to build RSs. Here, we propose a simple nano
version of a Da Vinci’s RS based on graphene nanoribbons. The stability and resistance against mechanical impacts
(ballistic projectile) were investigated through fully atomistic molecular dynamics (MD) simulations. We considered
different structures with three and four joins with and without RS topologies. Our MD results showed that structures
with RS topologies are more impact resistant than the ones without SR, despite the fact that the used graphene
nanoribbons are highly pliable. We discuss these results in terms of building self-sustained and resistant nano-domes
and nanocages and possible applications in nanoengineering.

SESSION MS01.02: Session II

1:30 PM *MS01.02.01
Mechanics of Optical-Tweezer Fabricated Micro-Granular Crystals Samira Chizari, Miles Lim, Michael Porter,
Sydney Austin and Jonathan Hopkins; University of California, Los Angeles, United States

The ability to engineer micro-granular crystals so that their constituent microspheres can be positioned within
lattices as desired would enable the control of extreme stress-wave propagation behavior due to the nonlinear
stiffness interactions between their microspheres. Whereas engineered granular media that consists of macro-sized
spheres (>1mm) support Hz-kHz stress waves for audible applications, engineered micro-granular crystals support
MHz-GHz stress-waves for more extreme high-energy applications. Such applications include armor that controls or
redirects the propagation of shock waves caused by explosions or high-speed impacts or acoustic lenses that
focus high-frequency phonons for underwater imaging, noninvasive surgery, and material damage detection
technologies.

Here we propose an approach that utilizes automated optical tweezers to simultaneously assemble many 1-10μm-
sized spheres at their intended locations within 3D micro-granular crystals. Unlike existing self-assembly, directed
self-assembly, or electrophoretic deposition approaches that can fabricate only a limited selection of ordered micro-
granular crystal lattices, the proposed optical tweezers approach possesses the flexibility to arrange microspheres of
different materials and sizes anywhere within a lattice to achieve high control over extreme stress-wave propagation
behavior. Moreover, the approach is automated to increase the placement accuracy and precision of the
microspheres and to dramatically increase the speed of assembly so that large test samples can be fabricated within
reasonable build-times. Once fabricated these samples, which can’t be made any other way, are tested to collected
data that is used to learn about the extreme mechanics that govern the behavior of these crystals.

We aim to present these results for both quasi-static compression tests and for dynamic laser-induced impulse force
tests conducted on differently packed micro-granular crystal lattices. The data collected is used to inform course-
grain molecular dynamic simulation models that when matched to accurately mimic the experimental results are
used to simulate numerous ‘what-if’ scenarios aimed to uncover what effects (e.g. sphere location, size, sphericity,
surface roughness, friction, electrostatic forces, adhesive forces, asperities, surface charges, and hydrodynamic
effects) govern the extreme mechanics of such crystals. This work sheds light on what mechanisms give rise to the
nonlinear stress-wave propagation behaviors of micro-granular crystals as well as those that explain how they
deform and ultimately fail.

2:00 PM MS01.02.02
Enhancing the Recoverability of Ceramic Nanolattices through Double Hollow Tube Architectures Marianna
Diamantopoulou, Thomas Tancogne-Dejean, Jeffrey Wheeler and Dirk Mohr; ETH Zurich, Switzerland

The design and fabrication of double hollow tube lattice architectures is pursued to enhance both the stiffness and recoverability of lattice materials. In essence, these structures correspond to the superposition of two truss lattices made from hollow tubes. Both trusses feature the same lattice parameters. As a result, the smaller diameter structure can be built inside a second structure of larger tube diameter. Design maps are developed through theoretical and computational analysis that express the stiffness of the proposed double hollow tube lattice as a function of the relative density and the outer-to-inner tube radius. Nanolattices with wall thicknesses ranging from 27 to 110 nm are fabricated from alumina through direct laser writing of a polymer scaffold, atomic layer deposition of alumina followed by removal of the polymer phase. In-situ compression experiments are performed on both single- and double tube configurations. While both configurations provide about the same stiffness of the same weight, a higher recoverability is observed for the new double hollow tube configurations.

Mechanical Behavior of Nonwoven Non-Crosslinked Fibrous Mats with Adhesion and Friction Vineet Negi and Catalin Picu; Rensselaer Polytechnic Institute, United States

Nonwoven fibrous mats are found in many applications such as cellulose nanofiber paper, electrospun polymeric fibrous scaffolds used in tissue engineering, filtration and insulation materials etc. In these materials, fibers are held together by adhesion and friction acting at inter-fiber contacts. We present a study of the mechanical behavior of random, non-crosslinked fibrous mats of nanofibers stabilized by inter-fiber adhesion. Fibers of various degrees of tortuosity, and of infinite and finite length are considered. The variation of structural parameters such as the mat thickness and the mean segment length between contacts with the strength of adhesion is determined. Mechanics in such systems has an energetic component, associated with stored strain energy in fibers, and a dissipative component, associated with friction. The dissipative component is dominant. The response to tensile loading of the mats has three regimes: a short elastic regime in which no sliding at contacts is observed, a well-defined sliding regime characterized by strain hardening, and a rapid stiffening regime at larger strains. Networks of finite length fibers loose stability during the second regime of deformation and do not exhibit stiffening. We relate the parameters that describe this behavior and the network strength to the structural network parameters. These results are relevant for the design of electrospun mats and other planar fibrous non-cross-linked networks.

Increasing the Structural Efficiency of Mechanical Metamaterials—Moving from Truss- to Plate-Lattice Architectures for Optimal Stiffness and Energy Absorption Thomas Tancogne-Dejean, Marianna Diamantopoulou, Colin Bonatti and Dirk Mohr; ETH Zürich, Switzerland

Beams, shells and plates are used as the basic building blocks of lattice materials. It is shown through combined theoretical and numerical analysis that the choice of the elementary building block strongly influences the mechanical performance of mechanical metamaterials. Increases in stiffness of up to 200% are observed when building isotropic lattices from plates instead of beams (while keeping the mass unchanged). Furthermore, it is shown that shell-lattices are ranked between truss- and plate-lattices as far as stiffness and yield strength is concerned. However, from the point of view of fatigue strength and impact energy absorption, shell-lattices might have a substantial advantage. In addition to deriving the effective yield surfaces through homogenization, the plastic anisotropy of elastically-isotropic metamaterials is analyzed in detail. All theoretical results are also validated through detailed finite element simulations. Selected metamaterials are additively fabricated from polymers using two-photon lithography and from stainless steel using selective laser melting. Static experiments are performed to confirm the theoretical modulus and yield stress estimates for uniaxial tension, compression and shear. Furthermore, dynamic experiments are performed on a Split Hopkinson Pressure Bar (SHPB) system to determine the effect of strain rate on the specific energy absorption response of mechanical metamaterials of 20% relative density.

Extraordinary Energy Absorption via High Rate Deformation of Multiwall Carbon Nanotube Mats

Edwin L. Thomas1, Jinho Hyon1, Owale Lawal2 and Ramathasan Thevamaran3; 1Rice University, United States; 2Eglin Air Force Base, United States; 3University of Wisconsin–Madison, United States

We present the ballistic energy absorption characteristics of thin (100-250 nm) mats comprised of an interconnected network of multiwall carbon nanotubes (MWCNT) investigated using a micro-projectile impact test with incident velocities from 300-900 m/s. The quasi-static properties of the MWCNT mats are quite modest but at the extreme strain rates and large strains of ballistic impact, a distinctive set of morphology dependent deformation mechanisms leads to extraordinary energy absorption. As the spherical projectile engages the film, the unoriented bundles of MWCNT tubes rotate, straighten, align and translate into the impact region, dissipating the kinetic energy of the projectile via frictional forces and elastic stretching energy of the principal tubes until axial fracture occurs. The specific energy absorption depends on impact velocity and film thickness and can range from 9-12 MJ/kg, much greater than any other material.

Elastocapillary Assembly of Cellular Structures

Shucong Li, Bolei Deng and Joanna Aizenberg; Harvard University, United States

Self-assembly is becoming increasingly important as a bottom-up method for building novel structures and controlling functions at length scales ranging from the nanometer to millimeter. Various driving forces for self-assembly have been studied at these length scales, including gravity, magnetic force, electrostatic interaction, entropy, and capillary interaction. Among these, capillary effects have received particular attention at the microscale because of their relatively significant magnitude, tunability, and simplicity, and a number of studies have demonstrated the formation of complex two- and three- dimensional structures by this method. However, such studies have been limited to isolated structures like pillars and posts where the neighboring units interact with each other only through capillary force, limiting the complexity of the assembly architectures can be achieved. In this project, we study the response of connected elastic lattices with the capillary force introduced via rapid evaporation of volatile organic solvents. Such micro lattices, different from micro-pillars, possess strong interaction between unit cells through capillary forces as well as the elastic coupling from the geometric compatibility of the underlying lattices, giving rise to programmable lattice transformations from the coalescence of the adjacent edges. Furthermore, as compared to micro-pillar systems, lattice structures are known to exhibit stronger mechanical strength and have a broader control space over the surface properties accompanied by lattice transformations.

Pulse-Driven Robot—Motion via Solitary Waves

Bolei Deng and Katia Bertoldi; Harvard University, United States

Soft robots have been shown to be able to perform a variety of tasks, including walking, grasping, crawling and swimming. However, to achieve all these functions their constituent actuators need to be inflated sequentially. In this work, we demonstrate a new generation of flexible machines that can be realized by harnessing propagation of non-linear elastic waves. To demonstrate this concept we focus on an iconic stretchable toy that has captivated children and adults all over the world: a Slinky. We show that by exploiting the propagation of nonlinear pulses this popular toy can be transformed into a robot capable of moving around without the need of legs.

From earthworms, snakes and caterpillars, to slugs and snails, many creatures successfully combine the flexibility of their body with the ability to locally manipulate frictional forces to move in complex environments without the need of legs. These limbless organisms have recently inspired the design of compliant robotic systems that take advantage of elastic deformation to crawl and maneuver through confined spaces. For example, snake-inspired robots with locomotive skills that surpass more conventional designs have been designed by incorporating anisotropic friction into soft elastomeric inflatable structures. Moreover, soft robots capable of worm-like motion have been realized by sequentially actuating contracting segments to induce peristalsis. However, these machines require multiple inputs to achieve the desired peristaltic motion, as each segment must be addressed independently according to a specific preprogrammed sequence.

Here, inspired by the retrograde peristaltic waves observed in earthworms, we show that the propagation of non-linear elastic waves in flexible structures provides opportunities for locomotion. To demonstrate the concept, we
focus on a Slinky -- an iconic stretchable toy that has captivated children and adults all over the world -- and use it to realize a pulse-driven robot capable of propelling itself. Our simple machine is built by connecting the Slinky to a linear actuator and using an electromagnet and a plate embedded between the loops to initiate nonlinear pulses that propagate from the front to the back. Notably, we find that the directionality of these pulses enables our simple robot to move forward. Moreover, our results indicate that the efficiency of such pulse-driven locomotion is optimal when the initiated waves are solitons - large amplitude (non-linear) pulses with stable shape and constant velocity along propagation. As such, our study expands the range of possible applications of solitary waves and demonstrate that they can also be exploited as simple underlying engines to make flexible machines move.

**Electrochemically Reconfigurable Architected Materials** Xiaoxing Xia¹,², Arman Afshar³, Heng Yang², Carlos M. Portela², Dennis Kochmann⁴,², Claudio V. Di Leo⁵ and Julia R. Greer²; ¹Lawrence Livermore National Laboratory, United States; ²California Institute of Technology, United States; ³Georgia Institute of Technology, United States; ⁴ETH Zurich, Switzerland

Architected materials represent an area of active research because they exhibit exotic properties such as negative Poisson’s ratios and negative refractive indices, and decouple historically correlated material properties such as strength vs. density and thermal conductivity vs. stiffness. Most architected materials reported to date are passive in the sense that they have a prescribed geometry fulfilling a single functionality. It was recently shown that architected materials can be reconfigured by mechanical deformation and instabilities, hydration-induced swelling, and magnetic actuation. Such smart, stimulus-responsive materials can make a long-lasting impact on adaptive, deployable, and dynamically tunable devices if they could overcome existing challenges of (1) requiring bulky external control, (2) toggling between “on” and “off” states, and (3) reverting to original configuration once external stimulus is removed. Most of these reconfigurable systems are small and idealized; scaling them up requires substantially increasing the number of repeating units that would inevitably introduce inhomogeneities similar to defects, gradients or grain boundaries that govern properties of classical materials.

Here we demonstrate a new mechanism to dynamically reconfigure architected materials by exploiting electrochemically driven alloying/dealloying reactions to induce continuous, non-volatile and reversible structural transformations. We used the alloying couple of silicon and lithium as a prototype system because Si is a high-capacity battery electrode material notorious for its ~300 % volumetric expansion after full lithiation. Buckling instabilities were observed in Si nanowires and etched honeycomb patterns during lithiation but they have not been systematically investigated as a design tool to achieve structural reconfiguration. Leveraging on Si’s mechanical resilience at small scales, we designed and fabricated Si-coated microlattices purposely structured to promote lateral in-plane buckling. *In situ* lithiation/delithiation observations revealed cooperative buckling among neighboring beams that reconfigures the tetragonal unit cells into curved ones with pairwise opposite concavity. Through experiments and finite element modeling, we discovered that the bistability of in-plane buckling leads to formation of multiple lateral domains separated by distorted domain boundaries, with domain sizes and distribution governed by defects and lithiation rate. We analyzed this phenomenon using a statistical mechanics approach analogous to the Ising model, and designed artificial defects to effectively program domain boundaries to emerge in prescribed patterns upon lithiation. Understanding and controlling defects provides a pathway to drive the dynamic response of architected materials along a particular trajectory. This new class of electrochemically reconfigurable architected materials has significant implications as it creates new vistas in designing dynamic mechanical metamaterials with novel stress-relief mechanisms and tunable phononic band gaps.

A Viscoelastic Beam Theory of Polymer Jets with Application to Rotary Jet Spinning Qihan Liu¹² and Kevin Kit Parker¹²;¹Harvard University, United States;²Wyss Institute for Biologically Inspired Engineering, United States

Complex deformation of a polymer jet appears in many manufacturing processes, such as 3D printing, electrospinning, blow spinning, and rotary jet spinning. In these applications, a polymer melt or solution is first extruded through an orifice and forms a jet. The polymer jet is then dynamically deformed until the polymer solidifies. The final product is strongly affected by the deformation of the polymer jet. And the deformation is strongly affected by the viscoelasticity of the polymer. Here we develop a beam theory to incorporate both the nonlinear viscoelasticity and the bending/twisting stiffness of a polymer jet. As a demonstration, we study the formation of a polymer fiber under strong centrifugal force, a fiber manufacturing process known as rotary jet spinning.

Extreme Mechanics of Epithelial Monolayers Marino Arroyo; Universitat Politècnica de Catalunya, Spain

Epithelial monolayers are very simple yet very important animal tissues with crucial mechanical functions. They consist of cohesive and highly organized cells that adhere to each other and often to an underlying matrix to form a barrier that lines internal and external organ surfaces, controls transport of gas or nutrients, protects us from pathogens or desiccation, and is involved in morphogenesis. Seen as materials, epithelial monolayers are truly remarkable. They can maintain barrier integrity while increasing their lateral area by 10-fold or while deforming into highly curved 3D shapes. In apparent contradiction, they can dynamically remodel by selectively disengaging cell-cell adhesions to heal wounds or to transport cellular materials through organized active flows during morphogenesis. This tunable mechanical behavior relies on a hierarchical organization. At a sub-cellular scale, structural proteins dynamically self-organize into cytoskeletal networks and adhesion complexes, which transduce chemical energy into mechanical work and determine cellular architecture and mechanics. In turn, groups of cells self-organize to form tissues and homeostatically maintain these tissues in a dynamical steady-state. A major question in mechanobiology is to understand the multi-scale self-organization of adaptable functional units at different scales and their integration to perform mechanical functions including morphogenesis, homeostasis, or motility. I will discuss our theoretical efforts to understand various aspects of cell and epithelial tissue mechanics and morphogenesis starting from sub-cellular models of the cytoskeleton and cellular adhesion. I will illustrate how subcellular dynamics, including molecular turnover and active force generation, determine mechanical properties at a tissue scale including solid-like or fluid-like rheology, active superelasticity, or pulsatile dynamics and ratcheting remodelling.

Domain Formations and Pattern Transitions via Instabilities in Soft Heterogeneous Materials Jian Li¹ and Stephan Rudykh²;¹Technion–Israel Institute of Technology, Israel;²University of Wisconsin – Madison, United States

We investigate instability-induced pattern transformations in soft particulate composites under large deformations [1]. The onset of instabilities are detected by numerical Bloch-Floquet techniques and experiments on 3D-printed specimens. We find that the system of stiff inclusions periodically distributed in a soft elastomeric matrix experiences dramatic microstructure changes upon the development of elastic instabilities. We observe experimentally the formation of microstructures with antisymmetric domains and their geometrically tailored evolution into a variety of patterns of cooperative particle rearrangements. In combination of numerical instability analyses and experiments, we find that the formation of domain occurs in macroscopic instability regime, while microscopic instability induces the cooperative new pattern of particles rearranged in a wavy chain. Our observation shows that these patterns can be tailored by tuning the initial microstructural periodicity and concentration of the inclusions. Thus, these fully determined new patterns can be achieved by fine tuning of the initial microstructure. Our findings open new ways for developing reconfigurable mechanical metamaterials that can find applications in a large variety of fields from acoustic metamaterials, actuators, and soft robotics to morphing devices remotely controlled by external fields for biomedical applications.

The Wild Complexity Born from a Simple Nonlinearity and How to Tame It—A Reprise of the "Beam on an Elastic Foundation" Ryan S. Elliott, Timothy J. Healey, Nicolas Triantafyllidis, Shrinidhi Pandurangi and Ariel Ibarra Pino; 1University of Minnesota, United States; 2Cornell University, United States; 3Ecole Polytechnique, France

The problem of a beam on an elastic foundation has a long history in engineering mechanics. Its deformation and onset of buckling behavior have been employed as a surrogate for understanding an extensive list of technologically important applications, including sun-kinking of railroads, pipeline transportation engineering, and thin films on hard or soft substrates in microelectronic and biological applications. Despite this history, the global bifurcation behavior of the problem has not been fully explored. Indeed, the complexity of the equilibrium solution set will come as a surprise to many practicing and research engineers.

With an eye toward the study of creasing and deformation-localization problems in soft materials, this work studies the behavior of an inextensible infinite Euler-Bernoulli beam that is subjected to a compressive axial force and connected to a nonlinear (polynomial) elastic foundation. We seek global post-bifurcation equilibrium paths and their stability as a function of the applied force. All bifurcating paths (stable and unstable) are of interest due to the possibility of stable segments occurring on any path in the deep post-bifurcation regime of the global solution set. However, standard solution techniques (incremental Newton-Raphson coupled with strategically chosen imperfections) are foiled by the complexity of the problem's bifurcation behavior. Thus, it becomes necessary to employ sophisticated equivariant bifurcation theory and numerical methods, based on group theory, to tame the complexity and systematically obtain the desired results. These methods will be reviewed and their application to the problem at hand will be demonstrated as a typical example of their power to solve and bring order to an otherwise intractable set of equations. Finally, the results will be interpreted physically to explain the existence of localized-deformation and crease-like behavior. Parallels with phase transformation problems will also be drawn.

Extreme Mechanics of Soft Structures Katia Bertoldi; Harvard University, United States

Although the study of the effect of shape and geometry on the mechanical response of solid objects has a long history, the surge of modern techniques to fabricate structures of complex form paired with our ability to simulate and better understand their response has created new opportunities for the design of architected materials with novel functionalities (also referred to as metamaterials). Since the properties of architected materials are primarily governed by the geometry of the structure (as opposed to constitutive ingredients at the material level), I’ll show that their deformation and instabilities can be harnessed to achieve new modes of functionality, including motion, energy trapping and releasing, wave guiding and shape changes.

10:45 AM MS01.03.07
Snap-Shaping Origami Sheets Anne Meeussen and Martin van Hecke; 1AMOLF, Netherlands; 2Leiden University, Netherlands

Origami is not rigid; facets and hinges bend and stretch. This compliance enriches the physics of origami, leading to mechanical multistability, and opens up a rich design space to control shape-morphing in thin materials. We explore this new design space starting from an undulating "origami" sheet. This simple material switches reversibly between many stable shapes via snap-through instabilities. Its reshaping results from a hierarchical, geometry-mediated competition between different sources of compliance, which we demonstrate via experiments and minimal computational models.
Interplay of Origami Structure Properties in Fold Path Bifurcation Analysis

Andrew S. Gillman, Matthew Grasinger, and Phil Buskohl; Air Force Research Laboratory, United States

Origami structures are finding numerous technological applications including lightweight composites, soft robotics, metamaterial design, and deployable space structures, where their nonlinear deformations and instabilities are leveraged to form novel material behavior. The contrast in material (stiffness mismatch among deformation modes) and geometric (slender elements) properties in origami structures can lead to highly nonlinear mechanical behavior with unique macroscopic properties, such as multi-stability. We have recently integrated our nonlinear origami truss model with a robust continuation solver for bifurcation detection and branch tracking to map multistable energy landscape in order to characterize the role of discrete fold stiffness distributions. Towards the goal of developing more robust design tools to navigate this non-convex design space, involving energy landscapes with many bifurcations and stable equilibrium points, we investigate how changing stiffness distributions (stretching, folding, and facet bending stiffness) and non-zero fold reference angles shift the bifurcation and equilibrium points. These insights are leading to the development of a generalized design tool for origami structures exhibiting many stable configurations for deployability and lightweight material design.

Morphing and Shape Control—From Mechano-Biology to New Technologies

Antonio DeSimone; 1SISSA, Italy; 2Scuola Superiore Sant'Anna, Italy

Locomotion strategies employed by unicellular organism are a rich source of inspiration for studying mechanisms for shape control. The ones used by unicellular organisms are particularly interesting because they are invisible to the naked eye, and offer surprising new solutions to the question of how shape can be controlled, and for which function.

In recent years, we have studied locomotion and shape control in several biological systems using a broad range of tools ranging from theoretical and computational mechanics, to experiment and observations at the microscope, to manufacturing of prototypes.

A particularly interesting case study is provided by *Euglena gracilis*. This unicellular protist is particularly intriguing because it can adopt different motility strategies: swimming by flagellar propulsion, or crawling thanks to large amplitude shape changes of the whole body (a behavior known as “metaboly”, or “amoeboid motion”). The shape changes required for the two strategies are completely different and consist of bending waves along the flagellum in swimming motility, peristaltic expansion/contraction waves of the body in crawling motility. Interestingly, however, both the general morphing principle and its embodiment in the microscopic architecture of the active structural elements enforcing the shape changes are the same. Shape changes are achieved by Gaussian morphing, the paradigm by which curvature can be produced by differential in-plane stretches of the mid-surface (the tubular shell of the flagellum in one case, the body envelope in another). These stretches are in turn produced by molecular motors walking along microtubules, and causing the bending of microtubule bundles (flagellum) and the twisting of pellicle strips (cell envelope).

The behavior displayed by *Euglena* has been observed under the microscope, and reproduced quantitatively thanks to mathematical and computational models. The detailed understanding of the mechanics of the shape-shifting mechanism in terms of the body architecture provides the basis to design new engineering devices, based on bio-inspired, morphable structures.

We will survey our most recent findings obtained also in collaboration with M. Arroyo, G. Cicconofri, G. Noselli, within this stream of research which has been supported by ERC Advanced Grant 340685-MicroMotility.
Highly Fatigue-Resistant Stretchable Materials

Zhigang Suo; Harvard University, United States

Stretchable materials—elastomers, hydrogels, ionogels, and organogels, along with their hybrids—are under intense development to enable numerous and far-reaching applications. In developing a material for a load-bearing application, attention inevitably falls on the resistance of the material to the growth of a crack, characterized by toughness under monotonic load, and by threshold under cyclic load. Many methods have been discovered to enhance toughness, but they do not enhance threshold. Here we describe a principle of stretchable and fatigue-resistant materials. To illustrate the principle, we embed unidirectional fibers of a soft and stretchable material in a matrix of a much softer and much more stretchable material, and adhere the fibers and the matrix by sparse and covalent interlinks. When the composite is cut with a crack and subject to a load, the soft matrix shears readily and delocalizes the high stretch of a fiber over a long segment. The material achieves a fatigue threshold more than one order of magnitude higher than natural rubber. The principle of stretchable and fatigue-resistant materials is applicable to various materials, layouts, and methods of fabrication, opening an enormous design space for general applications.

Negative Creep Behaviour and Thermomechanical Alleviation in Titanium Alloys under Cyclic Loading

Yilun Xu and Fionn Dunne; Imperial College London, United Kingdom

Aero-engine titanium components endure extremes of loading which may be both mechanical and thermal, and which are known to give rise to the phenomenon of cold dwell fatigue [1]. This is argued to develop through combined effects of crystallography, localised slip due to plasticity and creep [2], and the redistribution of stress, often termed load shedding [3], which occurs during the stress hold stage of flight cycles. Evidence is emerging that a potentially important aspect of the deformation occurring is that due to negative creep. This is the activation of localised reversed time-dependent slip resulting from back stress development in titanium alloy (IMI834) and occurs interestingly on partial stress unloads (which are representative of in-flight loading cycles). The negative creep is potentially helpful in contributing to the thermal alleviation of the dwell fatigue phenomenon, and this is addressed in this paper.

A new thermo-mechanically coupled discrete dislocation plasticity (DDP) formulation is established, incorporating thermally activated dislocation escape and creep, which is integrated with experiments on polycrystalline IMI834. The experiments consider dwell fatigue cycling without and with a partial unload, as well as the inclusion of a thermal cycle [4], which are investigated with the DDP model.

The mechanistic basis of negative creep is shown to be the establishment of dislocation pileups and back stress development such that on partial unloading, reversed creep occurs by thermally-activated dislocation escape and reverse glide during secondary stress hold. Anomalous cyclic strain accumulation in both isothermal and anisothermal stress-loaded alloy IMI834 is thus explained by negative creep.

The magnitude of predicted macroscopic negative cyclic creep strain in dwell fatigue loading is found to be consistent with independent experimental literature. The inclusion of the thermal cycle including elevated temperature facilitates further negative creep by promoting dislocation escape via thermal activation. The experimentally observed ‘anomalous’ macroscopic cyclic strain accumulation in both isothermal and anisothermal loadings has been explained by negative creep at the dislocation scale. The latter also provides the underpinning explanation for the beneficial effect of elevated temperature excursions in diminishing cyclic creep accumulation and hence reducing dwell fatigue sensitivity in titanium alloys by thermal alleviation.

Keywords: Negative creep; Thermal alleviation; Discrete dislocation plasticity; Titanium alloys; Dwell fatigue

Atomistic Modeling of Cyclic Loading and Heat Treatment Processes for Tuning the Mechanical Properties of Amorphous Alloys Nikolai Priezjev; Wright State University, United States

The development of novel fabrication techniques for amorphous materials, including metallic glasses and high entropy alloys, is important for various structural and biomedical applications. The processing routes often involve mechanical and thermal treatments of disordered alloys that lead to changes in potential energy, microstructure as well as mechanical and physical properties. In this presentation, we discuss recent results of molecular dynamics simulations of three loading protocols: oscillatory deformation, flash annealing, and elastostatic loading of metallic glasses. In each case, the simulations are performed in a wide range of processing conditions and the optimum control parameters for the most relaxed and rejuvenated states are determined. The structural analysis is performed by identifying clusters of mobile atoms with relatively large nonaffine displacements. It is generally found that the most rejuvenated glasses are characterized by reduced elastic moduli and lower yield stress, thus leading to improved plasticity. These results are useful for the thermomechanical processing of metallic glasses with optimized mechanical properties.

2:30 PM MS01.04.04
Extreme Fatigue Life of Graphene Teng Cui1, Sankha Mukherjee1, Parambath M. Sudeep1, Guillaume Colas1, Farzin Najafi1, Jason Tam1, Pulickel Ajayan2, Chandra V. Singh1, Yu Sun1 and Tobin Filleter1; 1University of Toronto, Canada; 2Rice University, United States

Materials can fail when subjected to cyclic loading at stress levels much lower than the ultimate tensile strength or yielding limit, which is known as mechanical fatigue. Understanding the fatigue behavior is critical for any emerging material in order to evaluate its long-term dynamic reliability. Two-dimensional (2D) materials have been widely applied to mechanical and electronic applications, where they are commonly subjected to cyclic stress. However, the fatigue life and underlying damage mechanisms of these atomically thin, nearly defect-free, materials are unknown. Here we show the first fatigue study of freestanding 2D materials, in particular graphene and graphene oxide (GO). Monolayer and few layer graphene were found to exhibit ultrahigh fatigue life of more than one billion (10^9) cycles at large mean stress of 71 GPa. Such a remarkable fatigue life is higher than that of any material reported to date at similar stress levels. Monolayer graphene exhibits global and catastrophic fatigue failure without progressive damage, and the failure is attributed to bond reconfiguration near the defective site. The presence of functional groups on GO imparts a local and progressive fatigue damage mechanism. The fatigue life of GO was found to diminish significantly when the material is scaled up in thickness (10s of layers). This work not only provides new fundamental insights into the widely observed fatigue enhancement behavior of graphene-embedded nanocomposites, but also serves as a starting point for the mechanical dynamic reliability evaluation of other 2D materials.

Ultrahigh Temperature In Situ TEM Single Boundary Coble Creep Experiments Shen J. Dillon; University of Illinois at Urbana Champaign, United States

Measuring thermodynamics and kinetics for single grain boundaries has long been experimentally laborious and challenging. Developments in small scale experimentation present opportunities to develop new more efficient approaches to obtain this important data. This presentation will discuss ultahigh temperature in situ transmission electron microscopy based mechanical testing experiments designed to measure grain boundary diffusivity, surface diffusivity, surface energy, and grain boundary energy. The general approach, based on laser heating, is also demonstrated for more conventional stress-strain measurements. The approach is applied to zirconium oxide at temperatures between ≈1700 °C and ≈2500 °C.
Coupled Models for Polycrystalline Deformation—Creep and Deformation at High Strain Rates Javier Segurado\textsuperscript{1,2}, Marco Magri\textsuperscript{2}, Jifeng Li\textsuperscript{2} and Ignacio Romero\textsuperscript{3,2}; \textsuperscript{1}Technical University of Madrid (UPM), Spain; \textsuperscript{2}IMDEA-Materials Institute, Spain; \textsuperscript{3}Technical University of Madrid, Spain

Two continuum frameworks will be presented to simulate the deformation of polycrystals under different scenarios using coupled crystal plasticity finite element models.

The first one is a model to study polycrystals at elevated homologous temperatures under relatively small stresses, where deformation is controlled by the diffusion of vacancies to-and-from the crystal bulk to the grain boundaries as well as the diffusion within the grain boundary. This creep model is formulated as a coupled problem of diffusion and mechanical equilibrium. It is assumed that vacancy emission and absorption within grain boundaries is due to the climb of grain boundary dislocations, and therefore the creep kinetics is derived from physically-based mechanisms. The effect of grain size, applied stress, and grain boundary dislocations mobility will be presented.

The second framework is a fully coupled thermo-mechanical framework including thermal strains, temperature dependency of the crystal behavior and heat generation by dissipation due to plastic slip. The framework allows to bridge the plastic deformation and its rate with heat diffusion at the microscale. The model is used to simulate the machining process accounting for the effect of the microstructure heterogeneity, in this case the presence of soft and stiff grains.

Plasticity Effects in the Buckling of Supported Thin Films Junyu Yang, Sameer Damle, Spandan Maiti and Sachin Velankar; University of Pittsburgh, United States

The past decade has seen enormous development of buckled materials, materials in which one or more elements is in the form of a slender structure that buckles under compression. Such buckled materials are being considered for flexible electronics, as surfaces with tunable adhesion and friction, or materials with unusual mechanical properties such as a negative Possion ratio. In theoretical and experimental analyses, such situations are almost always treated within an elasticity framework, i.e. all materials are generally regarded as elastic, often linearly elastic. Here we examine plasticity effects in such buckled materials.

The situation considered is of a thin film of stiff plastic material (polyethylene) attached bonded to a softer elastomeric film. Upon stretching this bilayer composite, the plastic thin film stretches irreversibly, whereas the elastomer stretches reversibly, thus creating a “strain mismatch”. Upon releasing, the elastomer imposes compressive stress on the polyethylene film which then buckles. We explore the effects of film plasticity in this situation by experiment and numerical simulations. We show that plasticity has numerous effects beyond simply causing the “strain mismatch”: the film can yield in-plane during release; the film can buckle during release to form a strongly wrinkled surface; the film can yield and form plastic hinges during wrinkling. We show that plasticity can be exploited to achieve wrinkled surfaces with aspect ratios much higher than possible with analogous elastic systems. We also point out that the tendency of the plastic film to undergo necking sets a lower limit on the rubber yield stress necessary to achieve uniform wrinkling. Although these results are obtained for the specific case of a layered thin film geometry, the insights apply in general to all buckled materials in which a plastic material is combined with an elastic one.

4:15 PM MS01.04.08

Ductile-to-Brittle Transition of Micron-Sized Niobium at Cryogenic Temperature Gyuho Song and Seok-Woo Lee; University of Connecticut, United States

Thermal environment has been considered as one of the most important extreme conditions that affect mechanical properties of materials. Particularly, the mechanical properties at a low temperature has been extensively studied due to their importance in space exploration or marine engineering. The decrease in temperature usually causes the ductile-to-brittle transition (DBT) in body-centered-cubic (bcc) metals, which must be prevented to avoid the catastrophic failure of engineering devices working at a low temperature. Recently, extreme mechanics at the micrometer scale began to receive a great attention due to the strong interests in the development of micro-electro-mechanical system (MEMS) working under extreme conditions. If these devices operate at a low temperature, it is critical to prevent the DBT in micron-sized components. At the micrometer-scale, mechanical behaviors of single crystalline metals are remarkably differently from those at bulk scale due to the size effects. Source-controlled plasticity causes the size-affected strength as well as the intermittent plastic flow. In order to prevent the DBT at the
micrometer scale, it is critical to understand how the source-controlled plasticity is influenced by the decrease in temperature. For bcc metals, the lattice resistance, cross-slip of screw dislocation, the evolution of dislocation structure, and the presence of free surface should be critical factors to affect the DBT at the micrometer scale. In this work, therefore, we present our recent results on the DBT in a [0 0 1] bcc niobium (Nb) single crystal at the micrometer scale. The dog-bone shaped tensile samples with 2μm in width were fabricated via focused-ion beam milling and were tested at the nominal strain rate of 10^{-3} s^{-1} at 298, 100 and 56K using custom-built in-situ cryogenic micromechanical testing system. Stress-strain data showed the extensive ductility (~25%) at 298K but the limited ductility (~6%) at both 56 and 100K. Post-mortem scanning electron microscopy revealed that samples tested at 298K underwent uniform and homogeneous plastic deformation while samples tested at 56 and 100K underwent highly localized plastic deformation followed by brittle fracture that was initiated at slipped regions. Thus, micron-sized niobium single crystals indeed show the ductile-to-brittle transition. Post-mortem transmission electron microscopy showed the significantly high dislocation density in samples tested at 298K, but almost no dislocations in samples tested at 56K. These results imply the strong suppression of dislocation multiplication at a low temperature. The reduction of mobile dislocation, i.e., dislocation starvation, would induce the DBT in Nb at the micrometer scale. This DBT mechanism differs from that at bulk scale, which is caused by the decrease in mobility of screw dislocation. At the micrometer scale, all mobile dislocations seem to be annihilated at the free surface. Brittle fracture would occur due to the stress concentration at slipped region before dislocation nucleation occurs. Note that this presentation reports the first observation of DBT in bcc metals at the micrometer scale and in cryogenic environments. Our results will not only enable a deeper understanding of the combined effects of sample dimension and temperature on plasticity and fracture processes in bcc metals, but also guide a design of mechanically-robust materials used at the micrometer scale and at a low temperature.

High Heat and Particle Damage Effects on Tungsten and Tungsten Carbide Minsuk Seo¹, Vincent F. Cintron¹, Alec M. Cacheris², Sean R. Kosslow¹, John R. Echols¹ and Leigh Winfrey¹; ¹The Pennsylvania State University, United States; ²The University of Tennessee, Knoxville, United States; ³Oak Ridge National Laboratory, United States

One of the great concerns in fusion reactor operation is disruption events that deliver 10s to 100s of GW/m² of heat over microseconds to first wall materials, severely damaging plasma facing components, and therefore hamper their long-term durability. Specifically, the diverter region is one the most sensitive parts of the plasma facing portion of the reactor. In addition to causing damage to the vessel wall, disruption events can produce debris or lead to the diffusion of high Z material into the fusion plasma region. Tungsten based materials are promising as plasma for use in plasma facing components because of its high melting point, high thermal conductivity, and low tritium retention. However, it also has disadvantages such as radiation induced embrittlement and thermally driven high ductile to brittle transition. Most importantly, erosion by particle bombardment is great issues in off normal, i.e. disruption, events which gradually weaken the function of the vacuum vessel. To date, different types of tungsten, alloys, and ceramics have been proposed to minimize these challenges in first wall materials selection.

In this study, tungsten carbide was used because of having comparable characteristics that of tungsten thus could perform as a plasma facing material. At the same time, tungsten metal was used as a reference material to compare the emerging features from the macroscale to the microscale. HELIOS, the electrothermal plasma experiment was used to replicate the small angle, high heat and particle flux like conditions that these materials will experience in off normal events. As prepared tungsten (W) and tungsten carbide (WC) samples were subject to HELIOS device with the controlled variables such as heat flux, particle flux, sample temperature, types of ions and their energy, and duration. Scanning Electron Microscope was used to visualize the microstructure of sample both at the surface and depth. Similarly, Energy Dispersive Spectroscopy (EDS) was carried out to see the compositional profiles both at the surface and along the depth direction. To see the cross-sectional view, surface treatment including cut, mount and polishing is necessary to take advantage of Focused Ion Beam (FIB) technique. Atomic Forces Microscope (AFM) was conducted on the surfaces of the samples to see the emerged surface morphology due to plasma interaction. X-ray Diffraction (XRD) patterns were recorded to reveal the possible alteration of lattice structure after exposure. Nanoindentation was performed to see any deviations in microhardness to obtain the microscopic mechanical strength information. Collection of data were then connected to draw the plasma material interaction at the surface and bulk materials. Based on the concentration profiles along the depth dimension, it is available to quantify the penetrative behavior of tungsten carbide and tungsten in these environments. The overall damage on
tungsten and tungsten carbide are analyzed and correlated to materials characteristics.

Investigation of Indentation Cracking of 6H-SiC at Elevated Temperatures Using HR-EBSD and FIB Tomography
Bo-Shiuian Li, Anna Kareer, Junliang Liu, Phani Karamched, Angus J. Wilkinson and David Armstrong; University of Oxford, United Kingdom

Indentation cracking of 6H-SiC up to 700 °C were introduced via a high-temperature nanoindenter equipped with a Berkovich tip. Fracture toughness (Kc) for indents with radial cracks (<400 °C) were calculated based on the Ouchterlony-modified Laugier equation. However, this equation does not apply for indents above 400 °C, due to the more complicated crack morphology revealed by FIB tomography. Here, an alternative method for calculating fracture toughness based on nanoindentation and FIB tomography was proposed. Good agreement with literatures was found for RT but slightly overestimates for 700 °C, suggesting the dissipation of energy through plastic deformation. High-resolution electron diffraction (HR-EBSD) was also conducted to measure the residual stress/strain distribution and geometrically necessarily dislocations (GNDs) density around the nanoindents. The combined effort of FIB tomography and HR-EBSD will provide better understanding of the thermally-controlled deformation process.

Understanding Multicomponent Alloy Phenomena via Quantitative Imaging and Spectroscopy
Mitra L. Taheri1,2; 1Drexel University, United States; 2Johns Hopkins University, United States

Multicomponent alloys (MCAs) represent a new class of alloy that are composed of multiple principal elements, contrasted to conventional alloys that rely on a single principal element with additional alloying elements in relatively small abundance. Despite their nominal chemical disorder, several studies have reported short range order (SRO) in MCAs – i.e. preferential bonding, local elemental enrichment and/or clustering – and such SRO may have broad implications for MCA performance. To tackle this problem, a suite of spatially resolved, electron imaging, diffraction, and spectroscopy techniques is used to correlate coordination chemistry and local order with microstructural evolution and related dislocation phenomena. Specifically, microstructures of so-called medium entropy alloys and high entropy alloys subjected to a variety of deformation regimes are analyzed. The resulting microstructures are quantified using diffraction-based techniques, and ultimately compared to simulations of similar alloy families in order to determine the extent to which localized dislocation-based phenomena play a role in microstructural evolution, and how alloy chemistry plays a role in these determining factors. The techniques presented allow for the direct observation of the interplay between chemistry and microstructure, and thus, provides us with key tuning knobs for future MCA development, especially for use in extreme environments such as high strain rate deformation, corrosion, and irradiation conditions.

Multiscale Investigation of the Microstructure-Mechanical Property-Processing Relationships in Mg and Mg Alloys
Xin Wang1, Lin Jiang1, Dalong Zhang1, Kehang Yu1, Timothy J. Rupert1, Irene J. Beyerlein2, Subhash Mahajan1, Enrique J. Lavernia1 and Julie M. Schoenung1; 1University of California, Irvine, United States; 2University of California, Santa Barbara, United States; 3University of California, Davis, United States

The hexagonal close packed (HCP) family of metals is of growing interest as it provides a potential solution to the ever-increasing variety of structural applications that require advanced materials with unprecedented combinations of mechanical properties. As an example, Mg and its alloys are promising candidates for light-weighted structural applications, e.g., aircraft, automobile, electronic, etc. Successful incorporation of Mg and Mg alloys into
engineering designs is however hindered by their limited plasticity compared to that of current structural metals, which can be attributed to the anisotropic dislocation slip and twinning behavior that is associated with the HCP structure. Higher critical resolved shear stresses (CRSS) are required to activate the non-basal slip systems on the prismatic and pyramidal planes to produce an arbitrary shape change.

Over the years, the scientific community has proposed various approaches to enhance the performance of HCP metals, including introducing pre-existing nano-scale growth or deformation twins and nano-particles/precipitates in a nanostructured matrix. While these strategies and many others have led to several 100% enhancements in strength, to simultaneously attain strength and strains-to-failure values that are comparable to those of other advanced metals requires important breakthroughs in fundamental science and innovative design and processing strategies. Recently, in-situ experimental techniques in TEM and HRTEM and multi-scale simulation tools have emerged as successful strategies to enhance our fundamental understanding of the deformation mechanisms in materials. In this presentation, results from our group on Mg and Mg alloys are discussed with particular emphasis on the following topics: recent findings on twin nucleation and its relationship to dislocation slip; the influence of slip-twin and twin-twin interactions on mechanical behavior; formation of twin-twin junctions in single crystal Mg at the nanoscale and synthesis of high densities of twin-twin junctions in polycrystalline Mg at the macroscopic scale; and rare earth element alloying effects on dislocation glide and twinning activity in Mg alloys. The fundamental deformation behavior and the underlying mechanisms in Mg and Mg alloys are discussed in an effort to facilitate the development of synthesis pathways to produce low-density, high strength, high toughness HCP materials that are suitable for advanced industrial applications.

9:00 AM MS01.05.03
Ultra-High Stress Mediated Lattice Disturbance and Twinning Nucleation Scott X. Mao; University of Pittsburgh, United States

It is well understood that strength of crystals goes up as specimen size goes down with defects in the crystals decrease. When the size is down to below 30–50 nanometer, stress for defects nucleation becomes extremely high for crystals with large lattice friction resistance such as W. In such extreme condition, high stress plasticity occurs with unique deformation mechanism. I will cover experimental molecular dynamics with the in-situ high resolution transmission electron microscope for observation on the ultra-high stress induced lattice disturbance, dislocation dipole nucleation, competition between slip and twinning, and twinning nucleation of nano-sized body center cubic metals pillar (30-50 nm diameter) with defects free condition under ultra high stress above 10 ~ 20 GPa compressive loading

9:15 AM *MS01.05.04
Healing of Nano-Cracks in Metals Due to Stresses Induced by Mechanically-Driven Grain Boundary Migration Ta Duong1, Abhilash Molkeri1, Christopher Barr2, Ankit Srivastava1, Khalid Hattar2, Brad Boyce2 and Michael J. Demkowicz1; 1Texas A&M University, United States; 2Sandia National Laboratory, United States

When external loads are applied to a material containing a crack, a characteristic stress field $s_{\text{rack}}$ builds up around the crack. If the material does not undergo any microstructure evolution during loading, the deflection of the crack faces depends on $s_{\text{rack}}$ alone. However, in polycrystalline metals, applied loads may cause the microstructure to evolve, e.g. through grain boundary migration, martensitic transformations, or differential distortion. This microstructural evolution generates complex stress fields $s_{\text{mstr}}$ of its own. The displacement of the crack faces then depends on the superposition of $s_{\text{rack}}$ and $s_{\text{mstr}}$, rather than on $s_{\text{rack}}$ alone. This coupling between mechanically-driven microstructure evolution and internal stresses gives rise to counterintuitive crack behavior, such as closure under applied mode I (tensile) loading. This talk will present atomistic and continuum-level simulations of stresses induced at a triple junction during mechanically-driven grain boundary migration and their effect on the behavior of a nearby nano-scale crack. The simulations will be compared with corresponding experiments on fatigue-induced nano-cracks in polycrystalline Pt.

9:45 AM MS01.05.05
Grain Boundary Engineering Leading to Enhanced Mechanical Properties of Superhard Boron Carbide Qi An1, Dezhou Guo1 and Madhav Reddy2; 1University of Nevada, Reno, United States; 2Shanghai Jiao Tong University, China
Boron carbide is superhard, but its extended engineering applications are prevented by the abnormal brittle failure arising from the high-density amorphous shear bands. To improve the mechanical properties of B₄C, we investigated how grain boundaries (GBs) determine the deformation and failure mechanism of B₄C. The deformation and failure mechanism of polycrystalline B₄C were studied using the reactive force field (ReaxFF) simulations. We found that the main deformation mechanism of nanocrystalline B₄C is grain boundary sliding, leading to a reverse Hall-Petch relationship. This GB sliding triggers the amorphous shear band formation at predistorted icosahedral GB regions with initiation of cavitation within the amorphous bands. Our simulation results are validated by the nanoindentation experiments in which an intergranular amorphous GB phase was observed due to GB sliding. Although most GB sliding events in our ReaxFF simulations lead to the intergranular amorphization, we do observe one intragranular amorphization initiates from grain boundaries (GBs) and propagates along the rhombohedral (011)[2-1-1] slip system. Combining density functional theory (DFT) and ReaxFF simulations, we found that the dislocation nucleation occurs along this particular slip system, accompanied with bond breaking of icosahedral-icosahedral bonds within B₁₁C cage. This leads to the amorphous shear band formation and intragranular amorphization. Our studies provide an atomistic explanation for the influence of GBs on the deformation behaviour of nanocrystalline ceramics, helping design strong and ductile superhard ceramics.

10:30 AM *MS01.05.06
Interface-Microstructure-Enabled Mechanical Behavior of Metallic Nanocomposites Amit Misra; University of Michigan–Ann Arbor, United States

An overview of the mechanical behavior of metallic nanocomposites in terms of the interface-dominated microstructure will be presented. The interface microstructure will be characterized using parameters such as interface spacing, morphology, crystallographic orientation relationship, texture with respect to processing direction, interface defect structure and chemistry. A series of model Cu-X systems where X is BCC element such as Mo, Ta, Nb, V, Cr, Fe, etc will be used to highlight the novel mechanical behavior enabled by interface microstructures. The presentation will highlight the integration of theory and computational simulations across relevant length scales and in situ characterization of defect phenomena and mechanical behavior. In particular, examples from high strain rate testing and failure by shear band formation in ultra-high yield strength metallic nanocomposites will be highlighted.

11:00 AM MS01.05.07
Advanced Multimodal Studies of Microstructural Evolution under Shear Deformation Arun Devaraj¹, Bharat Gwalani¹, Tamas Varga¹, Changyong Park², Jorge D. Santos³, Tiffany Kaspar¹, Peter V. Sushko¹, Suveen N. Mathaudhu¹ and Cynthia Powell¹; ¹Pacific Northwest National Laboratory, United States; ²Argonne National Laboratory, United States; ³Helmholtz-Zentrum Geesthacht GmbH, Germany

Shear deformation of metallic alloys can induce deformation and microstructural changes which can be used to process materials in solid state, helping avoid melt processing and in achieving highly refined microstructures not achievable by conventional processing. In order to develop such solid phase processing methods for metallic alloys, we aim to better understand the fundamental atomic scale mechanisms of mass and energy transfer in materials under shear deformation. To achieve this aim, we employed synchrotron based in situ and ex situ high energy x-ray diffraction capabilities under high pressure with and without shear deformation, to enable real time investigation of microstructural evolution under such high deformation conditions. Such synchrotron based XRD results were correlated with detailed microstructural characterization before and after shear deformation using transmission electron microscopy and atom probe tomography, to develop a comprehensive understanding of the structural and compositional changes in the microstructure due to the shear deformation. Our results on structural and chemical modifications of several metallic alloys such as Al-Si, Cu-Nb and Cu-Ni provide new insights on the unique role of shear deformation in formation of metastable states as well as modifying the phase transformation pathways of these alloy systems. These new insights will be presented and compared with what is currently understood about role of shear deformation on generating super saturated solid solution states or self-organized nanolayers in metallic alloys.

11:15 AM MS01.05.08
Shear-Induced Deformation under a Microscope—Intermixing and Metastability in Heterolayers Peter V.
Understanding mechanistic pathways of far-from-equilibrium processes can help design materials with desired properties and control their behavior. Here we investigate how shear stress applied to nano-scale heterostructures of immiscible metals leads to the formation of metastable intermixed regions and establish the conditions for their stability. Heterostructures of Cr and Cu were grown using molecular beam epitaxy and subjected to linear shear by performing atomic force microscopy (AFM) scratch test. Controlling the force applied to the AFM tip and the ordering of the Cr and Cu layers allows us to control the tip penetration depth, the width of the wear track, and the amount of debris formed by the displaced material. Subsequent analysis performed using transmission electron microscopy and atom probe tomography reveals the character of the deformation field and the extent of shear induced intermixing under the wear track. Complementary molecular dynamics simulations provide additional insight into the mechanistic pathways of these off-equilibrium processes leading us to establish how the coupling between nano-structuring in the as-grown material and the shear loading determine the formation of mechanically-driven Cu-Cr intermixed regions.

The Influence of 3D Atomic-Level Interface Structure on the Mechanical Behavior of Nanocomposites

2-dimensional (2-D) sharp interfaces with distinct boundaries demarcating an abrupt discontinuity in material properties in nanolayered composites have been studied for almost twenty years and are responsible for enhanced behaviors such as strength, radiation damage tolerance, and deformability. However, 2-D interfaces have their limitations with respect to deformability and toughness. 3-D interfaces are defined as heterophase interfaces that extend out of plane into the two crystals on either side and are chemically, crystallographically, and/or topologically divergent, in three dimensions, from both crystals they join. Here, we present the synthesis, structure, thermal stability, and mechanical behavior of nanolayered Cu/Nb containing interfaces with 3-D character. By co-sputtering the bimaterial interfaces between the constituent pure phases, the resulting compositional gradient gives rise to new interphase boundary structures. Micropillar compression results show that the strength of Cu/Nb nanocomposites containing 3-D interfaces is significantly greater than those containing 2-D interfaces. Mechanical anisotropy, as well as shear banding is observed during pillar compression with retention of continuous layers across the shear band. We will present our recent results on deformation of such 3-D interfaces and structures, and describe their structural evolution mechanistically through the use of atomistic simulations.

Dynamic Response of High Energy Materials

Polymer bonded explosives consist of high energy particles in a polymeric binder. When these composites are subjected to heat, impact, or other stimulus they may undergo a rapid chemical change. This process is controlled by the formation of high temperature localized regions known as “hot spots”. The mechanisms of hot spot nucleation are controlled by the microstructure, for example in the same sample some particles ignite while others do not.

The sensitivity of the microstructure to initiation is studied with finite element simulations. The results help to identify the mechanisms of hot spot formation under a range of mechanical stimulus. The finite element model incorporates anisotropic plasticity and fracture and heat transport using a phase field approach. Microstructures with
different initial defects, including cracks, debonding and voids are analyzed. Furthermore, we analyze the relative importance of plastic dissipation and friction for different crystal orientations and grain sizes.

2:00 PM MS01.06.02
Nanosecond Resolved Temperatures of Shock Initiated Insensitive Energetic Materials  
Meysam Akhtar and Dana D. Dlott; University of Illinois at Urbana-Champaign, United States

We measured the hot spot and combustion temperatures of shocked insensitive high explosives in plastic-bonded explosive (PBX) formulations with nanosecond time resolution using optical pyrometry. The experiments used our shock compression microscope, which generates short-duration (4 ns) shocks using laser-launched flyer plates with velocities of 1-4.5 km/s. The microscope has, in addition to the optical pyrometer, a Photon Doppler Velocimeter (PDV) and high-speed imaging cameras.

The explosives were fabricated in the form of an array with 187 charges 1 mm in diameter and various thicknesses. The tiny charges were 80% explosive and 20% binder. The binder was polydimethylsiloxane (PDMS) and the explosives were triaminotrinitrobenzene (TATB), 1,1-diamino-2,2-dinitroethene (FOX-7), and 2,6-Diamino-3,5-Dinitropyrazine-1-Oxide (LLM-105). These explosives are particularly interesting because they are powerful but insensitive to accidental initiation.

The explosive temperatures were determined by measuring the spectral radiance in the visible region and fitting the radiance to a graybody model. However, since all these explosives are yellow, their absorption in the blue region gives apparent temperatures that are too cold. We measured the absorption spectrum in the PBX using diffuse reflectance spectroscopy. Knowing the absorption spectra, we have developed a modified graybody model that accounts for this absorption which allows us to measure the temperature more accurately.

2:15 PM MS01.06.03
Tracking Hot Spot Growth and Temperatures in a Model Plastic-Bonded Explosive Under Shock Compression  
Belinda P. Johnson, Hoya Ihara and Dana D. Dlott; University of Illinois at Urbana-Champaign, United States

The ability to probe the time-dependent microstructural response in explosives under shock compression is critical to understanding the initiation of explosives used in munitions and nuclear weapons. We have developed a tabletop apparatus that allows us to send initiating/detonation shocks to a sample and study the effects of microstructure on initiation. By using laser-driven impactors, we impart shocks lasting several nanoseconds and compress sample targets up to 10s of GPa. Using multi-frame fast photography with nanosecond temporal resolution we visually track thermal emission and its evolution over time. Additionally, we measure the time-dependent temperatures using a multichannel optical pyrometer coupled to a microscope objective that can resolve features down to 2 μm. The sample targets in this study consist of miniature arrays of explosive crystals embedded in various polymers, but sample targets can range from miniature, cylindrical explosive charges, thin films, and liquids. To date we have produced the first time-resolved images and simultaneous temperature measurements of shock-induced hot spots in a plastic-bonded explosive.

3:30 PM *MS01.06.04
Novel Contributions to Deformation and Properties in Gradient Materials  
Suveen N. Mathaudhu 1,2; 1University of California, Riverside, United States; 2Pacific Northwest National Laboratory, United States

Metallic alloys with gradient microstructures have recently been shown to exhibit enhanced mechanical properties, namely increased strength with minimal loss in tensile ductility. One of the most common ways of engineering a gradient microstructure is via surface mechanical attrition treatment (SMAT) wherein hard balls are ultrasonically accelerated to impinge the surface and cause severe deformation and microstructural refinement. The improved properties are based on a number of proposed mechanisms, including dislocation cascading and mechanical incompatibility between layers, however less studied factors include the contributions of residual stress, texture, hardness and sample/process geometry. In this lecture, we will present research vignettes on each of these factors,
and deliberate on their overall roles in property enhancement. The results will be used to explain seemingly incongruent phenomena observed in many reports, and further unravel and decouple deformation mechanisms in gradient materials.

4:00 PM MS01.06.05
Distinct Driven Steady States Emerge from Diverse Initial Textures in Rolled Nanocomposites Ian Chesser1, Elizabeth A. Holm1 and Michael J. Demkowicz2; 1Carnegie Mellon University, United States; 2Texas A&M University, United States

Severe plastic deformation is a widespread method of making high-performance metallic materials. Single-phase polycrystalline metals undergoing severe plastic deformation develop steady-state textures that are characteristic of the mode of deformation. By contrast, we show that two-phase, Cu-Nb nano-laminate composites reach a variety of different steady-state textures under a single mode of deformation. Using molecular statics simulations and a novel algorithm for crystal rotation analysis, we observe that the final, steady state texture and interface character in these materials depends on the initial texture of the composite. This finding suggests that the range of bulk Cu-Nb nano-composite textures that may be made by severe plastic deformation is larger than previously demonstrated, with multiple plastically-driven steady states accessible, depending on initial texture. We propose a modification of accumulative roll bonding with highly textured seed layers as a means of accessing different driven steady states in layered composites.

4:15 PM *MS01.06.06
A Dynamic Look at MAX Phase Deformation and Damage Behavior Leslie Lamberson1, Xingyuan Zhao1, Hussien Badr2, Maxim Sokol2, Garritt Tucker1 and Michel Barsoum2; 1Colorado School of Mines, United States; 2Drexel University, United States

Layered solids are prevalent in both natural and synthetic systems from geological formations and ice, to microelectromechanical devices and traditional composites. MAX phases are a particular type of layered ternary transition metal carbide or nitride that essentially bridge the gap between ceramics and metals. They possess a unique deformation mechanism of atomistic buckling, termed ripplocations, which upon further load can lead to mesoscale nonlinear kink band formation (NKB). This mechanism is closely related to, but distinct from intrinsic rippling of 2D layered materials. Unlike dislocation motion, bulk ripplocations have no polarity or Burgers vector, allowing for a potentially useful energy absorbing intrinsic toughening mechanisms. On the bulk scale, MAX phases catastrophically fail in a nominally brittle manner due to the fact that critical resolved shear stresses have drastically reduced pathways for dislocation motion. As such, understanding the competition of ductile, pseudo-ductile and brittle deformation mechanisms across stress states and strain rates is imperative to moving toward tailoring the layered anisotropy for specific strength or stiffness performance metrics. Consequently, this talk presents orientation and strain rate investigations of randomly and highly-oriented MAX phase titanium silicon carbide (Ti3SiC2), among others. Specifically quasi-static and dynamic compression experiments both parallel and perpendicular to the c-axis (on highly-oriented MAX) and fracture investigations utilizing 2D digital image correlation with ultra high-speed imaging map surface kinematics, damage behavior and by extension, crack tip energetics through analysis. Ripplocation nucleation, self-assembly and propagation to the point of permanent kink banding, which is fundamental to the deformation of all layered solids, as well as the potential benefits of highly-textured MAX phases will be discussed. A model bulk experiment replicating ripple formation with associated nonlinear buckling analysis will also be presented.

4:45 PM MS01.06.07
High Strain Rate Compressive Behavior of Nanocrystalline Nickel Microlattices Rajaprakash Ramachandramoorothy1, Patrik Schürch1, Jakob Schwiedzik1, Thomas E. Edwards1, Damian Frey2, Jean-Marc Breguet2, Laetitia Philippe1 and Johann Michler1; 1Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 2Alemnis AG, Switzerland

Three-dimensional (3D) metallic printing of macroscale engineering structures is a well-established field that
promises precise spatial control and microstructure. The state-of-the-art metallic printer in the market that uses laser sintering has a minimum feature size of 20µm in thickness and 300µm in lateral direction. Thus the smallest structures that can be built are typically in the millimeter scale. On the other hand, micron scale metal architectures, with a simple extruded two dimensional shape such as micropillars and micro-cantilevers (with a length scale of ~2-30µm), can be fabricated only using focused ion beam (FIB) milling. Despite being widely used in the research communities, the use of FIB milling process in the industry is rather limited because of two key reasons: i) Defects are created in the milled structures due to gallium ion implantation and ii) it is an extremely time-consuming serial process, which severely limits the number of samples available for different studies. Thus, there is a critical need to develop a new method of 3D printing metals in the microscale (~1µm feature size) to create complex geometries (~10-100µm overall dimensions) such as microlattices, microsprings etc. Such a technology would enable us, for the first time, to design hierarchical microscale metallic structures with a unique combination of properties such as low density (<1000g/cc), high strength (>0.5GPa) and high ductility (>50% plastic strain). These full-metal microarchitectures can have profound applications in fabrication of freeform 3D metal microelectromechanical systems (MEMS) based devices and MEMS packaging for energy absorption/impact resistance.

In this presentation, for the first time, a new manufacturing technique for producing focused ion beam (FIB)-free templatable 3D metal microarchitectures such as microlattices, using a combination of two-photon lithography and electrodeposition will be described. The fabrication process which also involves a new electrodeposition overgrowth and inversion step, allowed the successful manufacture of full-metal 3D microlattices, with ~1µm feature size, to be made completely from nanocrystalline nickel, including the bottom substrate, the sample and a flat metal plate as the top-layer. Full-metal microlattices with such design are ideal for mechanical testing and for transfer to several applications/systems such as MEMS devices.

Subsequently, dynamic compressive properties of the full-metal nanocrystalline nickel microlattices, obtained using a state-of-the-art piezo-based \textit{in situ} micromechanical tester in a scanning electron microscope (SEM), will be presented as a function strain rate from 0.001/s to 200/s. Remarkably, the nickel microlattices with a density of ~1200g/cc (1/7th density of solid nickel) exhibit high yield strength of ~0.5GPa, due to the nanocrystalline nature of the electrodeposited metal. Also, the metal microlattices deform in an almost ideal plastic manner with a constant plateau-like crushing stress without initial stress peaks and are able to sustain significant strains up to 50% before densification. Further, given that the live monitoring of the high strain rate compression tests was not possible due to the low frame rates of the SEM (~35fps) finite element analysis (FEA) was used instead to understand the structural evolution of the nickel microlattices at high speeds. Thus the presentation will also report the results from FEA, including the determination of the constitutive laws using high strain rate nickel micropillar compression.

**Hydrostatic Compression of the Portland Cement Clinker Minerals—Computational Modeling Investigations**
*Nirmalay Barua, Ingrid Espinosa and Ram V. Mohan; North Carolina A&T State University, United States*

Atomic level modeling is a highly effective and has been recently used tool to study complex multiphase cement composite systems. It can be used to predict the mechanical characteristics and associated constitutive material constants of the composite system, as well as an atomistic level understanding of how individual material phases affects the overall properties of the composite structure. Cement paste is a complex composite system that consists of both hydrated and unhydrated minerals and voids. Being the most popular construction material, cement materials are regularly subjected to high pressure under different loading conditions including those from underwater applications, impact, and shock loading. The overall mechanical behavior of cement composite paste under hydrostatic compression is a result of the mechanical deformation of each constituent phase of this composite material system. In this study, predictive molecular dynamics was used to model the atomistic deformation of the unhydrated phases under increasing pressure. A reactive forcefield was employed to capture the appropriate material chemistry changes in contrast to the classical forcefield that fails to capture the molecular reactions. Hydrostatic compression behavior of major clinker minerals were determined by the pressure-specific volume Birch-Murnaghan
equation of state (EoS) for Tricalcium aluminate (C₃A), Dicalcium silicate (C₂S), Tri-calcium silicate (C₃S) phases. Current modeling results indicate that calculated bulk moduli of the phases are in good agreement with previous experimental work reported for C₃A and C₂A. Among these three phases, C₃S was found to exhibit larger bulk modulus as well as isotropic compressibility, which can influence the behavior of cement composite of hydrated and unhydrated components.

8:15 AM MS01.07.02
Continuum Dislocation Dynamics-Based Grain Fragmentation Modeling Georges Ayoub¹, Ali Al-Hadi Kobaissy² and Mu'Tasem Shehadeh²; ¹University of Michigan, United States; ²American University of Beirut, Lebanon

This work proposes a grain fragmentation modeling approach that couples continuum dislocation dynamics analysis with a crystal-plasticity framework. The proposed model investigates the microstructural features of FCC metals subjected to severe plastic deformation. Several aspects of the deformation process were considered, including texture evolution, statistically stored dislocations and geometrically necessary dislocations (GNDs) densities evolution, and grains fragmentation and its effect on the overall mechanical response. The proposed model was applied to a reference volume element in which the grains are distributed and assigned an initial position. Each grain has the ability to split into 1024 new smaller grains, that was modeled by accounting for the grain-grain interaction, for which the concept of the GNDs is incorporated into the mean free path of the dislocations. The simulation results give reliable predictions of the crystallographic texture, the evolution of dislocation density, and the final grain size based on available experimental data.

8:30 AM *MS01.07.03
Scale Bridging Damage Model for Quasi-Brittle Metals Informed with Crack Evolution Statistics Kevin Larkin¹², Esteban Rougier², Viet Chau², Gowri Srinivasan², Abdessattar Abdelkefi¹ and Abigail Hunter²; ¹New Mexico State University, United States; ²Los Alamos National Laboratory, United States

Computationally efficient methods for bridging length scales, from highly resolved micro/meso-scale models that can explicitly model crack growth, to macro-scale continuum models that are more suitable for modeling large machine components, have been of interest to researchers for decades. In this work, a brittle damage model that includes the effects of material plasticity is presented for the simulation of dynamic fracture in continuum scale quasi-brittle metal components. Crack evolution statistics, including the number, length, and orientation of individual cracks, are extracted from high-fidelity, finite discrete element method (FDEM) simulations and are used to generate effective material moduli that reflect a material's damaged state over time. This strategy allows for the retention of small-scale physical behaviors such as crack growth and coalescence in continuum scale hydrodynamic simulations. A stress-based degradation criterion is introduced for the degradation of individual material zones. This allows for the development of a heterogeneous damage distribution within the bulk material. The effective moduli constitutive model is used to simulate beryllium flyer plate experiments. The results of these simulations are found to be in good agreement with numerical and experimental velocity interferometer data. Extrapolation of the effective moduli model to a higher rate flyer plate case shows promise for further reducing computational costs associated with crack statistics generation from high-fidelity simulations.

9:00 AM *MS01.07.04
Finite Amplitude Buried Blast Loading on Additively Manufactured Lattice Structures Jeffrey Lloyd¹, Christopher Cummins¹ and Eric Faierson²; ¹U.S. Army Research Laboratory, United States; ²Western Illinois University, United States

The objective of this work is to determine the utility of three architected lattice types for energy dissipation when a sandwich panel is subjected to buried blast loading. The load is imparted on a panel by detonating a scaled explosive charge underneath a layer of engineered soil and monitoring the top surface deflection. Each panel was additively manufactured out of Ti-6Al-4V using powder bed fusion and the density of each panel was varied by changing the characteristic thickness of the lattice struts within a unit cell. The three classes of lattices studied in this work are octet, auxetic, and continuous shell lattices. Large finite element simulations of the structure-blast interaction, employing direct numerical simulation, are used to determine how the structure dissipates energy and ultimately collapses when subjected to the blast loading event. Finite element predictions of performance, which is
characterized as maximum dynamic deflection of the top surface of the panel, are compared with in-situ measurements taken via Digital Image Correlation to rank order the structures. The key dissipation mechanisms of each lattice type are discussed in detail based on the finite element simulations, in-situ measurements, and post-mortem X-Ray CT scans of the tested structures.

Continuum Dislocation Dynamics for Finite Deformation Plasticity Kyle Starkey1, Anter El-Azab1 and Grethe Winther2; 1Purdue University, United States; 2Technical University of Denmark, Denmark

Continuum dislocation dynamics (CDD) is becoming an important approach for modelling metal plasticity at the mesoscale. CDD is a density-based approach for modeling dislocation evolution under the effect of the applied load and the dislocation short and long range interactions. The method is based on transport equations for dislocations for which the driving force comes from the stress in the crystal. Most CDD models were developed for small deformation. In order to capture lattice rotation effects, a finite deformation kinematics must be accounted for in CDD model development. We present a finite deformation formalism of CDD that distinguishes between the dislocation measures in various configurations of the deforming crystal, thus yielding both Eulerian and Lagrangian forms of the transport equations governing those measures. A strain driven homogenization scheme is used to solve the coupled dislocation transport and crystal mechanics equations at finite deformation under periodic boundary conditions. A numerical scheme based on a staggered solution of the transport and stress equilibrium problems has been implemented within a finite element framework. We present simulations of several test problems such as large angle grain boundary formation, known geometrically necessary boundaries, as well as twist boundaries forming under special loading modes. We also present preliminary predictions of the dislocation microstructural patterns and compare them with TEM data of the same. The lattice rotation effects of the forming patterns will be discussed.

On the Implementation of Dislocation Reactions in Continuum Dislocation Dynamics Models for Mesoscale Plasticity Vignesh Vivekanandan1, Peng Lin1, Grethe Winther2 and Anter El-Azab1; 1Purdue University, United States; 2Technical University of Denmark, Denmark

Continuum dislocation dynamics is becoming a popular framework for investigating the collective dislocation dynamics in single crystals undergoing plastic deformation. Continuum dislocation dynamics describes the spatiotemporal evolution of dislocations by transport-reaction equations that are coupled and solved concurrently with crystal mechanics, which is often formulated as eigenstrain problem. We present an approach to that facilitates an accurate implementation of dislocation reactions and cross slip in continuum dislocation dynamics. This approach seeks to rigorously enforce the dislocation line continuity from single slip system perspective in describing the reactions and cross slip. This is accomplished by adding virtual dislocation densities on each slip system to provide closure for all dislocation loops involved in cross slip or junction reactions, thus rigorously enabling the dislocation population on each slip system to satisfy the divergence free condition individually. We discuss the implementation of this approach and present results for the following: the stress-strain behavior of single crystals and the dislocation density evolution, the dislocation patterns, and the orientation dependence of the stress-strain response and the dislocation pattern. The later will be compared with experimental data for [001], [011] and [111] loading for FCC crystals.

Structural Phase Transformation in Single Crystal Titanium During Dynamic Loading Curt A. Bronkhorst1, Biao Feng2, Benjamin Morrow3 and Ellen Cerreta3; 1University of Wisconsin - Madison, United States; 2Kimberly-Clark Corporation, United States; 3Los Alamos National Laboratory, United States

The mechanical loading of metallic materials to high pressures and over short time durations remains a technically challenging arena of research. These loading conditions typically preclude the availability of detailed experimental results for physics involving finite elasticity, plasticity mechanisms including slip and twinning processes, and structural phase transformation. Although wave dynamics study via free-surface velocity diagnostics is a long-standing discipline, much of what is believed about the response of materials to these loading conditions remains inferred from comparison to computational results. The pursuit of questions involving coupled physics and the
relationship between phase transformation and elastic and plastic deformation mechanisms is then best executed by integration of theory and experiment. We will present a study of structural phase transformation of high-purity titanium single crystals loaded by split-Hopkinson pressure bar (SHPB) and plate-impact conditions. Some sample material from these experiments was also soft-recovered and metallographically examined for structural evolution information. A thermodynamically consistent theory describing the finite elastic, dislocation slip, deformation twin, and phase transformation response of single crystals is presented. This theory presents physics coupling within both the energetic and structural components of the model for general high deformation rate loading conditions. The model performance is compared against the experimental results through numerical simulations of the experimental conditions. The SHPB and shock loading along the [0 0 01] and [1 0 -1 1] directions of single crystal high purity Ti is investigated computationally. Resonably good correspondence between simulation and experiment is obtained, which includes pole figures, volume fractions of components, free surface velocity, peak pressure, and phase transformation pressure. Multiple experimental phenomena are interpreted based upon the progression of dislocation slip, deformation twinning, and phase transformation. In compression with the [1 0 -1 1] crystal, a higher volume fraction in the primary twins but a lower secondary twin volume fraction in the [0 0 01] crystal in experiment was observed. The higher propensity for phase transformation occurs in the [0 0 01] crystal is reproduced. In addition to material texture, distributions of temperature, stresses, and plastic strains dependent on the impact loading directions are revealed.

11:00 AM MS01.07.08
Study of Pseudomorphically Transformed bcc Mg in Mg/Nb Multilayer Nanocomposite under Extreme Conditions
Manish Jain1, Marko Knezevic2, Johann Michler1, Nenad Velisavljevic4, Nathan Mara1, Irene J. Beyerlein1 and Sid Pathak1; 1University of Nevada, Reno, United States; 2University of New Hampshire, United States; 3Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 4Los Alamos National Laboratory, United States; 5University of Minnesota, United States; 6University of California, Santa Barbara, United States

In recent years two-phase nanolayered composites with individual layer thicknesses varying from 200-300nm down to 1-2 nm have been the subject of intensive study because of their unusual physical, chemical and mechanical properties. For example, with decreasing layer thicknesses (down to nanometer length scales) the mechanical response of these nanocomposites becomes increasingly interface dominated, and they exhibit ultrahigh strengths approaching the theoretical limit for ideal crystals. Moreover if the constituent phases present large differences in strength, elastic modulus and ductility, these multilayers give rise to new possibilities for the deformation mechanisms and properties of the composite as a whole. In this work we explore the possibility of synthesizing multilayered composites where one constituent phase has a low ductility, with a final goal of enhancing both the strength and ductility of the system.

Using physical vapor deposition (PVD) techniques we synthesized a hexagonal close-packed (HCP) – body-centered cubic (BCC) Mg-Nb system (where twinning in Mg leads to its lack of ductility), over a range of layer thicknesses ranging from 5 nm to 200 nm. We investigated the structure of the hitherto-unknown bcc Mg phase in the Mg/Nb multilayer nanocomposite under high pressures in a diamond anvil cell experiment using synchrotron radiation x-ray diffraction (XRD). We utilize a suite of small scale testing techniques to evaluate the deformation mechanisms in these nanocomposites that involve both compressive loading scenarios such as (a) high throughput nanoindentation testing, to more-specialized FIB-fabricated (b) micro-pillar compression, and (c) micro-tensile tests. The mechanical data obtained from these tests are correlated with the structure information at complementary length scales using techniques such as XRD, SEM, and TEM. The use of such diverse testing technologies allows a detailed characterization of the structure-property correlations at each length scale of interest; ranging from the response of each individual interface within the laminate to properties of the ensemble.

The specialized testing techniques such as FIB-fabricated micro-pillar compression and micro-tensile experiments are used to characterize the anisotropic response of the nanolayered composite, with interfaces oriented either normal, parallel and oblique (45°) to the compression axis. Each of these configurations generate unique mechanical information: thus while compressions and tensions normal and parallel to the interface are important for a complete understanding of the anisotropy of properties and size-related effects, the tests with the interfaces loaded obliquely provide a measure of interfacial shear strength. Ductility and fracture toughness at the micrometer level are investigated using in-situ observations inside an SEM coupled with a micro-tensile geometry. Tests repeated as a function of layer thickness and interface orientations provide us with valuable information regarding the Mg-X
We have also extended our techniques to measuring the strain rate sensitivity (SRS) of the Mg-X nanocomposites using \textit{in situ} strain rate jump experiments conducted under both indentation and micro-compression/micro-tensile loading scenarios. Elevated temperature measurements are especially important, since the SRS for nano-(bcc)Mg is expected to differ from its nano-(hcp)Mg counterpart as a function of temperature from which activation energies/volumes for deformation mechanisms can be extracted. Results from these tests were analyzed in terms of the measured activation energies and activation volumes from sub-micrometer sized Mg/Nb multilayer nanocomposites. These findings reveal an alternative solution to obtaining lightweight metals critical needed for future energy efficiency and fuel savings.

\textbf{11:15 AM MS01.07.09}

\textbf{Shock-Induced Softening in Single Crystal Magnesium} \textit{Tyler J. Flanagan}\textsuperscript{1}, \textit{Sriram Vijayan}\textsuperscript{2}, \textit{Benjamin Bedard}\textsuperscript{1}, \textit{Cyril Williams}\textsuperscript{3}, \textit{Mark Aindow}\textsuperscript{2} and \textit{Seok-Woo Lee}\textsuperscript{1}; \textsuperscript{1}University of Connecticut, United States; \textsuperscript{2}The Ohio State University, United States; \textsuperscript{3}U.S. Army Research Laboratory, United States

The residual mechanical properties acquired from shock-compressed solids are often times dramatically different from those received under quasi-static conditions. This suggests that the deformation mechanisms present during shock compression may be significantly different than those seen under quasi-static conditions.

In this presentation, we will discuss shock-induced softening in single crystal magnesium. Single crystal magnesium samples were shock compressed to approximately 0.8 GPa and 1.7 GPa respectively along the \textit{<a>} and \textit{<c>} axes then released back to ambient conditions. Nanoindentation was performed on the shock recovered samples at regions free of deformation twins. We compared the nanoindentation hardness of these samples to those received from samples compressed under quasi-static conditions as well as those of pristine samples that did not undergo any plastic deformation. Our results show that quasi-static deformation increases the hardness due to conventional Taylor hardening. However, if only the deformed specimens are compared, the hardness decreased with increasing strain rate. The microstructure of the shocked samples showed a large number of deformation twins but there seems to be negligible storage of dislocations. Even pre-existing dislocations seem to be swept out. We hypothesize that due to the nature of the shock-compression experiments, although dislocations will be generated during deformation, they are able to glide through the sample unimpeded and emerge at the free-surfaces, whereas they would normally be constrained in conventional quasi-static compression. The stress-driven removal of dislocations could lead to abnormal softening in shock-compressed magnesium. Our observation counters the conventional belief that large numbers of dislocations are stored in samples subject to severe plastic deformation as usually seen in shock-compressed face-centered cubic metals. These results give an insight into the fundamental understanding of the residual mechanical response in shock-compressed materials.

\textbf{11:30 AM MS01.07.10}

\textbf{Spatially- and Temporally-Resolved Measurement of Pore Size Distribution of Granular Media under Dynamic Penetration} \textit{Andrew F. Leong}, \textit{Elaine Asare}, \textit{Vignesh Kannan}, \textit{Kaliat T. Ramesh} and \textit{Todd Hufnagel}; Johns Hopkins University, United States

The heterogeneous structure of granular materials makes their response to dynamic deformation quite complex. The size, shape, and orientation of the grains as well as the pore structure influence the distribution of forces and thus the constitutive behavior of the material. These structure-properties relationships have been actively investigated for quasi-static loading, where imaging (such as x-ray computed tomography) can provide detailed information about the evolving 3D structure of the material. But relationships determined for low loading rates may not carry over to dynamic loading, where inertial effects become important. Several groups have used high-speed x-ray imaging to study dynamic deformation of granular materials but the insights obtained have mostly been qualitative, because the information available is limited to 2D projections of complex 3D structures. This has limited the usefulness of such studies for the development and validation of models of dynamic behavior of granular materials.

In this talk, we present a robust algorithm with which we can measure the heterogeneous pore size distribution of a granular material from single projected x-ray phase contrast images. As a demonstration we apply our algorithm to sandstones undergoing dynamic wedge impact, using a sequence of images to track from their measured pore size
distribution the evolution of porosity, pore number density, and median pore size with micron-scale spatial resolution and sub-microsecond temporal resolution. We observe initial pore compaction close to the wedge tip to form an extended wedge that induces pore dilation downfield, leading to the development of intergranular cracks and failure. The insights available from these studies can provide a better understanding of how granular material response on the mesoscale influences macroscopic properties such as shear strength. This improved understanding may be beneficial for understanding complex dynamic loading problems, including planetary impacts and mine blasting.

11:45 AM MS01.07.11
*In Situ Synchrotron X-Ray and Neutron Studies of Metals under Extreme Conditions—High Temperature, Plastic Deformation, High Pressure and Shock Impact* Klaus-Dieter Liss1,2; 1Guangdong Technion - Israel Institute of Technology, China; 2Technion—Israel Institute of Technology, Israel

In-situ neutron and synchrotron X-ray diffraction deliver unique and complementary insight into the material’s response to high temperature, deformation and extreme conditions. Neutrons illuminate a larger bulk volume and reveal quantitative phase abundance, bulk texture, lattice parameter changes and other ensemble averaged quantities. In contrast, fine-bundled high-energy X-rays deliver reflections from a number of individual grains. For each constituting phase, their statistics and behavior in time reveal information about grain growth or refinement, subgrain formation, static and dynamic recovery and recrystallization, slip systems, twinning, etc. Examples will be presented on selected in-situ examinations on materials undergoing thermo-mechanical processing, high-pressure and response to shock.

Towards Predicting a Microstructure's Susceptibility to Spall Jie Chen1, Eric N. Hahn2, David Jones2, George T. Gray2 and Saryu Fensin2; 1University of Connecticut, United States; 2Los Alamos National Laboratory, United States

Understanding and predicting the response of materials under dynamic loading is a challenging problem due to complexities involved with the loading state and its interaction with various features in the microstructure. Previous experiments to study dynamic fracture in Tantalum (Ta) manufactured via Additive manufacturing (AM) has shown differences not only in the elastic plastic transition but also its spall properties. The goal of this work is to understand this difference in the dynamic response of AM vs. wrought Ta through the use of non-equilibrium molecular dynamics (MD) simulation. Both experiments and simulation data showed that altering the processing conditions also changed the number fraction of specific grain boundary types in the wrought and AM materials. To investigate if this change in boundary type distribution is the main cause of differences in the dynamic response of these materials, bi-crystal simulations were performed to quantify the effect of boundary type and structure on spall strength.

2:00 PM MS01.08.02
Effect of Microstructure on Spall Void Formation in Magnesium Hao Sheng1,1, Debjoy Mallick2,1,1, Suhas E. Prameela1,1, Timothy P. Weihs1,1, Kaliat T. Ramesh1,1,1 and Todd Hufnagel1,1; 1Johns Hopkins University, United States; 2U.S. Army Research Laboratory, United States

Magnesium is a potentially useful lightweight structural material for applications such as aerospace and defense, where materials can be subjected to extreme environments such as hypervelocity impact. In this study, we examine the effect of microstructure on spall void initiation during shock loading of pure magnesium. Using equal channel angular extrusion (ECAE), we processed pure Mg to produce an average grain size of 10 microns. Subsequent
Annealing increases the average grain size and influences the crystallographic texture of the material.

To study void initiation in these materials, we carried out spall experiments with a laser-driven micro-flyer apparatus capable strain rates exceeding $10^6 \text{s}^{-1}$, using photon Doppler velocimetry (PDV) of the back-surface velocity to determine the spall strength. We use x-ray computed tomography (CT) to characterize the incipient spall voids, and correlate this with the microstructure (texture and grain size) measured with backscattered electron diffraction (EBSD).

2:15 PM MS01.08.03

Shock, Spall and Melt—Measuring Dynamics with Pump-Probe Imaging and Interferometry of Extreme Mechanical Response of a Material from Ultrafast Laser Irradiation Abdul R. Ansari, Alex Sarracino, Ben Torralva and Steven M. Yalisove; University of Michigan, United States

Ultrafast laser-induced shock waves in metals can produce strain rates as high as 10^{11} (1/sec). The mechanical response to these extreme strain rates is important for ultrafast micro-machining, the study of extreme strain rate phenomena, de-orbiting space junk with ultrafast lasers, the response to biological systems as in eye surgery, and many emerging ultrafast materials applications. What is unique about our approach to studying these extreme conditions, which are on the order of ~10^{4} K and pressures up to 100 GPa, is that we are able to recover the material afterwards to study as well as use pump-probe methods to observe the dynamics on picosecond timescales. We deposit thin films (1 nm to 10 microns) on sapphire or glass substrates and irradiate the material through the transparent substrate. The fluence we use dictates which path the material will take through a temperature-density phase field. We are especially interested in studying materials in the vapor dome, the two-phase region where the liquid and gas phases are in equilibrium. Our work has demonstrated that we can force a material into the vapor dome 10-12 ps after the laser pulse ends [1]. Depending on the material and the irradiating fluence, we are able to keep the material in the vapor dome for up to 25 ps while maintaining its temperature to be, at most, 90% of that at the critical point[1]. We have demonstrated mixing of W and Ni to thermally stabilize the quenched nanograin material (~2 nm grain size). We have also shown that we can mix Ni and Ag layers at the higher temperatures in the vapor dome. These studies exploit the extreme quenching that can be observed—we are capable of quenching at 10^{10} to 10^{15} degrees per second.

This talk will focus on the dynamics of high strain rate shock loading and rapid heating. We will study Ni films of 200 to 300 nm thickness that are calculated to be capable of supporting a strong shock wave. Multiple deformation mechanisms are observed upon irradiation including delamination and deformation without fracture, fracture, spall, and melt. Results from 1-D plasma hydrodynamics codes (HYADES) with DOE equations of state show that internal mechanical spall from the large tensile component of the shock wave is possible. Our modeling results suggest that, with a 150 fs, 780 nm laser pulse, we are able to generate up to 23 GPa of tensile stress at the trailing edge of shocks using a fluence (0.9 J/cm^2) that is just below the melt threshold for Ni. The spall strength of Ni in static conditions is about 3 GPa. We will present results of ultrafast pump-probe imaging and interferometry of the back side to extract the dynamics and relative competition between heat flow and mechanical stress. This experimental and computational platform will be used to explore the limits of the phonon drag regime and the ultimate strength of materials. We will present the in-situ observations of the dynamics along with ex-situ microscopy of the recovered material. These will be discussed in the context of our computational results to show that material heating and loading at these extreme conditions lead to unique final states. Finally, we will show that this experimental approach is ideal for studying a large variety of other high-temperature and high-pressure phenomena.

Extreme Deformation and Failure of Materials by High Power Pulsed Laser-Driven Shock Compression and Tension Shiteng Zhao, Bruce Remington, Christopher Wehrenberg and Marc Meyers; 1University of California, Berkeley, United States; 2Lawrence Livermore National Laboratory, United States; 3University of California, San
Diego, United States

Pulsed lasers with power on the order of terawatts, once deposited on a target surface, will launch a strong stress pulse that propagates into the material. Owing to the ultrashort duration of the laser pulses, unprecedented extreme conditions which combine high pressures (and/or shear stresses), strain rates and temperatures can be generated in materials, yielding a yet unexplored regime of study: extreme mechanical metallurgy. During the talk, I will first summarize our efforts on laser shock compression of four covalently bonded materials, namely, silicon, germanium, boron carbide and silicon carbide (SiC). These materials are known to have high Peierls-Nabarro stress and negative Clapeyron slope. The profile of the shock waves was measured by a velocity interferometer system for any reflectors (VISAR). The shock deformation microstructure has been revealed by high-resolution scanning/transmission electron microscopy and all the materials exhibit shock-induced amorphization. This discovery indicates shock-induced amorphization as a generalized deformation mechanism under strong shock condition. Laser shock experiments can also be extended to the tensile regime when the compressive wave was reflected by the free surface. The tensile wave, once exceeds the ultimate tensile strength of the materials, will lead to a catastrophic failure. Our recent efforts on dynamic tensile fracture of tantalum with different grain size will be discussed. In addition to laser shock experiments, I will also talk about the dynamic behavior of CoNiCr-based high entropy alloy (HEA). These materials show strong resistance to shear localization under impact loading, which is mainly due to HEA's low stacking fault energy and therefore easy propensity to undergo twinning. Our results suggest that CoNiCr-based HEA may have good ballistic protection application.

Atomistic Simulations of Shock Compression of Single-Crystal and Core-Shell Cu@Ni Nanoporous Metals
Anupam Neogi, Lijie He, Niaz Abdolrahim and Ali Khourshaei Shargh; University of Rochester, United States

We have investigated the performance and applicability of a single-crystal and core-shell Cu@Ni nanoporous (NP) structure under shock-loading using atomistic simulations. Core-shell structure exhibits lesser volume compressibility than a single-crystal NP. Core-shell NP also demonstrates increased plastic deformation i.e., enhanced shock-energy absorption efficiency of around 10.5% larger than a single-crystal NP, albeit shock Hugoniots reflect a weak dependency on core-shelling of an NP structure. Shock-induced deformation behavior of NP-Cu with and without nano-coating of Ni has been studied. At $u_p < 0.15$ km/s, partial collapse of the pores are observed via direct crushing in both NP structures. At $0.15 \text{ km/s} < u_p < 0.55 \text{ km/s}$, single-crystal NP Cu shows complete collapse of pores through ordinary dislocation-mediated softening in the ligaments, while the core-shell Cu@Ni NP demonstrates increased strain-hardening in Cu/Ni interface. At $u_p = 0.75$ km/s, shock-induced deformed microstructure of both structures has been observed to be recovered through recrystallization.

Micropillar Cyclic Compression Studies of an NiTi Thin-Walled Tube
Hyunmin Kim and Sharvan Kumar; Brown University, United States

A systematic examination of the cyclic compression response in three different orientations ($r, \theta$ and $z$) of micropillars obtained from a polycrystalline thin-walled NiTi tube (that is a precursor to laser machining of medical stents) was undertaken and correlated with texture measurements. The tube was textured with a strong $\{112\}-\{111\}$ duplex structure along the drawing direction ($z$), a strong $\{111\}-\{123\}$ along the $r$-direction and a near $\{011\}-\{012\}$ texture in the $\theta$-direction. Strain amplitudes examined included the entire transformation cycle as well as reduced amplitudes about targeted mean strains; the latter enables a comparison of the cyclic response of a predominantly austenitic microstructure with that of a predominantly martensitic microstructure. Further, single crystal micropillars were milled from an annealed NiTi sheet with 25-30 µm grain size with loading axis aligned in orientations corresponding to the tube texture and their cyclic response was compared to those obtained directly from the tube. Results from these studies will be presented and discussed.

3:45 PM MS01.08.07
Hierarchical Microstructure in Shear Bands of Pure Titanium
Dexin Zhao, Xiaolong Ma, Dinakar Sagapuram and Kelvin Y. Xie; Texas A&M University, United States
Shear bands in metallic systems are narrow regions of intense strained materials which could act as premature failure locations. A comprehensive understanding of shear band microstructure is the key to control the ductility of materials. However, large localized deformation usually develops within this thin region and nanoscale recrystallized grains are formed. Conventional characterization techniques such as EBSD and regular TEM imaging are inadequate to visualize the detailed microstructure inside these shear bands. For example, EBSD cannot provide high enough spatial resolution. TEM has the ability to determine the nanoscale grain size, but to elaborate the orientations of all grains is labor-intensive. Moreover, detailed orientation information cannot be obtained. In this work, we demonstrated that ASTAR (a technique that acquires the diffraction pattern of each pixel) could offer direct orientation information of microstructure feature down to 1 nm scale. Using the ASTAR results, we revealed the hierarchical structure including high-angle grain boundaries, low-angle grain boundaries, defect bundles in the shear bands.

4:00 PM MS01.08.08
Mechanical Properties of InP Nanowires—In Situ TEM Tests and Atomistic Simulations Zhilin Liu1,2, Ioannis Papadimitriou1, Miguel Castillo1, Gustavo Esteban-Manzanares1, Jon M. Molina-Aldareguía1 and Javier Llorca1,3,2, 1IMDEA Materials Institute, Spain; 2Central South University, China; 3Technical University of Madrid, Spain

The mechanical properties and fracture mechanisms of taper-free InP twinning superlattice (TSL) nanowires were ascertained by means of in situ uniaxial tensile tests in a transmission electron microscope. The nanowires were grown along the zinc-blende close-packed [111] direction and presented an average twin spacing of ~ 13 nm. The elastic modulus along the [111] orientation was 87 ± 17 GPa, while the fracture strain was 2.9 ± 0.3% close to the one reported in ZnO nanowires (~5%) but smaller than that of GaAs nanowires (10–11%). Fracture was brittle in all cases and occurred by the propagation of a crack along the twin boundary interface. No evidence of inelastic deformation mechanism was observed neither in the experimental stress-strain curve nor in the TEM images before fracture. MD simulations of the tensile deformation of untwinned and twinned InP nanowires of different diameters (12 to 30 nm) at 300 K were carried out to assess the experimental data. The elastic modulus obtained from the simulations (84 GPa) was fairly independent of the diameter and close to the experimental values. The failure strain and the tensile strength of the twinned nanowires in the MD simulations (~ 10% and ~ 6.7 GPa) were much higher than those observed experimentally but smaller than those simulated for untwinned nanowires, and these differences were attributed to the stress concentrations associated with the zig-zag waviness at the nanowire surface. Moreover, the simulations did not show any evidence of non-linear deformation mechanisms prior to fracture, that was triggered by the nucleation and propagation of a crack at the twin boundaries, in agreement with the experimental observations.

Extreme In Situ Mechanics of Ni-Based Superalloys: 800°C and Beyond Sanjit Bhowmick, Eric Hintsala and Asif Syed; Bruker Nano Surfaces, United States

High-strength structural materials such as Ni-based superalloys and diffusion bond coats are widely used in challenging environments and with exposure to mechanical fatigue, particle impact, and erosion at elevated temperatures. Diffusion aluminate bond coats are an example of compositionally and microstructurally graded coatings with significant variation in engineered mechanical properties across the cross-section. Nanoindentation and pillar compression, particularly in situ, can be considered as a well-suited technique for measuring the properties of such complex microstructural materials as the deformation volume can be carefully controlled to probe different precipitates and microstructural zones. In this study, an SEM nanomechanical instrument with an integrated high-temperature stage and an active tip heating was used to conduct pillar compression of aluminate bond coating and substrate at room temperature to well above 800degC. This is the first study of an in situ nanomechanical testing of any sample at such higher temperature with capturing deformation events in detail at that temperature inside an SEM. With combined analysis of chemistry and microstructural changes, the results were used to understand local mechanical properties variation as a function of temperature.

4:30 PM MS01.08.10
Recent Innovation in In Situ Extreme Mechanics at the Micro and Nanoscale Nicholas Randall1, Damian Frey1, Quentin Longchamp1, Jean-Marc Breguet1, Rajaprakash Ramachandramoorthy1, Jakob Schwiedrzik2 and Johann Michler2; 1Alemnis AG, Switzerland; 2EMPA, Switzerland
Nanomechanical tests are moving beyond the basic measurement of hardness and elastic modulus to encompass a host of different mechanical properties such as strain rate sensitivity, stress relaxation, creep, and fracture toughness by taking advantage of focused ion beam milled geometries. New developments, such as high cycle fatigue, are extending the range of properties which can be studied at the micro and nanoscale. However, such techniques are challenging due to low oscillation frequencies, long duration of tests and large thermal drift when attempted with standard indentation instruments. Novel piezo-based nanoindentation methods are now allowing access to extremely high strain rates (>10⁴ s⁻¹) and high oscillation frequencies (up to 10 kHz).

Until only recently, high strain rate testing of materials at strain rates from 100/s – 10000/s has only been possible using macroscale techniques, such as split Hopkinson bar, Kolsky bars and plate impact testers. At the microscale, strain rates have typically been limited to 0.1/s or less, owing to limitations in instrumentation and insufficient data acquisition rates.

This talk will focus on the most recent developments in instrumentation for in-situ extreme mechanics testing at the micro and nanoscales, with specific focus on a testing platform capable of strain rate testing over the range 0.0001/s up to 10’000/s (8 orders of magnitude) with simultaneous high speed actuation and sensing capabilities, with nanometer and micronewton resolution respectively.

Other recent innovations include cryogenic and high temperature tests covering the temperature envelope from -150 to 800 °C. The challenges in variable temperature tests and the associated technological and protocol advances will be discussed along with select case studies. The inherent advantages of using small volumes of sample material, e.g., small ion beam milled pillars, will be discussed together with the associated instrumentation, technique development, data analysis methodology and experimental protocols. Some examples of test data will be presented where a wide range of strain rate has been combined with variable temperature in order to investigate rate effects as a function of temperature. Finally, future research directions in this sub-field of micromechanics will be discussed.

High-Velocity Impact Induced Gradient-Nano-Grained Structure and Phase Transformation Claire Griesbach, Jizhe Cai and Ramathasan Thevamaran; University of Wisconsin--Madison, United States

We present a dynamically deformed material with a unique gradient-nano-grained (GNG) structure and martensitic phase transformation. GNG structures have been created through techniques such as surface mechanical attrition treatment [1], electroplating [2], surface rolling [3], and laser shock processing in germanium [4]. Studies show that nanograins provide increased strength while coarse grains retain ductility [1–3], simultaneously improving two mechanical properties that are often found to be mutually exclusive. However, a detailed structure-property relationship enabling predictions of material properties based on the gradient grain structure has not been developed yet. We investigate the process-structure-property relations in GNG metals through an experimental approach that allows us to tailor the grain structure and probe mechanical properties while observing microstructural changes. Using a laser induced projectile impact testing (LIPIT) apparatus, we impact single-crystal silver microcubes [5] onto a stiff target at ~400 m/s. The high-strain-rate deformation creates a gradient nano-grained structure with small ~10 nm grains near the impact plane and progressively larger grains farther from the impact region [6]. By varying impact parameters such as sample orientation and impact velocity, we produce different GNG structures with varying ranges of grain size and degree of gradient.

We show that a [100] impact orientation of the crystal initiates a phase transformation from a face-centered-cubic (fcc) to a hexagonal-close-packed (hcp) structure. Very rare naturally occurring hcp silver was found in north-eastern Russia in the 1970’s [7], and synthetic pathways have been developed recently [8]. A single-step method to dynamically induce such a phase transformation will allow for further tailoring of favorable material properties. We
also find that this phase transformation is orientation dependent as cubes impacted along the [100] direction undergo phase transformation while impact along the [110] direction does not yield a phase transformation. This is due to the varying stress states present in the sample during deformation and the favorable [100] loading geometry to create stacking faults on the {111} planes. We also show that over time small grains coalesce into larger grains due to recrystallization and results in a subsequent hcp-to-fcc phase transformation.

With an understanding of the process-structure relations, we investigate how these structures lead to improved mechanical properties of the material. Using a focused ion beam (FIB), we mill micropillars out of the impacted samples and perform micro-compression tests using an in situ SEM nanoindenter to measure strength and toughness. We also fabricate planar cross-sections of the sample using FIB and measure the hardness as a function of the gradient grain structure using the SEM nanoindentator. Developing detailed process-structure-property relations will enable the design of metals with optimal strength and toughness for a given engineering application.

Mechanical Properties of Micrometer-Size Cellular Foam-Like Auxetic Structures Ming Wang and David R. Harding; University of Rochester, United States

Two-photon polymerization (TPP) is a recently developed technique that was used in these experiments to “write” millimeter-size cellular structures (~0.2g/cm³) with micrometer-size resolution. This process is used to make auxetic structures, which are characterized by having a negative Poisson’s ratio. The purpose of this study is to develop a material that can dissipate energy from impacts or vibrations over a wide temperature range—from cryogenic to room-temperature conditions. Different auxetic structures were designed using finite element analysis methods to maximize the structural and plastic deformation that can occur at cryogenic temperatures without exceeding the strength properties of the material. These structures were then printed using a commercial laser writer (Nanoscribe GmbH) and tested at 23°C and 140 K using a thermal mechanical analyzer (Perkin Elmer) at loads ranging from 10⁶ to 10⁸ Pa and multiple cycles. The calculated energy (~32 J/kg) that is dissipated from a brief impulse (~17 ms) is compared to the measured energy dissipation. The robustness and performance of the structures is compared with the laser “writing” parameters used to make the structure, which requires full polymerization of the photosensitive material while avoiding embrittlement.

This material is based upon work supported by the Department of Energy National Nuclear Security Administration under Award Number DE-NA0003856, the University of Rochester, and the New York State Energy Research and Development Authority.

MS01.09.03
Designing a Mechanical Metamaterial Inspired from Crystalline Quartz Hye-in Na and In-Suk Choi; Seoul National University, Korea (the Republic of)

In this talk, we propose a design concept of architected mechanical metamaterials based on the crystalline quartz structure. Crystalline quartz is a repeating double helix structure of the SiO₄ tetrahedra with plenty of empty space that shows a zero-Poisson’s ratio. We mimic this crystalline alpha quartz structure to design a truss-based mechanical metamaterial. Both experiments and numerical analysis demonstrated that the inter-penetration of the
SiO₄ tetrahedra results in the zero-Poisson’s ratio similar to the crystalline quartz. Through dynamic analysis at various levels, it was possible to figure out several important features of this mechanical metamaterial.

MS01.09.04
High Temperature Mechanical Behavior of 3D Printed Inconel 718 Observed by In Situ Transmission Electron Microscopy
Supriya Koul, Le Zhou, Yongho Sohn and Akihiro Kushima; University of Central Florida, United States

Selective laser melting (SLM) refers to an additive manufacturing (AM) technique for metallic alloys, which uses a scanning laser to melt and fuse metallic powder bed layer-by-layer. It has advantages over traditional manufacturing methods in the design freedom and manufacturing flexibility. However, the SLM process with repeated melting and solidification leads to the unique microstructure that can include large columnar grains and periodic cracks. Moreover, the rapid solidification intrinsic to SLM can produce nanoscale structure different from traditional manufacturing processes. While post-heat-treatments are widely employed to improve the mechanical property of SLM-produced alloys, the unique, as-built microstructure can lead to varying response to traditionally defined heat treatment parameters. Therefore, the detailed understanding of the dynamic microstructure evolution as a function of temperature and its effect on the mechanical behavior is essential for optimizing the SLM and post-heat-treatment processes. Here, in-situ transmission electron microscopy (TEM) is a useful tool to observe nano-scale phenomena in real time. It provides direct observations of the deformation processes in nano-scale to study the deformation mechanism/procedures, and their relationships with the microstructural evolutions during heating. In this study, we designed a unique sample shape that enables tensile experiment of thin TEM lamellae without undesired off-plane deformations or bending.

We selected IN718 as representative SLM-produced alloy to discover the relationship between the microstructural evolution during heat treatment and the associated change in the mechanical behavior. The in-situ TEM captured a microstructural evolution of IN718 during exposure to a high temperature, with an emphasis on precipitation of spherical γ'/γ'' phases. Subsequent tensile experiment demonstrated brittle fracture in contrast to a ductile fracture of as-printed IN718 indicating a proper heat treatment (solutionizing and ageing) is necessary to improve the mechanical property. This study provides correlation among heat-treatment, microstructural evolution, and the mechanical behavior, which can be used to optimize the post-heat-treatment for SLM-produced alloy through microstructure control.

MS01.09.05
Revealing the Photo-Induced Non-Thermal Amorphization Mechanism of Phase Change Material
Subodh C. Tiwari¹, Aiichiro Nakano¹, Fuyuki Shimojo², Rajiv Kalia¹, Paulo Brancicio¹ and Priya Vashishta¹; ¹University of Southern California, United States; ²Kumamoto University, Japan

Phase-change materials (PCM) owing to their extreme electro-optical contrast between crystalline and amorphous states are used in optical data storage, flexible devices and neuromorphic computing. However, atomistic mechanisms governing photo-excitation induced non-thermal amorphization processes are still unknown. We perform excited-state dynamics within the framework of density functional theory to investigate the mechanism behind such crystalline to amorphous transition for Germanium Telluride (GeTe). Our study shows the GeTe non-thermal amorphization process is the key. Amorphous phase is characterized by computation of diffraction pattern in real time. Further analysis of bond-overlap analysis suggests a change in bonding behavior between Ge-Ge from anti-bonding to bonding state that leads to increase in Ge-Ge bonds and decrease in Ge-Te bonds. A rapid heat extraction during excited-state simulation does not lead to amorphous phase. Overall, our excited-state dynamics study demonstrates that the non-thermal amorphization in GeTe occurs due to antibonding character of excited electronic states. Since structural transformation limits the lifetime of PCM-based devices, a deeper understanding behind this mechanism may allow us to a new avenue in the design of future devices.

Stabilizing Laser Shock Peening Induced Compressive Residual Stresses for High Temperature Applications of Additively Manufactured Parts
Ali Beheshti¹, Kasra Momeni², Lloyd Hackl³, Keivan Davami⁴ and Michael Munther⁵; ¹George Mason University, United States; ²Louisiana Tech University, United States; ³Metal Improvement Company, Surface Technologies, Curtiss Wright, United States; ⁴The University of Alabama, United States; ⁵The University of Alabama, United States
States

Metal 3D printing is a versatile additive manufacturing (AM) process that produces parts from powders layer-by-layer directly from a digital model. Metal 3D printing allows for fabricating complex metallic components in an efficient and cost-effective manner compared to conventional manufacturing techniques. One significant roadblock for additively manufactured parts is that residual tensile stresses can be high in AM parts, which limits their applications, particularly for cyclic loading or at high temperatures. Post-processing methods to modify AM parts offer new opportunities for applications in extreme environments such as in turbines or nuclear reactors. Laser shock peening (LSP) is a technique that is used as a post-processing method to optimize the service life of critical components by inducing compressive residual stresses that increase the material’s resistance to surface-related failures such as creep, fatigue, stress corrosion cracking, etc. However, its application for ferrous materials has been limited to temperatures lower than ~400°C since the stresses are released at temperatures above that. A novel technique was developed to stabilize the LSP-induced compressive residual stresses at high temperatures (above 400°C). Nickel-based superalloy specimens (Inconel 718) were printed using a direct metal laser sintering (DMLS) technique. Various tests including X-ray diffraction spectroscopy, transmission electron microscopy, and nanoindentation were performed. Complementary molecular dynamics and phase field simulations were utilized to understand the underlying physical mechanisms governing the dislocation motion and their interaction with the microstructures to provide further insight to the effect of postprocesses on the final performance of printed parts, e.g. wear and fatigue. Nanoindentation hardness mapping showed that LSP increases the hardness of the top ~1.2 mm of the specimens, with a maximum hardness of ~6.6 GPa on the laser shock peened surface that gradually decreases with an increase in the distance from the surface and reaches 5.2 GPa. Electron microscopy proved that dislocation generation is the mechanism responsible for plastic deformation and hence hardening in laser shock peening. Specimens that were treated by our new technique, reserved more than 50% of the maximum magnitude of their compressive residual stresses, even after exposure to 700°C for 48 hours. The results will lead to AM materials with better performance at high temperatures, not only attributed to their inherent properties, but more importantly by optimizing microstructure, surface properties, and residual stresses.

MS01.09.07
Microstructure Evolution During Shear Banding in Compressed Nanocrystalline Ceramic Nanopillars Observed In Situ
Haw-Wen Hsiao, Shu Li, Karin Dahmen and Jian-Min Zuo; University of Illinois at Urbana-Champaign, United States

Shear banding is observed widely in a variety of materials and at different length scales. During shear banding, intense plastic shear is produced within a thin band, and shear localization strongly limits the material’s ductility, leading to catastrophic failure under stress. For these reasons, shear banding has attracted considerable research interest in uncovering the underlying mechanisms. However, connecting mechanical behaviors with microstructure evolution during shear banding is difficult, and the critical knowledge of structure-property relationship is still missing so far. In-situ observation during deformation is needed to uncover the origin of shear banding. Here, we report a direct observation of shear banding in nanocrystalline ZrN nanopillars. ZrN belongs to a class of materials, called nanocrystalline ceramics (NCCs), which are popular as protective coating because of their outstanding mechanical properties. The high strength of NCCs derives from the effect of nanograin size, following the well-known Hall-Petch relationship. A major drawback of NCCs, or nanocrystalline materials in general, is their low toughness due to the limited dislocation activities. However, when the grain size is reduced into the nanoscale regime, the effect of grain size begins to soften materials via the increased grain boundary activities. We show that plastic deformation in ZrN is carried out by intermittent granular activities in the NCC nanopillars without brittle fracture. Cooperative granular activities are found along the regions where shear bands form. Complementary cumulative distribution function (CCDF) of the associated stress drops suggests dislocation avalanches are suppressed by nanograin size.

Nanocrystalline ZrN was prepared in the form of thin film with an average grain size of 18 nm using unbalanced magnetron sputtering deposition. Nanopillars were fabricated in the plane view direction of the thin film. Compression tests of separate nanopillars were conducted in either bright-field imaging mode or nanobeam diffraction mode using Hysitron P195 picoindenter in JEOL 2010 LaB6 TEM. The experiments were simultaneously recorded as a video at the frame rate of 10 frames/s.

The study here demonstrates the secondary deformation mechanisms involving grain boundaries, in addition to the primary deformation mechanism operated by dislocations, and how together these mechanisms facilitate plastic deformation in nanocrystalline materials. The strong correlation of shear band formation and intermittent granular
activities are demonstrated, from which a shear banding model of NCC materials is proposed.

**Carbon Schwarzites Behavior Under Ballistic Impacts** Levi C. Felix¹, Cristiano F. Woellner² and Douglas S. Galvao¹; ¹State University of Campinas, Brazil; ²Federal University of Paraná, Brazil

Carbon Schwarzites are 3D porous crystalline pure carbon structures [1]. They contain rings with more than six atoms, which create negative Gaussian curvatures and the ‘flatness’ of these curvatures is dependent on the ratio of hexagon to non-hexagon rings. There are different Schwarzite families, such as primitive (P), gyroid (G), diamond (D), etc [2]. Previous studies suggested [3] that under compressive loadings, the mechanical properties of schwarzites is directly related to the local ‘flatness’ of each structure. Impact tests were performed on macroscopic 3D printed structures (cm size) [4], which showed that some qualitatively trends of the impact resistance and energy absorption are preserved from nano to macroscale. In this work we have investigated the Schwarzite behavior under ballistic impact. We considered four structures from two families (primitive (P688 and P8bal) and gyroid (G688 and G8bal)), which differ mainly by their local ‘flatness’. We used a spherical projectile with a diameter of 15 Angstroms and velocity range from 1 up to 3 km/s and with the same mass value of the target. We carried out fully atomistic molecular dynamics (MD) simulations using reactive force fields (AIREBO). Our MD results show that Schwarzites are very effective to absorb kinetic energy but their performance decreases as their ‘flatness’ increases. In P8bal and G8bal the projectile penetration is about four times deeper than in P688 and G688, with more extensive structural fractures. Considering that it was already demonstrated that macromodels of these materials can be 3D printed [4], our results open new perspectives to create new or to improve Schwarzite-based functional engineered materials.

**MS01.09.09**

**Role of Anisotropy in Swelling-Driven Fracture of Phase-Transforming Battery Materials** Ataollah Mesgarnejad and Alain Karma; Northeastern University, United States

Due to their high storing capacities, silicon and germanium have emerged as a promising anode material for high-capacity Li-ion batteries. Initial lithiation of both materials results in a crystalline to amorphous phase transformation accompanied by a large (300%) volume expansion that drives plastic flow and fracture above a critical particle size, which is several fold larger in Ge than Si. This difference is believed to be due to the fact that the motion of the atomically sharp crystalline-amorphous phase boundary is strongly anisotropic in Si but nearly isotropic in Ge. However, how this difference affects elastoplastic deformation and fracture remains poorly understood quantitatively. Here we exploit the phase-field approach to describe both the crystalline to amorphous phase transformation and stress-driven plastic deformation and fracture within a self-consistent mathematical framework to shed light on the role of anisotropy. We model the phase transformation using a modified Allen-Cahn model with anisotropic and isotropic mobilities, respectively. We model the mechanical response due to lithiation-driven swelling of the anode using neo-Hookean elasticity and finite J-2 plasticity. Finally, we model fracture using a variational phase-field formulation. Our model can describe both nucleation and propagation of cracks without interpenetration of crack surfaces under compression.

We use this multi-physics phase-field framework to investigate the lithiation of Si and Ge nanopillars as a function of yield strength and fracture energy. Using simulations without fracture, we first show that, for isotropic swelling, the tensile stresses driving fracture in the nanopillar remain capped by the yield strength. In contrast, for anisotropic swelling, tensile stresses become amplified severalfold by localization of plastic deformation near the particle surface. We relate this amplification to the existence of a critical yield strength below which plastic deformation occurs successively under compression and tension and above which it only occurs under compression. Next, using simulations with fracture, we show that this amplification of tensile stresses causes nanopillar to fracture at a smaller radius in Si than Ge as experimentally observed. Finally, we use our simulation results to obtain consistent estimates of elastic properties, yield strength, and fracture energy, which are compared to existing experimental data.
measurements.

**Microstructure and Tensile Behavior of Nanostructured Gradient TWIP Steel**  Jie Ding, Zhongxia Shang, Jin Li, Haiyan Wang and Xinghang Zhang; Purdue University, United States

Gradient nanostructured metallic materials have shown a combination of high strength and good ductility. A TWIP steel with large equiaxed grains was processed by surface mechanical grinding treatment, and the subsequent gradient structures formed near surface consist of surface nanolaminate layer, a mixed layer of deformation twins and shear bands, and a deformation twin layer. TEM studies reveal that detwinning occurs during microstructural evolution. Tensile studies show that the gradient structures increase the yield strength of TWIP steel prominently. The evolution of gradient microstructures and their influence on mechanical behaviors of the gradient TWIP steel are discussed.

**Low Temperature Compression of Glassy Carbon**  Dougal G. McCulloch¹, Sherman Wong¹, Thomas Shiell², Brenton Cook¹, Jodie Bradby³ and David McKenzie⁴; ¹RMIT University, Australia; ²Carnegie Institute of Washington, United States; ³The Australian National University, Australia; ⁴The University of Sydney, Australia

Diamonds are used in many industrial applications due to their extreme hardness, particularly for polishing, cutting, and pressure application. There has been an increasing interest in hexagonal diamond in recent years, largely due to its potential to be harder than diamond [1]. However, experimental hardness measurements for this technologically interesting material have yet to be reported due to the extreme temperature/pressure conditions required to form hexagonal diamond [2, 3] as well as the inability to form a phase-pure sample without cubic diamond inclusions [4]. Our recent study reports formation of pure hexagonal diamond at a record low temperature of 400°C that is proposed to be due to a shear-induced plastic flow [5]. This region of pure hexagonal diamond was observed in an annular region around the central region containing a graphite-like structure. In this work, the proposed shear-induced transformation pathway from this graphite-like structure to the phase-pure hexagonal diamond is explored and a pathway to further lower the required temperature is presented.

Transmission electron microscopy of lamellae containing both the graphite-like and diamond structures was examined to provide microstructural evidence for the shear-induced transformation mechanism. Within the graphitic regions, striations associated with plastic flow of graphitic sheets can be observed. The graphitic sheets are aligned along the flow direction, with the amount of orientation within these sheets increasing with increasing shear. At regions of higher shear, these flowing graphitic sheets were observed to progressively “lock-into” hexagonal diamond within a mixed region where both structures were present. The distribution of the hexagonal diamond is in good agreement with modelled shear-strain distributions. Density consistent with turbostratic graphite and hexagonal diamond are measured within their respective regions, with the density increasing linearly in the transition region. Graphitic inclusions within the hexagonal diamond and transition region were also found to have decreased interlayer spacing with increasing shear. The interlayer spacing of the inclusions within the hexagonal diamond region having a lower interlayer spacing than uncompressed graphite, making the transition to hexagonal diamond more energetically favourable. This is evidence for a step-wise transformation from the graphitic precursor to the hexagonal diamond structure due to a shear-induced flow mechanism.

Engineering Impact Modification of Polypropylene for Energy Absorption under Extreme Loading Conditions Chinmay Saraf and Alan J. Lesser; University of Massachusetts Amherst, United States

This contribution focuses on how impact modified polypropylene (iPP) is engineered to absorb energy and fail in a ductile fashion under extreme loading conditions. Herein, we report the results from a systematic investigation on three different polypropylene systems modified using soft block copolymers SEBS (Styrene-ethylene/butylene-styrene), POE (Polyolefinic elastomer) and a combination of SEBS and POE. Comparisons are made between extreme conditions (high strain rate at -15°C and -30°C) and quasi-static fracture tests at 25°C. The mechanisms of energy dissipation and fracture are then investigated in these systems with regard to soft particle size, spacing, shape, and other morphological features that govern their energy absorption.

At 25°C and quasi-static loading rates, the formulation containing lower modulus SEBS shows the highest fracture energy release rate when compared to the other two formulations. At extreme loading rates, the SEBS formulation still shows the highest energy absorption, but its relative performance is not as contrasting. Morphological investigation using a scanning electron microscopy (SEM) indicates the formation of phase-separated soft-particle domains with a larger particle size of 1-2 um for SEBS containing formulation as compared to a 200-300 nm domains for the other two formulations. Detailed investigation of failure mechanism shows the formation of interconnected crazes and a significant particle-particle interaction for polypropylene formulation containing SEBS, whereas, POE containing formulations show isolated craze formation. Failure mechanism in these formulations suggests that dilatational strain is relieved by a craze formation rather than cavitation and shear band formation. Results indicate that soft particle domains larger than the critical particle size (about 1um) governs the energy absorption for polypropylene under extreme conditions.

Herein, we also investigate the effect that an additional reinforcement in the form of talc has on these polypropylene formulations. It is observed that talc acts as a nucleating agent and improves the dispersion of soft particle domains. Morphology of talc containing formulations indicates a significant decrease in particle size, most predominantly for SEBS. These phase-separated domains have a particle size of 150 nm, smaller than the critical particle size. Room temperature fracture toughness evaluation for talc containing formulations show that SEBS containing formulation has 35% higher fracture energy when compared to the other two formulations. Interestingly, low-temperature testing at -15°C and -30°C with an impact velocity of 4 m/s shows that polypropylene formulation containing SEBS and POE in the presence of talc has 20% higher impact energy absorption as compared to the other two formulations. As seen for the formulations not containing talc, the mechanism of energy dissipation did not change; Craze formation provides release of the hydrostatic stress and acts as a major energy dissipating mechanism. Room temperature testing on polypropylene system shows that the lower modulus SEBS has a higher fracture energy release rate, with or without talc reinforcement.

The Role of High-Temperature Annealing of Graphene Aerogels Martin Silhavik, Zahid Ali Zafar and Jiri Cervenka; Institute of Physics of the Czech Academy of Sciences, Czechia

Graphene aerogels (GAs) are a three-dimensional porous form of graphene with a high surface area. GAs have attracted a significant amount of interest in recent years due to their unique mechanical and electrical properties that show great potential for numerous applications in batteries, supercapacitors, electrochemical sensors and absorption of oil and organic pollutants. These unique properties are originating from a clever arrangement of two-dimensional graphene sheets in a three-dimensional porous monolith structure containing air-filled pores. Here, we investigate the mechanical and electrical properties of GA prepared via hydrothermal synthesis from graphene oxide without any stabilizing polymer. GAs prepared by this method are generally brittle materials because they contain a lot of defects and oxygen groups. However, the thermal annealing at temperatures over 1000 °C under inert gasses causes a significant improvement of the mechanical and electrical properties, resulting in highly flexible and electrically conductive GA materials. The high-temperature annealing causes healing or repair of defects, eliminating most of the oxygen from the structure, thereby enhancing the amount of π–π stacking between graphene sheets. The as-prepared GA exhibits superior compressive elasticity and structural integrity when subjected to the ultrahigh pressing (MPa).
High Rate Mechanical Characterization of Glassy Polymer Thin Films Using High-Rate Micro-Particle Impact Test
Shawn H. Chen, Amanda Souna, Edwin P. Chan, Christopher Soles and Stephan J. Stranick; National Institute of Standards and Technology, United States

Mechanical toughness of polymeric materials has long been understood to depend on the relaxations and interactions on the molecular level. Toughness arises as impact energy is dissipated through these molecular relaxations. However, the time and length scale of the molecular mechanisms are typically several orders of magnitude faster and more localized than the traditional experimental techniques used to characterize them. Here, we employ an all optical laser-induced projectile impact test (LIPIT) to study the dynamic deformation response of polycarbonate thin films for impact mitigation applications. Micro-projectiles deposited on a polymeric launch pad are accelerated via laser ablation of an absorbing layer. The deformation response of PC films of different MWs and thicknesses are investigated at high strain rates (10^5 to 10^7 s^-1). LIPIT measurements can help to elucidate the rate-dependent ductile-brittle transition of polycarbonates and the molecular relaxation mechanisms that contribute to the toughening/dynamic stiffening properties that are desirable for impact mitigation applications.

Limit of Temporal Resolution with Atomically-Engineered Probes while Preserving Picometer Range Spatial Resolution
Omur E. Dagdeviren; Yale University, United States

With recent advances in dynamic scanning probe microscopy techniques, it is now a routine to image the sub-molecular structure of molecules with atomically-engineered tips which are prepared via controlled modification of the tip termination and are chemically well-defined. The enhanced spatial resolution is possible as atomically-engineered tips can preserve their integrity in the repulsive interaction regime. Although the mechanism of improved spatial resolution has been investigated both experimentally and theoretically, the ultimate temporal resolution while preserving picometer scale spatial resolution still remains an open question. Here, we computationally analyze the temporal resolution of atomic force microscopy imaging with atomically-engineered tips using previously developed computational models [1-3]. Our computational results reveal that non-metal terminated tips, e.g. oxygen-terminated copper, are well-suited for enhanced temporal resolution up to video rate imaging velocities while preserving picometer range spatial resolution. Contrarily, the highest-attainable spatial resolution of atomically-engineered tips with low-stiffness, e.g. CO-terminated, deteriorate with increasing imaging velocity. Our results reveal that when atomically-engineered tips terminated with molecules are in use, imaging velocities in the order of nanometers per second at most are inevitable even for atomically flat surfaces to retain the atomic resolution and avoid slip-stick motion. In addition to shedding light on the temporal resolution of atomic force microscopy imaging with atomically-engineered tips, our numerical results provide an outlook to the scalability of atom-by-atom fabrication using scanning probe microscopy techniques.

3D Helicoidally Architectured Thin-Film Composite for Tougher Bio-Inspired Material
Komal Agarwal¹, Sahay Rahul¹, Kento Yamagishi¹, Anbazhagan Subramani², Avinash Baji² and Arief S. Budiman¹; ¹Singapore University of Technology and Design, Singapore; ²La Trobe University, Australia

The helicoidal microstructures found in exoskeleton of mantis shrimp dactyl club, scarabaei, lobster provide them with remarkable toughness and high impact strength. During impact loading, these helicoidally arranged filaments tend to stretch, and twist along different planes and angles, absorbing energy, increasing the work of fracture and deflecting crack propagation. Such naturally occurring helicoidal architecture inspire us to develop bioinspired synthetic helicoidal structural materials to bolster toughness and impact resistance. Most existing studies employ conventional carbon epoxy or glass epoxy macroscopic prepregs to study the effect of helicoidal architecture in composites. We, however, use novel computer integrated near field solution electrospinning as an additive manufacturing method to fabricate 3D helicoidally arranged fiberous structures (micron/nano sized) using polyvinylidene fluoride. The aligned filament arrays are continuously collected one on top of the other with 45° angular offsets in polyvinyl alcohol bath to produce thin film composites (in range of 200 100 μm thick).
helicoidal arrangement of fibers in the matrix shows improvement in tensile behavior, crack propagation and toughness. These helicoidally oriented fiber composites show dramatical twisting and elongation of the fibers along the different directions, delaying the fracture events, as compared to its bulk counterparts. Further, surface treatment for interfiber and fibers-matrix adhesion shall be performed, and its influence on the mechanical characteristics of the helicoidal composite shall be studied.

**Carbon Nanotube Peapods under High-Strain Rate Conditions—A Molecular Dynamics Investigation**

José M. de Sousa¹, Cristiano F. Woellner², Leonardo D. Machado³, Pedro A. Autreto⁴ and Douglas S. Galvão⁵; ¹Instituto Federal do Piauí, Brazil; ²Federal University of Parana, Brazil; ³Federal University of Rio Grande do Norte, Brazil; ⁴Federal University of ABC, Brazil; ⁵University of Campinas, Brazil

Nanostructured systems under high-strain rate conditions, have been object of theoretical and experimental investigations in recent years. A recent joint theory-experiment study showed that carbon nanotubes (CNTs) and boron nitride nanotubes (BNNTs) under high-velocity impacts can be unzipped into nanoribbons [1]. However, the dynamics and fracture patterns of nanostructured systems under high-velocity impacts are not yet fully understood [2,3] and more studies are needed, especially involving hybrid systems, such as fullerenes encapsulated inside single wall carbon nanotubes (SWCNTs), the so-called CNT peapods [4]. In this work we have investigated C60 fullerene encapsulated inside SWCNTs (CNT-C60) under high-strain rate conditions. Our theoretical study was carried out through fully atomistic molecular dynamics simulations with the reactive force field ReaxFF. We have considered CNT-C60 shoot at high-kinetic energy (ultrasonic velocities values varying from 1 km/s up to 60 km/s) against a rigid substrate and into two different orientation relative to the target (lateral and vertical configurations). Our results show that for specific velocities and orientations, CNT-60 experience large deformations and are fractured at different configurations: i) just fullerene ejections; ii) tube fracture; iii) tube fracture with fullerene coalescence; and iv) under extreme conditions the formation of amorphous carbon structures. These results provide helpful insights in understanding the structural changes and fracture dynamics of nanostructures under high-rate conditions.

**Understanding Mechanical Behaviors of Auxetic Foams via Pore Structure Characterization Using X-Ray Tomography**

Lamei Du and Ye Xu; Beihang University, China

In this study, we aim to understand the connections between the negative Poisson's ratio and the pore structures of the auxetic polyurethane foam. The pore structure is visualized by X-ray tomography and key structure parameters were extracted. We found that the sphericity, tortuosity, bond angles are the most dominating structure parameters which determines the range and extent of the auxetic mechanical behaviors. In addition, the sensing performance of the CNT-coated polyurethane foams was also tested as a function of Poisson's ratio. The stronger the auxetic effect, the stronger the strain sensing capability.

**Characterization of Metal Strength and Toughness through Frictional Sliding Contact Mechanics**

Soheil Safari Loaliyan, Ryan Lacy, Parth Patel, Steven Palkovic and Simon Bellemare; Massachusetts Materials Technologies, United States

Contact mechanics provides a method of characterizing how a material responds to local deformation under controlled loading conditions. The most widely used implementation of contact mechanics is indentation hardness, where a hard stylus of known geometry is pressed into a softer material to measure the resistance to permanent deformation. In this research the mechanical properties of engineering metals are assessed using the concept of frictional sliding where a stylus is indented into a material and then slides across the surface leaving a permanent scratch or groove.
Frictional sliding with a spherical stylus on metals results in a ductile response that can be related to the elastic-plastic response of a power-law hardening material through equations developed with finite element analysis (FEA) simulations. Experiments performed on more than 20 steel and aluminum materials has shown that this approach can predict the material yield strength and ultimate tensile strength with close agreement to traditional laboratory tensile tests on the same sample. When a wedge-shaped stylus is used during frictional sliding tests, a chip of material separates from the substrate through fracture processes. If a small gap is included on the upstream face of the stylus then material in this region is subjected to increasing elongation as the separated chip flows up the wedge until a tensile fracture occurs. FEA simulations of crack propagation in elastic-plastic materials and frictional sliding experiments on steel have shown that the geometry of the fracture surface can be correlated to the material ductile fracture toughness ($J_c$). This concept can be extended to monitor fatigue behavior by applying cyclic loading at varying proportions of the steady state cutting force to determine the number of cycles required to propagate an existing crack. Overall, these examples show how contact mechanics can be used to correlate how a metal microstructure responds during frictional sliding to traditional mechanical properties of the substrate, including hardness, yield and tensile strength, fracture toughness, and fatigue.

Yin Liu and Changyong Cao; Michigan State University, United States

Magneto-active elastomers (MAEs) are soft polymeric materials embedded with magnetically responsive particles or carried with free currents, which respond to external magnetic fields by producing large deformations or varying mechanical properties. They have been increasingly used for many emerging applications such as soft robotics, printed untethered soft origami, magnetically anisotropic micro actuators, bistable switches and magnetoactive acoustic metamaterials. Thus, it is of interest and of paramount importance to develop a more rigorous continuum theory and numerical model to consider the strong field interaction in MAE analysis so as to have a deep understanding of the coupled mechano-magneto behavior of MAEs and facilitate the rational design of soft robotics with MAEs. In this paper, we present a continuum theory and finite element model to simulate the finite deformations of magneto-active elastomer (MAE) under applied magnetic fields or currents. The magnetic field is assumed to be measured in the background space with fixed spatial coordinates, rather than in the elastic MAE, leading to a concise and physically admissible continuum theory to describe coupled mechano-magnetic behaviors of MAE. Specifically, the magnetic field varies with prescribed free or localized currents and their spatial locations evolving with the motion of MAE, while the deformation of MAE is actuated by the surface or body forces applied by the external magnetic field or equivalent currents. A staggered finite element solution framework is developed to solve the strongly coupled governing equations in the two fields, and mesh distortion along the interfaces of MAE domain and free-space domain is resolved by considering concurrent deformation of the mesh in these two domains. Numerical examples are presented to demonstrate the validity and efficiency of the developed model for simulating the behaviors of MAE structures subjected to different sources of magnetic fields (e.g., free currents, magnetization or external magnetic field). This research offers a new method and mechano-magneto model for analyzing MAEs and will be useful for the rational design and analysis of MAE-based actuators and robotics in the future.

**Development of Energy Absorption Materials by Using the Fractal-Cut Concept**

Juhee Kim¹, Vivek A. Karupпасamy², Young-Joo Lee³, Jeong-Yun Sun¹, In-Suk Choi¹, Myoung-Gyu Lee¹ and Kijung Lee¹; ¹Seoul National University, Korea (the Republic of); ²Korea Institute of Science and Technology, Korea (the Republic of); ³University of Pennsylvania, United States

In this presentation, we will demonstrate an architected material for energy absorption based on the simple kirigami concept. We utilized our 2-dimensional hierarchical cut pattern named ‘fractal cut’ for an energy absorption structure. Both experimental and numerical analysis were carried out to systematically support the feasibility of our design concept. We found that the ‘Fractal cut’ structures can decrease the impulsive force of an incident object when implemented into soft materials because of high biaxial expandability. We were further able to optimize the effective design to dissipate the impulse energy through the dynamic analysis of fractal cut materials with various cut motifs and levels.

**Mechanical Property Changes of Tungsten Thin Films Due to Hydrogen or Helium Implantation**

Yoshiaki
Habu, Heun Tae Lee, Akira Nagakubo, Hirotugu Ogi, Kenzo Ibaro and Yoshio Ueda; Osaka University, Japan

Tungsten (W) plasma facing components in magnetic fusion devices experience extreme dynamical power (>10 MW/m²) and particle (>10²⁴ m⁻²s⁻¹) loads due to its interaction with the edge plasma [1]. The plasma-material interaction zone is a few nm deep, corresponding to the range of the implanted particles, leading to extreme concentration and thermal gradients. The large flux of implanted hydrogen or helium species, result in large near-surface strain fields due to their accumulation - driven by the low solubility of both hydrogen and helium in W. The resulting changes in the mechanical properties are critical to evaluate from the viewpoint of plasma operation and component lifetime issues. To date, the dynamical mechanical response of W under such non-equilibrium loading of hydrogen or helium far beyond its solubility limits is not well known due to: (1) the difficulty in probing the near surface properties, and (2) a lack of a suitable in-situ method that can be applied during plasma loading. This work focuses on overcoming the first problem, and we report on changes in the near-surface mechanical properties of W due to hydrogen or helium implantation using picosecond ultrasonics [2, 3]. W thin films (~40 nm) were implanted with deuterium (D) or helium using an ion or plasma beam, respectively. Ultrashort light pulses were used to excite and detect GHz-frequency elastic waves to determine the elastic modulus of the W thin films. It was found that the longitudinal elastic constant of the W thin film increased by up to 5 % following D implantation (1×10²³ m⁻²), while helium had a significantly larger effect. The results suggest picosecond ultrasonic method is a sensitive probe for characterizing the near surface changes in mechanical properties of plasma facing materials, opening the way towards in-situ applications.

Enhanced Damage Tolerance of Pre-Deformed Tungsten Microwires with High Dislocation Density Chaoqun Dang and Yang Lu; City University of Hong Kong, Hong Kong

Bulk tungsten is inherent room-temperature brittleness which limits its workability and performance in demanding applications. Pre-deformed tungsten microwires play a significant role in the strength, ductility, and damage tolerance of tungsten (W) fiber-reinforced metal matrix composites (MMCs) due to tungsten fiber’s ductile behavior and high tensile strength. Room-temperature fracture of extremely fibrous, pre-deformed tungsten wire does possess quite a different fracture in a ductile manner and substantial resistance to fracture at room temperature. It involves combinations of three fracture modes: cleavage, grain boundary delamination, and with individual grains necking to nearly 100% reduction in area. However, the difficulty of observing the action of individual tungsten fibers during plastic deformation has made it challenging to conclusively determine the mechanisms of a tungsten fiber-reinforced composite and presents a major bottleneck in the rational design of tungsten fiber-reinforced composites. Here, we conduct the in-situ tension of tungsten fibers as a promising platform to determine the precise role of individual tungsten fiber. It reveals that the continuous and massive dislocation nucleation and fast dislocation glide and escape by in situ TEM straining lead to the ultra-large elongation in nanoscale W fibers. This work could give insights for understanding pre-deformed tungsten wire at nanoscale and the design of pre-deformed tungsten wire based flexible devices and nanoscale tungsten fiber-reinforced composites.

Size Effects on Creep and Creep Fracture Mechanisms of Single-Crystal Metallic Nanomaterials Hiroyuki Hirakata, Takayuki Nagashima, Kotaro Yamaguchi and Takahiro Shimada; Kyoto University, Japan

It is well accepted that submicron- and nanometer-sized single-crystal metals demonstrate different mechanical properties from those of bulk counterparts; e.g. plastic resistance increases with decreasing specimen size. For the long time use of such nanomaterials, understanding of creep deformation and fracture is more important than plastic properties. It is significant to clarify whether small crystals can sustain high stress over a long period. The purpose of the study is to clarify the size effects on creep properties of submicron-sized single-crystal metals at room temperature and discuss the underlying mechanisms. We conducted long-term (up to 14 h) tensile creep experiments for submicron single crystal gold and aluminum under in situ field-emission scanning electron microscopy (FESEM) or transmission electron microscopy (TEM) observation. We directly measured the specimen elongation from the FESEM or TEM images to eliminate the measurement error in the displacement sensor owing to thermal drift and
evaluate the creep strain accurately. The creep behavior transitioned from continuous to discrete manner as the applied stress decreased, which was different from that of bulk metals. In the small stress region, although the creep strain increased with the passage of time, an arresting region appeared in which the creep deformation temporarily stopped. The in-situ TEM observation suggested that the appearance of the arresting region was due to the depletion of dislocations by recovery or the reduction of dislocations and activated dislocation sources. The smaller specimens required higher stress to reach a similar strain rate, indicating that the resistance to creep deformation increased with the decrease of specimen size. We discussed the mechanisms of the size effects based on the experimental results.

**Metal Doping Effects on the Sinterability and Mechanical Properties of Boron Carbide**

Toshiki Ota, Ryuichiro Koyama, Kouga Nakamura, Junya Watanabe and Satofumi Maruyama; Tokyo City University, Japan

Boron carbide materials possess attractive properties such as high hardness, lightweight and wear resistance, therefore it can apply various applications like cutting and grinding tools, ceramics bearing, etc. Boron carbide, so-called B<sub>4</sub>C, has a relatively wide range solid solution; B<sub>4.3</sub>C to B<sub>10.6</sub>C. However, boron carbide has a problem in sintering especially in boron-rich region in boron carbide because of the low self-diffusion coefficient in boron and boron carbide caused by the strong covalent bonding of boron. For example, boron carbide bulk materials are mainly sintered over 2273 K<sup>1</sup>,<sup>2</sup>. A few decades ago, Takagi et al proposed for new sintering method called “reaction boronizing sintering” for complex boride based hard materials<sup>3</sup>). In the reaction boronizing sintering, boronizing reaction is occurred by solid-state diffusion between metal and boron in first and the metal boride is generated. After the boronizing reaction, the eutectic liquid phase is appeared by the pseudo-binary eutectic reaction between boride and metal. In this method, the eutectic liquid phase has important roles for chemical reactions and the densification of the boride sintering body. In this study, we applied “reaction boronizing sintering” method to the sintering for boron carbide materials. 3d transition metals such as Mn, Fe, Co, Ni and etc. were adding to boron carbide to generate eutectic liquid phase between boron and metal element. Metal added boron carbides were synthesized by powder metallurgy method from metal powders, amorphous B powder, and C powder. To prevent the remain of free carbon in the sintering body and investigate the effect of molar ratios of B and C on the sinterability and mechanical properties, chemical compositions of boron carbide were B<sub>5.5</sub>C to B<sub>8.5</sub>C. Starting materials were mixed and sintered by Spark Plasma Sintering at 1973K. To refinement for the crystal structure and phase ratios, Rietveld analyses were carried out using Rietan-FP software. To investigate the microstructures and dispersion of the elements for the sintering body, SEM-EPMA measurements were performed. With the increase of the Mn contents, Vickers hardness was increasing and it reached more than 3000 HV2 for Mn 10mol% added B<sub>5.5</sub>C, which value was almost equal to standard boron carbide sintered body. According to the SEM images of Mn added B<sub>5.5</sub>C, observed pores in the fracture surface were decreasing with the increase of the Mn content. We will discuss about the effect of metal doping and chemical compositions of boron carbides on the microstructure and the mechanical properties for the boron carbide.

**Super Ductile Iron—Nano-Sized Structure and Fatigue Behavior**

Wentao Zhou, Kewen Dong and Cheng Liu; Yangzhou University, China

Ductile iron (DI) has attracted considerable interest in virtue of its good wear resistance, high strength together with good ductility, and high fatigue strength. A super DI with a multiphase structure was designed by a novel multi-step low-temperature austempering treatment. The influences of multiple microstructure on tensile strength and fatigue limit were examined applying tension and tensile-tensile fatigue tests. It showed that the tensile strength is over 1160MPa as well as an elongation of 3%, and fatigue life Nf exceeds 25,000 cycles in a high stress amplitude level of 600MPa, which were attributed to a synergistic strengthening and microcrack toughening from the super multiphase matrix comprising prior martensite (PM), bainitic ferrite (BF) and retained austenite (RA). It was found that the arrest and retardation of crack nuclei during either static stretching or dynamic deformation was controlled by a (BF+RA)<sub>nano</sub> structure, which was formed around the PM. The result can offer a great potential for super ductile iron in future critical application industry such as automotive
gears under heavily impact loads combined with wear.

_In Situ_ Micromechanical Characterization of Metallic Glass Microwires under Torsional Loading  
Sufeng Fan and Yang Lu; City University of Hong Kong, Hong Kong

Small-scale metallic glasses have many applications in microelectromechanical systems (MEMS) and sensors which require good mechanical properties. Bending, tensile, compression properties of metallic glasses at micro/nano-scale have been investigated previously. Here, by developing a micro robotic system, we investigated the torsional behavior of Fe-Co based metallic glass microwires inside a scanning electron microscope (SEM). Benefiting from the _in situ_ SEM imaging capability, the fracture behavior of metallic glass microwires has been uncovered clearly. Large plastic strain is found under torsional loading at room temperature, which could be evidenced by the large torsion angle. Through the postmortem fractographic analysis, it can be revealed that both spiral stripes and shear bands contributed to the fracture mechanism of the microscale metallic glass. Plastic deformation of the microwires included both homogeneous and inhomogeneous plastic strain, which began with the liquidlike region, then a crack formed because of shear bands and propagated along the spiral direction. Moreover, three stages fracture mechanism of this metallic glass microwire was proposed. Although the metallic glass microwire broke in brittle mode, the shear strain was not lower than that of conventional metal wires. Moreover, we found an inverse relationship between the plastic strain and the loading rates.

Non-Affine Deformation in the Flow of Metals and the Emergence of Roughness at Free Surfaces  
Wolfram G. Nöhring¹, Adam R. Hinkle¹,² and Lars Pastewka¹; ¹IMTEK, Germany; ²Sandia National Laboratories, United States

Almost all natural and man-made surfaces are rough, and this roughness controls many interesting phenomena, such as adhesion or friction between bodies, or transport across interfaces. The scaling of surface heights is often self-affine. This has been observed over many length scales, from atoms to mountains. However, the origin of self-affine roughness is not entirely understood. Here, plastic deformation is investigated as a possible generative mechanism for self-affine roughness in perfect crystals, High Entropy Alloys and metallic glasses. Bi-axial compression of initially flat samples is simulated using molecular dynamics. It is shown that the subsurface deformation field exhibits a fractal, self-affine geometry, independent of the atomic structure of the material. During deformation, the fractal structure of the subsurface displacement field is imprinted onto the free surface. Self-affine roughness is therefore a recording of the non-affine deformation process occurring in the bulk.

Modeling and Simulation of Pore Migration in Tin Solders at High Homologous Temperatures Subjected to Large Electric Currents and Stress Gradients  
Zachary J. Morgan¹, Yongmei M. Jin¹, Vahid Attari² and Raymundo Arroyave²; ¹Michigan Technological University, United States; ²Texas A&M University, United States

Pore migration in solder joints driven by electric current and stress gradient is an important phenomenon that impacts the performance and reliability of electronic devices. It is a diffusional process at high homologous temperatures under large thermodynamic driving forces caused by applied electric fields and internal stress concentrations in complex microstructures. With the miniaturization of electronic devices, anisotropic properties of individual grains play increasingly important roles since a solder joint consists of only several grains. Tin-based solder alloys, the most common lead-free solder material, exhibit significant anisotropic characteristics in electrical conductivity, elastic modulus, and diffusivity. To investigate the effects of these anisotropic properties on pore migration, a phase field model is developed to simulate pore evolution in beta-tin polycrystals. In the model, mass diffusion describing pore migration is coupled with charge conduction and elastic deformation by solving microscopic Ohm’s law and microelasticity equations, respectively. The simulations reveal various anisotropy-caused pore migration behaviors including pore velocity and path, pore-pore interactions, and pore-grain boundary interactions. The results are analyzed in terms of internal electric and stress fields which relate the pore migration behaviors to the underlying grain structures.

Fatigue Crack Growth Behavior of Multiferroic Concentric Composite Rings  
Ryan M. Stampfli and George Youssef; San Diego State University, United States
Multiferroic composites have been an area of recently increased research interest due to their potential in magnetoelectric coupling applications to increase efficiency and reduce component size when compared to traditional electromagnetic devices. Multiphase magnetoelectric composites exhibit coupling coefficients an order of magnitude larger than their single-phase counterparts by way of strain mediation of magnetic and electric energies. Concentric, toroidal ring structures are of a particular interest as they exhibit greater magnetoelectric couplings compared to similarly sized stacked laminated structures. In this study, a multiferroic ring composite consisting of lead zirconate titanate (PZT) piezoelectric ceramic concentrically bonded to Terfenol-D magnetostrictive alloy was investigated. To achieve their magnetoelectric coupling potential, these structures are typically operated at or near their resonant frequencies, hence a pre-existing crack at the interface propagates and degrades the strain mediation between the piezoelectric and magnetostrictive phases. Thus, a pre-defined crack was introduced at the interface, where the composite structure was subjected to an A/C electric field with near-resonant frequencies concurrently with a magnetic field corresponding to saturation. The crack behavior is reported along with its effect on the overall magnetoelectric performance of multiferroic composite ring structures.

Collective Motion of Quincke Rotating Bead

Etien Martinez Roman1, Tommy Fjelde Kristiansen1, Barbara Pacakova1, Jaako Timonen2, Paul Dommersnes1 and Jon O. Fossum1; 1Norwegian University of Science and Technology (NTNU), Norway; 2Aalto University, Finland

We present experimental results on collective dynamics and self-assembly in a suspension of Quincke electro-rotating granular particles (1). Depending of the value of the electric field or the concentration of the particles is it possible to find different active matter steady states such as gas or polar vortex structures. We perform Particle Image Velocimetry in order to compute the vorticity and velocity of the systems and also simple tracking procedure are performed as a complementary way of characterization (2,3). A striking new result is that the size of the vortices can be controlled with the electric field and also, that the shapes of the vortices are independent of the container’s shape. The results points to future applications in materials science to fabricate nano-/micro-structured surfaces with macroscopic functionalities including photonics, wetting, porosity and permeability.

Role of Shock Wave Propagation and Twinning/Detwinning Behavior on Spall Failure of Cu-Ta Multilayered Structures at the Atomic Scales

Marco J. Echeverria, Avanish Mishra and Avinash M. Dongare; University of Connecticut, United States

The shock response of multiphase metallic microstructures comprising of immiscible fcc/bcc phases is determined by the shock wave propagation and reflection behavior that generates heterogeneities in the microstructure such as dislocation slip and deformation twinning, which can determine the dynamic strength, i.e. the spall failure, of the microstructure. For pure fcc-Cu and bcc-Ta microstructures, MD simulations indicate a contrasting role of twinning in the void nucleation stresses of both phases. An increment in the density of twin partials in Cu increases the dynamic strength, whereas in Ta it decreases as the twin volume fraction increases. However, the role of structure, the spacing of interfaces on the shock wave propagation, and the interplay between dislocation slip and deformation twinning have not been widely studied for these types of materials. Thus, large scale molecular dynamics simulations are carried out to investigate the role of deformation twinning in multiphase tri-layer microstructures comprising of Cu/Ta/Cu layers with interfaces perpendicular to the shock loading direction for layer thicknesses ranging from 100 nm to 500 nm. These MD simulations suggest that shock wave reflections at the Cu/Ta interfaces affect the twinning/de-twinning behavior in the bcc-Ta phase that can result in modifications in the spall strengths of the multiphase alloy. The links between twin volume fractions, dislocation densities and spall strengths in Cu-Ta multilayered structures will be presented.

MS01.09.33
Effect of Deformation Twinning and Phase Transformation on Spall Failure of Fe

Avanish Mishra and Avinash M. Dongare; University of Connecticut, United States
Due to the incomparable strength of alloyed Iron among metals, an immense interest has been generated to characterize the deformation/phase transition behavior of single-crystal Iron under shock loading conditions for its applicability in extreme environments. Shock compression of Fe-based microstructures shows an interplay between dislocation slip, deformation twinning, and phase transformation behavior. Ductile failure behavior under the dynamic loading conditions (spallation) is characterized by nucleation, growth and coalescence of voids. Such failure transpires due to the interaction of reflected waves; forming triaxial tensile stresses in a microstructure deformed during the shock compression. For single crystal microstructures, the mechanical behavior of the system strongly depends on the crystal orientation and shock-loading conditions that render variations in dislocation plasticity, deformation twinning, and phase transformation behavior. This emphasizes the need for an in-depth understanding of the microstructure evolution of material under shock loading, and the interaction of voids, slips, twinning, etc., mechanisms, which tailors the spall failure at the atomic scale. Molecular dynamics (MD) simulations are carried out to investigate the spallation behavior of single-crystal Fe systems-oriented along [110], [112], and [111] directions subjected to various impact velocities ranging from 750-2000 m/s. The MD snapshots are characterized to quantify the evolution of twin volume fractions, fractions of HCP phase, and damage (void sizes and fractions) for the range of pressures generated. The effect of crystal orientation and impact velocities on the deformation response and the spall strength will be presented.

Theory of Dislocation-Precipitate Bypass Benjamin Szajewski, Joshua C. Crone and Jaroslaw Knap; U.S. Army Research Laboratory, United States

The interaction between glissile dislocations and precipitates within a continuum is responsible for marked increases in material strength. Due to their desirable engineering features, dislocation-precipitate interactions have been the subject of study for decades. Towards enhancing our mechanistic understanding of the dislocation-precipitate bypass process, we present an analytic model of the Orowan bypass stress ($\tau_{\text{Orowan}}$) required for a dislocation to bypass an array of precipitates. We initially consider spherical precipitates described by a diameter ($D$) and inner precipitate spacing ($L$). Our model suggests a $\tau_{\text{Orowan}}$ scaling logarithmically with the precipitate diameter, $\tau_{\text{Orowan}} \sim \ln \frac{D}{L}$, which we validate against a well-established, yet empirical model. We also examine the influence of precipitate aspect ratio on $\tau_{\text{Orowan}}$. Finally, we demonstrate the application of our model towards predicting the scaling of $\tau_{\text{Orowan}}$ for an array of plate-like $\theta$ precipitates within an Al-Cu molecular statics materials system. Our analyses provide insight into relationships between precipitate size, shape, density, orientation and metallic strengthening mechanisms.

8:45 AM MS01.10.02
Microstructural Predictions of Thermo-Mechanical Fracture of H.C. P. Alloys Subjected to High Temperatures M.A. Zikry, T. Hasan and I. Mohammed; North Carolina State University, United States

A dislocation-density based multiple slip crystalline plasticity formulation and a new computational fracture approach have been used to investigate and predict thermo-mechanical fracture in hexagonal close packed (h.c.p.) materials with a focus on h.c.p. alloys with hydrides that have different crystalline structures than that of the matrix. This predictive framework has been used to understand and predict the interrelated effects of dislocation-density interactions, generation, and recovery on the competition between intergranular and transgranular crack nucleation and propagation. The validated predictions indicate that transgranular fracture is dominated by dislocation-density interactions with hydrides and intergranular fracture is dominated by GB misorientations. The proposed modeling framework can provide guidelines for a fundamental understanding of materials subjected to thermo-mechanical loading conditions, such that failure resistant material systems can be attained for extreme loading conditions and environments.
Orowan Alternating Slip and Intervoid Necking—Crack Growth Mechanisms in Moderate Purity Single-Phase Aluminum Grades 1100 and 1050

Diana E. Burden1, Brendan P. Croom1, Clifton H. Bumgardner1, Helena Jin2 and Xiaodong Li1; 1University of Virginia, United States; 2Sandia National Laboratories, United States

Comprehensive knowledge of crack growth mechanisms is vital to monitoring and predicting failure in ductile materials such as aluminum. Mechanical testing, microscopy, and tomography of single-phase aluminum grades 1100 and 1050 were applied to illustrate Al failure mechanisms and how those mechanisms changed with alloy composition. Al1100 and 1050 have been previously overlooked in favor of high purity or more specialized grades. Through low strain rate uniaxial tension testing, Al dogbone samples were strained to separation to reveal their fracture surfaces. The fracture surfaces exhibited smooth, void-free edge regions and dimpled centers with a smooth transition and were oriented perpendicular to the loading direction. The texture of the fracture surfaces supports the assumption that Orowan alternating slip (OAS) contributes to the fracture mechanism for dog Al1050 and Al1100 but the perpendicular fracture angle indicates that intervoid necking is another contributing mechanism. Center hole rectangular Al samples were strained under the same conditions as the dogbone samples but paused at key points to monitor crack formation and growth using computed tomography. Diamond-shaped cracks extended from the center hole towards the sample edge surrounded vertically and laterally by small voids with larger voids just beyond the crack tip. As strain increased, voids at the crack tip coalesced with the growing crack. The crack shape is indicative of OAS while the existence and coalescence of voids indicate intervoid necking. These mechanisms work together and describe Al1100 and 1050’s complicated growth behavior more effectively than a single mechanism would allow.

Thermodynamic Theory of Crystal Plasticity—Formulation and Application to fcc Copper

Charles Lieou1 and Curt A. Bronkhorst2,1; 1Los Alamos National Laboratory, United States; 2University of Wisconsin–Madison, United States

We present a thermodynamic description of crystal plasticity. Our formulation is based on the Langer-Bouchbinder-Lookman (LBL) theory of dislocation motion, which asserts the fundamental importance of an effective temperature that describes the state of configurational disorder and therefore the dislocation density of the crystalline material. We extend the LBL description from isotropic plasticity to crystal plasticity with many slip systems. Finite-element simulations show favourable comparison with experiments on polycrystal fcc copper under uniaxial compression. The thermodynamic theory of crystal plasticity thus provides a thermodynamically consistent and physically rigorous description of dislocation motion in crystals. We also discuss new insights about the interaction of dislocations belonging to different slip systems.

Modelling Junction Reactions in a Continuum Dislocation Dynamics Framework

Peng Lin1, Vignesh Vivekanandan1, Grethe Winther2 and Anter El-Azab1; 1Purdue University, United States; 2Technical University of Denmark, Denmark

The performance of a crystal material depends on the evolution of underlying microstructures, e.g. dislocations. Continuum dislocation dynamics (CDD) is an effective tool to study the evolution of dislocations at microscale. In CDD, curved and connected dislocation lines are represented by density-like field variables. The evolution of dislocation systems are obtained by solving a set of transport equations. Here we discuss how the processes of dislocation reactions in which two interacting dislocations form junctions can be described within such a framework. The basic idea is that dislocation reactions are done by subtracting a dislocation density vector from each reacting slip system and adding to the corresponding junction density. This will result in an additional reaction term in
dislocation transport equations. Criteria including both Burgers vectors and dislocation line directions are established to determine whether reactions should happen. The model is solved within a 3D vector-density-based dislocation dynamics. Simple dislocation structures are tested for junction formation, followed by a loaded plastic deformation simulation. The results show that the model is able to capture the change of dislocation network due to reactions and the mechanical response is affected by dislocation reactions.

9:45 AM MS01.10.06
Effects of Microstructures on Superelasticity of CaFe2As2 Single Crystal Shuyang Xiao1, John T. Sypek1, Sriram Vijayan1, Paul Canfield2, Mark Aindow1 and Seok-Woo Lee1; 1University of Connecticut, United States; 2Ames Laboratory & Department of Physics and Astronomy, United States

Uniaxial micropillar compression tests on a CaFe2As2 single crystal have recently revealed the existence of extremely large elastic deformation, superelasticity, with an elastic limit up to 13%. The collapsed-tetragonal phase transition, which is the uni-axial process of making As-As bonding, is the main mechanism of superelasticity and differs entirely from the shear process of martensitic-austenitic phase transition in conventional shape memory alloys. Usually, superelasticity and its related structural transition are strongly affected by defect structures. In order to improve the superelastic performance of CaFe2As2, therefore, it is necessary to understand how defect structure influences the collapsed-tetragonal phase transition and the corresponding superelastic behavior.

In this study, therefore, we investigated the effects of microstructure on the superelasticity of [0 0 1]-oriented CaFe2As2 micropillar using the state-of-the-art in-situ micromechanical testing and transmission electron microscopy. Three different samples (Sn-solution grown, quenched FeAs-solution grown, and annealed FeAs-solution grown crystals) were prepared to produce different microstructures. Transmission electron microscopy showed that while a Sn-solution grown sample is nearly defect-free, a quenched FeAs-solution grown sample contains the extremely dense rectangular network of screw dislocations on a (0 0 1) plane. An annealed FeAs-solution grown sample contains nano-scale FeAs precipitates with coherent phase boundaries. Rectangular network of screw dislocations in a quenched FeAs-solution grown sample resembles the low angle twist boundary, and the corresponding lattice distortion would make the formation of As-As bonds more difficult, leading to the suppression of collapsed tetragonal phase transition as well as superelasticity. An annealed FeAs-solution grown sample showed the similar mechanical behavior with a defect-free Sn-solution grown sample, but fracture often occurred at a lower stress. The presence of nanoscale FeAs precipitates would act as a stress concentrator, which cause the early brittle fracture. In sum, superelasticity of CaFe2As2 is significantly influenced by defect structures, and our research outcomes will be generally useful to design the enhanced superelastic performance in other ThCr2Si2-type intermetallic compounds with the same crystal structure.

Metal-Ion-Controlled Growth of Topologically complex Cu/Fe Thin-Film Morphologies for Enhanced Dynamic Mechanical Performance Benjamin K. Derby, Max Powers and Amit Misra; University of Michigan, United States

Interface morphology and other microstructural heterogeneities ultimately determine thin film performance under extreme conditions, especially high-strain rate deformation. Synthesizing novel and complex thin films with morphologies that go beyond single crystal and single-phase materials, is needed to understand the properties exhibited by multiphase materials under dynamic loading conditions. In this work we present a new PVD sputtering technique to process topologically complex and bicontinuous thin film microstructures that are dense with interfaces. Using the innovative High-power Impulse Magnetron Sputtering, or HiPIMS, technique to co-deposit immiscible Cu and Fe, the direction of phase separation with respect to a substrate can be manipulated via the deposition conditions and the introduction of metal ions during deposition that is unique to HiPIMS. This level of control -- which can be expanded to other FCC/BCC immiscible systems -- over phase separated morphologies allows for governable interface crystallography, chemistry, shape, and defect structure. All of these parameters will broaden understanding of the dynamic mechanical response of complex, multiphase materials.

10:45 AM MS01.10.08
SRO and Planar-Slip Assisted Deformation Twinning in a CrCoNi Medium-Entropy Alloy (MEA) Ruopeng
The emerging concept of multiple-principle element alloys have received tremendous interest in the last decade due to the unprecedented mechanical properties [1]. The CrCoNi-based, fcc single-phase alloy exhibits exceptional tensile ductility, fracture toughness and impact resistance thanks to its continuous work hardening rate, high frictional forces on dislocations and the tendency of nano-twin nucleation. The ability of maintaining the mechanical properties at very large plastic strain is especially attractive for potential structural applications.

Traditionally, the CrCoNi MEA is treated as a random solid solution, where atoms form a random distribution in the lattice. Nevertheless, it is reported that chemical short-range order could form in the alloy to lower the energy, thus, changing the stacking fault energy of the alloy and affecting the mechanical properties [2]. Such formation, along with the impact on the mechanical properties has been experimental observed in our previous study. The formation of SRO significantly increases the stacking fault energy and induces a wavy-to-planar slip transition.

In binary alloy systems, the formation of SRO usually leads to deformation localization and jeopardized ductility due to the glide plane softening effect and the subsequent planar dislocation slip [3, 4]. However, in the CrCoNi MEA, the ductility remains unaffected with the SRO and planar slip present. Microscopically, the formation of a nano-twin/planar slip network was observed despite the larger stacking fault energy. We speculate that the planar slip could reduce the local stacking fault energy by interrupting the SRO structure and provide nucleation sites for deformation twinning. A new twinning mechanism was proposed based on the TEM observation and theoretical calculations.

11:00 AM MS01.10.09
Nanoindentation Based Properties of Laser Peened Additively Manufactured Inconel 718 Superalloy
Tyler Palma1, Michael Munther1, Montu Sharma2, Lloyd Hackel2, Ali Beheshti3 and Keivan Davami1; 1The University of Alabama, United States; 2Metal Improvement Company, Surface Technologies, Curtiss Wright, United States; 3George Mason University, United States

Additive manufacturing (AM) is a novel technology that is transforming product design, manufacturing, and marketing. While the technique needs to be studied to address current challenges, a meticulous look into possible post-processing techniques for material property modifications seems necessary. Laser peening (LP) is a technique that is used as a post-processing method to optimize the service lives of critical components for various applications by inducing compressive residual stresses that increase the material’s resistance to surface-related failures, such as fatigue, fretting fatigue, corrosion-fatigue, and stress corrosion cracking. Herein, the effects of LP on the nanomechanical properties of additively manufactured Inconel 718 (IN718) are reported. AM cubic specimens peened without a protective overlay were evaluated under vigorous microscopy and nanomechanical studies. Depth sensing through hardness and modulus mapping was conducted to evaluate the plastic deformation and hardness enhancement introduced by the process. X-ray diffraction was used to measure the residual stresses to correlate hardness and residual stresses. The results showed that LP induces plastic strain in the surface and beneath the surface of the material that represents itself by a moderate increase in hardness (~20% to 30%). Slight changes in the elastic modulus were also recorded in LP specimens.

Structural Evolution and Mechanical Evaluation of In Situ Amorphous Steel Matrix Composites
Arash Yazdani1, Darren Dewitt1, Zezhou Li1, Haocheng Quan1, Wei Huang2, Günther W. Höhne3, Scott T. Misture4, Javier Garay1, David Kisailus1, Marc Meyers1 and Olivia Graeve1; 1University of California, San Diego, United States; 2University of California, Riverside, United States; 3University of Ulm, Germany; 4Alfred University, United States
SAM2×5 is an amorphous steel with a chemical composition of Fe₄₉.₇Cr₁₇.₇Mn₁.₉Mo₇.₄W₁.₆B₁₅.₂C₃.₈Si₂.₄. In this study, we have determined the crystallinity of the dense specimens of our bulk metallic glass using a novel differential scanning calorimetry technique. The dense specimens were prepared using the spark plasma sintering (SPS) technique at a heating rate of 500°C/min, a pressure of 100 MPa, and temperatures ranging from 615 to 675°C. Room and high temperature X-ray diffraction results showed that increasing the SPS temperature resulted in the devitrification of mainly carbide-based phases from the amorphous matrix. TEM observations showed that crystalline domains of less than 20 nm in size are uniformly distributed within the amorphous matrix. The average macro and micro compressive strength values of the specimens was between 1.7 and 2.2 GPa. Split Hopkinson Pressure Bar tests were carried out to measure the mechanical response of the sintered specimens under dynamic deformation, showing a yield strength of 2200 MPa under a strain rate of 900 s⁻¹.

Temperature Dependent Morphology of Immiscible Binary Alloys for Applications of High Strain Rate Deformation Max Powers, Benjamin K. Derby and Amit Misra; University of Michigan, United States

Cu-X alloys, where X is a BCC metal from group V or VI in the periodic table, are nearly completely immiscible through a wide range of compositions and processing temperatures under the melting temperature of Cu. Cu-X thin films produced via physical vapor deposition will self-assemble into phase separated regions during fabrication. These phase separated regions have atomically resolved interfaces that impede the movement of dislocations in the system, resulting in elevated mechanical performance compared to bulk samples. The extent of elevated mechanical performance will depend on the microstructure morphological geometries. Micron thick films of Cu-Ta were deposited via magnetron sputtering at four distinct temperatures: 25, 400, 600, and 800 °C. STEM and TEM characterization revealed the films deposited at room temperature to consist of nanocrystalline Cu-Ta matrix and films deposited at elevated temperatures as having interwoven bicontinuous structures with large Cu islands within a Cu-Ta matrix. Nanoinindentation has demonstrated a direct correlation between the morphologies and the observed mechanical properties of hardness and Young’s modulus. The distinct morphologies arise due to the highly disparate temperature-dependent mobilities of the constituent elements. The morphologies can be affiliated with applications in extreme mechanics as a bicontinuous structure adds a third dimensional component to the dislocation-interface interaction and the exact thickness of phase separated regions in the film will control the dominant yielding mechanism during deformation.

11:45 AM MS01.10.12
Effect of Cold Rolling on the Indentation Size Effect and Related Mechanisms in Zr₄₁.₂Ti₁₃.₈Cu₁₂.₅Ni₁₀Be₂₂.₅ Abhilash Gunti¹, Parijat P. Jana¹, Min Ha Lee² and Jayanta Das¹; ¹IIT Kharagpur, India; ²Korea Institute of Industrial Technology, Korea (the Republic of)

Zr₄₁.₂Ti₁₃.₈Cu₁₂.₅Ni₁₀Be₂₂.₅ (Vitrelloy-1) bulk metallic glass (BMG) has been cold rolled at room temperature up to 4.5%, 10%, 20% and 31% reductions. The glassy nature of the as-cast and cold rolled samples has been investigated by the differential scanning calorimeter (DSC) and x-ray diffraction (XRD). The indentation size effect (ISE) in Vitrelloy-1 BMG has been examined during nanoindentation at various maximum loads in the range of 50 mN- 500 mN before and after cold rolling. It has been observed that the size effect varies in differently cold rolled specimen. The nano-hardness and the reduced modulus of the as-cast and the cold rolled samples have been reduced with the increase of the indentation depth. Whereas, the hardness of the cold rolled samples increased in 4.5% and 31%, whereas decreased in 10% and 20% than the as-cast sample for all the maximum loads during nanoindentation. Such variation of the hardness and reduced modulus is linked with the free volume change in the glassy structure upon cold rolling. The observed ISE of as-cast and cold rolled samples has been correlated with the dynamic mechanical softening during nanoindentation and the friction between indenter and sample.
Phase Transitions in Strontium Oxalate at High-Pressure

Iskander G. Batyrev, Petrika Cifligu, Jennifer A. Ciezak-Jenkins and Michael Pravica

U.S. Army Research Laboratory, United States; University of Nevada, United States

We report theoretical and experimental investigations on the structure of strontium oxalate and Raman spectra at high-pressure. The system has shown progress in the generation of CO₂ and in the synthesis of high-energy polymeric carbon monoxide after X-ray irradiation facilitating reactions such as: SrC₂O₄ + hv -> SrCO₃ + CO₂ + poly-CO [1]. Density functional perturbation theory was used to calculate the zone center optical phonons and to identify the vibration modes in terms of atomic displacements. The simulations were compared to experimental Raman spectra and previous IR spectroscopic studies [1] in an effort to elucidate the details of phase transition between monoclinic and triclinic phases. Additional calculations of the phonon dispersion and density of states, as well as the electronic band structure and elastic moduli were performed to gain better insight into the phase behavior in strontium oxalate under high pressure.

Defect Formation in 4 nm Au Nanocrystals under High Pressure

Abhinav Parakh, Sangryun Lee, Lindsey Hanson, Mehrdad T. Kiani, David Doan, Martin Kunz, Andrew Doran, Seunghwa Ryu and Wendy Gu

Stanford University, United States; Korea Advanced Institute of Science and Technology, Korea (the Republic of); Trinity College, United States; Lawrence Berkeley National Laboratory, United States

Permanent, plastic deformation occurs in crystalline metals that are subjected to large strains. This is due to the irreversible interactions between dislocations, and between dislocations and microstructural features such as grain and twin boundaries. Recently, reversible deformation from large strains has been observed in a number of metallic nanostructures[1,2]. Rapid surface diffusion and reversible dislocation motion have been proposed as two possible mechanisms for this behavior,[1,3] but the correct mechanism has not been determined conclusively.

To resolve these issues, 3.9 nm Au nanocrystals were compressed under non-hydrostatic pressure in a diamond anvil cell (DAC) up to ~7 GPa. These nanocrystals were colloidally synthesized, and contained twins. Structural changes were observed using in-situ x-ray diffraction (XRD), optical absorbance spectroscopy and MD simulations. We observed that XRD peak position and LSPR peak position recovered completely with pressure cycle, which indicates that the elastic strain in the lattice and the shape of the nanocrystal were recoverable. The XRD peak width increased with pressure and remained at larger values even after unloading, which indicates that the defects like stacking faults and dislocations were nucleated in the nanocrystals and remained in the nanocrystal even after unloading. LSPR peak height also reduced with pressure cycle, which corroborates the XRD results and indicates that defects form in the nanocrystals.

MD simulations were used to compress nanocrystals of a similar size. Partial and full dislocations were nucleated at the surface of the nanocrystals. Some of the full dislocations interacted strongly with twin boundaries within the nanocrystals and were present in the nanocrystal even after unloading. XRD patterns were generated from the MD simulations, and found to be similar to the experimental XRD patterns. Hence, we conclude that the interaction of dislocations and twin boundaries is responsible for the permanent deformation observed in the nanocrystals. This dramatically changes our current understanding of dislocation nucleation and recovery in such small nanocrystals.

Heterostructured Metastable Aluminum-Magnesium System Processed by High-Pressure Torsion

Megumi Kawasaki, Jae-Kyung Han and Klaus-Dieter Liss

Oregon State University, United States; Guangdong University of Education, China
Separate disks of Al and Mg were mechanically bonded through high-pressure torsion (HPT) processing for 100 turns under a compressive pressure of 6.0 GPa. The material after processing was followed by natural aging at room temperature for 60 days in order to evaluate the microstructural stability. The materials characterization revealed that such high straining through the HPT processing synthesized a bulk nanostructured metastable Al with grain sizes of 35-40 nm in a state of supersaturated solid solution with the measured maximum Mg solubility of ~38.5 at.%. A superhard Al solid solution with the maximum Vickers microhardness value of ~370 was observed consistently across the disk diameter and the high hardness was considered mainly due to grain refinement and solid solution strengthening. X-ray diffraction analysis was applied to quantitatively evaluate the supersaturated solubility of Mg in Al and the stability of metastability with computing microstrain and crystallite size of the aged material. Significantly high microstrain of 0.0202 was observed for the metastable Al and it was even enhanced to 0.0274 after natural aging. It was attributed solely to the high supersaturation of Mg solute in Al. Moreover, advanced analysis using high-energy synchrotron radiation was conducted to visualize the uncovered phase and texture heterogeneity in the metastable Al alloy. This study demonstrates one of the ultimate states of metals when they are diffusion bonded mechanically under severe plastic straining at ambient temperatures.

**The Transformation of Glassy Carbon to Diamond at High Pressure Using Pulse Laser Heating**

Brenton Cook, Thomas Shiell, Sherman Wong, David McKenzie, Matthew Field, Bianca Haberl, Reinhard Boehler, Jodie Bradby and Dougal G. McCulloch

RMIT University, Australia; The University of Sydney, Australia; Oak Ridge National Laboratory, United States; The Australian National University, Australia

The synthesis pathway to diamond from graphitic precursors using high pressures and temperatures has been studied and applied for many decade [1]. Industrial manufacturing methods require temperatures up to 1500 K, pressures between 5-6 GPa, and the use metallic catalysts [1]. Without these catalysts the pressure and temperature conditions required are far more extreme to overcome kinetic energy barriers. Recently, there has been considerable interest in the synthesis of pure, catalyst-free diamond and other novel forms of carbon from non-crystalline precursors, with the hope that the energy barrier impeding transformation will be reduced. For example, nanocrystalline diamond has been formed from carbon nanotubes following compression to 17 GPa at 2500 K [2]. The size of the nanocrystals were found to be similar to the diameter of the nanotubes, demonstrating that the type of precursor can influence the microstructure of the resulting diamond. Sumiya et al. observed the formation of nanocrystalline diamond (<10 nm in diameter) from a glassy carbon (GC) precursor when compressed for 10s at pressures of ~20 GPa and temperatures of ~3000 K [3]. When compressed for longer times, the nanocrystalline diamond evolved into larger crystals then exhibited a lamellar structure. Recently, it has been reported that it is possible to create an amorphous form of diamond has been synthesized from GC following compression to 50 GPa and laser heating to ~1800 K [4]. However, this previous work has only investigated the compression of non-crystalline graphitic precursors within a limited temperature range. There is a need for a more thorough experimental study at temperatures above 3000 K, in the region of the PT diagram encompassing the liquid-diamond phase boundary.

In this study, GC samples were loaded into diamond anvil cells with an Ar pressure medium and compressed to 16 GPa. A 1070 nm pulse laser was then used to heat the samples to temperatures ranging from 1900-4500 K. A total of 15 samples were made for *ex-situ* analysis using raman spectroscopy, scanning electron microscopy and transmission electron microscopy. At low temperatures (1900-2200 K), the GC was found to have transformed into an oriented graphitic material in which its graphene layers are preferentially aligned perpendicular to the compression axis. Nanodiamonds (~10-200 nm) begin to form near the surface of the GC at temperatures of ~2200 K. These nanodiamonds increase in size and density as the temperature increases up to 4500 K. Interestingly, above ~3500 K voids were observed in the microstructure, some of which contained Ar, which appears to have an epitaxial relationship with the surrounding diamond. This observation supports the proposition that at these high temperatures, the GC may have entered a liquid state prior to the formation of diamond crystallites.

Anomalies in Mechanical Response During Microscale Extrusion of Metals Bin Zhang and Wen Jin Meng; Louisiana State University, United States

Small scale metal forming, with characteristic forming dimensions ranging from millimeters down to micrometers, is of current interest in manufacturing of miniaturized components and devices. As compared to subtractive manufacturing techniques such as micro mechanical milling and micro electrical discharge machining, small scale metal forming offers the potential of high throughput, low cost, and dimensional repeatability. Metal forming operations typically involve deformation to large plastic strains [1]. Changes in the mechanical response of materials during forming as the characteristic forming dimension decreases to the meso/micro scale prevents straight forward adoption of macroscale forming practices to the small scales, such changes thus need to be better understood.

We report our recent results on characterizing the mechanical response and deformation characteristics of Cu in microscale axisymmetric reversion extrusion [2]. Specifically, the characteristic plastic strain for the extrusion process and the influence of the initial grain size of extruded material on the extrusion mechanical response and shape of extruded parts were examined through scanning electron microscopy (SEM), electron backscatter diffraction (EBSD), and transmission electron microscopy (TEM). We show that the mechanical response of extrusion exhibits deviations from continuum scaling behavior as the characteristic forming dimension becomes small as compared to the initial grain size. Materials based justification to the observations will be discussed.

Quasi-Plastic Zone Characterization of Regular and Si-Doped Boron Carbide Sisi Xiang and Kelvin Y. Xie; Texas A&M University, United States

Boron carbide (B4C) is a hard and lightweight material, which has many engineering applications. However, B4C loses its strength and toughness when subjected to high shear stresses. To improve its mechanical properties, the pervious computation work has suggested micro-alloying B4C with Si. Very limited understanding of the failure mechanism of boron carbide, both Si-free and Si-doped, under high shear stress conditions is due to the lack of direct experimental observation at the relevant length scale for damage zone. Here we investigate the local deformation microstructure of regular and Si-doped boron carbide under indents, using a novel precession electron diffraction technique and high-resolution transmission electron microscopy. We observed that Si-doped boron carbide displays dispersed micro-cracks, while Si-free boron carbide exhibits major local cracks and low interfaces.

Superior Energy Dissipation by Nanoscale Semi-Crystalline Polymer Films under High-Speed Micro-Projectile Impacts Jizhe Cai and Ramathasan Thevamaran; University of Wisconsin-Madison, United States

Developing revolutionary lightweight protective materials with superior specific energy dissipation and specific strength is critical for many impact mitigation applications—from ballistic protection of soldiers to foreign object damage prevention in air and spacecraft. Recent advancements in high strain rate experimental characterization
techniques have revealed the excellent properties of nanoscale polymer thin-films over conventional bulk polymers. For glassy polymer thin-films, decreasing the film thickness effectively modify the polymer chain morphology and mobility, therefore bringing additional energy dissipation mechanisms, such as crazing, yielding, and adiabatic heating, which increases the projectile’s kinetic energy required to perforate the film. Comparing to glassy amorphous polymer thin-films, semi-crystalline polymers exhibit more complex deformation mechanisms, being strongly related to their microstructure, including crystallinity and molecular conformation. In this work, we study the dynamic mechanical behavior of PVDF-TrFE polymer thin-films with thicknesses varied from 75 nm to 400 nm using a micro-ballistic testing apparatus with projectile speeds ranging from 200 m/s to 1000 m/s. We examine the size- and strain-rate-dependency of the specific penetration energy and the dynamic deformation mechanisms of the thin-films. The polymer films that are thinner than 100 nm exhibit superior protective properties, with specific penetration energy as high as 3.7 MJ/Kg for 1000 m/s impact, about 5 times larger than bulk steel plate from macroscopic experimental measurements. It is demonstrated that as the film thickness is decreased or impact projectile speed is increased, there is increase in the specific penetration energy and evident transition in failure mechanisms of the film. The microstructure of PVDF-TrFE thin-films is further modified by applying appropriate heat-treatment. We additionally study the relationship between intrinsic crystalline microstructure and dynamic mechanical properties in semi-crystalline polymer thin-films. Understanding those key structure-property relations in nanoscale semi-crystalline polymer thin-films will provide promising approaches for developing novel flexible and lightweight polymer-based protective materials.

Microstructural Instability of Polycrystalline Zirconia under High Temperature and Extreme Electrochemical Conditions Yanhao Dong¹, I-Wei Chen² and Ju Li¹; ¹Massachusetts Institute of Technology, United States; ²University of Pennsylvania, United States

Electroceramics are often subject to high temperature, reducing/oxidizing environment and/or applied electric field. Such is the case for stabilized zirconia during field-assisted processing and many applications in solid oxide fuel/electrolysis cells, thermal barrier coatings and others. Against the conventional wisdom that stoichiometry and microstructure of zirconia is insensitive to reduction because of its large bandgap of ~5 eV, we found hugely enhanced grain growth under severe electrochemical reduction, creating (i) a graded microstructure with 100 times grain size difference at the cathode and anode side and (ii) a sharp grain size transition halfway across the electrically loaded sample. Continuum-level transport theory and first-principles calculations were conducted to gain better mechanistic understandings, which bring out the hidden yet critical role of electronic defects (localized electrons on Zr⁴⁺, i.e. reduced cations; and localized holes on O²⁻, i.e. oxidized anions) on microstructural evolution in nominally ionic compounds under extreme conditions.

Suboptimal Toughness of Uniform Grain Boundary Distribution Edwin Chiu, Michael J. Demkowicz and Ankit Srivastava; Texas A&M University, United States

Fracture toughness of a material depends on the crack path, which in turn depends on the material microstructure. In a variety of technologically important structural materials, fracture involves preferential crack nucleation and growth along the grain boundaries particularly under extreme environmental loading conditions. For example, stress corrosion cracking, hydrogen embrittlement and low damage tolerance are all dominated by the grain boundaries. Over the past decades, our understanding of the relation between specific grain boundaries and their resistance to the aforementioned processes has increased along with the ability to choose processing routes leading to specific grain boundary character distributions, geometrical properties of the grains and chemical parameters. Recently, we have shown that the crack growth resistance of a crack propagating through a grain boundary network can be described by discrete unit events, and the final crack path in a specified grain boundary network is not necessarily the path of
least resistance. This raises an important question; if the crack path is not dictated by the path of least resistance then can we change the crack path through a grain boundary network by introducing heterogeneities such as weak grain boundaries. The extent to which an admixture of weak grain boundaries can enhance the fracture toughness of a grain boundary network and the corresponding toughening mechanism will be discussed.

Thermal Conductivity of Earth Minerals at Extreme Conditions Irina Chuvashova, Zachary Geballe and Alexander Goncharov; Carnegie Science, United States

Thermal transport properties of minerals and melts at high pressures and temperatures is of central importance to the evolution and dynamics of planets. The pressure of the Earth’s interior continuously increases with the depth from the surface of the Earth: several hundred MPa at the region of the crust, ∼20 GPa at the upper mantle and ∼130 GPa at the lower mantle. Precise data of thermal conductivity and/or thermal diffusivity for minerals at elevated pressure make it possible to estimate the heat budget in the Earth.

In the Earth’s core and mantle, thermal conductivity of minerals containing dominantly iron-bearing silicates and iron alloys defines the heat and energy flow as well as the geodynamo over the Earth’s history. Direct measurements of thermal conductivity of Earth minerals at extreme pressures and temperatures are very challenging; the available data are limited, inconclusive, and not corresponding to the theoretical calculations. Therefore, there is a lack of experimental data, which is currently substituted by extrapolations and estimations.

In the present work, we have studied the direct measurements of thermal conductivity of iron-bearing and non-iron-bearing minerals as well as iron alloys at different high pressure and temperature conditions up to 130 GPa using diamond anvil cells with continuous and pulse laser heating. Fast measurements allowed us to resolve the heating response through the sample and understand the tendency of minerals behavior within the mantle and core. The analysis of the obtained experimental data is currently in progress and the results will be reported at the conference.
Graphene, the prototypical 2D material, has attracted a considerable degree of attention for device applications since its discovery in 2004. The material is commonly synthesized via chemical vapor deposition (CVD) and can contain a variety of intrinsic and extrinsic defects. To enable applications that utilize the unique properties intrinsic to graphene, these defects will not only need to be controlled during synthesis, but will also need to be engineered to different degrees and patterns after synthesis. The current methods of defect engineering and patterning of graphene are either uncontrollable or result in deleterious side effects (i.e. dangling bonds) that reduce materials performance in fabricated devices.

In this work, we use electron-beam (e-beam) chemistry to engineer defects in CVD graphene by performing a highly controlled and tunable process that is ideal for photonic and electronic device fabrication without the use of photoresist. To enable e-beam chemistry on graphene, radiolysis products were produced by the interaction of the e-beam with water vapor inside a scanning electron microscope (SEM) [1]. These products reacted with the carbon atoms of the graphene at precise locations scanned by the e-beam. E-beam chemistry was performed on CVD graphene transferred using PMMA onto a Si/SiO2 substrate [1]. The effectiveness of this precise maskless, resistless process in creating defects at precise locations were verified using different characterization techniques. Raman spectroscopy in the defect engineered areas of graphene revealed the presence of large defect band signals at ~ 1350 cm\(^{-1}\) (D-band) and at ~ 1625 cm\(^{-1}\) (D'-band) with peak widths < 50 cm\(^{-1}\). To explore the degree of control in defect engineering exerted via e-beam chemistry, e-beam parameters (e.g. dwell-time, scan-rate, pressure etc.) were varied and their effect on intensity ratios (such as D/G ratio, where G-band corresponds to the graphitic peak at ~ 1590 cm\(^{-1}\), D/D' ratio, and G'/G ratio, where G' is the second order graphitic peak at ~ 2690 cm\(^{-1}\)), peak widths and average distance between defects (LD) were studied. Raman intensities were also theoretically calculated by considering scattering of incident photon by the phonons, electrons and holes in defect engineered graphene [2]. Comparison of experimental and theoretical analysis of Raman spectra revealed the presence of out-of-plane (sp\(^3\)-type; LD > 5 nm and IM/ID ~ 13) defects with no vacancies on the graphene lattice.

Our study also revealed the high resolution patterning via e-beam chemistry, as we observe negligible D-band intensity near the boundary of the defect engineered area. Atomic force microscopy images show higher phase contrast (as observed for oxidized graphene [1]) on the e-beam patterned regions compared to the non-patterned regions with ~ 100 nm spatial resolution. In addition, the e-beam engineered defects could be healed by annealing graphene at ~ 300 °C in air, which resulted in the complete removal of the D-band, thus demonstrating that the e-beam chemistry process is reversible and does not damage (or introduce vacancy in) the graphene lattice itself. E-beam chemistry thus enables us to employ a mask-less, resist-free process to directly engineer reconfigurable defects in graphene.

mechanical stretchability accompanying well-preserved electrical integrity and modulated transport properties. We employed a concept of strain engineering inspired by an ancient paper-cutting art, known as kirigami patterning, and developed 2D TMDs-based kirigami electrical conductors. Specifically, we directly integrated 2D platinum diselenide (2D PtSe$_2$) layers of controlled carrier transport characteristics on mechanically flexible polyimide (PI) substrates by taking advantage of their low synthesis temperature. The metallic 2D PtSe$_2$/PI kirigami patterns of optimized dimensions exhibit an extremely large stretchability of ~2000% without compromising their intrinsic electrical conductance. They also present strain-tunable and reversible photo-responsiveness when interfaced with semiconducting carbon nanotubes (CNTs) benefiting from the formation of 2D PtSe$_2$/CNT Schottky junctions. Moreover, kirigami field-effect-transistors (FETs) employing semiconducting 2D PtSe$_2$ layers exhibit tunable gate responses coupled with mechanical stretching upon electrolytes gating. The exclusive role of the kirigami pattern parameters on resulting mechano-electrical responses was also verified by finite-element modeling (FEM) simulation. These multifunctional 2D materials in unconventional yet tailored 3D forms are believed to offer vast opportunities for emerging electronics and optoelectronics.

9:00 AM MS02.01.03
The Role of Strain and Defects on the Electronic Properties of Atomically Thin Semiconductors Chitraleema Chakraborty$^1$, Christopher J. Ciccarino$^1$, Dirk Englund$^2$ and Prineha Narang$^1$; $^1$Harvard University, United States; $^2$Massachusetts Institute of Technology, United States

Atomically thin semiconductors have gained a lot of interest owing to their unique quantum optical and optoelectronic properties which are strongly dependent on inevitable structural distortions due to strain and defects in their lattice [1-2]. In this work, we study the modification of intrinsic electronic properties using first-principles methods due to the introduction of strain as well as defects in monolayer transition metal dichalcogenides (TMDCs). Our recent theoretical results predict the importance of spin-orbit and electron-phonon interaction on the studied dynamics [3-4]. Here we present the effect of biaxial strain on microscopic interactions in monolayer TMDCs. Our calculations predict a modulation of the spin-orbit splitting ($\approx$ 13 meV/%) at the K point of both band edges as a function of strain, where we also find a crossover from a direct to indirect band-gap. Carrier coupling with phonons is also modified with increased strain levels due to changes in intervalley energetics. The resulting dynamics from the static effect of strain were captured via calculation of the wavevector-resolved electron-electron and electron-phonon scattering rates. Along with strain, the formation of atomic defects is unavoidable in 2D materials with currently available growth techniques [1]. Nevertheless, there is a myriad of functionalities in modern optoelectronic and nanophotonic devices that leverage quantum defects including the recent demonstration of single photon emitters in 2D materials [2,5]. Therefore, we present theoretical calculations and analysis of the vibronic structure of a singly charged sulfur vacancy in monolayer TMDCs. Further, we show a pathway to strain and defect engineering for tailoring the valley properties in monolayer TMDCs and enabling sources of quantum emitters that would provide a physical implementation of a localized qubit.

How Does Strain Modify the Electron Mobility of 2D MX2 Semiconductor Yuanyue Liu; The University of Texas at Austin, United States

The strain has been widely used to engineer the electronic properties of 2D transition metal dichalcogenide (MX2) semiconductor. Although there are lots of studies about the strain effects on the band gap, effective mass, excitons etc, much less is known about the mobility. Here using Boltzmann transport theory with the scattering rates determined from first principles, which allows us to accurately calculate the intrinsic (phonon-limited) mobility, we will show how does the isotropic strain modify the electron mobility of 2D MX2 semiconductor. Particularly, we find two distinct behaviors in these materials, which can be explained by a simple physical factor.
Understanding the deformability, flexibility, and bending of two-dimensional (2D) materials is critical for the realization of next-generation electronics and nanomechanical devices. While the mechanics of few-layer graphene have been studied for more than a decade, there is still no consensus on bending stiffness and how it scales with thickness [1-3]. Electron microscopy provides a powerful platform for addressing these challenges by enabling measurements of the conformation and strain of 2D materials at atomic resolution. Using aberration-corrected scanning transmission electron microscopy (STEM), we show that bending in few-layer graphene is dominated by slip and shear between the atomic layers. These results, in combination with density functional theory (DFT) simulations, reveal an unusual, curvature-dependent bending stiffness in few-layer graphene. Unlike in conventional metals where bending produces dislocations which stiffen and embrittle the crystal, we find that slip between the atomic planes of 2D materials dramatically softens few-layer graphene by rendering the layers nearly frictionless when it is curved.

We explore how the bending stiffness of few-layer graphene varies with both thickness and bending angle by systematically examining its conformation over atomically-sharp hexagonal boron nitride (h-BN) steps. These geometries offer direct control over two key variables: number of graphene layers and h-BN step height. Using aberration-corrected STEM images, we extract the bending profiles of few layer graphene over the h-BN steps as a function of the graphene thickness and curvature, then use these values to calculate the bending stiffness of few layer graphene. We find the bending stiffness of few-layer graphene decreases sharply as a function of bending angle, tuning by almost 400% for tri-layer graphene. This softening results from shear, slip, and the onset of superlubricity between atomic layers and corresponds with a gradual change in scaling power of bending stiffness with thickness, from cubic to linear as it is curved. These behaviors are a direct result of changes in atomic registry between the atomic layers; as few-layer graphene is bent, its interlayer interactions transition between two limits: the strong coupling characteristic of Bernal-stacked graphite and the weak, superlubric interactions characteristic of multi-walled carbon nanotubes. Our results indicate that the bending stiffness of few layer graphene can be orders of magnitude smaller than previously thought and provide a new lower limit for the fabrication of ultra-soft, high mobility electronic nanodevices based on 2D materials.

A challenge and opportunity in nanotechnology is to understand and take advantage of the breakdown in continuum mechanics scaling laws as systems and devices approach atomic length scales. Such challenges are particularly evident in two-dimensional (2D) materials, which represent the ultimate limit of mechanical atomic membranes as well as molecular electronics. For example, after more than a decade of study, there is no consensus on the bending modulus of few-layer graphene, with measured and predicted values ranging over two orders of magnitude, and with different scaling laws[1–5]. However, comparing these studies is challenging because they probe very different and often fixed curvatures or magnitudes of deformation. To unravel the discrepancy, a systematic measurement of bending stiffness versus deformation is needed. The results have practical implications on predicting and designing the stiffness of many 2D mechanical systems like origami/kirigami nanomachines, stretchable electronics from 2D heterostructures, and resonant nanoelectromechanical systems. Moreover, many studies implicitly use the bending modulus to extract important parameters like the interfacial adhesion and friction or to predict the wavelength of 3D rippling in strained membranes.
In this study, we combine atomistic simulation and atomic scale imaging to theoretically and experimentally examine the bending behavior of few-layer graphene. First, we experimentally probe the nanoscale bending by laminating few-layer graphene over atomically sharp steps in boron nitride(h-BN) and imaging the cross-sectional profile using aberration-corrected STEM. Second, we use DFT simulations to examine the bending of few-layer graphene under compression. By measuring the nanoscale curvatures, we extract the simulated and experimental bending modulus while varying both the number of layers and the degree of nanoscale curvature. We further apply this framework to measure the bending stiffness of van der Waals heterostructures, by stacking graphene-MoS$_2$ heterostructure on the terraced h-BN. We find remarkable agreement between the theory and experiment and observe an unexpected curvature dependent bending stiffness of few-layer graphene that deviates from continuum scale bending mechanisms. We find that the bending stiffness of few-layer graphene versus curvature corresponds with a gradual change in scaling power with thickness from cubic to linear. We find that the transition in scaling behavior originates from a transition from shear, slip and the onset in superlubricity between the graphene layers at the van der Waals interface, verified by a simple Frenkel-Kontorova model. In contrast to few-layer graphene, the graphene-MoS$_2$ heterostructure shows an additive bending stiffness for stacking each layer. Thus we evaluate the impact of superlubricity at the van der Waals heterostructure interface under bending deformation. Our results provide a unified model for the bending of 2D materials and show that their multilayers can be orders of magnitude softer than previously thought, among the most flexible electronic materials currently known.

2D Memory—An Application of Defects in Monolayers Saban Hus, Ruijing Ge, Xiohan Wu, Jack Lee and Deji Akinwande; The University of Texas at Austin, United States

This presentation focuses on the progress on 2D nanomaterials towards greater scientific understanding and advanced engineering applications. In particular the talk will highlight our pioneering work on monolayer memory (atomristors) that can enable various applications including zero-power devices, non-volatile RF switches, and memristors for neuromorphic computing. Non-volatile memory devices based on 2D materials are an application of defects and is a rapidly advancing field with rich physics that can be attributed to sulfur vacancies or metal diffusion. Recent studies based on atomistic modeling and imaging as identified point and cluster defects as primarily responsible for the non-volatile memory effect. Areas with defects typically exhibit memory effect while clean defect-free areas are absent of memory effect. Much work remains to be done to elucidate the underlying phenomenon and realize optimized devices for practical adoption.

Ultra-High Uniaxial Strain of Freestanding 2D Materials Jakob A. Genser, Maximilian G. Bartmann, Viktoria Ritter, Daniele Nazzari, Ole Bethge, Emmerich Bertagnolli and Alois Lugstein; TU Wien, Austria

Due to the ever-growing need of small-scale and high-performance semiconductor devices, two-dimensional (2D) materials have emerged as promising candidates for future device integration. Due to their exceptional mechanical properties, strain engineering is effectively used to exploit induced mechanical strain in order to tune the carrier mobility and optoelectronic properties of 2D materials. Although strain in 2D materials has been well studied in recent years, most straining methods rely on stretchable substrates to introduce strain and are thus limited to rather low strain values. Here, we present a novel straining approach enabling the application of ultra-high uniaxial strain on freestanding 2D materials and 2D heterostructures, while simultaneously allowing in-situ electrical and optical characterization.

The micromechanical straining devices patterned from SOI wafers enables ultra-high strain levels up to 15%. Mono and few layer 2D materials are transferred onto the straining device using state of the art mechanical exfoliation and dry viscoelastic stamping techniques minimizing unintentional contaminants. To enable reliable electrical contacts and to avoid slipping of the 2D materials they are pinned down by extended Ti/Au contacts. The applied strain was investigated by in-situ Raman measurements in a back-scattering geometry using a confocal μ-Raman setup. The Raman-active modes of graphene, hBN and MoS$_2$ are very sensitive to strain-induced shifts and are clearly observable during the experiments, thus proving the viability of this approach.

Light Scattering and Emission from Coupled Layered Materials Andrea C. Ferrari; University of Cambridge, United Kingdom
Graphene is an ideal material for optoelectronic applications. Its photonic properties give several advantages and complementarities over Si photonics. I will show that graphene-based integrated photonics could enable ultrahigh spatial bandwidth density, low power consumption for next generation datacom and telecom applications.

Heterostructures based on coupled layers of atomic crystals have a number of properties often unique and very different from those of their individual constituents and of their three dimensional counterparts. I will show how these can be exploited in novel light emitting devices, such as single photon emitters, and tuneable light emitting diodes. The role of defects and strain and non-radiative recombination channels will be discussed.

Electrical Manipulation of Exciton Dynamics in Nanodevices Based on Atomically Thin Heterostructures
Luis A. Jauregui; University of California at Irvine, United States

Van der Waals heterostructures constructed of 2-dimensional (2-D) materials such as single layer transition metal dichalcogenides (TMDs) have sparked wide interest because of their large excitonic binding energy, allowing the exploration of novel quantum optical effects in a solid-state system and new opto-electronic devices. In this talk, I will discuss our results in van der Waals heterostructures formed by stacking together two different TMDs (forming a staggered heterojunction) encapsulated with hexagonal boron nitride (h-BN) with electrical contacts in each layer and a dual gate configuration. Interlayer excitons, with electrons and holes residing in spatially separated quantum wells, have long lifetimes (200nS, 5 orders of magnitude longer than intralayer exciton lifetimes). Because of their repulsive Coulomb interaction, they diffuse across the entire sample (20 mm long) driven by interaction, allowing their manipulation towards condensation. Also, we observed and manipulated long-lived charged interlayer excitons which can be used as carriers for quantum information. Interlayer excitons are important for novel opto-electronic devices such as high-temperature interlayer exciton condensates, valley-tronic devices, near-infrared tunable lasers and light emitting diodes. Our work opens a new frontier to explore novel low-dimensional opto-electronic devices and circuits.

2:00 PM MS02.02.02
Robotic Mechanical Exfoliation of Graphite and BSCCO
Young J. Shin1, Boyu Wang2, Minh H. Nguyen2, Kevin Yager1 and Charlse T. Black1; 1Brookhaven National Lab, United States; 2Stony Brook University, The State University of New York, United States

Van der Waals heterostructures are made of stacked atomically thin 2D materials, providing access to novel properties relevant to quantum information sciences. Despite the exciting promise of stacked 2D heterostructures, fabrication remains a laborious low-yield process requiring considerable human expertise and time. We present the development of an automatic robotic exfoliator, meant to automate the repetitive manual tasks of mechanically exfoliating thin flakes of such materials, as well as optically searching for flakes of desired characteristics. We provide statistical mappings between robotic exfoliation motion parameters and flake characteristics, such as thickness, in-plane size, and yield. We present preliminary results demonstrating the exfoliation of graphene, and BSCCO (Bi2Sr2CaCu2O8+y) flakes. In the near future, we will expand this methodology to a wider range of 2D materials.

2:15 PM MS02.02.03
Deep Learning Enabled Measurements of Single-Atom Defects in 2D Transition Metal Dichalcogenides with Sub-Picometer Precision
Chia-Hao Lee1, Chuqiao Shi1, Di Luo1, Abid Khan1, Nahl Sobh2, Blanka Janicek1, Sangmin Kang1, Wenjuan Zhu1, Bryan Clark1 and Pinshane Huang1; 1University of Illinois at Urbana-Champaign, United States; 2Beckman Institute for Advanced Science and Technology, University of Illinois at Urbana-Champaign, United States
Defect and strain engineering of 2D materials is an emerging area of research, where homogeneous or heterogeneous alloying can stabilize exotic electronic phases such as Weyl semimetals or pattern the properties of 2D nanoelectronics and optoelectronics on the nanoscale. Aberration-corrected scanning transmission electron microscopy (STEM) is an important tool to study how atomic defects such as vacancies and substitutional dopants impact the structure and properties of 2D materials. Yet, high-precision characterization of defects in 2D materials remains challenging because they are irradiation sensitive, making it difficult to achieve high resolution and signal-to-noise ratio (SNR) measurements without modifying the intrinsic structure. Here, we apply deep learning techniques based on convolutional neural networks (CNNs) to process large volumes of atomic-resolution images of 2D transition metal dichalcogenides (TMDCs). CNNs have revolutionized image recognition in fields such as medical diagnosis, weather forecasting, and facial recognition; recently, they have been applied to detect defects in atomic-resolution STEM images [1]. In our work we utilize fully convolutional network (FCN), a variant of CNN, to identify defects in monolayer WSe₂₃Tex. Using the resulting data, we determine local picometer-scale strain fields to understand how single-atom defects interact with one another and the surrounding lattice.

In order to enable pm-scale structural measurements in 2D materials, we use an approach analogous to the single-particle reconstruction methods used in cryo-electron microscopy. First, we construct FCN models to identify and classify defects, including substitutions and single and divacancies. We then generate high quality class-averaged images of each defect type by rigid-registration [2] and averaging hundreds of nominally identical atomic defects. These methods result in final images with high SNR yet low dose acquisition, allowing us to extract the detailed atomic structure of defects such as single vacancies, which are highly sensitive to electron beam irradiation. Finally, we measure the locations of each atomic column using 2D Gaussian fitting and determine the local strain. We show that we are able to measure projected atom-atom separations with precisions of up to 0.38 pm, a 22-fold improvement over measurements using single images—representing the highest reported precisions for experimental strain measurements at single-atom defects. We find that two Te substitutions on top of each other in WSe₂₃Tex increase the projected W-W nearest neighbor distance by 4.1 pm, while single Se vacancies decrease the W-W distance by 16.3 pm. Picometer-scale precision also enables studies of long-range strain fields around single-atom defects, up to 1 nm away from the defect center. Our experimental strain maps quantitatively match simulations of continuum elastic theory using Eshelby’s inclusion approach [3]. In summary, we have developed measurement techniques using FCN to locate, classify, and measure the local structure of single-atom defects in 2D materials with sub-picometer precision for the first time.

Novel Quantum Light Sources in Layered Materials Mete Atature; University of Cambridge, United Kingdom

The attractiveness of single-photon sources in layered materials stems from their ability to operate at the fundamental limit of single-layer thickness, foreseeing high extraction efficiency and providing the potential to integrate into conventional and scalable high-speed optoelectronic device systems. In this talk, I will discuss recent progress on scalable and deterministic generation of quantum-emitter arrays in layered materials, charge and spin control, and progress towards confinement of interlayer excitons.

3:30 PM MS02.02.05
Stability, Scalability and Reproducibility—A Study of Emission Sites in CVD Grown Monolayer h-BN James
Defect-induced sub-bandgap emission from hexagonal boron nitride (hBN) is not only hugely interesting for quantum technology, opening a promising route for the design of next-generation single-photon sources [1], but equally offers a new high-throughput characterisation pathway for large-area h-BN films, an urgent requirement given the recent progress in synthesising h-BN; particularly by chemical vapour deposition (CVD) [2]. We present our latest data employing multidimensional super-resolution fluorescence microscopy and other techniques to simultaneously measure spatial position, intensity, and spectral properties of the emitters in h-BN [3,4]. We specifically focus on CVD grown mono-layer h-BN samples over cm areas, which readily offers scalable device integration routes. Our data reveals a correlation in blinking and spectral diffusion for single emitters in monolayer h-BN, closely reminiscent of the behaviour observed in quantum dots [3]. We explore a range of CVD growth, transfer [2, 5] and encapsulation methods warranting controlled, clean and direct emitting-monolayer interfacing, giving us the ability to vertically place emitters with high accuracy. We report on detailed emitter statistics dependant on process conditions and how surface interactions heavily influence the photodynamics. Drawing on quantum dot literature, we devise approaches to enhance and control h-BN emitter properties. We also compare this optical characterisation with a range of other h-BN characterisation techniques to develop a holistic understanding.

3:45 PM MS02.02.06
Manipulating Emission Characteristics of Quantum Defects in Few-Layered Hexagonal Boron Nitride Interfaced with a Phase Change Material Pankaj K. Jha, Yonghwi Kim, Hamidreza Akbari and Harry A. Atwater; California Institute of Technology, United States

Single-photon sources are elementary building blocks for photonic quantum networks, quantum information processing, and quantum metrology, where the photons are used as “flying” qubits [1]. In this work, we investigate the optical properties of quantum defects in few-layered hexagonal boron nitride interfaced with a phase change material, such as vanadium dioxide (VO₂) on a sapphire substrate. It is well known that VO₂ exhibits an insulator-to-metal phase transition when heated just above room temperature [2] which is accompanied with large change in its electrical and optical properties. By inducing this insulator-to-metal phase transition of VO₂ film of thickness ~100 nm, we control the emission characteristics of point-defects with emission centered (zero-phonon line) in the visible regime. We show that far-field radiation pattern and lifetime of the point-defects undergoes a sharp change around the phase transition temperature. Furthermore, we optimize the thickness of the VO₂ film to enhance the optical response of the defects in the vicinity of the phase transition temperature. Our simulations show a modulation of more than 50% in the lifetime of these defects when VO₂ undergoes the phase transition. Interfacing quantum emitters in atomically thin materials [3] with phase change materials opens new opportunity for manipulating single-photon sources near room temperature.

Microsecond Lifetime of Defect-Bound Excitons in Single-Layer WSe₂ with Focused Ion Beam Irradiation Qingkai Qian1, Lintao Peng2, Nestor Perea1,1, Kazunori Fujisawa1,1, Kunyan Zhang1, Xiaotian Zhang1, Tanushree H. Choudhury1, Joan M. Redwing1,1, Mauricio Terrones1,1,1, Xuedan Ma2 and Shengxi Huang1; 1The Pennsylvania State University, United States; 2Argonne National Laboratory, United States

Transition-metal dichalcogenides (TMDCs) have been extensively studied for both fundamental science and optoelectronic applications owing to their unique properties, such as the atomic layer thickness, dangling-bond free
surface, strong light absorption, and layer-tuned direct/indirect bandgap [1]. Valley polarization of excitons can be realized in monolayer TMDCs by optical pumping [2]. However, valleytronics based on TMDCs typically relies on the delocalized excitons, which have an intrinsically fast recombination lifetime due to the large exciton oscillator strength. This short lifetime has placed a strict limitation on the pseudo-spin manipulation before the valley depolarization. Valley selectivity can be preserved for defect-bound excitons and the selective creation of defect-bound excitons with long lifetime could make significant breakthroughs for the practical valleytronics applications [3]. TMDCs are also promising platforms for solid state quantum light emissions, which have great flexibility in heterogeneous assembly and large extraction efficiency. Even though the position of quantum emitters can now be deterministically controlled by nanoscale strain engineering, the broad energy range of uncontrolled impurity- or defect-induced excitons brings a central obstacle to the development of single photon sources with high purity and indistinguishability based on TMDCs [4]. The lack of control over the presence and spatial distributions of defects in TMDs currently limits their utility for scalable devices.

Controlled defect engineering can be an important means for tailoring the electronic and optical properties of two-dimensional materials. In this work, defect densities ranging many orders of magnitude in single-layer WSe2 are controllably created by focused ion beam (FIB) irradiation. The influences of defects are systematically characterized by room-temperature Raman scattering/photoluminescence (PL), low-temperature PL and PL dynamics. Only when the FIB dose is higher than $10^{13}$ cm$^{-2}$ in WSe2, Raman spectroscopy can discern the defects at room temperature, which shows blue shifts for both $A_{1g}$ and $E_{2g1}$ peaks. Photoluminescence (PL) intensity of WSe2 drops with increased FIB doses, while the PL peak position and width show no significant changes for different FIB doses at room temperature. Low-temperature PL further reveals the peak of defect-bound excitons, which redshifts and broadens with increased FIB doses. Similar Raman shifts and PL intensity drops are observed for chemical vapor deposition (CVD) grown WSe2 after FIB irradiation. PL dynamics reveals a microsecond-long lifetime for these defect-bound excitons of single-layer WSe2, which is three orders of magnitude longer than that of the defect excitons without FIB treatment. This controllably generated ultra-long lifetime of defect-bound excitons in single-layer WSe2 can be useful for photo-catalytic reactions, valleytronics and quantum light emissions owing to the longer carrier separation/manipulation time.

Mechanics of Spontaneously Formed Nanoblisters Trapped by Transferred 2D Crystals Daniel Sanchez, Zhaohe Dai, Peng Wang, Andrei Dolocan, Arturo Cantu-Chavez, Christopher J. Brennan, Rui Huang and Nanshu Lu; The University of Texas at Austin, United States

Layered systems of two-dimensional (2D) crystals and heterostructures are widely explored for new physics and devices. In many cases, monolayer or few-layer 2D crystals are transferred to a target substrate including other 2D crystals, and nanometer-scale blisters form spontaneously between the 2D crystal and its substrate. Such nanoblisters are often recognized as an indicator of good adhesion but there is no consensus on the contents inside the blisters. While gas-filled blisters have been modeled and measured by bulge tests, applying such models to spontaneously formed nanoblisters yielded unrealistically low adhesion energy values between the 2D crystal and its substrate. Typically, gas-filled blisters are fully deflated within hours or days. In contrast, we found that the height of the spontaneously formed nanoblisters dropped only by 20%-30% after three months, indicating that liquid instead of gas is likely trapped in them. The blister contents are further analyzed using time-of-flight secondary ion mass spectrometry (ToF-SIMS) showing a mixture of water and organic matter at the 2D material-substrate interface. We therefore developed a simple scaling law and a rigorous theoretical model for liquid-filled nanoblisters, which predicts that the interfacial work of adhesion is related to the fourth power of the aspect ratio of the nanoblister and depends on the surface tension of the liquid. Our model was verified by molecular dynamics simulations, and the adhesion energy values obtained for the measured nanoblisters are in good agreement with those reported in the literature. This model can be applied to estimate the pressure inside the nanoblisters and the work of adhesion for a variety of 2D interfaces, which provides important implications for the fabrication and deformability of 2D heterostructures and devices.

4:30 PM *MS02.02.09
Quantum Calligraphy—Writing Single Photon Emitters in a Two-Dimensional Materials Platform  Matthew R. Rosenberger1, Chandriker Kavir Dass2,3, Hsun Jen Chuang1, Saujan V. Sivaram1, Kathleen McCreary1, Joshua Hendrickson2 and Berend T. Jonker1; 1U.S. Naval Research Laboratory, United States; 2Air Force Research Laboratory, United States; 3KBRwyle, United States

We present a paradigm for encoding strain into two dimensional materials (2DM) to create and deterministically place single photon emitters (SPEs) in arbitrary locations with nanometer-scale precision. Our material platform consists of a 2DM placed on top of a deformable polymer film. Upon application of sufficient mechanical stress using an atomic force microscope (AFM) tip, the polymer layer plastically deforms. While the AFM tip is in contact with the sample, the AFM tip forces the 2DM to deform with the polymer layer, resulting in tensile strain buildup in the 2DM. When the AFM tip is removed, the adhesive interaction between the polymer and the 2DM prevents the 2DM from relaxing back to its original, strain-free geometry, resulting in a permanent and highly localized strain field in the 2DM. We demonstrate control of indent size by modifying the applied load. Also, we show excellent repeatability of both indent shape and size. We show that SPEs are created and localized at nanoindents in a WSe2/PMMA structure, as confirmed by antibunching measurements. The SPEs exhibit single photon emission up to 60 K. This quantum calligraphy allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities, and plasmonic structures. We further use the AFM to create trenches in the WSe2/PMMA structure, leading to nominally one-dimensional strain profiles. We find that the linear polarization orientation of SPEs in the trenches correlates with the orientation of the one-dimensional strain profile. This result holds for trenches made at different orientations relative to the WSe2 crystal orientation, suggesting that the polarization orientation of SPEs in WSe2 is determined by the strain profile alone. In addition to enabling versatile placement of SPEs, these results present a general methodology for imparting strain into 2DM with nanometer-scale precision, providing an invaluable tool for further investigations and future applications of strain engineering of 2DM and 2DM devices.

Mutual Strain in MoS$_2$/WS$_2$ Heterobilayers  
Robert Waelder and Erik Einarsson; University at Buffalo, The State University of New York, United States

Lattice mismatch in heterostructures traditionally manifests as accumulation of strain in a thin film that has been grown on a bulk substrate. The strain persists until some critical thickness is reached, at which point the lattice relaxes and returns to its unstrained state. In short, only the deposited material bears the strain. Here we investigate the case in which both sides of a heterostructure are atomically thin transition metal dichalcogenide monolayers. We grew WS$_2$ on MoS$_2$ by chemical vapor deposition, and characterized the heterobilayer regions using photoluminescence (PL) spectroscopy. Density functional theory calculations predict a change in the optical bandgap of each monolayer under uniform, biaxial strain. The observed shifts in the A exciton peaks, determined from PL spectra, agree well with the numerical predictions. This suggests a mutual equilibrium is reached in which both materials bear some of the strain. Using the relation between strain and band gap, we calculated the strained in-plane lattice parameters based on the A exciton peak positions. Monolayer MoS$_2$ and WS$_2$ have in-plane lattice parameters of 3.16 Å and 3.19 Å, respectively, but both of these values become approximately 3.17 Å in the heterobilayer, differing by less than 0.4 pm. Our findings indicate that lattice matching occurs in 2D heterostructures, and should be taken into consideration when designing van der Waals solids for optoelectronic applications.

MS02.03.04
Strain-Induced Enhancement of Catechol Sensing Using 2D - WO$_3$ Nanofibers  
Sushmitha Veeralingam and Sushmee Badhulika; Indian Institute of Technology, Hyderabad, India

A low cost, flexible, sensing platform which can detect catechol in biological fluids and environment is of utmost importance in healthcare. In this work, we demonstrate a facile, low-cost approach to fabricate 2D-Tungsten (VI) oxide (WO$_3$) nanofiber-based strain induced highly sensitive and selective catechol sensor. 2D-WO$_3$ was synthesized using electrospinning technique followed by the drop casting of annealed nanofibers on to flexible PET substrates. X-Ray Diffraction (XRD) and Raman studies confirmed the formation of Hexagonal phase-WO$_3$ and O-W-O bending modes respectively while scanning electron microscopy (SEM) studies revealed the uniform distribution of WO$_3$ nanofibers on PET substrate. The sensor responded to a wide dynamic range of catechol concentrations from 1µM to 400µM, exhibited a sensitivity of 49.29 µA/µM cm$^2$ and a limit of detection of 0.52µM which were far more superior than previously reported catechol sensors fabricated using sophisticated fabrication techniques. The sensing response can be ascribed to the oxidation of catechol to benzoquinone in presence of n-type WO$_3$ nanofibers thus resulting in increased current flow through the device. Interestingly, when the sensor was subjected to compressive strain during catechol sensing, a remarkable increase in sensitivity of 86.34 µA/µM cm$^2$ was observed. The limit of detection also further reduced to 42 nM. Upon subjecting the sensor to a strain ranging from 3.14% to 47.6% an exceptional increase in current was observed. This strain induced increase in sensitivity can be attributed to the increase in the density of interconnected WO$_3$ nanofibers which enhances the potential active sites for catechol interaction. Furthermore, to explore the practical utility of the sensor, it was used to detect catechol in simulated blood samples for which it showed excellent selectivity towards catechol in presence of other interfering analytes like Ascorbic acid, Uric acid, Na+, Ca+, and glucose. The strategy outlined here can be used to fabricate wearable, chemiresistive platforms for detection of various biological analytes useful in point-of-care medical diagnostics.

MS02.03.05
Two-Phase State and Elastic Instability in Small Clamped Systems Undergoing Symmetry Changing Structural Phase Transitions  
Arkadi P. Levanyuk$^1$, Sergey Minyukov$^2$ and Ibrahim B. Misirlioglu$^3$; $^1$University of Washington, United States; $^2$Russian Academy of Sciences, Russian Federation; $^3$Sabanci University, Turkey

Understanding phase transitions in constrained crystalline systems such as in thin films on substrates has often been driven by the motivation to tailor the interesting physical properties coming about near the transition. Ferroelectric-paraelectric transitions in perovskites are an example. In all bulk perovskites these transitions are of the first order. There is no consensus in answering the question as to what happens with these transitions in thin films clamped on a substrate. The prevailing opinion is that a first order transition in bulk turns second order though it is in disagreement with results concerning first order transitions in large clamped systems. The apparent reason of this opinion is that in many reported cases the first-order transition in free crystal is relatively weak and would convert
into a second order in film form if the system remained homogeneous. In this talk, we report our theoretical analysis of this case both for laterally clamped slabs with free surfaces and for thin films on stiff substrates. The case of clamped objects allows a consistent analytical analysis in 1D case where the system is laterally finite but relatively large. For systems with small lateral sizes we perform numerical simulations. We observe formation of two-phase state that extend to a temperature range more than 10 degrees, likely smearing the transition anomalies. This temperature interval shrinks with diminishing of the lateral size and may disappear for very small sizes. For films on substrates no analytical theory of two-phase formation is possible though it is possible to analyze the loss of elastic stability of non-symmetrical phase when, at heating, the nucleation is inhibited and the homogeneous state conserves even in the region where the two-phase state is more energetically profitable. Although within a different approach this loss of elastic stability in large clamped systems has been predicted earlier but not for films on substrates. There exists a critical thickness for the stability loss and, seemingly, for the two-phase state formation which is fairly small for studied systems. We demonstrate our approach for an isotropic system that is possible to extend albeit rather cumbersome to experimentally studied perovskite systems where the elastic anisotropy might be important.

**MS02.03.06**

**Comparison of Characteristics of Sn:In$_2$O$_3$ Electrode with Different Sn Doping Concentration for Electrodes of Transparent Thin-Film Transistors**

Jin H. Park, Sang-Hwi Lim, Sung H. Jung, Hyung K. Cho and Han-Ki Kim; Sungkyunkwan University, Korea (the Republic of)

In this work, we studied the effect of tin doping concentration on the electrical, optical, morphological, and crystallographic characteristics of tin doped indium oxide (ITO) and comparison of interfacial characteristics between indium-gallium-zinc oxide (IGZO) and ITO with different tin doping concentration to improve the properties of ITO electrode which applied in transparent thin film transistors (TFTs). We deposited ITO films on the glass with 4 inch-sintered ceramic target with low (In:Sn=99:1) and high (In:Sn=90:10) concentration of tin doping by magnetron sputtering system at room temperature. To compare the characteristics of ITO films with high and low concentration of tin doping, Hall measurement, UV-vis spectroscopy, filed emission scanning electron microscopy (FE-SEM), atomic force microscopy (AFM), x-ray diffraction (XRD), x-ray photoelectron spectroscopy (XPS), and ultra-violet photoelectron spectroscopy (UPS) were conducted. Both ITO films with high and low concentration of tin doping showed low electrical resistivity about 10$^{-4}$ ohm-cm and superior optical transmittance above 85 % in visible range. In detail, ITO film composed 1 wt% tin doping concentration showed lower sheet resistance and higher optical transmittance. As thickness of films increased, transmittance of both films shifted to red side. The highest figure of merit was obtained at the thickness of 150 and 125 nm in the case of low and high tin concentration ITO films, respectively. Through SEM image, both ITO films with high and low tin doping concentration showed crystalline microstructure. XRD results indicated both ITO films are bixbyite-In$_2$O$_3$ crystal structure. Therefore, we fabricated the top gate-transparent IGZO TFTs and circular transmission line method (CTLM) devices with ITO electrodes. Top gate-transparent IGZO TFTs consist of 100nm thick of ITO gate electrode, 80nm thick of Al$_2$O$_3$ gate insulator layer, 30nm thick of IGZO channel, and 100nm thick of ITO source/drain electrode. The transfer curve of both high and low tin doping concentration ITO electrode TFTs showed traditional n-type transistor characteristic and operated in depletion mode. And also, transistor parameters such as threshold voltage, field effect mobility, subthreshold swing, and on-off ratio were extracted. Saturation mobility and on-off current ratio in 1 wt% tin doped ITO TFT was higher than those in 10 wt% tin doped ITO TFT. In conclusion, we found that low doping level of tin in ITO is more proper to transparent TFT with room temperature process.

**MS02.03.07**

**Large Areal Coverage of MoS$_2$ Monolayer on Various Substrates and a Study of the Role of Interface Effects on Electrical Performance of Devices Based on these Monolayers**

Yan Jiang and Usha Philipose; University of North Texas, United States

A planar distribution of source material and a promoter enabled centimeter-scale growth coverage of molybdenum disulfide (MoS$_2$) monolayers by conventional ambient pressure chemical vapor deposition (APCVD). The molybdenum source and sodium chloride promoter were spin-coated on select planar substrates like silicon, sapphire and quartz. This technique was found to contribute to stable and consistent growth of MoS$_2$ monolayers. Results of Raman and photoluminescence spectroscopy attested to the high crystalline quality of the as-grown layers, while results of atomic force microscope verified the monolayer film thickness. The electronic quality of the films was found to depend on the growth substrate; the study enabled by fabrication of field effect transistors with MoS$_2$ monolayers functioning as the active layer. It was experimentally determined that MoS$_2$ monolayers grown on
sapphire substrates and contacted by two Cr/Au electrodes provides the most effective ohmic contact with very low
contact resistance. On the other hand, MoS$_2$ monolayers grown on silicon and contacted by identical metal contacts
yield high contact resistance, inadvertently affecting transport performance of devices with and without gate bias.
This work on the effective distribution of source and promotors on the growth substrate for the synthesis of high-
quality MoS$_2$ monolayers sheds light on the growth mechanism and the critical role of promotors on growth. The
correlation between electrical performance and growth substrates implicates the role of interface effects and its study
provides a path to improve device performance of MoS$_2$ monolayers.

**MS02.03.08**
Electronic Effects in Nanotribology by Using Few-Layer MoTe$_2$ under Semiconductor to Metal Transition
Shuyu Huang, Yongkang Wang, Lijian Zhan, Xiongyu Wu and Yunfei Chen; South East University, China

Friction is inherently a process of energy dissipation where electronic and phononic contributions are considered as
two primary channels of dissipative process. Mechanical strain has been demonstrated to be able to reversibly
control the phase transition of few-layer MoTe$_2$ semiconductor (2H) to metal phase (1T') at room temperature under
ambient conditions. Reversibly controlling of the phase transition enabling the monitor of electron concentration in a
same region in few-layer MoTe$_2$, which make it an ideal platform to study the electronic effects in nanotribology.
Herein, the nanoscale friction is measured in situ in few-layer metallic and semiconductor MoTe$_2$ by atomic force
microscopy (AFM) to extract the electronic effects, where the phase transition is controlled by mechanical strain.
First of all, mechanically exfoliated MoTe$_2$ thin film is transferred onto SiO$_2$/Si substrate pre-coated with 200 nm
gold by the wetting transfer method. Due to the intrinsic roughness of the thermal evaporation Au film, a tensile-
strain-modulated phase transition occurred when a certain amount of normal force is applied in MoTe$_2$. Both the
semiconductor and metal phase region existed, which has been confirmed by Raman spectra and conductive AFM
(CAFM). Then, we use AFM to characterize the nanoscale friction on the few-layer MoTe$_2$ while in situ record the
current by using CAFM to characterize the phase transition. Compared with the semiconductor region, the metal
region shows significantly higher current and greater friction. And the current between the metal phase MoTe$_2$ and
the tip is positively correlated with the friction force. Furthermore, we changed bias between conductive tip and
substrate, the results show that the friction in metal phase region increase with the increase of the external bias and
can be regulated by an external electric field. The experimental results reveal that much higher electron
concentration in 1T'-MoTe$_2$ cause a remarkable increase of friction force implying that friction energy can also be
dissipated through the electron channel.
Draw support from the few-layer phase transition material MoTe$_2$, we are able to extract the electronic contributions
in friction energy dissipation avoiding the effects of deformation, surface roughness, and changes in atomic
structure. This work facilitates an understanding of electronic effect in nanotribology and provide a new strategy to
study the electronic effects in nanotribology.

Nanoscale Strain Engineering of Giant Pseudo-Magnetic Fields, Valley Polarization and Topological
Channels in Monolayer Graphene
Nai-Chang Yeh, Chen-Chih Hsu, Marcus Teague and Jiaqing Wang; California
Institute of Technology, United States

The existence of nontrivial Berry phases associated with two inequivalent valleys in graphene can provide
interesting opportunities for investigating the valley-projected topological states. Examples of such studies include
observation of anomalous quantum Hall effect in monolayer graphene, demonstration of topological zero modes in
“molecular graphene” assembled by scanning tunneling microscopy, and detection of topological valley transport
either in graphene superlattices or at bilayer graphene domain walls. However, all aforementioned experiments
involved non-scalable approaches of either mechanically exfoliated flakes or atom-by-atom constructions. Here we
report a new approach to manipulating the topological states in monolayer graphene via nanoscale strain
By placing strain-free monolayer graphene on architected nanostructures to induce global inversion symmetry breaking, we demonstrate the development of giant pseudo-magnetic fields, global valley polarization, and periodic one-dimensional topological channels for protected propagation of chiral modes in strained graphene, thus paving a pathway towards realizing scalable graphene-based valleytronics and strain-induced superconductivity.

9:00 AM MS02.04.02
Zero-Dimensional Graphene and Its Behavior under Mechanochemical Activation with Zinc Ferrite Nanoparticles Monica Sorescu1, Matthew Knauss1, Alice Perrin2 and Michael McHenry2; 1Duquesne University, United States; 2Carnegie Mellon University, United States

Equimolar mixtures of zero-dimensional graphene (SkySpring Nanomaterials, 1-5 nm particle size) and zinc ferrite nanoparticles (Alfa Aesar, 50 nm particle size) were exposed to mechanochemical activation by high-energy ball milling for time intervals of 0-12 hours. Their structural and magnetic properties were analyzed by Mossbauer spectroscopy and magnetic measurements. The spectra of zinc ferrite milled without graphene were fitted with one quadrupole-split doublet (quadrupole splitting 0.5 mm/s, isomer shift 0.23 mm/s) and indicated that zinc ferrite was superparamagnetic. The line width of the doublet increased from 0.41 to 0.64 mm/s, which correlates with a reduction in particle size as effect of the ball milling processing performed. When graphene was added to the milling powders, the Mossbauer spectra showed the appearance of another quadrupole doublet, with a quadrupole splitting of 0.84 mm/s and an isomer shift of -0.38 mm/s. Its abundance to the spectrum remained constant to 4.48% while the milling time was increased. This second doublet could be related to carbon atoms occupying neighborhoods in the proximity of iron atoms. Hysteresis loops were recorded in an applied magnetic field of 5 T at a temperature of 5 K. A change in the approach to saturation of the loop was observed, with saturation being achieved for the sample milled for 12 hours with graphene. Zero-field-cooling-field-cooling (ZFC-FC) was performed on all samples between 5-300 K with an applied magnetic field of 200 Oe. Graphene was found to stabilize the magnetic properties of the milled system of powders to a blocking temperature of about 90 K.

Colossal Room-Temperature Magnetoresistances at Strongly-Coupled Graphene/Complex-Oxide Heterostructures J. Hu1,1, M. Yang2, J. Guo1,1, A.T.S. Wee1,1 and A. Ariando1; 1National University of Singapore, Singapore; 2Agency for Science, Technology and Research, Singapore

Magnetoresistance, the change in electrical resistance under an external magnetic field, has been widely used in magnetic sensing, recording and memory devices. Even though the mass production of single-layer graphene has entered the stage of commercialization, the magnetoresistance of single-layer graphene yielded limited success at room temperature, usually ranging from 60% to 775 % at 9 T which were achieved through various routes, such as decorating with gold nanoparticles, by fluorination and nitrogen doping, or through phonon-mediated effect. In this talk, we demonstrate a colossal magnetoresistance of single-layer graphene, nearly 5,000% at 9 T and 300 K, achieved by forming a graphene/perovskite-oxide heterostructure. For single-layer graphene fabricated on various perovskite oxides, we demonstrated a universal twentyfold enhancement in magnetoresistance compared to previous single-layer graphene devices at the same conditions. Combining scanning tunneling microscopy with theoretical calculations reveals that the colossal magnetoresistance stems from an inhomogeneous charge distribution due to the strong interfacial coupling between graphene and perovskite oxides, which creates a random resistor net-works in graphene. Our results suggest that the perovskite oxides can be an appealing substrate for high performance graphene-based magnetoelectronics.

New Imaging Capabilities Enabled by the Electron Microscope Pixel Array Detector (EMPAD) for 2D Materials Kayla X. Nguyen; University of Illinois at Urbana-Champaign, United States

Scanning transmission electron microscopy (STEM) has been a ubiquitous characterization platform for reconstructing atomic-resolution images from highly scattered electrons or from the direct electron beam. These signals have become the standard for imaging in the electron microscope because of their ease of collection and
interpretability. Yet in these imaging modes, only a single contrast value is extracted at each scan position; all other information about the specimen encoded in the electron diffraction pattern is thrown away. Previous attempts to utilize the full electron scattering signal have been limited by electron detectors based on scintillators and charge-coupled devices which have slow acquisition speeds and limited dynamic ranges. Recently, a new generation of high-speed and high-dynamic range detectors have allowed for fast collection of the full electron diffraction pattern at each scan position from which information is no longer limited to conventional imaging techniques - but can extend beyond this to uncover quantitative measurements of thickness, strain, tilt, polarity, atomic fields and the long-range electromagnetic fields. Here, we highlight the electron microscope pixel array detector (EMPAD) whose previous demonstrations have shown broad, cross-disciplinary impact, this includes: (1) the development of the highest resolution electron microscope in the world, (2) quantitative imaging of fields from polarization vortices in ferroelectrics, and (3) strain and dislocation mapping of 2-dimensional (2D) materials with picometer accuracy.

Here, the high-dynamic range of the EMPAD is extremely advantageous when capturing the full scattering signature of 2D materials. In 2D materials, the incident electron beam tend to dominate the scattering signal such that intensities from diffracted spots are washed out by the incident beam. Using the high-dynamic range and high-speed of the EMPAD, we can map strain in 2D materials with high-precision at micrometers field of view; this method can be used to study lattice distortions to identify where lattice strain and dislocations most commonly occur. With the EMPAD, physical properties of 2D materials can be investigated and directly imaged to provide an interesting playground for exploration where new material physics can be recovered without the complications from multiple scattering.

Crumpled MoS2-Graphene Photosensor with Enhanced Photoresponsivity Enabled by Exciton Drifting
Juyoung Leem1, Pilgyu Kang2,1, Jihun Mun3, Yeageun Lee1, Mohammad A. Hossain1, Arend M. van der Zande1, Sang-Woo Kang1 and SungWoo Nam1; 1University of Illinois at Urbana-Champaign, United States; 2George Mason University, United States; 3Korea Research Institute of Standards and Science, Korea (the Republic of)

Atomically-thin two-dimensional (2D) materials exhibit extraordinary optical, electronic, and mechanical properties, which make them promising material platforms for optoelectronic applications. Monolayer molybdenum disulfide (MoS2) is one of the widely used semiconducting 2D materials for photosensing owing to its direct bandgap. In addition to its intrinsic material properties, mechanical strain applied to the semiconducting material can modulate intrinsic electronic properties, such as bandgap. In this presentation, we report a mechanically self-assembled, crumpled MoS2 photosensor with graphene electrical contacts. Graphene was used as electrodes because it is mechanically robust and electrically conductive 2D material forming barrier-free electric contact with MoS2. Furthermore, by crumping monolayer MoS2, we introduced strain gradient over crumpled MoS2 structure, and such strain gradient enables nanoscale bandgap modulation, which induces exciton drift with light illumination. The exciton drift enables higher photoresponsivity in crumpled MoS2 photosensor, compared to photoresponsivity of flat MoS2 photosensor. We demonstrate power dependent photoresponsivity of our crumpled MoS2 photosensor as well as local photocurrent generation with photocurrent mapping. Our approach to mechanical self-assembly of atomically thin materials offers a simple but effective way to enhance photosensitivity and suggests a new way to engineer exciton funneling in 2D material system.

10:45 AM MS02.04.06
Electrical Actuation of Drum Type h-BN Nano-Mechanical Resonator Yusuke Morimoto, Kuni Takei, Takayuki Arie and Seiji Akita; Osaka Prefecture University, Japan

Nano-electro-mechanical resonators (NEMR) consisting of atomically thin two dimensional (2D) materials such as graphene are considered to be capable of highly accurate force measurements. The resonance properties of NEMR consisting of optically opaque 2D materials are highly affected by the light irradiation because of the photothermal effect. A hexagonal boron nitride (h-BN) is transparent in the visible light range. Thus, the photothermal effect on the h-BN NEMR would be suppressed. In addition, h-BN is an emergent material for single photon emitters that
are ultrabright and stable under ambient conditions. Very recently, theoretical prediction regarding quantum effects in a mechanically modulated single photon emitter composed of h-BN NEMR has been reported.[3] To discriminate the photothermal effect, the light induced effects on the resonance should be clarified. In this study, we investigate the photothermal effect on resonance properties of the electrically actuated drum type h-BN NEMR.

To compose the h-BN NEMR, a multilayered h-BN flake, which was prepared by mechanical exfoliation of bulk h-BN, was transferred using gel transfer method onto a predetermined pair of drum-shaped electrodes on a patterned n’Si / SiO$_2$ substrate. To form the h-BN NEMR suspended by metal electrodes, the SiO$_2$ layer underneath the h-BN drum (6 μm in diameter) was etched using buffered HF. The frequency resonance of the h-BN NEMR was measured in vacuum by optical detection method, where a laser with a wavelength of 520 nm was irradiated to the center of the h-BN drum as the probe. Additional laser with a wavelength of 685 nm was irradiated to investigate the photoinduced effect on the resonance.

The h-BN NEMR was successfully oscillated by applying the AC + DC bias voltage between the n’Si substrate and the Au electrode. The resonance frequency and Q factor were 26.48 MHz and 115, respectively. The oscillation amplitude increases linearly with increasing the AC or DC voltages. This behavior can be explained by the model based on the electrical actuation induced by the dielectric effect. Under additional light irradiation with a wavelength of 685 nm around the center of the drum, the linearity of the resonance properties were maintained under high intensity of 1 mW. Contrary, in the case of graphene drum resonator, which is optically opaque, the resonance property was affected even under the weak laser irradiation less than 10 mW because of the photothermal effect, which results in the modification of oscillation modes between linear and nonlinear.[1] Thus, the resonance mode of the h-BN NEMR is robust against the photothermal effect owing to the optical transparancy of h-BN.

Impacts of Stress and Dissipation in van der Waals Interfaces on 2D Material Nanoelectromechanical Systems

SunPhil Kim and Arend M. van der Zande; University of Illinois at Urbana-Champaign, United States

Two-dimensional materials such as graphene and MoS$_2$ represent the ultimate limit of both nanoelectronic and nanoelectromechanical systems due to their intrinsic molecular scale thickness.[1] While 2D materials exhibit many useful properties, many of the most exciting phenomena and applications arise at the van der Waals interface. Electrically, the van der Waals interface enables the constructing of heterostructures and molecular scale electronics. Mechanically, the van der Waals interface displays superlubricity[2] or solitons[3] depending on whether the interface is aligned. A fascinating question is how the van der Waals interface affects the mechanical properties of 2D membranes. Answering this question is important to incorporating 2D heterostructure electronics into diverse applications such as highly tunable nanoelectromechanical systems from suspended 2D membranes, stretchable electronics from crumpled 2D materials, and origami/kirigami nano-machines.

In this study, we explore the impact of the van der Waals interface by comparing mechanical resonance of electrostatically contacted circular drumhead resonators made from atomic membranes of monolayer graphene to commensurate (Bernal stacked) bilayers, incommensurate (twisted) bilayer, and graphene-MoS$_2$ heterostructures (2D bimorph).

For Bernal stacked bilayer, we observe the creation and destruction of individual solitons manifesting as stochastic jumps in the mechanical resonance frequency tuning. We find individual dislocation creation and destruction of single solitons lead to shifts in membrane stress of < 10 mN/m or an in-plane interlayer slip distance of < 1.42 Å. We observe similar jumps in the few-layer graphene and heterostructure, but not in the twisted bilayer. For twisted bilayer, amplitude dependent studies reveal that the resonators show a factor of 3 to 5 higher dissipation rate at room temperature. A further increase in amplitude leads to a large peak broadening rather than Duffing nonlinear behaviors observed in monolayer and Bernal stacked bilayer graphene resonators. In addition, the interface dissipation is strongly dependent on temperature, displaying tuning of nonlinear behaviors with a decrease in temperature.

These results show that van der Waals interfaces strongly affect stress and dissipation of many multilayer 2D atomic membranes; an important consideration in engineering 2D nanomechanical devices.

Tuning Physicochemical Properties of MoS2 by Mechanical Strain Xiaolin Zheng and Sangwook Park; Stanford University, United States

Monolayers of 2D materials have ultrahigh mechanical strength, which enables the application of very large elastic strains (e.g., ~11% for MoS2 and 25% for graphene). The ability to sustain such large elastic strain offers unprecedented opportunities to engineer the physicochemical properties by applying mechanical strain. In this talk, I will present two examples on the effect of strain on the properties of MoS2 layer. The first example shows that elastic tensile strain reduces the bandgap of MoS2. When a gradient strain field is applied to MoS2 monolayer, the created bandgap gradient acts as an efficient funnel of photogenerated excitons that leads to enhanced photoluminescence. The second example shows that when elastic strain is applied to the sulfur vacancy on the basal planes of monolayer 2H-MoS2, the strain modifies the local electronic structure and catalytic activity. The proper combinations of S-vacancy and strain allow us to achieve higher intrinsic activity for hydrogen evolution reaction than the edge site of MoS2.

1:30 PM *MS02.05.01
Lattice Moire Characteristics and Electromechanical Properties of Multilayer Graphene Kyung-suk Kim; Brown University, United States

Lattice misalignments between the two layers of a bilayer graphene are found to provide peculiar electromechanical properties of the graphene. An example is the unconventional superconductivity in magic-angle graphene superlattices (Cao, et al. Nature, 556, 2018), and another the localization of electric polarization at the flexoelectric crinkle kinks (Kothari, et al. Roy Soc Proc, 474, 2018). The lattice misalignments are typically represented by the super-lattice moire-interference patterns for translational and rotational misalignments. Electronic force-field interactions, e.g. van der Waals and Coulomb interactions, between the atoms typically relax the super-lattice configuration from the geometrical moire interference pattern. In particular, non-uniform translational misalignments in translation lead to formation of van der Waals dislocations and flexoelectric crinkles. On the other hand, non-uniform misalignments in rotation generate in-plane disclinations and out-of-plane wrinklons. Here, we present studies of the dislocation, crinkle, disclination and wrinklon characteristics of a bilayer graphene. The characteristics could be investigated with an atomic-lattice interferometry (ALI), which is carried out with a dual-tip AFM interferometer (DT-AFMI). The optical coupling system of the DT-AFMI enables sensing differences between two simultaneous dual-tip scans of sample and reference graphene lattices, which in turn impart the moire fringes of the interference between the sample and reference lattices. The ALI moire fringes indeed reveal the relaxation of the super-lattice configuration. We compare the relaxations with those evaluated by density functional theory (DFT) calculations. Then, presented are correlations between the lattice moire patterns and the electromechanical properties of the bilayer graphene. Moreover, looked after are studies on stabilities of the van der Waals dislocations, the flexoelectric crinkles, the in-plane disclinations and the out-of-plane wrinklons in the bilayer.
Abstract: Two-dimensional materials constitute an exciting platform for investigation of both fundamental phenomena and electronic applications. However, many 2D materials are not air stable, making their studies and integration challenging. Here we discuss routes to stabilize such materials, using few-layer black phosphorus, a 2D semiconductor, and chromium triiodide, a 2D magnetic insulator, as examples. The chemical degradation pathways of both materials are accelerated by light. While simple encapsulation by Al₂O₃, PMMA and hexagonal BN (hBN) are sufficient to ensure air stability for few-layer black phosphorus devices, it only leads to modest reduction in degradation rate for CrI₃. We find that minimizing exposure of light markedly improves stability of CrI₃, and CrI₃ sheets sandwiched between hBN layers are air-stable for >10 days. By monitoring the transfer characteristics of CrI₃/graphene heterostructure over the course of degradation, we show that the aquachromium solution hole-dopes graphene. Finally, I will also discuss our latest results on transport measurements of twisted bilayer graphene devices that show both superconductivity and insulating behaviors.

Manipulating Valley Currents in Graphene Nanostructures Stephen Power; Trinity College Dublin, Ireland

Two-dimensional materials, such as graphene, are promising valleytronic candidates due to the K and K' valleys at the Dirac points. All-electronic control is particularly desirable for device applications. Many proposed setups exploit strain-induced pseudomagnetic fields which act oppositely in the K and K' valleys. This is illustrated for graphene nanobubbles, which can filter or split a charge current into its different valley components [1]. Experimental approaches in this direction are advancing, but the most promising signatures of valley-dependent phenomena have instead emerged from graphene/hexagonal boron nitride heterostructures. Large non-local resistance signals here have been interpreted in terms of a valley Hall effect (VHE) driven by a bulk Berry curvature [2], which in turn emerges from a gap-opening sublattice-asymmetric potential (mass term). A complete understanding of such measurements in terms of either bulk [3]- or edge-driven [4] mechanisms is very much an open question.

Here I demonstrate the emergence of a valley-splitting bulk transport mechanism in the absence of a global band gap [5]. This phenomenon requires instead the presence of local spatial regions (dots) with finite mass. An exact analytic solution to the scattering problem is derived for simple dots, which establishes a strong valley dependence for scattering at low energies. Tight-binding simulations confirm that this behaviour is robust for a wide range of mass distributions, and gives rise to a valley Hall conductivity in periodic systems.

Our findings provide an alternative mechanism for the generation of bulk valley currents and suggest that valley-dependent scattering may give rise to analogous effects to those expected for Berry-phase induced deflections. They also suggest more reliable guidelines for valley engineering, in contrast to proposals which require atomically precise edges or strain profiles.

Controlling Rotation in 2D Material Flakes Harley T. Johnson¹, Shuze Zhu¹ and Pascal Pochet²; ¹University of
Interlayer rotation in van der Waals structures of 2D materials couples strongly to electronic properties and, therefore, has significant technological implications. Nevertheless, controlling the rotation of an individual 2D material flake remains a challenge in the development of rotation-tunable electronics. Here we reveal a general moiré-driven mechanism that governs interlayer rotation, relying on the concept of interlayer or van der Waals (vdW) dislocations. We present a theory to explain the connection between the moiré pattern and the arrangement of vdW dislocations, which can be understood to minimize the interfacial energy in the system. As a demonstration of this theory, we consider the arrangement of vdW dislocations due to growth or rotation of finite-sized MoS₂ flakes on larger crystalline substrates. We compare this to the classic critical thickness problem in thin film mechanics, and explain the small, stable rotation angles in finite 2D material flakes on crystalline substrates that are commonly observed experimentally. We show that by applying strain, and thereby controlling the moiré pattern, it is possible to select the amount of interlayer rotation between flake and substrate. The approach provides a powerful tool for the on-demand design of rotation-tunable electronics.

3:45 PM MS02.05.05
Exploiting Moiré Effects to Control Thermally-Activated Motion and Plasma Patterning in Twisted Bi-Layer Graphene Soumendu Bagchi, Harley T. Johnson and Huch Beng Chew; University of Illinois at Urbana-Champaign, United States

Recent studies have established synthesis protocols to enable twisting of bilayer graphene to change the stacking order, thereby controlling the resulting moiré pattern. Due to the moiré, electronic transport properties of the twisted bilayer graphene are found to be strongly-dependent on the twist angle, thus yielding a potential new class of low-dimensional carbon electronics. However, being driven by weak van der Waals interactions at the interfaces (~1/10th of room-temperature KT), these structures are susceptible to nontrivial thermal fluctuations which may severely affect their device level performance. Using large-scale molecular dynamics simulations, we uncover a size dependent thermal stability of Moiré patterns in free-standing twisted bi-layers. We show that small twisted graphene flakes on the order of 10nm in size can rapidly re-orient themselves into stable AB stackings at room temperature, while twisted graphene flakes on the order of 100nm and larger remain thermally-stable even at temperatures exceeding 1000° C. This size-effect on the thermal stability and kinetic behavior of twisted bilayer graphene is related to the incomplete moiré periodicity of the graphene flakes and is explained using a dislocation-based framework. For thermally-stable twisted graphene flakes, we show that the different stacking arrangements present in the moiré pattern can be used to bias the hydrogen-plasma etching rates. Specifically, the AA and SP regions in the bilayer graphene have much lower barrier energies, compared to the perfect AB stacking, for ion transmission through the top graphene layer for etching of the bottom layer. These results suggest that selective patterning of twisted graphene can be achieved, which is of significant importance in the top-down fabrication of porous graphene.

4:00 PM MS02.05.06
Ultrabright Trion Generated by Impact Ionization in High Quality Monolayer MoSe₂ Bumho Kim¹, Yue Luo², Daniel Rhodes¹, Yusong Bai¹, Song Liu¹, Jue Wang¹, Baili Huang¹, Zhaochen Li¹, Takashi Taniguchi², Kenji Watanabe³, Timothy Berkelbach¹, David Reichman¹, Stefan Strauf², Xiaoyang Zhu¹, Katayun Barmak¹ and James Hone¹; ¹Columbia University, United States; ²Stevens Institute of Technology, United States; ³National Institute for Materials Science, Japan

As atomically thin direct-gap semiconductors with strong light-matter interaction, monolayer transition metal dichalcogenides (TMDs) are promising for a broad range of optical and optoelectronic applications. In TMDs, strong electron-hole interactions due to quantum confinement and reduced dielectric screening produce strongly bound composite quasiparticles, including both neutral (e.g., excitons and biexcitons) and charged species (e.g., trions and charged-biexcitons). Of particular interest are trions, three-body charge-exciton bound states, which simultaneously carry charge and excitation energy, and inherit the robust valley polarization of the parent excitonic states. As charged quasiparticles, trions can be manipulated by electric fields. Furthermore, trions in monolayer TMDs have much stronger binding energy, compared to those in traditional semi-conducting materials of GaN, InN, and GaAs, an important factor to prevent dissociation under applied fields. These unique properties offer new opportunities to manipulate charge and excitonic energy in 2D TMDs, which can be exploited for optoelectronic applications including light emitting and photodetecting devices where directional energy or charge transport is
critical.
To date, the promising utilities of trions have been hindered by their short lifetime (∼15 ps), limiting drift length of trions under applied electric fields. The lifetime of trion in TMDs is governed by fast non-radiative decay processes such as trion-phonon interaction and defect-mediated non-radiative recombination. Also, the low trion quantum yield (QY) in monolayer TMDs is another obstacle to realization of trion-based optoelectronic devices. QY of monolayer TMDs is reported to be 0.1 - 8 %. The enhancement of the low QY has been demonstrated through the superacid treatment or the plasmonic cavity coupling techniques. However, the superacid treatment, which passivates charge sources, suppresses trion generation. Also, the cavity coupling approach enhances the spontaneous emission rate by the Purcell effect, thereby preventing the achievement of long trion lifetime. Therefore, the alternative approach to achieve both high trion quantum yield and long lifetime is to improve materials quality, since the low quantum yield and the short lifetime are attributed to the fast, non-radiative recombination rate of trion species in current TMD monolayers. In other words, the currently low QY and trion lifetime primarily arise from mediocre quality of TMDs with point defects concentrations on the order of 10^{12}-10^{13} cm^{-2}.
Here we report near-unity emission quantum yield, ∼89.2 %, by using monolayer MoSe₂ with a significantly lower defect density. Importantly, this produces the photoluminescence (PL) intensity which is mainly contributed to the trion species (>98%). The high trion PL quantum yield in the high-quality monolayer MoSe₂ is attributed to greatly suppressed non-radiative decay rate, leading to the long lifetime of trion (∼250 ps) approaching intrinsic radiative lifetime. Moreover, we propose that band-trap impact ionization in the high-quality monolayer MoSe₂ contributes to generation of ultrabright trion light emission over a wide range of doping concentrations. Our experimental results indicate that point defects as charge sources promote efficient trion generation in high quality MoSe₂. The high trion quantum yield and the long trion lifetime in the high-quality MoSe₂ provide the platform to explore new physics, including trion valley Hall effect and Moire excitons in heterostructures, demanding both high quantum yield and long lifetime. The superior optical properties of MoSe₂ are also expected to enhance the performance of the optoelectronic devices including light-emitters and photodetectors. Furthermore, the secondary carrier induced by band-trap impact ionization is expected to improve performance of optoelectronic devices, including solar cell and avalanche photodiodes.

4:15 PM MS02.05.07
Multiscale Nanostructures Enable Spatially-Defined Graphene Properties Shikai Deng¹, Dongjoon Rhee¹, Won-Kyu Lee¹, Songwei Che², Bijentimala Keisham², Vikas Berry² and Teri W. Odom¹;¹Northwestern University, United States; ²University of Illinois at Chicago, United States

Selectively functionalized graphene can realize spatially-defined properties that are highly desirable for atom-thin devices. Because curvature tunes the surface reactivity of graphene, patterning graphene into regions of different local curvatures can achieve domains with different levels of functionalization. Previous buckling methods were limited by the range of tunability over curvature and control of the orientation at the microscale. This presentation describes a scalable approach to achieve spatially selective graphene fluorination using multiscale wrinkles. Graphene wrinkles were formed by relieving the strain in thermoplastic polystyrene substrates conformally coated with fluoropolymer and graphene skin layers. Chemical reactivity of a fluorination process could be tuned by changing the local curvature of the graphene nanostructures. Patterned areas of graphene nanowrinkles and crumples followed by a single-process plasma reaction resulted in substrates with regions having different fluorination levels. We also demonstrated the conductivity of the functionalized graphene nanostructures could be locally tuned as a function of feature size without affecting the mechanical properties.

4:30 PM MS02.05.08
Computational Analysis of Tunability in the Electronic and Optical Response of Two-Dimensional Materials with Defects Ruth Pachter and Jie Jiang; Air Force Research Laboratory, United States

Defects play an important role in tuning the electronic and optical functionality of 2D materials that are useful for biosensing and nanoelectronics, or in providing the basis for single-photon emission for quantum information processing. We show that patterned graphene with vacancies may offer a route to bandgap generation, and potentially improvement of the I_{ON}/I_{OFF} ratio in a field effect transistor (FET) by nanohole passivation, e.g. through hydrogenation. FETs based on patterned graphene with small pores could have a high level of performance similar to graphene nanoribbons, however with the added benefit of no width confinement. In this context, we report on the theoretical characterization of Raman spectroscopy defect-induced intensities in graphene, which is difficult to achieve experimentally. Defective graphene oxide nanostructures are investigated in comparison to experiment,
where we find that the Raman $I(D)/I(D')$ intensity ratio decreases with increase in the nanohole size and the number of adsorbed oxygens, explaining the decrease of this characterization signature with increase of the exposure time to oxygen plasma. Predicted Raman spectroscopy intensity ratios are also confirmed by measurements for graphene oxide quantum dots. In addition, we discuss the optical spectra of monolayer transition metal dichalcogenides upon introduction of defects. The tunability in the optical response of mechanically deformed WSe$_2$ in comparison point defects is described. Finally, Raman intensity calculations demonstrate that a comparison between pristine and 2D WSe$_2$ with a single vacancy can provide a fingerprint for defect characterization.

SESSION MS02.06: Physico-Chemical Effects I

8:30 AM *MS02.06.01
Fracture and Strain Engineering of Two-Dimensional Materials Jun Lou; Rice University, United States

Two-dimensional (2D) materials, such as Graphene, hBN and MoS$_2$, are promising candidates in a number of advanced functional and structural applications, owing to their exceptional electrical, thermal and mechanical properties. Understanding mechanical properties of 2D materials is critically important for their reliable integration into future electronic, composite and energy storage applications. However, it has been a significant challenge to quantitatively measure mechanical responses of 2D materials, due to technical difficulties in the nanomechanical testing of atomically thin membranes. In this talk, we will report our recent effort to determine the engineering relevant fracture toughness of graphene with pre-existing defects, rather than the intrinsic strength that governs the uniform breaking of atomic bonds in perfect graphene. Our combined experiment and modeling verify the applicability of the classic Griffith theory of brittle fracture to graphene. In another example, we systematically characterize chemical vapour deposition-grown MoS$_2$ by photoluminescence spectroscopy and mapping and demonstrate non-uniform strain in single-crystalline monolayer MoS$_2$ and strain-induced bandgap engineering. Strategies on how to improve the fracture resistance in graphene, and the implications of the effects of defects and strain on mechanical and other functional properties of other 2D atomic layers will be discussed.

9:00 AM MS02.06.02
Bending of Multilayer van der Waals Materials Guorui Wang$^{1,2}$, Zhaohui Dai$^3$, Shizhe Feng$^4$, Luqi Liu$^1$, Zhiping Xu$^4$, Rui Huang$^1$ and Zhong Zhang$^1$; $^1$National Center for Nanoscience and Technology, China; $^2$University of Toronto, Canada; $^3$The University of Texas at Austin, United States; $^4$Tsinghua University, China

Out-of-plane deformation patterns, such as buckling, wrinkling, scrolling, and folding, formed by multilayer van der Waals materials have recently seen a surge of interest. One crucial parameter governing these deformations is bending rigidity, on which significant controversy still exists despite extensive research for more than a decade. Here, we report direct measurements of bending rigidity of multilayer graphene, molybdenum disulfide (MoS$_2$), and hexagonal boron nitride (hBN) based on pressurized bubbles. By controlling the sample thickness and bubbling deflection, we observe plate-like responses of the multilayers and extract both their Young's modulus and bending rigidity following a nonlinear plate theory. The measured Young's moduli show good agreement with those reported in literature ($E_{\text{graphene}}$ > $E_{\text{hBN}}$ > $E_{\text{MoS}_2}$), but the bending rigidity follows an opposite trend: ($D_{\text{graphene}}$ < $D_{\text{hBN}}$ < $D_{\text{MoS}_2}$) for multilayers with comparable thickness, in contrast to the classical plate theory, which is attributed to the interlayer shear effect in the van der Waals materials.

9:15 AM MS02.06.03
Study of Fracture Initiation Behavior of MXene with MD Modeling Congjie Wei and Chenglin Wu; Missouri University of Science and Technology, United States

Due to the directionality of Ti$_3$C$_2$T$_x$ and Ti$_2$CT, MXene, the fracture initiation property varies with loading directions. Understanding this rarely explored anisotropic fracture behavior of MXene is essential for material
design and engineering application. In this work, a series of molecular dynamics (MD) modeling is conducted on mono-layer Ti$_3$C$_2$ and Ti$_2$C MXene. Pre-cracks of both zigzag and armchair directions are created by removing atoms. For both cases, pre-cracked MXene is stretched to the crack initiation point and then energy minimization is conducted with canonical ensemble, where the stress distribution and J-integral are calculated and compared. Both mode-I and mixed mode scenarios with ranging loading directions are conducted to explore the combined effect of structural and loading directionality. Also, mode-I crack initiation scenario of graphene is conducted and compared with the Ti$_3$C$_2$Tx and Ti$_2$CTx MXene to explore the thickness effect. Results show that the thickness variation leads to difference of stress distribution around the crack tip, thus influences the crack initiation property.

Probing Anisotropic Thermal Conductivity of Transition Metal Dichalcogenides and Their Alloys Ronggui Yang$^1$, Puqing Jiang$^2$ and Xin Qian$^{1,3}$; $^1$University of Colorado at Boulder, United States; $^2$Huazhong University of Science & Technology, China; $^3$Massachusetts Institute of Technology, United States

Transition metal dichalcogenides (TMDs) and their alloys have attracted great interest in recent years due to their potential electronic, photonic and energy applications. However, due to the challenges on anisotropic thermal conductivity measurements, the thermal conductivities of layered TMDs and their alloys remain largely unexplored despite their critical roles in the reliability and functionality of TMD-enabled devices. Motivated by this perspective, we employed frequency-dependent time-domain thermoreflectance (TDTR) with variable spot sizes to systematically and accurately measure the anisotropic thermal conductivities of a series of TMD crystals, including MoS$_2$, MoSe$_2$, WS$_2$ and WSe$_2$, and TMD alloys, WSe$_2$(1-x)Te$_2$x, in both the in-plane direction (parallel to the basal planes) and the cross-plane direction (along the c-axis). In both the TMD crystals and the WSe$_2$(1-x)Te$_2$x alloys, the cross-plane thermal conductivity was consistently observed to be dependent on the heating frequency (modulation frequency of the pump laser). A two-channel thermal model was used to analyze the experimental data and the frequency dependence was attributed to the non-equilibrium thermal resistance between different groups of phonons in the substrate. In WSe$_2$(1-x)Te$_2$x alloys, a clear discontinuity in both the cross-plane and the in-plane thermal conductivities is observed as x increases from 0.4 to 0.6, due to the phase transition from 2H to Td phase in the layered alloys. The temperature dependence of thermal conductivity for the TMD alloys was also found to be weaker compared to the pristine 2H WSe$_2$ and Td WTe$_2$ due to the atomic disorder. Our measurements serve as an important baseline to understand the thermal conductivity of TMDs and other layered materials.

Vibrational Energy Transport across Correlated Random Interfaces Taishan Zhu, Kiarash Gordiz, Arthur France-Lanord, Asegun Henry, Giuseppe Romano and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Interfaces provide an effective opportunity to enable novel functionalities and avenues where intriguing physics occurs. While pristine interfaces have been mostly studied, random interfaces have thus far been less explored. In this work, we investigate the effects of correlated interfacial disorder on vibrational energy transport, using graphene-hexagonal boron nitride (G-hBN) interfaces as our model system. More than Poisson point process (white noise, uncorrelated) type of randomness, we studied different types of correlated disorder with varying correlation functionals. When disorder is present, in contrast to the conventional scattering theory (e.g. Rayleigh’s theory), our non-equilibrium Green’s function (NEGF) results show surprising enhancement of energy transmission for a wide spectrum of vibrational modes. To underpin the transport physics, we send probing wavepackets across the interfaces with (q, w) modal resolution. These wavepacket simulations demonstrate an identical frequency regime of transmission enhancement predicted by NEGF analysis, and reveal the effects of mode conversion absent for pristine interfaces due to structural disorder. Beyond the above single-particle picture, we calculate modal correlation matrix based on Green-Kubo modal analysis, and show the effects of interfacial disorder on modal correlation, as well as their contribution to overall interface conductance, both diagonal and off-diagonal. This work could help understand the physics of phonon transport across random interfaces, and would be interesting to practical interface designs, such as thermoelectric and acoustic applications.

10:45 AM MS02.06.06
Determination of Thermal Conductivity in Graphene and Related Materials Srinivasan Mahendran1, Jesús Carrete2, Georg Madsen2, Andreas Isacsson1 and Paul Erhart1; 1Chalmers University of Technology, Sweden; 2TU Wien, Austria

Graphene is viewed as a promising material with unique properties. Thanks to their excellent thermal conductivity, graphene and related materials can for example be used as composite filler materials. There is, however, a crucial lack of information regarding the connection between transport properties and materials morphology. For computing the thermal transport properties, traditional methods based on systematic enumeration of finite differences scale poorly with system size, especially in simulations with low symmetry and for systems with defects. Here, we combine advanced regression techniques for the extraction of force constants with the T-matrix approach [1] to systematically explore the impact of defects of varying dimensionality on the thermal conductivity. We employ the HIPHERGE [2] package for the extraction of force constants, which exploits crystal symmetries and advanced regression algorithms to dramatically reduces the number of reference calculations. As the latter are commonly carried out using computationally expensive first-principles methods, this reduces the computational effort by orders of magnitude.

11:00 AM MS02.06.07
Predicting Thermal Conductivity of Defective MoSe2 Using First-Principles and Modified Empirical Equations Zhequan Yan and Satish Kumar; Georgia Institute of Technology, United States

MoSe2 as one of the promising two-dimensional transition metal dichalcogenides (TMDCs) recently emerged as a promising alternative of graphene for nano-electronic and opto-electronic devices due to its unique transport properties. The inefficient heat removal due to the low thermal conductivity of monolayer MoSe2 can cause critical challenges for its devices. The defects due to the imperfection of growth processes, such as vacancies significantly reduced thermal conductivity and aggravate the thermal management challenges. Very few studies has focused on exploring the effect of defects on the thermal transport in monolayer MoSe2. In addition, a fully parameter-free defect model is needed to examine and estimate the thermal properties considering the influence of defects; this requires improvement in the existing empirical models. The first-principles Density Functional Theory (DFT) and the phonon Boltzmann transport equations based simulations are used to study the phonon transport properties of pristine and defective monolayer MoSe2 with Se vacancies. A model, which is fully parameter-free, is developed using first-principles approach. The impact of three different types of Se vacancies on the thermal conductivity of monolayer MoSe2 is studied. The findings indicate how the vacancy-induced phonon states and different phonon scatterings are influenced by different types of Se vacancies. The existing Se vacancies redistribute the phonon DOSs by lowering the frequency cutoff and generating defect-induced phonon states, which soften the phonon modes in the dispersion relations and result in a lower phonon group velocity. Furthermore, an empirical model to estimate the effect of Se vacancies is developed to compare with the DFT results. It’s found that the empirical defect model overestimates the influence of point vacancy at low temperature. Additional terms are introduced to the modified empirical model to consider defects providing a better match with the parameter-free DFT simulation. The results from this study will help us understand the mechanism of phonon transport under the influence of different types of point defects. This work provides insights and directions for validating and improving the empirical defect model, which can be used for estimating the material properties considering the influence of defects.

2D Heterostructures under Pressure—The Graphene/h-BN Case—From van der Waals to Covalent Ana Barboza1, Alan Souza2, Matheus Matos1, Juliana Brant2, Tiago Brabosa2, Helio Chacham2, Mario Mazzoni2 and Bernardo R. Neves2; 1UFOP, Brazil; 2University Federal-Minas Gerais, Brazil

Graphene atop (or sandwiched in) h-BN is, by far, the most investigated 2D material heterostructure. Their weak van der Waals interlayer interaction enables the investigation of exquisite physical properties. On a different path, the present work indicates a van der Waals-to-covalent interaction transition for such heterostructure under pressure. Insulating and conductive states appear depending on the number of graphene layers and pressure. While it benefits from weak van der Waals interaction for fabrication, the present study both induces and investigates the effects of strong interlayer interaction. As a consequence, it shows the emergence of different properties from their parent 2D materials with eventual intricate competing mechanisms. More specifically, scanning probe microscopy and ab initio
calculations reveal modifications on the electronic and structural properties of graphene/h-BN heterostructures induced by compression. Using AFM and EFM techniques, with charge injection being made in the heterostructures at different pressures, the charge injection efficiency monotonically decreases with increasing pressure for monolayer-graphene (MLG)+BN heterostructures, indicative of a conductor-insulator electronic modification. Bilayer-graphene (BLG)+BN and trilayer-graphene (TLG)+BN heterostructures show a non-monotonic behavior of charge injection versus pressure, indicative of competing electronic structure modifications. First-principle calculations of these systems indicate a pressure-induced van der Waals-to-covalent interlayer transition, where such interlayer covalent binding, in the presence of water molecules, results in a disordered insulating structure for the MLG+BN case, while it leads to an ordered conducting structure for both BLG+BN and TLG+BN heterostructures. Besides introducing a distinct perspective on the study of 2D materials and their van der Waals heterostructures, the present work stresses the importance of interlayer interaction in any device based on such heterostructures. For example, flexible optoelectronic devices are expected to suffer a significant strain variation, which may lead to different interlayer interaction regimes, ultimately affecting device performance. In other words, the present work shows that there is a strong role for interlayer interaction in the (initially) weakly-bound van der Waals heterostructures.

Tuning Thermal Transport in van der Waals Solids under Extreme Strain Xianghai Meng¹, Tribhuwan Pandey², Abhishek K. Singh², Jung-Fu Lin¹ and Yaguo Wang¹; ¹University of Texas at Austin, United States; ²Indian Institute of Science, India

Strain is an effective tool to tune physical properties in a wide range of materials. In transition metal dichalcogenides (TMDs), a family of two-dimensional (2D) van der Waals (vdW) solids, strain can alter the interlayer distance, as well as bond strength, length and angle between the transition metal and chalcogen atoms, modifying the interatomic orbital coupling, interlayer wavefunction overlap and valence band splitting. In traditional mechanical bending/stretching experiments, the 2D materials sit on a flexible substrate and strain is determined by the elongation or radius of curvature of the substrate. Any slippage across the sample/substrate interface or imperfect strain transfer across layers can introduce large uncertainties. Moreover, strains generated in stretching/bending experiments are typically only less than 4%. Hydrostatic pressure created in a diamond anvil cell (DAC) can generate compressive strain as high as 30%, without introducing any damage to the samples. DACs have been extensively used in the geophysics field to simulate the high-pressure environment in planetary interiors. Pressure in a DAC is determined by monitoring the fluorescence peak of a ruby crystal placed adjacent to the sample, with an accuracy better than 1 GPa.

Previous studies demonstrated that with about 9% cross-plane compressive strain, molybdenum disulfide (MoS₂) exhibits a semiconductor to metal (S-M) transition, with an electrical conductivity enhancement from 0.03 S/m to 18 S/m. Extreme strain should also have a profound impact on phonon transport properties, which can affect the thermal transport in MoS₂. In this talk, I will present our recent work about tuning thermal transport of MoS₂ under extreme strain. A DAC device is integrated into our recently developed picosecond transient thermoreflectance (ps-TTR) system to measure the strain-tuned cross-plane thermal conductivity (κ) in bulk MoS₂ up to ~19 GPa (over 9% cross-plane strain). We observed roughly a 7x increase of κ, from 3.5 W m⁻¹K⁻¹ at ambient pressure to about 25 W m⁻¹K⁻¹ at 19 GPa. First-principles calculations and electrical conductivity measurements suggest that this drastic change arises mainly from the substantially strengthened interlayer force and heavily modified phonon dispersions along the cross plane direction. The group velocities of coherent longitudinal acoustic phonons (LAP), measured with coherent phonon spectroscopy (CPS), increase by a factor of 1.6 at 19 GPa due to phonon hardening, while their lifetimes decrease due to the phonon unbundling effect. These results suggest possible parallel tuning of structural, thermal and electrical properties of vdW solids with strain in multi-physics devices.

Revealing the Full Spectrum Layered Materials with Super-Human Predictive Abilities  
Evan J. Reed and Gowoon Cheon; Stanford University, United States

We have utilized data mining approaches to elucidate over 1000 2D materials and several hundred 3D materials consisting of van der Waals bonded 1D subcomponents, or molecular wires. We find that hundreds of these 2D materials have the potential to exhibit observable piezoelectric effects, representing a new class of piezoelectrics. A further class of layered materials consists of naturally occurring vertical hetero structures, i.e., bulk crystals that consist of stacks of chemically dissimilar van der Waals bonded layers like a 2-D super lattice. We further combine this data set with physics-based machine learning to discover the chemical composition of an additional 1000 materials that are likely to exhibit layered and two-dimensional phases but have yet to be synthesized. This includes two materials our calculations indicate can exist in distinct structures with different band gaps, expanding the short list of two-dimensional phase change materials. We find our model performs five times better than practitioners in the field at identifying layered materials and is comparable or better than professional solid-state chemists. Finally, we find that semi-supervised learning can offer benefits for materials design where labels for some of the materials are unknown.

Moire Quasiperiodicity in the van der Waals Heterojunctions  
Philip Kim; Harvard University, United States

Heterogeneous interfaces between two dissimilar materials are an essential building block for modern semiconductor devices. The 2-dimensional (2D) van der Waals (vdW) materials and their heterostructures provide a new opportunity to realize atomically sharp interfaces in the ultimate quantum limit for the electronic and optoelectronic processes. By assembling atomic layers of vdW materials, such as hexa boronitride, transition metal chalcogenide and graphene, we can construct atomically thin novel quantum structures. We demonstrate the enhanced electronic optoelectronic performances in the vdW heterostructures, suggesting that these a few atom thick interfaces may provide a fundamental platform to realize novel physical phenomena. In this presentation, we will discuss two topics associate with the commensuration and incommensuration between the vdW layers. Many exotic physical phenomena occur associated with the incommensurability of the moiré superstructures; the fractal energy spectrum of Hofstadter butterfly and recently discovered Mott insulating and unconventional superconducting behavior of the ‘magic’ twist angle bilayer graphene have demonstrated the wealth of the nontrivial topology of electronic band structures. We find that the vdW interaction energy that favors interlayer commensurability competes against the intralayer elastic lattice distortion to form a quasi-periodic domain structure, inducing profound changes in electronic structure. Particularly, we show quantitative analysis of the engineered atomic-scale reconstruction completely controlled by the twist angle between two graphene layers and anomalous electron transport occurring in the network of topologically protected propagation modes along the domain boundaries.

Crack-Free, Area-Specific Graphene Wrinkles with Switchable Orientation on Soft Skin Layers  
Dongjoon Rhee1, Jeffrey T. Paci2, Shikai Deng1, Won-Kyu Lee3, George Schatz1 and Teri W. Odom1; 1Northwestern University, United States; 2University of Victoria, Canada; 3Harvard University, United States

The buckling of graphene via strain relief of elastomeric substrates can engineer its physical properties such as
electrical conductivity and plasmon resonances without using lithographic processes. Because the wavelength and orientation of resulting crumples can change in response to applied strain, graphene functionalities can be dynamically modulated by stretching or bending the substrate. Graphene crumples, however, have been limited by crack formation under tensile strain, particularly in delaminated regions. Furthermore, area-specific tuning of structural parameters and hence properties is not possible because only textures with globally uniform wavelength and orientation can be produced. This presentation will describe a conformal wrinkling strategy that creates crack-free graphene nanostructures with locally different wavelengths on an elastomeric platform. By sandwiching fluoropolymer skin layers with spatially varying thicknesses between graphene and the substrate, we formed multiscale graphene wrinkles with predetermined wavelengths after strain relief. Because delamination was suppressed with the presence of the skin layer, the wrinkle orientation could be switched under cycles of stretching and releasing without significant cracking—even beyond the intrinsic fracture limit of graphene. Through mechanics modeling, we revealed that the fluoropolymer layer mediated structural evolution of the graphene wrinkles without cracking via conformal adhesion. With exquisite control over wrinkle topography, our crack-free, multiscale wrinkling strategy will be useful for optoelectronics and plasmonics based on graphene and other two-dimensional nanomaterials.

**Keynote: Molecular Transport through Two-Dimensional Capillaries** Andre Geim; University of Manchester, United Kingdom

I will review our group’s work on the molecular transport properties of angstrom-scale channels fabricated by der Waals assembly of 2D crystals. These channels can be viewed as if individual atomic planes were extracted from a bulk crystal leaving behind two edge dislocations with an empty space in between. Gas, water, ion and proton transport have been studied in capillaries down to one atom in height.
applications will be also discussed.

9:00 AM *MS02.09.02
Defect-Mediated van der Waals Epitaxy of Transition Metal Dichalcogenides Xiaotian Zhang, Tanushree H. Choudhury, Benjamin Huet, Mikhail Chubarov and Joan M. Redwing; The Pennsylvania State University, United States

Direct growth of transition metal dichalcogenides (TMDs) such as WS\textsubscript{2} and WSe\textsubscript{2} on graphene and hexagonal boron nitride (hBN) is of interest for the fabrication of 2D heterostructures as an alternative to exfoliation and 2D layer stacking. Commensurability between the TMD lattice and graphene or hBN is favorable for epitaxy, however, it is difficult to control nucleation and wetting of the TMD on pristine van der Waals surfaces due to the low surface energy and lack of chemical bonding. In addition, mirror twins and inversion domains can form due to rotational symmetry which introduces grain boundaries in coalesced TMD films. However, the presence of defects in hBN and graphene can dramatically alter the energy landscape providing an alternative route to control nucleation and epitaxy.

Our recent studies have focused on the epitaxial growth of WSe\textsubscript{2}, WS\textsubscript{2} and related TMD monolayer films by gas source chemical vapor deposition (CVD) on hBN and graphene. The CVD process is carried out in a cold-wall reactor using metal hexacarbonyls and hydride chalcogen precursors in a hydrogen carrier gas. In the case of growth on epitaxial graphene on SiC, nucleation of WS\textsubscript{2} and WSe\textsubscript{2} occurs primarily at wrinkles and step edges resulting in different WS\textsubscript{2} rotational orientations. In the case of WSe\textsubscript{2} growth on hBN, however, single atom vacancies in the hBN were found to act as sites for metal atom trapping which facilitates the nucleation of WSe\textsubscript{2} domains on the surface. In this case, the TMD nucleation density can be controlled by manipulating the density of surface atom vacancies which can be achieved through plasma irradiation and annealing in NH\textsubscript{3}. In addition, the metal atoms break the surface symmetry which leads to a preferred orientation (~95%) for WSe\textsubscript{2} domains on hBN. Through careful control of nucleation and extended lateral growth time, fully coalesced WSe\textsubscript{2} monolayer films on hBN were achieved which exhibit optical and transport properties superior to comparable films grown on sapphire substrates. The results demonstrate the important role of defects in nucleation and epitaxial growth of 2D heterostructures.

9:30 AM BREAK

10:00 AM MS02.09.03
Controllably Strained Layered Transition Metal Dichalcogenides Grown on Single-Crystal Quartz Substrates via Chemical Vapor Deposition Fangze Liu, Oleg V. Kozlov, Vladimir Sayevich, Igor Fedin, Hsinhan Tsai, Wanyi Nie and Victor I. Klimov; Los Alamos National Laboratory, United States

Strain engineering is widely used for tuning the properties of materials and thereby realizing high performance electronic and optoelectronic devices. In bulk three-dimensional materials, the strain-controlled tunability is, however, limited by low values of ‘failure strain’ which triggers formation of lattice defects. On the other hand, two-dimensional (2D) materials such as graphene and layered transition metal dichalcogenides (TMDs) can tolerate much greater strain, and thus are perfect materials for practically implementing the ideas of strain engineering. [1] Among many different methods to introduce strain in TMDs, mismatch between coefficients of thermal expansion (CTE) of a growth substrate and a TMD layer is one of the most promising method mainly due to two reasons: (1) large-area strained TMDs can be directly prepared through bottom-up synthesis such as chemical vapor deposition (CVD) or molecular beam epitaxy (MBE); (2) the induced strain is maintained intrinsically without any external force or treatment since the as-grown TMD is anchored to the substrate at the fabrication stage. Previous reports on CTE mismatch of CVD-grown TMDs have been only able to achieve tensile strain or low compressive strain (<0.2%). [2] While tensile strain normally decreases the band gap of TMDs, compressive strain tends to increase the band gap. Moreover, recent theoretical and experimental studies [3, 4] have shown that a large compressive strain can be used to stabilize a nominally unstable 1T TMD phase, which is attractive for applications including hydrogen evolution and low-contact-resistance electronic devices. [5]

Here, we use single crystal quartz substrates, which have large CTE compared with MoS\textsubscript{2}, to achieve compressive strain up to 1%. The strong built-in strain is indicated by the increased photoluminescence and optical absorption energies as well as ‘stiffening’ of characteristic A\textsubscript{1g} and E\textsubscript{1g} Raman modes. Owing to the different CTE of single crystal quartz along the a- and c-axes, MoS\textsubscript{2} grown on different facets experiences different levels of strain.
Specifically, the layers grown on the c-plane exhibit higher strain compared to those prepared on the x-plane which is direct consequence of the higher CTE. Additionally, the MoS$_2$ layers grown on the AT-cut quartz are highly aligned due to the strongly anisotropic nature of the underlying quartz surface. [6]

The ability to tune electronic properties of TMD layers by engineered strain can be especially useful for controlling interfacial interactions in complex hetero-structures comprising TMD materials as electronically and/or optically active components. Presently, we are exploring this capability for manipulating charge and energy flows in multi-dimensional materials assembled from TMDs and colloidal quantum dots.

**Chemical Vapour Deposition Growth of Graphene from Petroleum Coke Feedstock upon Pre-Existing Graphitic Edges**
*Thomas P. Raine, Mark A. Bissett and Ian Kinloch; University of Manchester, United Kingdom*

Petroleum coke (PC), a cheap and readily available hydrocarbon feedstock has great potential as a starting material for synthesis of high value graphitic materials. Graphene produced by traditional graphitization of carbon materials at up to 3000 °C [1], and subsequent exfoliation, comes at a large energy cost. By utilising chemical vapour deposition (CVD), graphitic materials can be produced at far lower temperatures, thus providing a large cost and energy saving. Direct exfoliation of high quality coke (carbon content > 96 wt%) has been reported [2], however, lower quality coke requires modification prior to exfoliation.

In this work we present evidence for the synthesis of graphene directly from low quality PC powder by CVD growth from defective graphitic edges. Subsequent exfoliation of the coke materials after treatment allows for the isolation of high quality graphene flakes. We investigate low temperature plasma treatment of the coke powders in order to yield functionalised graphitic materials, with potentially useful properties. We examine the strain behaviour of the PC-derived graphene and their plasma functionalised analogues in order to understand the role of functional defects upon the properties of the graphene. Finally, we investigate the potential of PC for carbon nanotube (CNT) production by seeding coke powder with transition metal nanoparticles, thus synthesising graphene/CNT hybrid powders.

10:30 AM MS02.09.05
**Sweet Green Graphene—A Mechanochemical Synthesis**
*Ester Vazquez; UCLM, Spain*

Green Chemistry protocols have been recently applied to the design of nanomaterials, being the preparation of gold and silver nanoparticles successful examples of this trend. However, the preparation of graphene still offer challenging opportunities for the development of green technologies, involving the use of natural sources, safe solvents and energy efficient processes. Moreover, the implementation of the concept safe by design also applies to the preparation of nontoxic graphene products.

During this talk we will try to give answers to these questions: Can we design an aqueous soluble graphene material, suitable for being employed in biomedical studies, without changing graphene chemical characteristics? Can this design be optimized for Green Chemistry principles?
Following our previous experience in the preparation of graphene materials, we will describe the use of a mechanochemical treatment, in solvent-free conditions, using carbohydrates to exfoliate graphite in a simple and green approach. Among glucose, fructose and saccharose, the former shows the best behavior in terms of exfoliation, generating graphene materials with a relatively low number of defects. Once exfoliated, glucose can be washed and recovered, just by using water, and the final graphene material can be thoroughly characterized. Moreover, the addition of molar equivalents of water to the ball milling treatment, allows the formation of glucose-graphene cocrystals. Analogously to what happens with drugs, glucose-graphene cocrystals display higher performance in terms of stability in aqueous dispersions. In addition, we will show preliminary toxicological tests illustrating the safety of the designed material.

10:45 AM MS02.09.06
Mussel-Inspired Defect Engineering for High Performance of Graphene Liquid Crystalline Fibers  
Inho Kim, Taeyeong Yun and Sang Ouk Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Here, we present an effective fabrication method of graphene liquid crystalline fibers to attain high mechanical and electrical properties simultaneously inspired by mussel adhesive polydopamine (PDA). Two-step defect engineering was designed relying on bioinspired surface polymerization within GO dispersion and subsequent solution infiltration of PDA to improve the intrinsic limitation of graphene fibers arising from structural defects of graphene layers during wet-spinning process. For a straightforward understanding of the PDA-induced defect engineering mechanism, interfacial adhesion between GO flakes was carefully analyzed by AFM pull-off test. In addition, PDA could be converted into N-doped graphitic domain within the fiber structure by following pyrolysis resulting in mechanically strong fibers without scarifying electrical conductivity. This bioinspired graphene-based carbon fiber retains a great potential for a wide range of applications such as flexible electronics, multifunctional textiles, and wearable sensors.

11:00 AM MS02.09.07
The Effects of Graphene and Its Defects on Hydrogen Permeation in Cu  
Katherine T. Young1, Dale Hitchcock2, Colter Smith1, Tim Krentz2 and Eric M. Vogel1; 1Georgia Institute of Technology, United States; 2Savannah River National Lab, United States

Industrial processes such as natural gas separation, hydrogen production, etc. rely heavily on gas separation. For instance, hydrogen reforming from methane uses several techniques such as metallic, silica, zeolite, and polymer membranes for gas separation. The thickness of these membranes can range from tens of nanometers to microns. The efficiency of these membranes depends heavily on permeance through the membrane as well as gas selectivity. Ideally, a membrane would have pore sizes close to the kinetic diameter of the desired gas, while being as thin as possible to increase permeance. 2D materials with high impermeability, high aspect ratio, high strength, chemical inertness and atomic thickness may be able to fulfill this need.

Graphene has been shown to be an extremely impermeable barrier, largely due to its unique structure. Graphene is composed of C with sp² bonds in plane with π orbitals perpendicular to the surface, which form a delocalized cloud repelling other molecules. It was shown that mechanically exfoliated, pristine graphene is impermeable to He. Thus, any permeability must be induced by adding pores to the system. Adding uniformly distributed pores of a specific size has been a challenge, and has not yet been demonstrated with an adequate level of control. Other groups have focused on graphene synthesized by chemical vapor deposition (CVD) due to its scalability compared to mechanically cleaved graphene; however, transferred CVD graphene often has holes from the transfer process. These holes seriously degraded the selectivity of the graphene composite membrane so that it was only selective to molecules with diameters of > 1 nm, and smaller diameter gases were able to pass freely. Groups have tried to alter transfer methods, plug the induced holes, or stack graphene sheets, but these transfer-induced defects make it difficult to study the effects of intrinsic defects in CVD graphene, such as grain boundaries and point defects.

In this work, single layer graphene was synthesized by CVD on a Cu foil catalyst. H₂ is permeable in many metals, including Cu. Thus, the permeability of CVD grown graphene can be measured directly while still on the catalyst using a gas driven technique. The difference in permeability of the graphene-coated Cu from the bare Cu can be attributed to the permeability of the graphene. The graphene-coated samples consistently showed lower permeability compared to the bare Cu sample. Furthermore, since pristine graphene has already shown impermeability to gases, any permeability through the graphene should be through intrinsic defects like grain boundaries and point defects in
the graphene. Graphene grain sizes with varying orders of magnitude were synthesized, and the H₂ permeabilities measured. This work is able to systematically measure and model the effects of grain size by measuring gas permeation of graphene that is not transferred (so that cracks are not induced), and the only permeation must be through graphene defects. Thus, graphene with different grain sizes can be engineered to create membranes with different permeabilities to H₂, without needing to induce nanopores or fix transfer-induced cracks.

The project depicted is supported by the Savannah River National Lab (SRNL) Laboratory Directed Research and Development program (LDRD-2017-00028). SRNL is managed and operated by Savannah River Nuclear Solutions, LLC under contract no. DE-AC09-08SR22470 with the U. S. Government. This work was performed in part at the Georgia Tech Institute for Electronics and Nanotechnology, a member of the National Nanotechnology Coordinated Infrastructure, which is supported by the National Science Foundation (Grant ECCS-1542174).

Nanoscale Characterisation of Graphene to Determine the Level and Location of Functional Groups and the Effect on Mechanical Properties of Composites Barry Brennan1, Elizabeth J. Legge1,2, Keith Paton1, Magdalena Wywijas1, Rory Pemberton1, Naresh Kumar1, Greg McMahon1, Arun P. Raju1, Craig Dawson1, Andrew Strudwick1, James W. Bradley4, Vlad Stololjan2, Ravi Silva2, Stephen A. Hodge5 and Andrew Pollard1; 1NPL, United Kingdom; 2University of Surrey, United Kingdom; 3University of Manchester, United Kingdom; 4University of Liverpool, United Kingdom; 5Versarien Plc, United Kingdom

Graphene is a highly desirable material for a variety of applications due to its inherent material properties. However, realising the full potential of these properties has proved challenging due in part to difficulties in uniformly incorporating it within other media. One route towards tailoring the properties of graphene to allow better interaction with other materials and thereby improving the ultimate product performance is through functionalisation. For example, in nanocomposites the incorporation of functionalised graphene can lead to changes in tensile strength, optical transparency and electrical and thermal conductivity. However, often the resulting structure of the functionalised graphene material, and the location and level of the chemical species added via different functionalisation processes is not known or understood.

In this study we characterise a commercially available powder containing few-layer graphene (FLG) flakes, and the subsequent composite products, after both plasma and chemical functionalisation of the FLG with amine and -OH groups. Alongside confocal Raman spectroscopy, scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM) results, tip-enhanced Raman spectroscopy (TERS) and secondary ion mass spectrometry (ToF-SIMS and NanoSIMS) were used to show chemical changes in the FLG material at both the nanometre and micron scale and monitor the dispersion of the flakes within the composite for the various functionalisation processes. [1] These are the first reported TERS measurements on commercially available graphene materials and show the location of the defects associated with the attachment of functional groups to the FLG. Nanoscale TERS images of the D-peak intensity show changes within flakes [2] and variations between the different types of functionalisation, indicating that it is possible to discriminate between functionalisation taking place at the edge of the flakes or within the basal plane.

The plasma functionalisation process was observed to produce flakes with higher levels of functionalisation than chemical functionalisation. The amine functionalisation via plasma process created defects in the basal plane of the flakes, whereas the –OH functionalization appeared to have functional groups present predominantly at the edges of the flakes. ToF-SIMS depth-profiling results of nanocomposites subsequently produced with polyurethane suggested that the plasma –OH material agglomerated the least within the polymer matrix. However, the non-functionalised material produced the largest improvement in mechanical properties for the nanocomposite.

Defect-Mediated Chemical Modification of Semiconducting 2D Metal Chalcogenides Qing Hua Wang; Arizona State University, United States

Metal chalcogenides that can be isolated as 2D semiconducting layers form a diverse family of materials with unique properties. Defects that are found or can be created in these materials are an important route for controlling their chemical reactivity. This talk will highlight our recent work on several defect-mediated chemical modifications of 2D metal chalcogenides. First, the covalent functionalization of the basal planes of the transition metal dichalcogenides (TMDCs) MoS2, MoSe2, WS2, WSe2, and the pnictogen chalcogenides (PCs) Bi2S3, and Sb2S3 using aryl diazonium salts occurs at initial point defect sites and edges, but propagates across the surface in a chain-like morphology. This functionalization scheme is studied in detail using density functional theory (DFT) and kinetic modeling for MoS2, and the diazonium salts can also be modified to enable tethering of proteins to the MoS2 surface. Second, MoO3 and WO3 nanoscrolls are formed by transformation from 2D MoS2 and WS2 nanosheets, respectively, via atmospheric plasma treatment which occurs due to the combination of different radicals in the plasma that simultaneously form defects and cracks in the 2D layers and oxidize them, so that the strain of the altered crystal structure is relieved by rolling into nanoscroll geometries. Finally, self-assembled monolayers of fullerene molecules on the surface of WSe2 are studied using atomic resolution scanning tunneling microscopy to show that the molecules exhibit a 2x2 rotational superstructure due to the interplay of molecule-molecule, molecule-substrate, van der Waals, and Coulomb interactions to form a charge redistribution network with long-range ordering.

Flexoelectricity Induced Electromechanical Response of Two-Dimensional Transition Metal Dichalcogenides Md Farhadul Haque1, Hyung Jong Bae1, Jin Myung Kim1, Chullhee Cho1, Michael C. Wang2 and SungWoo Nam1; 1University of Illinois at Urbana-Champaign, United States; 2University of South Florida, United States

Flexoelectricity is the strain gradient (direct effect) or electric field gradient (converse effect) induced electromechanical response in a dielectric material. Unlike piezoelectricity, flexoelectricity is ubiquitous in materials, not limited by inversion asymmetric crystal structure. However, flexoelectricity is limited in bulk material, because any significant amount of polarization would require large amount of strain gradient which is limited by mechanical fracture. Thanks to the atomically thin dimension, 2D materials can withstand large amount of strain gradient without mechanical failure. Therefore, flexoelectricity has enabled new opportunities in micro or nano electro-mechanical systems. However, a study of the mechanism of this universal yet underappreciated flexoelectricity in 2D materials has been limited. In this work, we investigated the converse flexoelectric response of 2D transitional metal dichalcogenides (TMDCs) by piezoresponse force microscopy (PFM). PFM is widely used technique to quantify effective piezoelectric coefficients, providing a direct correlation between applied electric field and resulting deformation in materials. Our results showed that the effective out-of-plane piezoelectric coefficient (d33) rises from mono-layer to bi-layer for MoS2 and WSe2, then saturates at a slightly reduced magnitude for tri-layer and quad-layer structures. We have correlated the d33 trend observed in our TMDC layers with materials adhesion to the substrate, flexural rigidity of the 2D materials and possible charge transfer between the substrate and the materials. We believe that the converse flexoelectric effect observed in 2D TMDCs arises from a combination of the effects of flexural rigidity of the atomically thin materials and charge transfer between the material and substrate. We further report that in-plane tensile strain reduced d33 by restricting the out-of-plane deformation. Our findings
can help understanding the fundamentals of flexoelectric behavior in 2D materials and pave the way for next generation actuators and energy harvesting devices.

1:45 PM MS02.10.02
Extreme Tensile Strain States in La_{0.7}Ca_{0.3}MnO_{3} Nanomembranes Seung Sae Hong1,2, Mingqiang Gu3, Manish Verma4, Di Lu2,1, Varun Harbola2,1, Arturas Vailionis1, Yasuyuki Hikita2, Rossitza Pentcheva1, James Rondinelli3 and Harold Y. Hwang1,2; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States; 3Northwestern University, United States; 4University of Duisburg-Essen, Germany

A defining feature of emergent phenomena in correlated systems is the competition and cooperation between ground states, which can be sensitively tuned by the lattice. This has been explored using hydrostatic pressure, epitaxial lattice-mismatch in films, and uniaxial strain. Manganites provide canonical examples where various metallic and insulating phases, and associated magnetic and orbital ordering, are delicately balanced. Extending the range of lattice control would enhance the ability to access and investigate new phases. Recent advances in the thin film epitaxy of a water-soluble layer enable the synthesis of many types of complex oxides and heterostructures as macroscale freestanding 2D nanomembranes [1] with considerable mechanical flexibility. Here we stabilize extreme tensile strain in nanoscale La_{0.7}Ca_{0.3}MnO_{3} membranes, exceeding 8% uniaxially and 5% biaxially [2], and study their magnetotransport properties down to cryogenic temperatures. These macroscopic strain states are found to correspond to microscopic lattice parameter changes, i.e. elastic deformation. The systematic control of biaxial strain reveals a rich phase diagram of competing phases, including a dramatic shift in the metal-to-insulator and magnetic transition, as well as a new insulating ground state that can be extinguished by magnetic field. Electronic structure calculations indicate that the insulator consists of charge-ordered Mn^{4+} and Mn^{3+} with staggered strain-enhanced Jahn-Teller distortions within the membrane plane. This highly-tunable strained membrane approach provides a broad opportunity to design and manipulate correlated states in 2D quantum materials.

2:00 PM MS02.10.03
Adhesion of Two-Dimensional Titanium Carbides (MXenes) to MXenes and Graphene Yanxiao Li, Shuohan Huang, Congjie Wei, Chenglin Wu and Vadym Mochalin; Missouri University of Science and Technology, United States

Two-dimensional (2D) transition metal carbides (MXenes) have attracted a great interest as a relatively new and large class of materials with unique electronic and optical properties. Among 20 different kinds of MXenes, Ti3C2Tx and Ti2CTx are most widely investigated. Understanding of adhesion between MXenes and MXenes or other 2D materials is critically important for 2D layered nanostructure composites fabrication, which are promising candidates for conducting high-performance energy conversion and environmental remediation. Herein, through atomic force microscopy (AFM) experiment on Ti3C2Tx-Ti3C2Tx, Ti3C2Tx-Ti2CTx, Ti3C2Tx-Ti2CTx-Ti3C2Tx, Ti3C2Tx-1-5 layer graphene interfaces using a Ti3C2Tx functionalized spherical tip, adhesion energy was measured respectively. To obtain adhesion energy more accurately, the Maugis-Dugdale theory which considers surface roughness was applied to convert the AFM measured adhesion force to adhesion energy. Our preliminary showed that the adhesion energy between Ti3C2Tx and Ti3C2Tx or Ti2CTx, MXenes are in the same level of the adhesion energy between Ti3C2Tx and graphene. In addition, no layer dependency was observed with the MXene adhesion measurements.

2:15 PM MS02.10.04
Ordered Buckling in 2D Single Layer Solids Guided by Self-Assembled Peptide Nanowires Hadi M. Zareie1, David Starkebaum1, Tyler D. Jorgenson1, Fadil Iyikanat2, Hasan Sahin2, Rene Overney1 and Mehmet Sarikaya1; 1University of Washington, United States; 2Izmir Yuksek Technology Institute, Turkey

Ubiquitous periodic structures formed at the nanometer scale on the surface of exfoliated graphite has been interpreted as ripples, stripe domains, 2D molecular patterns, corrugations, and wrinkled networks. The true origin for the formation of these periodic structures on single layer solids and the ways to control their formation and organization are fundamental to their potential utility in band gap engineering in graphene and single layer semiconductors such as MoS2 and WSe2 towards their utility, e.g., as strain sensors. Using both graphite and MoS2,
we show here that the nature of the buckling is indeed due to strain induced sub-nm scale periodic buckling and that its pattern can be controlled on atomically flat surfaces using the self-assembled solid-binding dodecapeptides that form 2D self-organized pattern in aqueous solutions forming ordered peptide nanowires commensurate and aligned with the underlying crystalline substrate. We attribute nanobuckling to be due to out-of-plane rippling effect caused by compressive strain within the top single layer introduced during mechanical exfoliation. The electronic behavior of the nanobuckled regions have been examined by scanning tunneling microscopy and spectroscopy show that the tunneling current varies with the peaks and valleys in the buckled region consistent with the tension and compressive stresses that we estimated by computational modeling using density functional theory. The phenomenon is observed both in graphite (semimetal) and MoS2 (semiconductor) may be a strong indication that nanobuckling is a universal phenomenon likely to be present also in other 2D layered solid systems. The results of the conductive atomic force microscopy (C-AFM) was also used to interrogate the electrical properties of the buckled samples of MoS2 showing changes in the gap energy that can be correlated with the compressed and expanded density of states in the top layer. While the study of new physical phenomena is enabled in the nanobuckling by the self-assembled peptides, they also facilitate controlled pattern formation in a wide range of 2D solids in designing new devices by controlling the local chemical and band-gap engineering by local strain. Periodic buckling patterns guided by self-organized peptides may pave a simplistic way for tailoring the surface nanostructures and electronic properties of single atomic layer solids towards designing new devices based on periodic local surface chemical potential and band gap by periodic surface-confined strain. The research is supported by NSF-DMREF program through the grant DMR-1629071 as part of the Materials Genome Initiative.

2:30 PM *MS02.10.05
Graphene Application for OLED Display Jong Hyun Park, Hoyoung Jeong, JiGon Kim, Shin-Bok Lee, Eunju Kim, Ju Young Bang, MoonBong Song, Harkjin Kim, Ji-Man Seo, Byungsam Yu, Sungpil Ryu, Hanshin Hwang and Soo-Young Yoon; LG Display Laboratory, Korea (the Republic of)

Graphene has been the promising material for flexible optoelectronic devices because of its outstanding material properties. Many research groups have shown potentials of graphene for various flexible devices such as touch-screen sensors, organic light-emitting diodes and organic photovoltaic devices. However, Graphene still faces some hindrances to overcome for the success of real commercialization. In this talk, from the commercial perspective, we'd like to share our opinion on most probable application fields of graphene for OLED displays. Specifically, we will highlight the application of graphene as a transparent electrode for OLED displays because of its extraordinary optical, mechanical and electrical material properties. In addition, we will also emphasize superior moisture barrier properties of graphene which have potentials for the application of OLED encapsulation. Graphene's unique mechanical flexibility combined with barrier property will be able to replace inorganic materials which have been widely used in OLED encapsulations. we will also briefly mention other possible application fields of graphene for OLED display.

For your information, we will also introduce the outline of LG display which has a global No.1 display market share. Finally, we will suggest some requirements and specifications to realize the commercialization of graphene for OLED displays. In my view, this presentation will be a chance to discuss the practical use of graphene for OLED displays.

Dynamic Strain Ageing of ARB Cu/Nb Nanoscale Multilayers
Zhilin Liu1,2, Jeromy Snel1, Miguel A. Monclús1, Jon M. Molina-Aldareguía1 and Javier Llorca1,3; 1IMDEA Materials Institute, Spain; 2Central South University, China; 3Technical University of Madrid, Spain

Cu/Nb metallic multilayers with individual layer thicknesses in the range 7 nm to 63 nm were manufactured by accumulative roll bonding (ARB). Micropillars of square cross section of 5 x 5 µm² and an aspect ratio 2-3 were milled with a focused ion beam. The mechanical properties of the Cu/Nb multilayers were determined by means of in situ micropillar compression tests within a scanning electron microscope. Test were carried out at different strain rates (10⁻² to 10⁻⁴ s⁻¹) and temperatures (25°C to 400°C) and the yield strength, strain rate sensitivity and activation volume were determined from these tests for each multilayer as a function of temperature. In addition, the deformation and fracture mechanisms were ascertained from in situ observations during deformation and from transmission electron microscopy analysis of foils extracted from the deformed micropillars.

The strain rate sensitivity of all the multilayers at ambient temperature was in the range 0.015 s⁻¹ to 0.008 s⁻¹ and decreased slightly as the layer thickness increased. Mechanical tests at 400°C showed a large increase in the strain rate sensitivity, which ranged from 0.16 s⁻¹ for a layer thickness of 7 nm to 0.05 s⁻¹ for a layer thickness of 64 nm. Surprisingly, the strain rate sensitivity of the nanoscale multilayers with layer thickness below 34 nm dropped to 0 at 200°C while increased slightly with respect the ambient temperature value in the multilayer with 64 nm layer thickness [1]. In addition, serrations were observed in the stress-strain curves of the multilayers with small layer thickness tested at 200°C. From these experimental observations, it was hypothesized that the unexpected reduction in the strain rate sensitivity of the multilayers with small layer thickness at 200°C was due to dynamic strain ageing of the Nb layers due to the presence of oxygen in solid solution, following the results in the literature for dynamic strain ageing of Nb at this temperature [2]. The presence of oxygen in the Nb layers was confirmed by energy-dispersive X-ray microanalysis and atom probe tomography. The evidences for dynamic strain ageing of Cu/Nb nanoscale multilayers were discussed to the light of the experimental evidences and to the deformation mechanism map proposed for this system.

Nanoporous Tungsten—A Novel Low-Density and Ultra-Strong Nanocrystalline Material
Mingyue Zhao1, Inas Issa1, Michael Wurmshuber2, Manuel Pfeifenberger2 and Daniel Kiener1; 1University of Leoben, Austria; 2Erich Schmid Institute of Materials Science, Austria

Metallic nanofoams are a unique class of materials possessing low density, large surface area, excellent attributes and energy absorption ability, making them good candidates as future radiation shielding materials. Tungsten is ideally suited as the base material for such a foam, as it is commonly used as a shielding material in nuclear facilities, medical diagnosis systems and a number of other circumstances in order to protect personnel and sensitive equipment from radiation. Therefore, it is of great value and scientific interest to tailor such a novel nanoporous tungsten, which combines the beneficial properties of tungsten with the positive attributes of nanoporous foams and
has a great potential to satisfy the need for high performance materials that can endure harsh environments.

In this work, nanoporous tungsten was created on a bulk scale through a unique technique route involving the severe plastic deformation followed by reverse selective dissolution. Scanning electron microscopy and high-resolution transmission electron microscopy were utilized to characterize the microstructural evolution and analyze how the etching solutions affect the resulting nanoporous structures. The mechanical properties, which are an important consideration during many practical applications, were investigated by employing depth-sensing nanoindentation and other small-scale testing in situ in the SEM. Based on this, the elemental plasticity mechanisms governing the mechanical behavior were elucidated.

This work for the first time provides an innovative and adaptive approach to create nanoporous tungsten on a bulk scale. The developed reverse phase dissolution method is generally applicable and can be transferred to other refractory metals in the future. The promising mechanical results of nanoporous tungsten will serve as foundation for forthcoming related scientific studies and engineering applications.

**Toughening in Cu/Mo Hierarchical Nanocomposite Tested by In Situ Bending in SEM** Yuchi Cui¹, Benjamin K. Derby¹, Nan Li² and Amit Misra¹; ¹University of Michigan, Ann Arbor, United States; ²Los Alamos National Laboratory, United States

The fracture behavior of high-temperature co-sputtered Cu/Mo nanocomposites were investigated in this study through in situ bending test of pre-notched microbeams in SEM. The as-synthesized nanocomposites present hierarchical heterogeneous architectures that are composed of matrices of bicontinuous interpenetrating Cu/Mo with nanoscale ligaments and sub-micron scale Cu-rich islands containing Mo-rich nanoparticles. From previous nanopillar compression tests, the nanocomposites possess high strength over 2 GPa and good deformability without shear band formation. Our micro-scale bending test further shows that the hierarchical nanocomposite has higher toughness compared to Cu/Mo nano-multilayers and monolithic Cu-Mo nanocomposite, where only interpenetrating Cu/Mo with nano-scale ligaments presents. The Cu islands were observed to neck and bridge the crack surfaces, as well as blunt the crack tip, deterring crack propagation. As a result, crack formation in multiple directions was observed after the initial crack propagation during the bending test. From this study, our hierarchical nanocomposite presents a successful approach to break through the strength-toughness trade-off dilemma.

**On the Multifunctional Response of Bicontinuous Metal/Polymer Nanocomposites** Erica T. Lilleodden¹,², Murilo Hablitzel¹, Yijuan Wu¹, Kaixiong Hu³, Markus Ziehmer¹ and Jürgen Markmann¹,²; ¹Helmholtz-Zentrum Geesthacht, Germany; ²Technische Universität Hamburg-Harburg, Germany; ³Wuhan University of Technology, China

Composite materials bring together the structures and properties of two or more materials to create improved functionality. The chemistries, microstructures, and topologies of the phases dictate their individual constitutive response, while those characteristics combined with the properties of the associated interfaces dictate the composite behavior. Exploiting size effects and unconventional structural geometry is a clever approach to achieving novel materials that go beyond functions predicted by conventional models of composite response. In the case of nanoporous gold (NPG) - based composites, the strong size effects found in nanoscale gold structures lead to a strongly tailorable strength of the nanoporous gold phase, while the high surface area allows actuation and sensing functions when submerged in electrolyte. When infiltrated or coated with a polymer, the boundary conditions governing the behavior of the nanostructured gold are modified.

In this presentation we consider two NPG-based nanocomposites: NPG fully infiltrated with epoxy to improve strength and ductility, and PPy coated NPG which enhances the electro-chemo-mechanical coupling in an electrolytic environment. Using various micromechanical testing methods and the quantification of the 3D network structure, the novel functional response has been investigated. It was found that the dependence of the strength on the mean ligament diameter is much weaker in the NPG/epoxy composites compared to pure NPG, while no size effect in the nanoporous epoxy phase was found. The failure of the composite presented as in-plane “horse-shoe” shape delaminations between the gold and epoxy phases, which serves to dissipate energy while maintaining its load.
bearing capacity. In the case of NPG submersed in NaF electrolyte, electro-chemo-mechanical coupling resulted in a considerable increase of strength of pillars when surface adsorption occurred, i.e. under positive applied potential, and the stress response to potential jumps was found to be fast and reversible. Coating NPG with an electrically conductive polymer, PPy, allows additional strengthening and stiffening of the NPG while also exploiting the actuation and sensing capabilities of the high specific surface area NPG network structure under potential in the NaF electrolyte.

Results will be discussed in terms of the individual constitutive relations, topological characteristics, and interfacial chemistry and strength, and perspectives for further exploitation of this class of nanocomposites will be given.

11:00 AM MS03.01.06
Formation of Ultra-Fine Spheric Microstructure Consist of Dual Phase in Mg85Zn6Y9 Alloy Masafumi Matsushita1,1, Daiki Yamauchi1, Yuki Kawabata1, Toru Shinmei1, Hiroaki Ohfuji1, Michiaki Yamasaki2 and Yoshihito Kawamura2; 1Ehime University, Japan; 2Kumamoto University, Japan

High-pressure and high-temperature (HPHT) treatment can make fine and unique texture in materials. We have realized HPHT treatments on the Mg85Zn6Y9 alloy and then quenched and decompressed to ambient pressure. The alloy have a 18R-type long period stacking ordered structure synchronized with chemical concentration at ambient pressure, however it transform to duplex structure consist of “soft” hcp (α-Mg) phase and “hard” fcc-based superlattice (D03) phase at high-pressure condition (Matsushita, et al., Mater. trans. 56, 910, 2015, Mater. Let. 155, 11, 2015). The high-pressure phase can be recovered at ambient pressure. The recovered alloys after being treated at HPHT condition have ultra-fine and unique solidification pattern.

The alloy recovered after being treated at 10 GPa and 973 K have a lamella structure alternating layers of hcp and D03 phases with the layer thickness of 80~100 nm. On the other hand, the alloy recovered after being treated at 10 GPa and 1273 K takes spherulite with the diameter of 5~15μm. The term “spherulite” suggests a nearly spherical polycrystalline solidification pattern, which is rarely observed in solidification metals. As far as our knowledge, this is the first case the alloy takes spherulite of the volume percent above 80 %. The spherulite also contains duplex phase consist of hcp and D03. In the core part of spherulite, small grain considered as D03 in size below 50 nm distributed Mg matrix (Matsushita, et al. JALCOM, 784. 1284, 2019). Further fine column shape grains consist of D03 and hcp phases were spread from radially from the core. Similar unique spherical microstructure can be observed in the alloy treated at 5 GPa/1273 K and 15 GPa/1273 K.

The compression yield stress of the alloy consisted from spherulite structure is over 700 MPa, which much higher than that of lamella structure and the other magnesium alloys with similar composition made by severe plastic deformations. These results show the HPHT treatments and spherulite structure have great potential to develop the alloy with high strength.

11:15 AM MS03.01.07
Mechanical Response of Bicontinuous Copper-Molybdenum Nanocomposites Nathan J. Beets1, Yuchi Cui2, Diana Farkas1 and Amit Misra2; 1Virginia Polytechnic Institute and State University, United States; 2University of Michigan–Ann Arbor, United States

We present the results of a combined experimental and atomistic simulation study of the mechanical properties of a Co- Mo bicontinuous nanocomposites with varying ligament sizes. Simulations of bicontinuous nanocomposites under compression using atomistic molecular dynamics are compared to experimental results on in situ SEM and TEM microscale compression tests on co-sputtered Cu-Mo. The simulations allow the elucidation of the defect nucleation, glide and storage phenomena within individual Cu and Mo phases and Cu/Mo interfaces. The simulation results are also compared with the predictions of a dislocation theory based analytical model of glide of individual dislocations in nanoscale metallic phases confined by interphase boundaries that are strong barriers to slip transmission. The integrated simulation-experimental study shows that the bicontinuous intertwined morphology is effective in suppressing localized shear bands and promoting homogeneous distribution of plastic flow in metallic nanocomposites.

11:30 AM MS03.01.08
Alloyed and Layered Composite Nanofoams—A Multiscale Modeling and Experimental Validation Ioannis Mastorakos1, Hang Ke1, Andres Jimenez1 and David Bahr2; 1Clarkson University, United States; 2Purdue University, United States
Pure metal nanofoams in the form of interconnected networks of ligaments have shown strong potential over the last few years in areas of catalysts, batteries, and optics. However, they are often fragile and difficult to integrate into engineering applications. In order to mechanically strengthen them two new types of foams are studied in this work: alloyed and nanolayered. These materials will operate at the macroscale but they will maintain a nano or atomistic ordering requiring a multiscale approach for the study of their properties. For that purpose, in this work, we combined molecular dynamics and finite elements to study the mechanical behavior of these metallic structures made of copper and nickel and compared them to their pure metal counterparts. Furthermore, manufactured nanofoams were tested using nanoindentation and the findings are used to compare and validate the simulation results.

11:45 AM *MS03.01.09
Novel Stress-Assisted Structural Transformation and Plasticity Enhancement in Mo/Cu Bicontinuous Intertwined Composites Lijie He and Niaz Abdolrahim; University of Rochester, United States

Structural transition in Molybdenum has been reported to occur under large stresses in thin nanowires and tip of a crack. Here, we use Molecular Dynamics (MD) simulations to demonstrate that a uniform 3-step structural transformation of Molybdenum atoms can occur in Mo/Cu bicontinuous intertwined materials during tensile loading. The Mo atoms first transit from a <001>-oriented bcc structure to a <001>-oriented fcc structure via Bain transformation. The <001>-oriented fcc phase then transforms to a <110>-oriented bcc via Pitsh transformation. This novel homogenous transformation results into a stress-strain curve containing two elastic and two plastic regimes as well as enhanced plasticity with few dislocation slips and no twinning. Our results reveal that the driving force for such phase transformation is the high interfacial stress in the bicontinuous intertwined structure. This study suggests new strategies for improving the ductility of ultra-strong nanocomposite metals.

1:30 PM *MS03.02.01
High Speed Nanoindentation Testing—Indent Spacing and Analysis Tools Jennifer Hay, Phani Sudharshan and Warren C. Oliver; KLA, United States

The field of micro and nanomechanical testing has expanded dramatically. Many sample geometries and testing techniques have been developed to investigate a variety of mechanical material properties. Nanoindentation contact experiments with pyramid shaped indenters have led the way. The properties that one can determine using contact mechanics has expanded as well. In this talk we will focus on high speed indentation. This technique requires that dynamic mechanical effects must be considered to correctly to perform the experiments. The instruments must be carefully designed and characterized so that the dynamic effects of the instrument and sample on the combined results obtained can be separated and quantitatively understood. In addition, the spacing of the contact experiments must be sufficiently large to avoid interactions between the indentations. We will examine the question of how close they can be in detail. The results indicate that the indentations can be safely spaced twice as close as has been suggested in the literature. Once these experiments are performed several analysis techniques help make the data useful. In particular, data clustering algorithms can be used to separate phases in multiphase materials. We will show the results of such analysis on the technologically important example of bond layers in thermal barrier coatings on turbine blades.

2:00 PM MS03.02.02
In Situ TEM on Deformation and Fracture of Single Lattice Pillar Scott X. Mao; University of Pittsburgh, United States

Structural nanomaterials and nanocomposites have excellent mechanical performance, which can be tuned through
both structural architecture and material size effects. However, the behavior of individual component normally sized
at 5 - 50 nanometer in the structural nanomaterials is key important, has not been explored before. This talk will be
the in-situ mechanics for studying the mechanical behavior at atomic scale for 5 to 50 nanometer-sized pillars (so-
called lattice pillar) of metallic crystals. The experimental molecular dynamics with the in-situ high resolution
transmission electron microscope is going to open a new approach to directly characterize atomic-scaled
deformation with in-situ mechanics for such small sized pillar. I will cover the stress-strain behavior, high stress
induced lattice disturbance, dislocation dipole nucleation and competition between slip and twinning in the
deformation process, which potentially can be related to individual component of structural nanomaterials such as
nano-porous and nano-lattice materials.

2:15 PM MS03.02.03
Metastability and Hardness Variation of Metallic Nanocrystals under External Stimuli Zhitong Bai and Yue
Fan; University of Michigan–Ann Arbor, United States

Recent experiments show that metallic nanocrystalline materials can be rejuvenated under the stimuli of
femtosecond laser and the system’s hardness can be effectively tuned. However, a mechanistic understanding on
such phenomenon remains unclear. Here we investigate the responses of a group of <100> symmetric tilt grain
boundaries (STGBs) in a Cu modeling system under the driving of fast thermal cycling. A universal hysteresis
behavior is observed during such process, and the GB is driven to a higher energy state after the pulsive stimulus.
By employing an enhanced data-mining algorithm to analyze the annealing behavior of GBs at various thermal
conditions, we are able to construct a high-resolution pixel map for the GB’s energetic evolution and show that it
can be divided into an ageing regime and a rejuvenating regime over the broad energy—temperature parameter
space. We further demonstrate that the origin of ageing/rejuvenating is attributed to the energy imbalance along with
the elementary hopping processes in the GB’s underlying potential energy landscape (PEL). The hereby established
picture then allows us to develop a self-consistent kinetic equation to describe the GB’s energetic and mechanical
responses to external stimuli, which can qualitatively explain the recent femtosecond laser experiment. The present
study thus enables a deeper mechanistic understanding towards the non-equilibrium evolution of nanocrystalline
materials.

2:30 PM MS03.02.04
Programmable Nanoscale Origami Triggered by Electron Beam Irradiation Chunhui Dai1, Lianbi Li1,2, Daniel
Wratkowski1 and Jeong-Hyun Cho1; 1University of Minnesota, United States; 2Xi’an Polytechnic University, China

Origami inspired self-assembly of three-dimensional (3D) micro- and nanostructures shows diverse applications
across a broad range of areas, such as metamaterial and plasmonic devices, electronics, and biomedical devices.
Significant development of the assembly technique has been achieved based on various stimuli responsive materials.
However, precise bidirectional motion control with a desired sequence remains a challenge due to the limited
capability of delivering localized stimuli, resulting in constrained functions of origami. In this work, we report a
route to fully mimic the functions of origami including bidirectional curving, folding, stretching, and even knitting.
The mechanism involves electron irradiation triggered in situ crystallization in amorphous material, which results in
volume shrinkage, generating sufficient stress for assembly. The scanning electron microscopy (SEM) offers
capability of real time monitoring and fine focus, which enables precise stimuli delivery, leading to programmable
assembly. Prototypes including nano-machines, nanoscale test platforms, and advanced optical devices have been
demonstrated using this strategy, showing the possibility for innovation of next generation devices and smart
materials.

2:45 PM MS03.02.05
3D Periodic Tungsten–Silicon-Carbide Nanocomposites Designed for Mechanical Robustness Andreas Stein,
Zhao Wang, Kevin Schmalbach, David Poerschke, R. Lee Penn and Nathan Mara; University of Minnesota, United
States

Metal-ceramic nanocomposites exhibit exceptional mechanical properties with combinations of high strength,
toughness, and hardness not achievable in monolithic metals or ceramics, which make them valuable for
applications in fields, such as the aerospace and automotive industries. It has been shown that the interface between
components in a nanocomposite plays an important role in controlling these properties. Here we demonstrate the
preparation and mechanical properties of nanostructured tungsten–silicon-carbide composite materials, which
contain a ductile metal component and a brittle ceramic component interspersed at the submicron scale in periodic fashion. In these nanocomposites, the ratio of interfacial area to volume is systematically controlled through templating and nanocasting methods, permitting a systematic investigation of the brittle-to-ductile transition through nanoindentation and micropillar compression tests.

The material synthesis is enabled through colloidal crystal templating of three-dimensionally ordered macroporous (3DOM) materials as host structures to create nanocomposites with high interfacial area. 3DOM materials are porous solids that feature a highly ordered, fully interconnected, porous structure with pore sizes in the 200–500 nm range and struts that are tens of nanometers in diameter. The macropores can be infiltrated with a second phase in a nanocasting process to form periodic composite structures. The component ratio is controlled by the choice of the host and guest components and through processing, and the interface-to-volume ratio through the pore size. Here we investigate 3DOM W and 3DOM SiC materials infiltrated with SiC and W guests, respectively. Silicon carbide is a material with high hardness, high thermal conductivity, and high mechanical strength/oxidation resistance. However, it suffers from unwanted brittleness at elevated temperature. Introduction of tungsten can introduce the ductility of a metallic phase to modulate the composite strength and strain hardening behavior. Moreover, compared to other metals, tungsten has only a small mismatch in coefficient of thermal expansion with silicon carbide. Because tungsten and silicon carbide can react with each other to form tungsten carbide or tungsten silicide phases at different temperatures, we found that various interfacial compositions could be achieved by controlling the synthesis temperature. Nanoindentation and micropillar compression testing reveal enhanced strength, as well as significant deformation prior to fracture.

Mechanics of Architected Carbon: From Rubber-Like Deformation in Pyrolytic Nano-Carbon to Ultrastrong and Impact-Resistant Nano-Architected Glassy Carbon Julia R. Greer1, Bryce Edwards1, X. Zhang2, Andrey Vyatskikh1, D. Veysset3, Keith A. Nelson3, Huajian Gao4 and X. Li2; 1California Institute of Technology, United States; 2Tsinghua University, China; 3Massachusetts Institute of Technology, United States; 4Brown University, United States

Creating materials with a combination of high strength, substantial deformability and ductility, large elastic limit, and low density represents a long-standing challenge in materials science because these properties are typically mutually exclusive. Using a combination of two-photon lithography and high-temperature pyrolysis, we demonstrate micro-sized pyrolytic carbon with a tensile strength of 1.60+/-0.55 GPa, a compressive strength approaching the theoretical limit of ~13.7 GPa, a substantial elastic limit of 20–30%, and a low density of ~1.4 g cm⁻³. This corresponds to a specific compressive strength of 9.79 GPa cm³ g⁻¹, a value that surpasses that of nearly all existing structural materials. Glassy carbon samples with dimensions below 2.3 μm exhibit rubber-like behavior and sustain a compressive strain of ~50% without catastrophic failure; larger ones exhibit brittle fracture at a strain of ~20%. Large scale atomistic simulations reveal that this combination of beneficial mechanical properties is enabled by local deformation of 1 nm-long curled graphene fragments within the pyrolytic carbon microstructure, the interactions among neighboring fragments, and the presence of covalent carbon–carbon bonds. Building on these individual carbon nano-building blocks, we developed a process to create nano-architected glassy carbon that attains specific strength of up to one to three orders of magnitude above that of existing micro- and nanoarchitected materials. Experiments and simulations demonstrate that for densities higher than 0.95 g/cm³ the nanolattices become insensitive to fabrication-induced defects, allowing them to attain nearly theoretical strength of the constituent material. A key challenge in studying mechanics of nano-architected materials is their lack of a proper separation-of-scales between unit cell size and sample dimensions, which precludes proper impact testing when the impact time scale allows elastic waves to propagate information from the free boundaries back to the projectile. Another difficulty in dynamic testing of nanomaterials is the lack of reliable methods to achieve consistent loading conditions while capturing proper temporal and length scales. We developed a method to design, fabricate, and test nano-architected materials at supersonic impact speeds of up to 1 km/s that address these challenges by employing Laser Induced Particle Impact Test (LIPIT). In this method, a
pulsed laser accelerates a microscale impactor to velocities <1.2 km/s, and the impact is captured using frames from a high-speed camera within a microscope, allowing for nanosecond temporal and micrometer spatial resolution. We probed different impact regimes by selecting spherical SiO2 impactors of different diameters while varying impact velocity from 50 to 1,100 m/s. Post-mortem analysis of impacted samples via confocal and electron microscopy indicates that nanolattices with 26% relative density can withstand impact speeds that exceed 700 m/s, either absorbing or rebounding the projectile.

The combination of high specific strength, low density, impact resistance, and extensive deformability before failure lends such nano-architected pyrolytic carbon to being a particularly promising candidate for applications under harsh thermomechanical environments.

Improvement of an Electrocharging Assisted Fabrication Method for Nanocarbon-Aluminum Composites
Madeline Morales1,2, Xiaoxiao Ge1, Christopher Klingshirn1, Daniel Cole2 and Lourdes G. Salamanca-Riba3;
1University of Maryland, United States; 2U.S. Army Research Laboratory, United States

Carbon nanostructures represent a growing area of research due to their excellent mechanical, electrical and thermal properties. Research studying their synthesis has rapidly populated academic journals, but these procedures are difficult to implement in large-scale manufacturing due to their complexity and cost. In contrast, electrocharging assisted bulk processing of a novel class of materials, termed “covetics,” presents a practical option for macroscale production of nanocarbon-metal composites. Notably, this process facilitates incorporation of carbon on the order of a couple weight percent in metals where carbon solubility is normally in the low ppm range. A 40% increase in tensile strength and 40% increase in electrical conductivity has been measured in Al covetics; however, there is minimal understanding of the structure-process-property relationship and consequently there is high variability in measured properties among trials. To investigate the relationship between fabrication conditions and properties of the composite material, the parent alloy, Al 1350, is melted in a graphite crucible nestled within induction coils. Following the addition of activated carbon precursor, a DC current is applied to the molten mixture via a graphite electrode to initiate the electrocharging assisted conversion process. Raman spectroscopy is used to evaluate the structure and degree of crystallinity of carbon incorporated into the Al lattice via the Tuinstra-Koenig relation for graphitic carbon. XPS is used to measure the amount of carbon incorporated and determine the sp2/sp3 ratio. XRD is used to identify the formation of any secondary phases or carbides. Following structural characterization, four-point probe testing is performed to measure the bulk electrical conductivity of the covetic material. Atomic force microscopy techniques are used to measure the local electrical and mechanical behavior of the covetic by Kelvin probe force microscopy and nanoindentation, respectively. Results to date have found that the activated carbon precursor is converted to sp2 hybridized graphitic carbon with an increase in crystallite size as measured by Tuinstra-Koenig. From XRD and XPS, it has been determined that there is no measurable formation of carbide phases despite a couple weight percent of incorporated carbon. The electrical conductivity of the covetic material has also been shown to increase. The local electromechanical behavior of the covetic measured by AFM techniques will be used to develop a fundamental understanding of the improved properties measured in the composite and used to inform adjustments to the fabrication process accordingly.

Hybrid Hierarchical Nanolattices with Porous Platinum Coating
Ehud Almog1, Amit Sharma1, Yuanshen Qi1, Julia R. Greer2 and Eugen Rabkin1; 1Technion - Israel Institute of Technology, Israel; 2California Institute of Technology, United States

Nanolattices exhibit wide range of unique properties and attract a growing interest in many scientific fields. The architected hierarchical structure allows tailoring the nanolattice properties to obtain objects of relatively large dimensions with nano-size features. In our work we fabricated a core-shell polymer-platinum nanolattice by combining several fabrication techniques. The polymeric nanolattice was designed by CAD, and fabricated by a two photon lithography technique to achieve the required architecture. The lattices were then coated with thin film of platinum using atomic layer deposition (ALD) method. The unique interaction of the gaseous ALD precursor with
the polymer surface resulted in a porous film with nano grains, providing a hierarchy ranging from the micrometer-size overall dimensions down to the microstructural features of a few nanometers. The microstructure evolution (i.e. grain size, pore size and defects) caused by annealing at elevated temperature was investigated, and correlated to the mechanical behavior of the lattices during in-situ compression inside a scanning electron microscope.

**Strengthening of Thin Metal Films Using Graphene Monolayer** Kaihao Zhang, Mitisha Surana and Sameh Tawfick; University of Illinois at Urbana-Champaign, United States

A practical route to exploiting graphene’s supreme properties for a variety of applications is to incorporate graphene layers in composite materials. Harnessing the high stiffness, intrinsic strength as well transport properties of graphene in its composites requires the combination of high-quality graphene having low defect density, and the precise control of the interfacial interactions between the graphene and the matrix. These requirements equally fold for polymer and metal matrices, and enable the use of graphene in applications ranging from tough thin films for flexible electronics to the design of advanced aerospace structures. In this study, to address the synthesis and control of these composites and their mechanical properties at the nano to the microscales, we propose a model system of ultrathin metal films coated with graphene monolayer via chemical vapor deposition (CVD) to study as-grown graphene’s contributions in graphene-metal nanocomposites.

However, several factors need to be considered to assure the stability of ultrathin catalysts at the elevated temperatures (1000-1100 C) for high quality graphene synthesis. We develop a highly dynamic CVD synthesis route (less than two minutes) to achieve high quality graphene monolayer growth on ultrathin (100-150 nm) Pd films while avoiding solid-state dewetting which easily takes place at the high temperatures. We study how the competition between temperature-driven segregation and precipitation of carbon atoms governs the graphene’s nucleation and growth kinetics on ultrathin Pd films. The result of the dynamic recipe is repeatable growth of graphene monolayers with over 2.5-fold faster graphene growth rate than that in typical Cu catalyzed synthesis, as well as very low defect density as confirmed in Raman spectroscopy.

Precise mechanical characterization of as-grown ultrathin graphene-Pd films is carried using micro bridge Nanoindentation. CVD grown graphene-metal composite thin films exhibit unusual increase in the elastic modulus, strength and toughness. For example, there is 35 % and 57 % increases in the Young’s modulus and tensile strength in graphene-Pd nanocomposites compared to those for a bare Pd film having a thickness of 66.4 nm. Notably, this enhancement is beyond the rule of mixtures limits, and exhibits scale effects, where the composite modulus increase varies with the thickness, and is highest for the thinnest metal thicknesses. This usual elastic modulus enhancement is attributed to the significant change in the surface stress of ultrathin films after coating with graphene. Raman spectroscopy and electron imaging of graphene-Pd surface reconstructions confirm the high interfacial stresses due to the combination of the lattice mismatch between the graphene and the underlying metals and the kinetics of CVD synthesis. We also observed significant increase in toughness and qualitatively different modes of crack propagation owing to the addition of the high stiffness graphene shield on the metal surface during synthesis. The findings of this study promote graphene-based thin film composites for flexible electronic devices, and enable fundamental studies of exploiting strain engineering at the graphene-metal interface for electronics, chemistry and mechanics.

SESSION MS03.03: Poster Session I: Metallic Nanocomposites

**Compressed Exponential Relaxation Originated Negative Strain Rate Dependency of Metallic Glass Flow Stress** Akio Ishii1, Tomoaki Niiyama2, Takahiro Hatano1, Tomotsugu Shimokawa1 and Shigenobu Ogata1; 1Osaka University, Japan; 2Kanazawa University, Japan

It is reported that negative or no strain rate dependency of the flow stress of metallic glasses appears at high strain
rate or low temperature condition [1][2]. We reveal that this curious strain rate dependency is strongly related to the rate of glass relaxation process from a rejuvenated glass state induced by activation of shear transformation. We use a constitutive model which estimates average residence time of thermal activation process and calculate the flow stress of metallic glass at certain strain rate and temperature [3]. In the model, we assume relaxation process recovers the activation energy of shear transformation of rejuvenated glass state and the relaxation is expressed as stretched or compressed exponential form. Interestingly, we find the negative or no strain rate dependency appears when the timescale of the activation of shear transformation approaches the characteristic timescale of glass relaxation process. Especially, the negative strain rate dependency only appears with the compressed exponential relaxation. The compressed exponential relaxation is always observed in the material with gel or colloid-like structure, and in this decade, it is observed in metallic glass too [4].

MS03.03.02
Mechanical Behavior of Metallic Thin Films Passivated by Ultra-Thin Layers Sunkin Choi, Yuhyun Park, Ho Jang Kim, Pragya Rani, Tae Soo Kim, Minsoo Kang, Kibum Kang and Gi-Dong Sim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Understanding the mechanical behavior of metal thin films at elevated temperature is essential for the design of reliable devices, which often operate above room temperature. So, from the past, several studies have been performed on the high-temperature behavior of freestanding metal thin films to understand their intrinsic properties. However, in real applications, there are very few cases where the thin films are placed as freestanding. Also, the mechanical behavior of metal thin films can be changed when they are layered with another thin materials due to the existence of interface. Therefore, understanding the performances of thin films with passivation layers at elevated temperature is important, but studies have been limited due to difficulties associated with sample handling, oxidation, temperature uniformity, and fabrication of multi-layers with passivation layers such as dielectric or 2D materials.

In this poster, we introduce an apparatus to perform micro-tensile tests at elevated temperatures inside a scanning electron microscope. The apparatus has a stroke of 250μm with a displacement resolution of 10nm and a load resolution of 9.7μN. Measurements at elevated temperatures are performed through use of two silicon-based micromachined heaters that support the sample. Each heater consists of a tungsten heating element that also serves as a temperature gauge. To demonstrate the testing capabilities, tensile tests were performed on submicron-thick freestanding metal thin films with and without the passivation layers from room temperature to elevated temperature. Ultra-thin dielectric (Si₃N₄) and 2D layers (e.g. MoS₂, graphene) were chosen as passivation layers, which are mainly used in electronic devices with metal thin films. Stress-strain curves show a significant decrease in yield strength and initial slope for the samples tested at elevated temperature, which we attributed to diffusion-facilitated grain boundary sliding and dislocation climb. However, when passivation layer is added on the film, the decrease of yield strength and necking of the metal thin films are expected to be inhibited and strain hardening may become significant due to dislocation pileups at the interface.

MS03.03.03
Mechanical Characterization of Sputter Deposited Nickel-Molybdenum-Tungsten Thin Films for High Temperature Metal MEMS Applications Yuhyun Park, Sunkin Choi, Hosun Jun, Won Seok Choi, Pyuck-Pa Choi and Gi-Dong Sim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Taking microelectromechanical systems (MEMS)-based devices such as sensor, actuator, micropower generator into the harsh environments (temperature greater than 200°C, power level above 100W) would greatly expand the applications ranging from miniature internal combustion engines, to high frequency switching, microheaters and high temperature sensors. However, the dominant structural material used in conventional MEMS devices are silicon, which can not be used in thermal environment due to its loss of mechanical properties at elevated temperatures. Therefore, the development of metallic MEMS alloys that possess enhanced mechanical and functional properties at intermediate to high temperature range, requisite dimensional stability, and the ability to be shaped on the microscale would provide the wider design space for novel MEMS applications. Metals and alloys are...
especially attractive in MEMS applications that require high density, electrical and thermal conductivity, strength, ductility and toughness.

Electrodeposited nanocrystalline LIGA Ni offers a route for microfabrication of metallic parts with high aspect ratios and have good room temperature yield strength, but temperatures as low as 200°C can result in grain growth and a significant loss of strength. Alloying elements with limited diffusivity can strongly suppress grain growth, in particular, Ni-W thin films prepared by magnetron sputtering are known to exhibit thermally stable nanocrystalline microstructures. Adding another solute element Molybdenum to the system can effectively improve dimensional stability by lowering the coefficient of thermal expansion over long temperature range while retaining mechanical integrity.

Here we report the mechanical behavior of sputter deposited Nickel (Ni)-Molybdenum (Mo)-Tungsten (W) ternary alloy thin films at various temperatures. The microstructure and chemical composition of deposited materials are characterized using transmission electron microscopy (TEM), scanning electron microscope (SEM), X-ray diffraction (XRD) and energy dispersive X-ray spectroscopy (EDS). The as-deposited films go down as single-phase solid solutions and possess high nanoindentation hardness of approximately 9 GPa. Custom built micro-tensile tester which operates inside the SEM is used to perform comprehensive in-situ thermomechanical study on Ni-Mo-W thin.

First, the in-plane mechanical response of the as-deposited and heat-treated freestanding Ni-Mo-W thin films are investigated at room temperature. Then the mechanical properties of films annealed at 400°C are explored at elevated temperatures by Joule heating of two micromachined tungsten heater that support the tensile specimen.

MS03.03.04
Effect of Bonding Temperature on Thermal Residual Stress Near Edge of Interface on Ceramics to Metal Joint with Arbitrary Interface Conditions Shunsuke Muraoka1 and Masayoshi Tateno2; 1Kogakuin University Graduate School, Japan; 2Kogakuin University, Japan

This study provides that relationship between distributed thermal elastoplastic stresses near the edge of the interface and practical tensile strength of ceramics/metal joint system with arbitrary wedge angles. Interface wedge angles were defined as a configuration angle between interface and free surfaces of both materials. The wedge angles on ceramics and metal were described as $\phi_1$ and $\phi_2$ respectively. The wedge angles of the metal side $\phi_2$ were set over the range in $20^\circ < \phi_2 \leq 180^\circ$, as kept maintaining one of the ceramic side $\phi_1 = 90^\circ$.

Thermal elastoplastic FEM was carried out to clarify the distribution of the thermal residual stress near the edge of the interface each wedge condition using ceramics to metal joint FEM models bonded at high temperature ranges. The stress singularity was confirmed near the edge of the interface on the free surfaces of ceramic side each FEM model. The gradient of stress distribution was evaluated and compared in FEM elastoplastic analysis.

The numerical results were compared with the experimental results, which showed effects of the wedge angle on the practical tensile strength of silicon nitride to nickel joints specimens bonded at the same as numerical temperature conditions. Changing the wedge angle from a specific wedge angle improves the tensile bonding strength, since the residual stress was decreased by changing the wedge angle. This result corresponds with the FEM results as increasing $\phi_2$ from the right angle decreases the concentration intensity of the residual stress.

The dependency of the optimum interface condition on the bonding temperature was discussed based on both results of numerical and experimental in high bonding temperature ranges.

MS03.03.05
Metal or Alloy - Gr Composite Coatings via Electro- or Electroless Deposition for High Surface Performances Sishi Li, Gongsheng Song and Chunxu Pan; Wuhan University, China

In general, surface coating technology includes painting & organic coating, electro-& electroless deposition, physical vapour deposition, chemical vapour deposition and thermal spraying et al. Electro-deposition and electroless deposition are widely used in industry. Electro-deposition, is a kind of process that the metal ions in the electrolyte are reduced into metal with external electric assistance, and deposited on the surface of the substrate for forming a compact metal or alloy coating. Electroless deposition is a kind of process that the metal ions in the solution are reduced into metal under a strong and suitable reducing agent without external electric assistance, and deposited on the surface with catalytic active sites of the substrate for forming a compact metal coating.

As a new type of two-dimensional (2-D) carbon nanomaterial, graphene (Gr) is of many excellent properties, such as high strength, ductility, thermal conductivity, wear resistance, extremely large specific surface area, remarkable chemical inertness unless exposed to harsh reaction conditions, etc., and shows great application potential as an excellent reinforced phase in the field of composite materials. In recent years, our group engages in preparation of
the metal or alloy - Gr coatings via electro-deposition or electroless deposition for high surface performances, and explores their industrial applications.

1. **Zn-Gr composite coating via pulse reverse electro-deposition.**

In this work, the hydrophilic graphene oxide (GO), instead of the hydrophobic Gr, was chosen and added into the electrolyte bath. Due to the reduction of GO into Gr during deposition, a Zn-Gr composite coating was prepared successfully by using a pulse reverse electro-deposition method on the iron substrate. The experimental results reveal that: 1) The coating exhibits a strong adhesion with the substrate; 2) The Zn crystalline and morphologies change greatly due to the co-deposition of Gr, i.e., the main preferred orientations of (112) and (101) crystal planes in pure Zn coating gradually transform into the (103), (102) and (110) planes in the Zn-Gr composite coating. 3) There is an optimal GO adding amount in a range 0.3–0.5g/L in the electrolyte, at which the Zn-Gr coating exhibits the highest corrosion resistance and corrosion current density just be a hundredth comparing with that of pure Zn coating in simulated seawater environment.

2. **Alloy (Zn–Ni)-Gr composite coating via pulse reverse electro-deposition.**

The alloy (Zn–Ni)-Gr composite coating was prepared by using pulsed-reverse electrodeposition. It was found that: 1) the coating grain size became smaller after GO added into the electrolyte; 2) the presence of Gr could effectively inhibit the corrosion of the substrate; 3) comparing to regular Zn-Ni coating, the (Zn–Ni)-Gr coating's microhardness and elastic modulus were increased.

3. **Cu-Gr composite coating via electroless deposition**

In this work, the Cu-Gr composite coating was prepared successfully by using electroless plating with sodium hypophosphite (NaH2PO2) as the reducing agent. The experimental results reveal that: 1) Gr exhibits a significant effect on the microstructure of the coating, for example, the grain size of the composite coating varies from the concentration of the added GO, and the optimal value shows the smallest grain size and the highest compactness. 2) At the optimal GO concentration, the Cu-Gr coating also is of the highest mechanical properties. 3) Compared with regular pure Cu coating, the corrosion resistance of the Cu-Gr coating has a significant improvement, i.e. the $E_{\text{corr}}$, $i_{\text{corr}}$, corrosion rate and inhibition efficiency are also optimized at the optimal GO concentration. It is expected that the Cu-Gr coating will have broad application prospects in the fields of electronics industry, marine engineering and military industry.

**MS03.03.06**

**Micro-Mechanical Properties of Electrodeposited Au-TiO2 Composite Film**

Yu-An Chien, Tso-Fu Mark Chang, Chun-Yi Chen, Daisuke Yamane, Hiroyuki Ito, Katsuyuki Machida, Kazuya Masu and Masato Sone; Tokyo Institute of Technology, Japan

Electrodeposition is a widely applied method in fabrication of metal-based components in micro-electrical-mechanical systems (MEMS) devices. As an example, gold material, which has a high mass density of 19.3 x 10³ kg / m³ at 298K, is utilized as the proof mass in a MEMS accelerometer since performance of a MEMS accelerometer is highly related to overall mass of the proof mass. However, the relatively weak mechanical strength of gold limits the structure stability and reliability when used in movable micro-structures. Enhancing the mechanical strength is an important task to ensure high structure stability of movable structures in novel MEMS.

Co-deposition of metal matrix-oxide nanoparticles (NPs) composites is a simple and effective method to improve mechanical properties of the material. The NPs can be oxides such as Al₂O₃, TiO₂ and Cr₂O₃, carbides like SiC and TiC or graphitic materials like carbon nanofiber, carbon nanotube, and graphene oxide. A wide range of metals includes zinc, nickel, copper, nickel and silver has been used as matrix of the composite. In this study, TiO₂ NPs are introduced into the gold electrodeposition bath to enhance mechanical strengths of electrodeposited gold-based materials by forming TiO₂ NPs-reinforced gold matrix composites. Effects of the strengthening provided by the TiO₂ NPs are evaluated by micro Vickers hardness test and micro-compression test.

The Au-TiO₂ composite films were deposited on 1 cm² area copper plates. A common two electrode system was use for the electrodeposition with the copper plates as the working electrode, a platinum plate as the counter electrode, and a commercial non-cyanide sulfite-based gold bath containing various amounts of TiO₂ NP powder (AEROXIDE® TiO₂ P 25, Evonik) as the electrolyte. Temperature of the electrolyte was kept at 40°C. All the electrodeposition was carried out through galvanostatic method with a current density of 5 mA/cm² for 1.5 hours. A pure gold film was also deposited with the same electrodeposition parameters but without TiO₂ NP powder in the electrolyte for comparison. Composition and crystal structure of the composite films were characterized by energy dispersive X-ray spectrometry (EMAX, Horiba) equipped in an scanning electron microscope (SEM, S-4300SE, Hitachi) and an X-ray diffractometer (XRD, Ultima IV, Rigaku). Surface morphologies of the as-deposited films were observed with the SEM. Hardness of the films were evaluated by micro Vickers hardness measurement (HMV-
Micro-compression tests were conducted using micro-pillars fabricated by focus ion beam (FIB, FB-2100, Hitachi) from the composites films. Surface morphologies of the Au-TiO$_2$ composite films were found to be composed of particles through the observation of secondary electron images. A decrease in particle size was observed with an increase in content of TiO$_2$ NPs in the film from 1.45 to 2.72 wt%. XRD spectrum of electroplated gold, TiO$_2$ NPs, and Au-TiO$_2$ composite films were measured to confirm the crystal structure of composite films. The primary characteristic peak of P 25 TiO$_2$ NPs at $2\theta = 25.1^\circ$ (corresponding to characteristic peak of (101) plane, anatase phase) was also observed in spectrum of Au-TiO$_2$ composite films, which confirm the existence of TiO$_2$ NPs in the deposits. Broaden characteristic peaks of the Au-TiO$_2$ composite film indicated grain refinement caused by co-deposition with the TiO$_2$ NPs. Improvement of the mechanical properties was verified from the micro Vickers hardness measurement and micro-compression tests. The Vickers hardness increased from 135 HV (pure gold) to 207 HV (2.72 wt% TiO$_2$) and the Yield strength increase from 0.44 GPa (pure gold) to 0.84 GPa (2.72 wt% TiO$_2$). The results demonstrated the significant enhancement of mechanical strength by introducing TiO$_2$ NPs into the gold matrix.

TEM Investigation of Local Mechanical Behavior in Nanocarbon-Aluminum Composites Made by the Electrocharging Assisted Process

Christopher Klingshirn$^1$, Xiaoxiao Ge$^2$, Madeline Morales$^2$, Karen Gaskell$^2$, Manfred Wuttig$^2$, Daniel Cole$^1$, Christopher M. Shumeyko$^1$ and Lourdes G. Salamanca-Riba$^2$; $^1$U.S. Army Research Laboratory, United States; $^2$University of Maryland, United States

Novel nanocarbon-metal composites called “covetics” have the potential to significantly improve upon the mechanical and electrical properties of established metals and alloys, including Al, Cu and Ag. When a stir-cast Al melt containing a C source is subjected to electric current above a threshold value, carbon atoms are ionized, causing nanoscale graphitic ribbons and chains to form and become incorporated within the resulting Al lattice. Greater understanding of the atomic-scale behavior of covetics is essential to improve desirable properties of Al alloys, and by extension their performance in aerospace, structural, and power transmission applications.

This work explores the relationship between the structure of nanocarbon-Al composites and their local mechanical and electrical properties. We characterize nanocarbon-Al interfaces in covetics using Raman spectroscopy, conductive AFM and nano-indentation, and TEM. AFM modulus mapping reveals areas of locally stiffer microstructure. All characterization is performed within a few µm of a chosen region of interest as guided by fiducial marks milled using a dual focused ion beam (FIB)/SEM. The FIB is also used to prepare TEM specimens from the region of interest for analysis of the dislocation structure. Dislocation densities on the order of $10^{10}$ cm$^{-2}$ are observed along with sub-grain misorientations of 2–3 degrees. Through close inspection of features identified by surface characterization techniques, we glean information about the role of nanocarbon phases on the mechanical and electrical performance of covetics.

Composition analysis is obtained by electron energy loss spectroscopy (EELS) in TEM as well as X-ray photoelectron spectroscopy (XPS). Raman and EELS spectrum images analyzed by nonlinear fitting and machine learning techniques reveal increased ordering of nanocrystalline carbon embedded within the Al lattice. The degree of ordering is found to depend on the applied electric current, with greater exposure corresponding to greater graphitic order as indicated by Raman G and D peak intensities and shifts. Further evidence of $sp^2$ carbon bonding and Al-C bonding is seen by EELS and XPS. Preliminary results indicate directionality in the microstructure potentially coordinated with applied current direction, which will be investigated for correlation with highly ordered graphitic features. The relationship between nanocarbon incorporation and grain growth behavior will also be explored.

This work is supported by the U. S. Department of Energy under Award No. DE-EE0008313.

Multiphase Nano-Ductile Cast Iron with Super Wear Resistance

Kewen Dong, Wentao Zhou and Cheng Liu; Yangzhou University, China

Ductile cast iron (DCI) is becoming an increasingly important engineering material due to its remarkable strength, ductility, wear resistance and low production cost. However, the industrial heavy-loading components, like gears
and bearings, require a highly improved wear resistance of DCIs. A new austempering process is developed in a commercial unalloyed DCI, which comprises the following heat treatment cycle: austenitizing at 900 degrees Celsius for 30min, rapidly quenching into a patented water-based liquid at 60 degrees Celsius isothermally holding at 190 degrees Celsius (slightly lower than the starting temperature of martensite formation of DCI matrix) for 8h and air cooling. A multiphase matrix consisting of lenticular prior martensite (PM), bainitic ferrite (BF), retained austenite (RA) and a nano-scaled super bainite ((BF+RA) nano) is produced. It is shown from the pin-on-ring wear test that a super wear resistance under the load range from 20 to 500N during dry sliding is mainly due to the synergistic strengthening between multiple phases and nodular graphite. In the initial stage of wear, the main mechanism is adhesive due to the strip-off and breaking effect of graphite. In the later stage, the more martensite can be induced from (BF+RA) nano and RA through a TRIP effect with increasing the normal load, which is attributed to the higher wear resistance. The result shows a reasonable value of wear performance, which recommends the designed nanostructured multiphase DCI for more extensive application prospects.

MS03.03.09
Micromechanical Studies of Hypereutectic Al-20Si Alloy Heterogeneous Structure by Laser Surface Remelting
Huai-Hsun Lien, Amit Misra and Jyoti Mazumder; University of Michigan–Ann Arbor, United States

Heterogeneous metallic materials with multimodal grain size distribution of constituent grains and phases show significant improvements in ductility at yield strength comparable to their nanocrystalline counterparts. However, the fundamental mechanisms for the increased plasticity were not well understood. Model system heterogeneous hypereutectic Al-20Si with µm-size Al coarse grains (CGs) embedded in nm-size Al-Si eutectic ultrafine grains (CGs) was fabricated by laser surface remelting (LSR). In this report, the mechanical properties of the LSR heterogeneous Al-20Si were studied. Hardness testing and micropillar compression reveal different mechanical properties for as-cast Al-12Si eutectic and LSR heterogeneous Al-20Si. In addition, the hardness increases as the fraction of nanoscale Al-Si eutectic UFGs increase. In-situ SEM and in-situ TEM further reveal the deformation behavior of micropillars and nanopillars. The different mechanical properties and in-situ observations of LSR heterogeneous Al-20Si may provide an explanation to the enhanced plasticity.

MS03.03.10
Structural and Mechanical Properties of Nanocomposites Formed by Deposition of Metals in Porous Silicon
Vitaly Bondarenko; Belarusian State University of Informatics and Radioelectronics, Belarus

Silicon is a main semiconductor material used for fabricating different devices and systems including but not limited to integrated circuits, microelectromechanical systems and various sensors. Physical properties of silicon are very well-studied and scientists have almost exhausted the possibilities of changing these properties by traditional methods based on implantation and diffusion of appropriate chemical elements in silicon. In this regard, there is a great interest in finding new methods for creating silicon-based composites exhibiting properties that silicon does not have. Such materials have been identified as a new solution for a significant expansion of the functional abilities of silicon.

This work is aimed at developing a simple and efficient method for the synthesis of nanocomposite materials that can be easily integrated with silicon wafers [1]. Our approach consists in formation of pore channels in a silicon wafer followed by deposition of different metals, which impart new functional properties to silicon. Research of mechanical properties of nanocomposites based on porous silicon is very important because these new materials (consisting of silicon skeleton and metals) are subjected to different chemical and thermal treatments at extreme conditions during fabrication of endpoint device or system.

Ferromagnetic metals (Ni, Co and Fe) were introduced into the pore channels to create new silicon-based materials demonstrating unique magnetic properties. To provide the luminescence, rare-earth metals and ZnO were deposited in porous silicon. Nanoparticles of noble metals were formed on the surface of silicon skeleton to ensure plasmonic properties.

Mechanical and structural characteristics of nanocomposite materials based on porous silicon and metals were investigated together with their magnetic and optical features. The most outstanding results are presented and discussed in this work.

**MS03.03.11**  
Characterization of Sn-Bi-Graphene Oxide Nanocrystalline Electrodeposited Coatings to Establish Microstructure-Property Correlation  
Abhay Gupta and Chandan Srivastava; Indian Institute of Science, India

Sn-Bi alloy provides a low melting, non-hazardous and feasible alternate to the conventional Sn-Pb solder alloys for circuit packaging and interconnects. In this work, Sn-Bi (Bi 27 wt.%) coating with varying concentrations of graphene oxide (GO) was electrodeposited over mild steel substrate. Microstructure-corrosion property correlation in SnBi-GO composite coatings was then investigated as a function of GO content. All the coatings exhibited compact and crack-free morphology with GO sheets embedded within the matrix. XRD analysis of SnBi-GO coatings revealed the formation of a two-phase matrix containing Sn-rich and Bi-rich phases. Tafel polarization measurements and electrochemical impedance spectroscopy (EIS) test results revealed that the corrosion rate of the coatings was sensitive to the amount of GO in the coating. The corrosion rate decreased with initial additions of GO to reach a minimum before increasing for higher GO additions. This indicated towards the presence of an optimum with respect to the amount of GO for achieving highest corrosion resistance performance. Microstructural characterization conducted using the electron back scatter diffraction (EBSD) technique correlated the observed corrosion behaviour with the relative fraction of the low and high angle grain boundaries present within the coating matrix. It was observed that the coating with highest corrosion resistance performance contained maximum fraction of low energy low angle grain boundaries. Transmission electron microscopy based analysis revealed that the addition of GO led to enrichment of Sn rich phase and dissolution of more Sn in Bi phase. TEM, EBSD and zeta potential studies were used to correlate the fraction of LAGBs with the amount and distribution of Bi in the matrix and the corrosion resistance performance of the Sn-Bi-GO coatings.

Electrodeposition of Au-Cu Alloy Micro-Cantilevers and the Young’s Modulus by Resonance Frequency Method  
Kyotaro Nitta1, Haochun Tang1, Chun-Yi Chen1, Tso-Fu Mark Chang1, Daisuke Yamane1, Shinichi Iida2, Katsuyuki Machida1, Hiroyuki Ito1, Kazuya Masu1 and Masato Sone1; 1Tokyo Institute of Technology, Japan; 2NTT Advanced Technology Corporation, Japan

Gold materials are commonly applied in electronic devices because of the superior corrosion resistance, electric conductivity, and chemical stability [1]. Recently, micro-electro-mechanical systems (MEMS) inertial sensors utilizing gold materials in the main components are reported to have 1000 times higher sensitivity than conventional MEMS inertial sensors [2,3], which is mostly because of the high mass density. For application of gold-based materials in next generation MEMS devices, further strengthening is needed to ensure high structure stability. Regarding strengthening of gold materials, grain boundary strengthening and solid solution strengthening mechanisms can be applied simultaneously by alloy electrodeposition process [4], which the yield stress reached 1.15 GPa when the grain size was refined to 5.3 nm with the copper concentration at 12.3 wt%. On the other hand, Young’s modulus of the high strength Au-Cu alloys is also needed in design of MEMS components, such as the micro-scale spring in MEMS inertial sensors. In this study, Young’s moduli of micro-cantilevers composed of the Au-Cu alloy are measured by a non-destructive resonance frequency method [5].

The Au-Cu alloy micro-cantilevers were fabricated by electrodeposition and lithography. The Ti adhesion layer and the Au seed layer were deposited by sputtering, and the layer thicknesses were both at 100 nm. The Au-Cu electrolyte used in this work was a commercially available electrolyte provided by MATEX Co. Japan, which contained 17.3 g/L of X3Au(SO3)2 (X = Na, K), 1.26 g/L of CuSO4, and EDTA as the additive with pH at 7.5. The electrodeposition was carried out at 50 °C, and the current density was varied from 0.5 to 2 mA/cm². A piece of Pt plate was used as the anode. Design-length of the micro-cantilever was varied from 50 ~ 1000 μm, and design-width of the micro-cantilever was ranged from 5 ~ 20 μm. Thickness of the Au-Cu alloy layer was from 2.6 ~ 4.0 μm. Composition of the films was characterized by energy dispersive x-ray equipped in a scanning electron microscope. Young’s moduli of the Au-Cu alloy micro-cantilevers were calculated from resonance frequencies of the micro-cantilevers. The resonance frequencies were experimentally obtained as shown in the following. First, a voltage pulse (amplitude: 10V, pulse width: 100μs) was applied between the cantilever and a fixed electrode to initiate free vibration mode. Next, a laser doppler vibrometer was used to measure displacements of tip of the cantilever. Finally, the resonant frequency was obtained from a FFT (fast Fourier transform) analyzer.

Surface conditions of Au-Cu alloy micro-cantilevers produced at a current density ranged from 0.5 to 2 mA/cm² were all uniform and smooth. The Cu content increased from 1.40 to 4.03 wt% as the current density increased from
0.5 to 2 mA/cm², which is because standard reduction potential of Cu is more negative than that of Au, and an increase in the current density leads to a more negative applied potential. Young’s modulus of a micro-cantilever composed of 98.3 % Au with the length at 700 μm, the width 20 μm, and the thickness at 3.95 μm was 80.9 GPa. The value is close to that of pure gold (79 GPa) and much lower than that of pure copper (117 GPa). On the other hand, no obvious trend was observed when the width changed from 10 to 20.

Fabrication of Multifunctional Nanostructured Superhydrophobic Surface on Aluminium Alloy by Simple Hot Water Treatment
Priya Mandal, Gopinath Perumal, Abhilash Shishodia, Harpreet Singh Arora, Sajal K. Ghosh and Harpreet S. Grewal; Shiv Nadar University, India

In this work, we have reported a very simple and facile route for the fabrication of multifunctional metal surface by simple hot water treatment (HWT). Micro-nano hierarchical structures were successfully fabricated on aluminium (Al) following a mechano-thermal synthesis. A self-assembled monolayer of low surface energy material 1H,1H,2H,2H-perfluorooctyltriethoxysilane (FOETS) was also coated on the processed samples using a vapour deposition technique. The samples fabricated with process conditions exhibited a vivid range of wettability ranging from near 0° to 165°. Apart from high static and dynamic contact angles, the processed Al surface also showed extremely low contact angle hysteresis (CAH). The developed surfaces also showed extreme chemical stability while retaining the de-wetting behaviour as assessed by the immersion tests performed with salt water. The obtained results are explained on the basis of the ability of the processed surfaces to entrapped air resulting in the formation of the Cassie state. This entrapped air work as a protective layer and lowers the contact area with the corrosive media. These surfaces are thermally stable to a wide range of temperature from -25° to 200°C and exhibit excellent self-cleaning property. Our work introduces a simple strategy to fabricate multifunctional aluminium surface on a large scale which can be easily extended to other materials.

MS03.03.15
Effect of Post-Deformation Annealing on the Microstructure and Micro-Mechanical Behavior of Zn-Mg Hybrids Processed by High-Pressure Torsion
David Hernández-Escobar⁴, Josh Marcus⁴, Jae-Kyung Han², Raymond R. Unochic³, Megumi Kawasaki¹ and Carl J. Boylelter¹; ¹Michigan State University, United States; ²Oregon State University, United States; ³Oak Ridge National Laboratory, United States

Heterostructured metals have attracted increasing interest because of their unique capability to overcome the strength-ductility tradeoff typically observed in engineering materials. Here, a new strategy for synthesizing heterostructured Zn-Mg hybrids is proposed using quasi-constrained high-pressure torsion (HPT) under an applied pressure of 6 GPa and a rotational speed of 1 rpm up to 30 turns, followed by a post-deformation annealing (PDA) treatment at 200 °C for 1h. Experimental results indicate a transition from a relatively homogenous nanograined structure of ~ 100-200 nm with an even distribution of Mg₂Zn₁₁ and MgZn₂ nanoscale intermetallic precipitates after 30 turns HPT, to a heterogeneous microstructure consisting of a bimodal grain size distribution with the nanosized intermetallics segregated in Mg-rich grains upon subsequent PDA. The microstructural evolution during HPT and PDA was characterized through SEM, XRD and TEM/STEM. The resulting micro-mechanical behavior was investigated using Vickers hardness and nanoindentation testing, and it was concluded that PDA led to a simultaneous increase of hardness and strain rate sensitivity. Close inspection of the strain hardening capability revealed that Zn-Mg HPT-processed hybrids followed a three-regime behavior during plastic deformation. This mechanical response is suggested due to the activation of multiple strengthening mechanisms during HPT and subsequent PDA, including grain refinement, in-situ precipitation, and back-stress strengthening associated with geometrically necessary dislocations. Moreover, the synergistic effect of PDA in this strategy can be further extended to the fabrication of other metal hybrids, paving the way to the design of novel materials with attractive
properties for task-specific applications. In particular, the understanding gained on heterostructured Zn-Mg hybrids is intended to aid the development of Zn-based materials able to satisfy the demanding mechanical requirements of absorbable medical implant devices.

**Ultra-High Strength and Plasticity Mediated by Partial Dislocations and Defect Networks in Metallic Multilayers**

Ruizhe Su\(^1\), Dajla Neffati\(^2\), Qiang Li\(^1\), Sichuang Xue\(^1\), Jaehun Cho\(^1\), Jin Li\(^1\), Jie Ding\(^1\), Yifan Zhang\(^1\), Cuncai Fan\(^1\), Haiyan Wang\(^1\), Yashashree Kulkarni\(^2\) and Xinghang Zhang\(^1\); \(^1\)Purdue University, United States; \(^2\)University of Houston, United States

Deformation mechanisms governing the strength of nanostructured metallic multilayers have been studied extensively for various applications. In general, size effect is the most effective way to tailor the mechanical strength of multilayers. Here we report that three Cu/Co multilayer systems with identical layer thickness but different types of layer interfaces exhibit drastically different mechanical behavior. *In situ* micropillar compression tests inside a scanning electron microscope show that coherent FCC (100) and (110) Cu/Co multilayer systems have low yield strength of about 600 MPa, and prominent shear instability. In contrast, the incoherent Cu/ HCP Co multilayers show much greater yield strength, exceeding 2.4 GPa, and significant plasticity manifested by a cap on the deformed pillar. Molecular dynamics simulations reveal an unexpected interplay between pre-existing twin boundaries in Cu, stacking faults in HCP Co, and incoherent layer interfaces, which leads to partial dislocation dominated high strength, and outstanding plasticity. This study provides fresh insights for the design of strong, deformable nanocomposites by using a defect network consisting of twin boundaries, stacking faults and layer interfaces.

**Bioinspired Metal-Coordinate Mineralization: Effective Metal-Binding Pathway for Mechanical Reinforcement of Organic-Inorganic Hybrid Materials and for Future Hard Tissue Engineering Application**

Sungjin Kim, Abigail Regitsky, Jake Song, Gareth McKinley and Niels Holten-Andersen; Massachusetts Institute of Technology, United States

Biology has evolved to recruit metal ions from surroundings to produce structural materials and enhance their mechanical properties in remarkably efficient manners. One such way is to reinforce the soft matrix with the strong metal-binding interaction utilizing metal-affinitive organic ligands (e.g., mussel holdfast, marine worm jaws) and another is to go through the biomineralization of the recruited metal ions to produce stiff bioinorganic components (e.g., chiton teeth, nacre, bones). Herein, using metal-binding chemistry inspired by mussels holdfast, we showcase the control and combination of both pathways - the macromolecular crosslinking and mineralization for reinforcing soft matter mechanics and for producing high-value organic-inorganic nanocomposite materials towards potential hard tissue engineering application. First, we introduce the highly efficient mechanical reinforcement of hydrogel network via *in situ* mineralization of the metals (with very small amount: < 0.1 vol %) localized at the monodisperse metal-coordinate crosslinking sites. As such, the viscoelastic behavior of the hydrogel could be dramatically tuned from liquid-like to solid-like with increased modulus and strength. Furthermore, we demonstrate that this metal-binding mechanism can work universally as a mineralization controller for inducing amorphous or metastable calcium carbonates and their effective transition to hydroxyapatite (i.e., bone minerals) nanocrystals. The ability of bioinspired metal-binding chemistry controlling the mineralization thus suggests the efficient material design/processing strategy for reinforcing materials and for applying to the practical biomedical technology.

**MS03.03.18**

**Quantitative Analysis of Retarded Sintering Behavior in Ni Alloy Thin Film for MLCC Internal Electrode**

Youngran Jung\(^1\), Wonhyo Joo\(^1\), Minjeong Choi\(^1\), Cheol Kim\(^1\), Kyungryul Lee\(^2\) and Young-chang Joo\(^1\); \(^1\)Seoul National University, Korea (the Republic of); \(^2\)Samsung Electro-Mechanics, Co., Korea (the Republic of)

Downsizing trend of Multi-Layer Ceramic Capacitor (MLCC) required the structure of alternating stacking layers of dielectric and electrode in MLCC to be as thin as possible to microscale. For a thinner layer, smaller nanoparticles for dielectric and Ni paste for electrode are used. One of the major issue caused by the smaller particle size is the enlarged sintering behavior difference between the ceramic and metal layer of MLCC during the high-temperature sintering process in the manufacturing process. Eventually, the difference in sintering behavior between the layers causes fracture of the device. Therefore, suggesting a Ni- alloy material for the electrode layer for sintering process delay and *in-situ* tool to analyze the sintering behavior of thin film is in demand. In this study, Ni alloy films were
fabricated and the sintering behaviors of Ni nanoparticles in thin films were quantitatively analyzed by optical laser stress analysis. First, several metal precursors were selected using the phase diagram and surface energy to delay the sintering. The Ni paste and metal precursors were mixed and fabricated to thin films by spin coating. Then, the fabricated films were heated in the closed chamber. During this process, in situ stress curve versus temperature graph was obtained using the optical laser system. The inflection points for Ni films were analyzed thoroughly. The microstructure analysis was carried out for the film samples quenched above and below the inflection point temperature. Therefore, specific inflection point resulted to be significantly related to the sintering process. In addition, retardation of sintering behavior was observed from the microstructure analysis of Ni alloy films. Lastly, for a deeper understanding of sintering behavior, crystal structure analysis for Ni alloy films was performed to identify delayed sintering mechanism. This study suggests an in-situ quantitative analysis method for sintering behavior and new material to reduce sintering behavior gap between the ceramic and metal layer of MLCC.

**MS03.03.19**

**Atomistic Simulation of the Strain Rate-Dependent Ductility in Metallic Glass Nanowires**  
Yanming Zhang\(^1\), Penghui Cao\(^2\), Liping Huang\(^1\) and Yunfeng Shi\(^1\); \(^1\)Rensselaer Polytechnic Institute, United States; \(^2\)University of California, Irvine, United States

Metallic glasses are very promising structural materials and their mechanical properties as well as deformation mechanism have been extensively investigated from both simulations and experiments. However, a complete understanding of the strain rate effect on mechanical response of metallic glasses is absent given the disparity in time scales between classical molecular dynamics simulations (MD) and experiments. Using accelerated MD simulations, we aim to, for the first time, report the mechanical properties of metallic glass nanowires ranging from 10^-8 s^-1 (classical MD simulations scale) to 10^-2 s^-1 (experimental scale). Specifically, embrittlement and reduction of failure strength is observed as the applied strain rate reduces, accompanied by a transition from shear fracture to cleavage. We suggest that the reduction of ductility in metallic glass nanowires as the applied strain rate decreases is due to the gradual relaxation of liquid-like structure. Finally, the metallic glasses quenched from more fragile liquids will be subjected to slow-rate mechanical tests, where the correlation between strain rate sensitivity of ductility and fragility will be established.

**MS03.03.20**

**Microstructure Design for Ductile Glass Composites Using Exclusively Brittle Metallic Glasses**  
Yanming Zhang\(^1\), Ying Zhang\(^1\), Binghui Deng\(^1\), Huijuan Zhao\(^2\), Mohammed Alnaggar\(^1\), Liping Huang\(^1\) and Yunfeng Shi\(^1\); \(^1\)Rensselaer Polytechnic Institute, United States; \(^2\)Clemson University, United States

Metallic glasses are promising structural materials owing to high strength, excellent wear and corrosion resistance. Brittleness of bulk metallic glass is the main drawback researchers have been trying to improve over the past decade. So far, compositing ductile crystalline phases is the major effective means of ductility enhancement in brittle metallic glass, which not only limits the materials selection for composites design but usually results in substantial decrease of strength in metallic glasses. Herein, using molecular dynamics simulations, we incorporated two brittle metallic phases with different stiffness and surprisingly obtained strong, ductile and work hardenable composites. Compared to monolithic metallic glasses (failure strain is ~7%), significantly enhanced ductility (over 80% in terms of failure strain) has been achieved for brittle-brittle composites. To understand the toughening mechanism, we have identified two figures of merits to characterize the flexibility of the strong glassy filament, and the propensity for crack deflection, respectively. Furthermore, we have constructed a ductility map using the above two figures of merits, which agrees with our MD simulation of over five hundred different composite designs. The composite design principles delineated here is likely to be applicable to other material systems beyond metallic glass system.

**MS03.03.22**

**The Advantages in Real-Time Imaging of Mechanical Tests (Including In Situ Nano-Mechanics)**  
Noa Lachman; Tel Aviv University, Israel

Composites are a large and versatile group, incorporating various materials such as metals, ceramics and polymers in multiple scales from the macro to the nano. As such, composites can be tailored to highly specialized applications such as biomed, sensors, energy storage and aerospace. Such tailoring requires understanding of the different
mechanisms dominant at different length-scales, as well as correlating the composite morphology and said mechanisms – correlation that can work both ways. This correlation calls for means of observation at the desired scale in real-time stimulation of the material – be it mechanical, electrical or other types of stimulation.

In this talk, the need for real-time imaging of mechanical tests will be explained using various length-scale case studies. These case studies will include digital image correlation (DIC) used to analyze standard tensile tests, micro-mechanics under scanning electron microscope (SEM), and nano-mechanics under transmission electron microscope (TEM). Discussion will include the additional data acquired from real-time imaging at such scales and its importance, as well as possible future applications for other nanoscale materials. The methods presented in these case-studies can therefore provide deeper understanding of composite materials behavior, which can be used to improve planning and designing of composites as multifunctional materials.

MS03.03.23
Fabrication and Properties of Selected High-Strength Composite Conductors Ke Han, Rongmei Niu and Vince Toplosky; Florida State Univ, United States

Nanostructured composites, which have been successfully used in high field magnets, reach their most desirable strength level when their interface spacing is below 100 nanometers. The usual fabrication methods for these composites are severe plastic deformation, which refines interface spacing and create anisotropy. The fabrication may also introduce shear-bands into the microstructure. Investigating both anisotropy and shear-bands helps to understand the deformation mechanisms of these composites under external force. The goal of our research is to relate microstructural anisotropy to the mechanical and physical properties of these composites in various geometries. Our current work is shedding new light on the detailed correlation between microstructure and properties. This presentation describes microstructure in different orientations, with emphasis on the impact of anisotropy and shear-band on properties.

This work was performed at the National High Magnetic Field Laboratory, which is supported by the National Science Foundation Cooperative Agreement No. DMR-1644779 and the State of Florida

MS03.03.24
The Role of Electron Beam Induced Heating During 3D Nanoprinting Eva Mutunga1,2, Robert Winkler3, Jurgen Sattelkow4, Philip Rack1,2, Harald Plank3,4 and Jason D. Fowlkes2,1; 1University of Tennessee, Knoxville, United States; 2Oak Ridge National Laboratory, United States; 3Graz University of Technology, Austria; 4Graz Centre for Electron Microscopy, Austria

Focused electron beam induced deposition (FEBID) is a direct-write technique where an electron beam dissociates surface bound precursor molecules at the focal point of the electron beam. FEBID has become a more viable 3D nanoprinting tool due to the sophisticated applications shown recently, such as FEBID simulation [1] that predicts and controls the growth of 3D nanostructures by modeling the dynamic interaction of the electron beam and the precursor molecules, and its accompanying 3D CAD program (3BID) [2]. The ability to fabricate functional deposits such as plasmonic 3D nanostructures [3] and, scaffolds for 3D magnetic nanowires [4] with high degrees of freedom and precision using 3D FEBID show it is a promising additive nanomanufacturing tool. Unfortunately, distortions such as deflections in overhang 3D nanowires where linear growth is prescribed limit the reproduction of 3D FEBID designs. The 3BID program offers a tool to correct the distortions, but these are empirical. A pattern generating algorithm [5] released recently adjusts for proximity effects and compensates for height-dependent precursor coverage. The results show quite good congruence between the prescribed and deposited 3D nanostructures. Here, however, we quantify the mechanism that causes these distortions, paving the way to a more quantitative correction strategy.

We will show a combination of experiments, models, and simulations that reveal beam-induced heating as the culprit that constrains the replication of 3D FEBID designs. The electron beam facilitating deposition during nanowire growth also causes Joule heating at the beam interaction region (BIR). The BIR temperature increases gradually during growth as nanowire elongation impedes heat flow. Heat transfer from extended surfaces is used to model the heat flow from the BIR, through the nanowire to the substrate. The temperature gradient in the deposit gives rise to an opposing precursor concentration gradient resulting in a deflected nanowire where otherwise a linear nanowire was specified. This vital role beam-induced heating plays in determining the final deposit shape will be discussed.

**Additive Manufacturing of Metallic Materials—Mechanical Properties**

Prashanth Konda Gokuldoss; Tallinn University of Technology, Estonia

Laser-based powder bed fusion processes like the selective laser melting (SLM) is one of the additive manufacturing processes used to produce 3-D metal parts by selective melting of powders dictated by CAD data. Because of the high degree of freedom given by processing through additive manufacturing, it is possible to build parts with extremely complex geometries that would otherwise be difficult or impossible to produce using conventional manufacturing processes. However, until now, only conventional alloys like the AlSi10Mg, 316L, Ti6Al4V, etc. that either is developed for cast or wrought processes have been used for fabrication. Some of the alloys work well for the additive manufacturing process like the Al12Si, AlSi10Mg, because they have good fluidity and are readily weldable. Nevertheless, most of the materials fabricated by SLM show superior mechanical properties than their case counterparts. Even though superior mechanical properties were recorded, there are reports showing a premature failure of the materials (i.e.) the material fail before they achieve their maximum strength. Some of the reasons behind these premature failures will be discussed in detail.

**SESSION MS03.04: Nanocomposites I**

**Hybrid Materials Based on Micro Mechanical Interlocking and Interpenetrating Composites**

Rainer Adelung; Kiel University, Germany

The demands on modern materials are highly challenging and partially contradictory. For example, materials should be strong like metals but chemically inert like soft low surface energy polymers. Another example is the need for extreme lightweight but fail-proof and high temperature stable materials. Furthermore, “intelligent” stimulus responsive materials and adaptive structures are requested. Those conflicts can be overcome by effectively combining disparate materials in composites that allow a fusing of the traditional material classes like ceramics, polymers and metals. For that purpose, in this presentation two basic concepts utilized in the functional nanomaterials group are introduced that might be employed to overcome such challenges. One is based on micromechanical interlocking at the interface, the other on interpenetrating composites with micro framework materials. In both cases, the chemistry and chemical compatibility of the materials play a negligible role, the selection of the constituents can be done by focussing exclusively on the material properties. This allows a targeted tuning of the micro-structure and enables the realization of atypical material properties like flexibility in ceramics. Furthermore, self reporting and actuating concepts can be added to create materials that replace complex micro-systems. Examples will be given including mechanical interlocking as universal material connection technology.
[1,2], a versatile template framework material [3], aero materials [4, 5], as well as sensor [6], and self reporting concepts [7].

Geologically-Inspired Ceramics—Shedding Light on Room-Temperature Cold Sintering Matthias Haug¹, Florian Bouville² and André R. Studart¹; ¹ETH Zurich, Switzerland; ²Imperial College London, United Kingdom

In the Earth’s upper crust, dense ceramic materials can be formed at mild pressures and nearly ambient temperature. This represents a tremendous reduction in energy used for densification compared to technical ceramic processing, in which temperatures above 1'000 °C are needed to produce dense structures. Inspired by this geological phenomenon, we demonstrated a new method called room-temperature cold sintering. In this process, small amounts of water and pressures up to 500 MPa are utilized to produce calcium carbonate compacts reaching 85 % relative density within only 30 min. While the densification process in geological carbonates is presumably based on dissolution – precipitation of the inorganic material and the diffusion through the thin water film present on the surface of the particles, the mechanisms underlying the densification of synthetic carbonate nanoparticles remain unknown. From the several compositions that have been proven to be compatible with cold sintering, carbonates are one of the very few classes of material that can be densified at room temperature. To better understand this unique process, we developed a methodology to probe the time-dependent structure of these carbonates at multiple length scales during water-assisted densification. We combined the observation of in-situ compaction behavior of calcium carbonate particles with high-energy X-Ray tomography to small-scale creep experiment using instrumented indentation. The synchrotron tomography experiments allowed us to directly observe the deformation of the particles in real-time and thus discriminate between mechanisms involving deformation or simple rearrangement of the particles. For a quantitative analysis, we used digital volume correlation to calculate local deformations and strains within the sample. Indentation was utilized to further probe the mechanical behavior of the sample from the micron to the nanometric length scale, allowing us to pin point the influence of the water on the room-temperature sintering process. Combined the tomography and indentation experiments provide a powerful multiscale temporal platform to shed light on the main factors that drives the room-temperature sintering of nanopowders under pressure.

9:15 AM MS03.04.03
Shape Memory Effect in Single-Crystalline Micro-Sized ZrHfO2-Based Ceramics Haolu Zhang¹, Justin Jetter², Hanlin Gu³, Xian Chen⁴, Manfred Wuttig⁵, Julia R. Greer¹, Richard D. James³ and Eckhard Quandt²; ¹California Institute of Technology, United States; ²University of Kiel, Germany; ³University of Minnesota, United States; ⁴The Hong Kong University of Science and Technology, China; ⁵University of Maryland, United States

Martensitic transformations, which give rise to the interesting properties of Shape Memory Alloys (SMA), have long been studied in metals and alloys, but understanding and emergence of their presence in metal oxides have been limited. Known for their transformation toughening mechanism, chemical composition of zirconia-based ceramics can be altered to increase the interphase compatibility between its high temperature phase (austenite) and low temperature phase (martensite), which suggests possible emergence of Shape Memory Effects (SME) in these ceramics. We synthesized samples with weight percentage \( x \) of ZrHfO₂ ranging from 0.6 to 0.9 by pressing and sintering oxide powders. Transmission Electron Microscopy (TEM) and Electron Backscattering Diffraction (EBSD) characterization of these synthesized ceramics reveal finely twinned microstructure within single 5µm grains, with no visible defects in the composition \( x=0.735 \), which aligns with theoretical prediction. We performed uniaxial compression experiments on single-crystalline cylindrical pillars with diameters of 200nm to 2µm that were carved out of individual 5um average grains using Focused Ion Beam (FIB). These nanomechanical experiments
revealed that the stress-strain response was elastic plastic with favored deformation mechanism through martensite rearrangement, and that the yield strengths follow a smaller is stronger power-law relationship, similar to the ubiquitously observed size effects in metals that deform by crystallographic slip. This prominent size effect can give insight into the role of deformation twinning in ceramic plasticity. We further demonstrate the one-way shape memory effect by heating the deformed samples to above their phase transformation temperatures to recover their original shape and reveal a strong dependence of shape recovery on chemical composition.

Flexible and Extremely Scratch-Resistant Hard Coating Materials from Molecular Necklace-Like Cross-Linkers
Jiae Seo, Sung Wook Moon, Byoung-ho Choi and Ji-Hun Seo; Korea University, Korea (the Republic of)

A flexible hard coating material displaying scratch resistance and flexibility was developed through the design of organic-inorganic hybrid coatings using alkoxysilyl-functionalized polyrotaxane cross-linkers (PRX_Si1). PRX_Si1 has a unique structure like a molecular necklace that can form organic-inorganic cross-linking points and can provide large molecular movement. Hybrid cross-linking points and dynamic molecular motion have been assumed to simultaneously increase scratch resistance and flexibility. To confirm this hypothesis, the crystalline structure and mechanical properties of PRX_Si1-based hard coating materials were analyzed by transmission electron microscopy, small angle X-ray diffraction, tensile, pencil hardness and scratch tests. Finally, the hard coating material based on PRX_Si1 was able to form homogeneously dispersed nanoscale siloxane crystalline domains, and the deformation at the breakpoint was three times higher than the commercial hard coating material so that even after 5,000 folding test runs, Did not occur. In addition, this material has very high pencil hardness (9H) and scratch resistance.

9:45 AM MS03.04.05
Electrochemically Switchable Elasticity of Hybrid Nanocomposites Based on Nanoporous Gold and Conductive Polymer
Jie Li1, Jürgen Markmann1,2, Jörg Weißmüller1,2 and Nadia Mameka1; 1Materials Mechanics, Helmholtz-Zentrum Geesthacht, Germany; 2Hamburg University of Technology, Germany

Dealloying derived nanoporous gold (NPG), a 3D bicontinuous network of nanoscaled ligaments and pores with large surface area, exhibits a plethora of mechanical and functional properties that can be precisely controlled by electric signals in electrolyte environments. Among them, actuation [1], switchable elastic modulus [2], Poisson’s ratio [3] and strength [4,5] are of special interest to understand interfacial phenomena at the nanoscale and to design novel materials with an adaptable mechanical behavior.

Recently, the actuation performance of NPG has been significantly improved by decorating the gold ligaments with a conducting polymer polypyrrole (PPy) film [6]. The enhanced length change of the gold skeleton was promoted by actuation of PPy upon ion exchanges in the polymer layer with surrounding electrolyte. The elastic modulus behavior of the NPG-PPy hybrid, which is also crucial for the functionality, has not been studied yet. In this work, a uniform PPy film with various thicknesses was formed on mm-size NPG by electropolymerization without blocking the original nanopores. The elastic moduli of the resulting NPG-PPy nanocomposites were monitored in situ during potential cycling in aqueous electrolytes in a dynamic mechanical analyzer (DMA). Remarkably, the in situ DMA experiments reveal a non-monotonic modulus response as a function of the potential during charging-discharging processes, as opposed to a nearly linear variation of the macroscopic length. Moreover, the modulus variation amplitude is enlarged for the thicker PPy films. In this contribution, we will discuss the origin of the stiffness behavior and elucidate a role of the Au/PPy interface in the unusual elastic modulus response of the hybrid material.

Bio-Inspired Polymer Toughening of Graphene Oxide
Horacio Espinosa, Hoang D. Nguyen, Xu Zhang, Lily Mao, Rafael Soler-Crespo, SonBinh Nguyen and Jiaxing Huang; Northwestern University, United States
Two-dimensional materials in mono- or few-layer forms have been used in the design of novel sensors, filtration membranes, and wearable electronic devices. In their multilayer form, nanocomposites are engineered to exhibit unprecedented combinations of specific stiffness and strength. However, the intrinsic brittle behavior of these atomically thin 2D materials, and their associated risk for catastrophic failure, has thus far precluded their adoption in practical applications requiring superior mechanical properties.

In the area of nanocomposites (structural materials), lightweight 2D materials are addressing high demand for safer and more energy efficient transportation systems, e.g., in automotive and aeronautical applications. Similarly, the next generation of protective body armor has inspired the search for lightweight materials with exceptional piercing resistance. Composites based on two-dimensional materials appear to be excellent candidates to address these societal needs. Unfortunately, the presence of “architectural defects” such as voids and wrinkles found in previously produced 2D materials, in thin film form, resulted in somewhat limited mechanical performance. This has precluded fundamental understanding of their full potential and their robust implementation in the aforementioned engineering applications.

A strategy to gain fundamental understanding of the potential of 2D materials, in their few layer or structural material forms, is to investigate 2D material specimens with tailored chemistries and controlled architectures in the form of a few layers. Here we present a combined experimental and computational approach, based on graphene oxide (GO) and poly-vinyl alcohol (PVA), as a model material system, to investigate surface chemistry effects and pathways for improved ductility and fracture of 2D materials. We will show that a larger-scale “extrinsic” toughening mechanism can be incorporated into GO monolayers through surface modification by an ultrathin strongly interacting polymer layer.

In this presentation, we will discuss nanoscale experiments that demonstrate such a crack-bridging and toughening behavior for GO-derived materials. We will show that by incorporating an atomically thin layer of a hydrogen bond-forming polymer, onto the surface of a GO nanosheet, the toughness of the resulting GO-Polymer nanolaminates is increased up to 300% that of GO monolayers, making them highly attractive as scalable building blocks for the next generation of engineered materials. Multiscale characterization reveals the presence of a hydrogen-bonding network on the surface of GO that can be exploited to reinforce its mechanical integrity via polymer adhesion to the oxidized domains in GO. This pairing results in a synergistic toughening mechanism in which the polymer chains effectively bridge a developing crack and allow the nanolaminate to exhibit superior piercing resistance, as verified by combined nanomechanical experimental and computational studies. As cracks develop, clusters of hydrogen bonds between GO and the polymer chains break and reform, which permits the polymer to act as a self-healing load-bearing element. Such a deformation mechanism provides key insight not only for the design of 2D materials-based nanocomposites but also for the engineering of more reliable sensors, filtration membranes, and wearable electronics devices.
A Three-Dimensional Unit Cell Model for the Analysis of Thermal Residual Stresses in Polymer Composites Reinforced with Wavy Carbon Nanotubes  

Yunfa Zhang, Andrew Johnston, Ali Yousefpour, Jingwen Guan, Benoit Simard and Christopher Kingston; National Research Council Canada, Canada

Similar to conventional carbon and glass fibre reinforced polymer composites, high temperature curing is mostly inevitable in the fabrication of polymer nanocomposites reinforced with carbon nanotubes. This paper presents a numerical approach to predict the thermal residual stresses in polymer nanocomposites reinforced with a periodic array of wavy carbon nanotubes. A novel unit cell model is established to accurately account for the waviness of the nanotubes. Periodic boundary conditions are rigorously determined for the three dimensional unit cell with a pair of curved surfaces. To validate the model, effective elastic constants of composites with compliant matrices are evaluated using the finite element method, and the results are compared with those in literature. Notably, orthotropic elastic constants are correctly predicted for the unit cell configuration which has only two planes of symmetry manifested explicitly in the model. By employing material properties of the two constituents, the thermal residual stresses induced by high temperature curing and cooling-down are examined for an epoxy/wavy-nanotube composite. In particular, temperature-dependent material properties are used for the matrix to better capture its response within the wide temperature range associated with the curing and cooling-down process. Numerical results show that the waviness has a significant influence on the distribution of the local residual stresses. Finally, it is demonstrated that the curing and cooling-down process tends to increase the waviness of the nanotube.

Embracing Instability—Hierarchical Nanoengineered Composites with Buckling-Densified Carbon Nanotube Arrays Reinforcement  

Xinchen Ni, Luiz Acauan and Brian L. Wardle; Massachusetts Institute of Technology, United States

Nanofiber (NF) arrays, such as aligned carbon nanotubes, with exceptional intrinsic and scale-dependent properties, along with their easy tunability, have enabled applications in diverse areas including aerospace, energy, and biomedicine. Here, we use photolithography-based patterning and mechanical buckling to form densified aligned NF arrays, which exhibit wavelike folding buckling shapes. Such hierarchical shapes are known to introduce multiscale and mixed-mode reinforcement mechanisms in nanocomposites, leading to composite strength and toughness enhancement. In this study, we introduce the buckling-densified aligned NF arrays into the resin-rich ply-ply interface of laminated carbon microfiber composites as a through-thickness reinforcement. Short-beam shear (SBS) and double-edge notched tension (DENT) tests are performed to assess the effect of buckling-densified aligned NF array reinforcement. The aligned NF-reinforced composites are found to have a 7% increase in SBS strength and a remarkable 25% increase in the in-plane DENT strength. Scanning electron microscope imaging and lab-based high-resolution micro-computed tomography scans of post mortem specimens reveal that the buckling-densified aligned NF arrays suppress delamination and drive the crack into the more desirable intralaminar region. The findings demonstrate great potential for harnessing instabilities to fabricate high-volume-fraction and shape-tunable NF arrays, opening avenues for uses that extend beyond composite mechanical reinforcement, such as supercapacitors, thermomechanical devices, and sensors. Future work includes developing a model that can fully predict the buckling response of aligned NF arrays as a function of pattern size, NF elastic properties, and NF/substrate adhesion, as well as conducting 4D in situ mechanical testing of the DENT configuration by using synchrotron-radiation computed-tomography to reveal the 3D progressive damage state.

Influence of Detailed Nanostructures of Organic-Inorganic Hybrid Aerogels on Their Unique Mechanical Behaviors

Influence of Detailed Nanostructures of Organic-Inorganic Hybrid Aerogels on Their Unique Mechanical Behaviors  

Kazuki Nakanishi1,2, Kazuyoshi Kanamori1 and Ryota Ueoka1; 1Kyoto University, Japan; 2Nagoya University, Japan
Organic-inorganic aerogels have extensively been studied to overcome the inherent poor mechanical strength (friability) of their inorganic counterparts which necessitate supercritical drying for their preparation processes. In order for the low-density wet gels to be evaporatively dried without fracture under ambient pressure conditions, the network should exhibit large reversible deformations, i.e. shrinkage and re-expansion, while enduring the stresses exerted by capillary force during the solvent removal process. So far, the authors’ group has been attempting to prepare such organic-inorganic hybrid networks with a broad spectrum of mechanical properties utilizing appropriate combinations of precursors, additives, solvents and catalysts. Approaches can be classified into three categories; (1) Methyl-modified silsesquioxane (MSQ) using tri-functional methyltrialkoxysilanes as presursor, (2) Organo-bridged siloxane networks from bis-type di- or tri-functional alkoxysilane precursors, and (3) Double-crosslinked networks by hydrolysis-polycondensation of oligomeric precursors containing pre-polymserized hydrocarbon chains connecting Si atoms in the monomeric precursor. For each system, preparation conditions have been specified for the product to give low density (0.1-0.2 g cm$^{-3}$) and transparency/translucency to visible light.

(1) Supercritically dried MSQ exhibited reversible deformation against uniaxial compression up to 80 % of the original height, suggesting the network is recoverable against isotropic deformations. The slow evaporation of nonpolar solvents such as hexane enabled one to remove the solvent under ambient pressure without causing serious cracks and fractures. A size recovery from ca. 70 % compressed (shrunk) state by the spring-back gave highly transparent, low-density xerogels in a monolithic form [1,2].

(2) Introduction of relatively short hydrocarbon chains between Si atoms resulted in the improvement of flexural strength evaluated by three-point bending tests without sacrificing other properties such as low-density and visible-light transparency. The decreased functionality of siloxane bridges further increased the range of flexural deformation reflecting in part the relaxation behavior of polymeric networks [3].

(3) Integration of longer organic crosslinks into di- or tri-functional siloxane resulted in the highest degree of dutility while minimizing brittle nature of inorganic aerogels. The ambient-dried gels could be easily cut into shapes with blade and was stable against the resorption of organic solvent into their hydrophobic pores. These unique mechanical behavior of hybrid aerogels are under analysis in more details using an electron microscope to characterize the morphological features of the network in relation to the chemical interaction among precursors, additives and solvents [4].

Behavior of Glass/Carbon Nanoengineered Hybrid Composites for Aerospace Applications under Mechanical Loading
Shashwata Chakraborty, Mohammad Uddin and Ajit D. Kelkar; North Carolina A and T State University, United States

Carbon fiber reinforced polymer composites are widely used in aerospace applications because of their high strength and stiffness properties. One of the disadvantages of using carbon fiber reinforced composites is lack of strength and stiffness in the transverse direction and that makes them vulnerable to out of plane loading situations like bird impact, lightning strikes, etc. To alleviate this problem, typically aircraft structures are designed with a sacrificial layer of fiberglass composite in conjunction with carbon fiber composites. Even though this type of hybridization has many advantages, still much research is needed to understand the interlaminar failure of glass/carbon interface under out of plane loadings. The present study investigates the effects of mechanical loading on glass/carbon hybrid nanoengineered fiber reinforced composites. Hybrid 9 layers composite laminates with a single layer of glass fiber lamina on the outer surface and 8 layers of carbon fibers lamina were fabricated using aerospace grade epoxy and vacuum assisted resin transfer molding (VARTM) technique. In-plane mechanical properties such as tensile,
flexural, impact and interlaminar shear strength (ILSS) characteristics were investigated. In addition, to improve interlaminar properties a layer of electrospun glass and carbon nanofibers are being used between glass fiber lamina and carbon fiber laminates.

High Volume Fraction Aligned Carbon Nanotube Carbon Matrix Nanocomposites for Next Generation Lightweight and Superhard Architectures Ashley L. Kaiser, Itai Y. Stein, Chloe Sackier and Brian L. Wardle; Massachusetts Institute of Technology, United States

Nanomaterials, such as polymer-derived pyrolytic carbons (PyCs), have great potential for next-generation lightweight structural materials due to their high mass-specific strength and stiffness. In particular, PyC matrices are most desirable for low density structural applications when they are reinforced with high strength nanowire arrays, such as aligned carbon nanotubes (A-CNTs) at high volume fractions ($V_f$), which addresses brittleness, enhances hardness, and allows tailoring of multifunctional properties. While modeling indicates that CNT-PyC nanocomposites at $V_f \sim 30\%$ could show $>300\%$ enhancements in hardness when compared to the neat PyC matrix, performing similarly to diamond and cubic boron nitride for superhard lightweight structures, it is unknown how CNT confinement at these packing densities influences the structural evolution of the PyC matrix. Therefore, a study of these effects on the formation, self-organization, and geometry evolution of the graphitic crystallites that comprise the PyC matrix of the nanocomposites is necessary. In this report, we synthesize CNT-PyC nanocomposites via the pyrolysis of CNT-phenol formaldehyde precursors to create superhard and lightweight aligned CNT-carbon matrix nanocomposites. In this study, the influence of CNT proximity interactions on the atomistic, nanoscale, and mesoscale structural evolution of PyC is determined experimentally as a function of CNT $V_f$ (up to 30%) using scanning electron microscopy, X-ray diffraction, Raman spectroscopy, and Fourier transform infrared spectroscopy to quantify the CNT-PyC matrix morphology, graphitic crystallite geometry, bonding character, and chemical structure evolution, respectively. This work identifies how high CNT confinement leads to modification of the graphitic nature of the PyC matrix, and it shows that the governing CNT-PyC interactions exist at the $< 10$ nm scale, thereby becoming increasingly significant as the inter-CNT spacing decreases below this value at $V_f \geq 20\%$. Using this approach, these results provide new insights to explain the predicted CNT-PyC hardness enhancements at high $V_f$ and enable the design and manufacture of next-generation superhard lightweight nanocomposites.

Sodium-Based Carbon Nanotube Synthesis for the through-Thickness Reinforcement of Advanced Filamentary Composites Richard Li, Erica F. Antunes, Andrew Liotta, Luiz Acauan, Estelle Kalfon-Cohen, Kehang Cui, Clementine Mitchell, Harden Cornwell and Brian L. Wardle; Massachusetts Institute of Technology, United States

The direct synthesis of carbon nanotube (CNT) on substrate surfaces and interfaces has been of great interest for enabling performance improvements of electronics, electrochemical energy systems, and advanced multifunctional composites among others. However, the extent of applications that may benefit from CNTs have been limited by the operational range of temperatures and substrates for traditional transition metal catalysts (Fe, Ni, and Co). Here, a new element has been discovered to catalyze CNT growth at temperatures below 400 °C using a thermal chemical vapor deposition technique: sodium. As the first alkali metal reported to catalyze CNTs, sodium enables direct and low temperature CNT growth across a wide array of substrates, including alumina fibers, polymer-coated fibers, silicon wafers, silicon nitride, titanium, and others. Aqueous solutions of common sodium-based compounds such as sodium hydroxide, sodium bicarbonate, sodium chloride, and sodium carbonate are all demonstrated to result in CNT growth on carbon fabrics using a single dipcoate step prior to CVD. Ex situ scanning electron microscopy and transmission electron microscopy analyses with energy dispersive x-ray spectroscopy as well as x-ray photoelectron spectroscopy performed on catalyst particles prior to growth and CNTs after growth confirm the identity of sodium as the active element for CNT catalysts. In addition, unlike transitional metal catalysts, Na exhibits a vanishing catalyst phenomenon in which catalyst-free CNTs can be formed during synthesis for applications that are sensitive to residual metal impurities, thus avoiding the need for post processing steps that may employ the use of harsh chemicals.

Moreover, as an exemplary application of Na-catalyzed growth, CNTs are circumferentially grown on carbon fibers
(CFs) to form “fuzzy” CFs that can be laminated into hierarchical nanoengineered polymer composites with the potential for interlaminar reinforcements and electrical conductivity increases. Previous efforts required harsh surface roughening techniques of carbon fibers to enable Fe catalyst adhesion and high temperature growths typically on the order of 800 °C, resulting in carbon fiber strength losses as much as 60%. Here, we demonstrate that carbon fibers dipcoated in NaOH solutions and subjected to CVD at 480 °C resulted in conformal CNT growth and retained microfiber strength as assessed through single fiber tests. These fuzzy CF fabrics were then infused with epoxy resin to form unidirectional fuzzy carbon fiber reinforced plastic (UD fuzzy CFRP) laminates that were trimmed into short-beam shear specimens for interlaminar shear strength (ILSS) enhancement characterization. Taken together, we present sodium as a facile and new low temperature versatile CNT growth catalyst with the potential to expand the range of substrates and applications that may benefit from direct CNT synthesis.

Tensile, Compressive and Tunable Large-Scale Strain Sensor Based on Carbon Nanotubes/Thermoset Foam Nanocomposites by Additive Manufacturing Chao Liu and Junjun Ding; New York State College of Ceramics at Alfred University, United States

Strain sensors are widely used as stretchable electronic, human motion detector, and health monitor due to their ability to convert large-scale mechanical deformation to the resistance change [1-3]. Forming the porous foam structure is a more promising method to build large-scale deformation strain sensor than forming the solid structure [4]. To quantitatively control the relationship between deformation and resistance change, carbon nanotubes (CNTs), with numerous surface area, are used as a component due to its good electrical conductivity [5]. Compared to traditional strain sensor manufacturing methods, material extrusion-based 3D printing (ME3DP) is a more suitable method to form viscous slurry into complex stacked models.

In this work, we fabricate a superelastic strain sensor based on CNTs/PDMS foam nanocomposites with controllable electrical properties by ME3DP. Low viscous PDMS Sylgard 184 and high viscous SE 1700 were mixed in the ratio of 3:2 for good moldability and printability of slurry. Sodium chloride (NaCl powder, 10-20 μm) was added into PDMS precursor as a sacrificial material to generate foam microstructures. Multi-walled CNTs (1 and 2 wt. % of PDMS) were added for adjustable electrical conductivity. ME3DP with a mechanically driven syringe extruder was used subsequently for the formation of 3D models. Both solid and hollow scaffolds were printed to investigate the influence of macro-voids on mechanical and electrical properties. NaCl microparticles were then removed by DI water bath for 24 hours to create porous open-celled microstructures. Based on our hypothesis, the interconnection rate of CNTs in micro-voids will affect the electrical conductivity when the structure is stretched or compressed, resulting in the different performance of the strain sensor. Further study will be focused on controlling density and size of micro-voids, the gap of macro-void scaffold structures, infill ratio of CNTs, and how these parameters affect stretchability, compressibility, and electrical conductivity.

3D Printing Aerogels Marcus A. Worsley; Lawrence Livermore National Laboratory, United States

Graphene has shown the potential to significantly impact a number of different technologies. Properties such as high surface areas and electrical conductivity make it a promising material for hydrogen storage, battery, and ultra capacitor applications. One route to realizing the full potential of graphene in these energy storage applications is the assembly of three-dimensional macroscopic graphene networks that retain the properties of individual graphene sheets. However, given the low density and nanoporous structure of these graphene aerogels, they suffer from mass transport and mechanical fragility, both of which are detrimental. Here, we use additive manufacturing (AM) to 3D print graphene aerogels with improved mass transport and mechanical robustness. Using techniques such as direct
ink write and projection microstereolithography are shown as promising routes to improve the properties of graphene aerogels. The details of the synthesis and characterization of these 3D printed aerogels will be presented.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DEAC52-07NA27344.

Deformation Behavior of Nano-Composites with Hierarchical NP Organization Josef Jancar, Frantisek Ondreas, Petr Lepcio, Marek Zboncar and Klara Zarybnicka; Brno University of Technology, Czechia

Understanding the role of preparation protocol in morphogenesis of polymer nano-composites and developing theories quantitatively relating their nano-scale structural features and dynamics to the macro scale properties is vitally important. Here, we report on the effects of kinetic variables on the spatial organization of nanoparticles with strong and weak interfacial attraction to the polymer matrix. While individually dispersed NPs provide the largest elastic moduli and strength, chain bridged NP clusters endow the largest ductility. Hierarchical systems combining both chain bridged NP clusters and individually dispersed NPs exhibit simultaneous enhancement of stiffness, strength and ductility with its extent tunable by the cluster content. Our results provide an experimental insight into the role of processing and kinetic traps on the structure development in real polymer nano-composites which can enable their broader exploitation as building blocks of lightweight dynamic engineering structures.

Bulk Supercrystalline Ceramic-Organic Nanocomposites—New Processing Routines and Insights on the Mechanical Behavior Diletta Giuntini, Berta Domenech, Buesra Bor, Alexander Plunkett and Gerold A. Schneider; Hamburg University of Technology (TUHH), Germany

In the strive to produce nature-inspired hierarchical materials with an enhanced combination of mechanical properties, supercrystalline ceramic-organic nanocomposites have been produced in bulk form and characterized from a variety of perspectives. Through an interdisciplinary collaboration at the crossroad between materials science, chemistry and mechanical engineering, a bottom-up approach has been designed. It consists of a sequence of self-assembly, pressing and heat treatment, and it leads to macroscopic poly-supercrystalline materials with exceptional mechanical properties and behavior. The crosslinking of the organic phase induced by the heat treatment does not only increase the materials’ stiffness, hardness and strength (elastic modulus up to 70 GPa, hardness up to 5 GPa and bending strength up to 630 MPa), but alters also their constitutive response. Fracture toughness values higher than theoretical predictions have emerged, implying the presence of extrinsic toughening mechanisms, such as the crack-path deviation observed at indents’ corners. Ex-situ nanoindentation and in-situ SAXS/microcompression studies also suggest the possibility for supercrystalline materials to accommodate compressibility and plastic-like deformation. Defects analogous to the ones typically observed in crystalline lattices, such as stacking faults, dislocations and slip bands, are detected at the superlattice scale (even if one order of magnitude larger than the atomic one, and with interactions among the nano-building blocks controlled by the organic phase). Correlations between defects, processing and mechanical properties have been drawn by adapting the classic theories of mechanical behavior of materials. These same materials are additionally being used as bricks for the development of novel hierarchical composites, via additive manufacturing or fluidized bed techniques.

Enhancing Water-Based Coating Corrosion Resistance with Boron Nitride Nanotube Additives Yu Ren Zhou, Ju Li, Michael P. Short and Bilge Yildiz; Massachusetts Institute of Technology, United States

Water-based anti-corrosion coatings have great potential as environmentally-friendly alternatives to solvent-based coatings due to lower volatile organic compound (VOC) emission during drying. However, state-of-the-art water-based coatings exhibit inferior corrosion resistance in marine and oceanside environments. Careful in-situ observations of acrylic-TiO2 composite water-based coatings on carbon steel substrates aged by the ASTM B117 salt spray test, simulating a marine environment, suggest that these coatings fail by loss of substrate adhesion, crack propagation and corrosive chemical species (e.g. H2O, O2, NaCl) penetration. Boron nitride nanotubes (BNNTs) hold great promise as corrosion resistance-enhancing additives since they potentially bridge surfaces of crack tips and raise crack propagation energy, and potentially form an inter-coating scaffold offering tortuous diffusion paths for corrosive species. Furthermore, the electrically insulating nature of BNNTs prevents the formation of galvanic
couples with the steel substrate (as observed with conductive nanomaterials such as graphene), thereby avoiding accelerated anodic dissolution of the substrate. Water-based acrylic-TiO$_2$ coatings infused with 0.1 wt.% BNNTs will be fabricated by ball mill mixing of aqueous BNNT dispersion with water-based paint, followed by drawdown bar application of BNNT-infused paint onto carbon steel substrates. In-situ observations of unmodified and BNNT-infused coatings on carbon steel during salt spray aging will be compared to confirm superior corrosion resistance of BNNT-infused coatings. Enhanced crack propagation resistance of BNNT-infused coatings will be determined by in-situ scanning electron microscope (SEM) observation of a crack tip while the free-standing coating is subject to a tensile stress test. Solubility and diffusivity of H$_2$O, O$_2$ and aqueous Na$^+$ and Cl$^-$ ions in unmodified and BNNT-infused coatings will be measured using various permeation tests, and differences in these values will be correlated to high-resolution observations of unmodified and BNNT-infused coating structure. To understand the kinetic processes leading to the dried coating morphologies, the 3D structural evolution of unmodified and BNNT-infused coatings during the coating drying process will be tracked in-situ with nanoscale computed tomography (nano-CT) at the National Synchrotron Light Source-II (NSLS-II) at the Brookhaven National Laboratory (BNL).

Mechanical Dissipation in Polymer-Grafted Nanoparticle Assemblies—Design of Ultra-High-Rate-Impact-Resistant Thin Films
Allen B. Schantz$^1$, Florian Käfer$^2$, Jason Streit$^1$, Jinho Hyon$^3$, Christopher Ober$^2$, Edwin L. Thomas$^3$, Lawrence Drummy$^1$ and Richard A. Vaia$^1$; $^1$Air Force Research Laboratory, United States; $^2$Cornell University, United States; $^3$Rice University, United States

Assemblies of canopy-entangled, polymer-grafted nanoparticles (PGNs) provide a method to avoid nanoparticle aggregation common in polymer-nanoparticle blends, and have enabled mechanically robust designs for a variety of structural, electronic, and optical applications. Recent studies have elucidated the relationship between PGN design (graft density ($\Sigma$), graft length ($N$), and nanoparticle size ($r_0$)) and the plasticity of the assembly below $T_g$, and identified the key design parameters for PGN assemblies to retain polymer-like plasticity (i.e. crazing). Herein, we discuss the extension of PGN mechanical robustness to ultra-high strain rates ($>10^6$ s$^{-1}$) examined with Laser Induced Projectile Impact Testing (LIPIT). Assemblies of polystyrene-grafted silica and Fe$_3$O$_4$ nanoparticles exhibit unexpected deformation mechanisms at these extreme deformation rates, resulting in unprecedented energy absorption, and kinetic energy dissipation of the micro-projectile. Mechanistically, instantaneous plastic deformation of the nanocomposite glass adiabatically heats the impact site, triggering cumulative energy dissipation processes, such as melt-draw. Linear polystyrene exhibits similar behavior, and successful PGN design should fulfill the requirements for both instantaneous and cumulative mechanical dissipation processes, i.e. retention of polymeric-like plasticity, such as crazing, and optimization of elongational viscosity to maximize energy dissipation while avoiding premature melt-rupture. PGNs with high-molecular-weight, entangled canopies ($N/N_c > 5$, $2 < r_0\Sigma^{0.5} < 10$) exhibit specific penetration energy ($E_{p*}$) >30% more than prior record-setting reports of comparable polystyrene thin films. Understanding the impact of PGN design on melt viscosity and elongational flow provides a framework to maximize the high-rate impact performance of PGNs through cumulative dissipation processes, and to guide gram-scale synthesis of next-generation PGNs via a novel mini-monomer encapsulated ARGET ATRP emulsion polymerization process.

Grain Size Effect on Mechanical Properties of Polycrystalline Graphene
Sangil Hyun, Youngho Park and Myoungpyo Chun; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Characteristics of nanocrystalline materials are known substantially dependent on the microstructure such as grain size, crystal orientation, and grain boundary. Thus it is desired to have systematic characterization methods on the various nanomaterials with complex geometries, especially in low dimensional nature. One of the interested nanomaterials would be a pure two-dimensional material, graphene, with superior mechanical, thermal, and
electrical properties. In this study, mechanical properties of “polycrystalline” graphene were numerically investigated by molecular dynamics simulations. Subdomains with various sizes would be generated in the polycrystalline graphene during the fabrication such as chemical vapor deposition process. The atomic models of polycrystalline graphene were generated using Voronoi tessellation method. Stress strain curves for tensile deformation were obtained for various grain sizes (5–40 nm) and their mechanical properties were determined. It was found that, as the grain size increases, Young’s modulus increases showing the reverse Hall-Petch effect. However, the fracture strain decreases in the same region, while the ultimate tensile strength (UTS) rather shows slight increasing behavior. We found that the polycrystalline graphene shows the reverse Hall-Petch effect over the simulated domain of grain size (< 40 nm).

MS03.06.02
Fabrication of Graphene Grafted with Nylon 6,6 Grafted Multi-Walled Carbon Nanotubes for Mechanical Reinforcement of Nylon 6,6 Muhyeon Kim, Dong Eun Kim, Seung Youn Lee and Chang Keun Kim; Chugang University, Korea (the Republic of)

Reduced graphene oxide grafted with multi-walled carbon nanotubes (MWCNT-RGO) was prepared to reinforce mechanical properties of the nylon 6,6 (PA66). Aminopyrene (AP) and 1-pyrenebutyric chloride (PBC) were attached on the MWCNT (MWCNT-PBC) and RGO (RGO-AP) by physisorption, respectively, followed by reacting acyl chloride groups in the MWCNT-PBC with amine groups in the RGO-AP to graft MWCNT on the RGO. The resulting MWCNT-RGO was melt mixed with PA66 with an expectation of reaction between acyl chloride groups remained on the MWCNT-RGO and PA66. As a result, PA66 grafted MWCNT-RGO (PA66-g-MWCNT-RGO) was fabricated. Formation and properties of MWCNT-RGO were confirmed by several analyses including FE-SEM, XPS, TGA and its interfacial adhesion behavior with PA66. The interfacial adhesion energy of the composites was characterized by using drop-on-fiber method, and PA66 composite containing MWCNT-RGO exhibited enhanced interfacial adhesion energy compared with PA66 composite containing pristine MWCNT and RGO. The PA66/MWCNT-RGO composite showed better filler dispersion than the PA66/MWCNT/RGO composite owing to improved interfacial affinity. For fixed filler content in the composite, the tensile strength and fatigue life of the PA66/MWCNT-RGO composite were the highest among the composites examined.

MS03.06.03
Liquid Collecting 3D Surface Decorated with Hierarchically-Structured TiO2–Al Flake Inspired from the Mimosa Leaf Microstructure Sun Mi Yoon1,2, Hyebin Lee1, Sahn Nahm2 and Myoung-Moon Moon1; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Korea University, Korea (the Republic of)

The surface functions of living organisms have drawn attention because of their unique properties caused by their intrinsic topological structures as well as chemistry for various applications such as self-cleaning surfaces, water harvesting, and nano-micro robotics. Among the plants or animals having functional surfaces or structures, Mimosa pudica is well known as a sensitive plant that can react in response to environmental changes like mechanical touches of even small pressure by raindrops. Furthermore, for maintaining its pressure sensitivity, the leaf surface shows the extreme wettability of a strong superhydrophobicity as well as robust self-cleaning against water drops, which is attributed by the well-distributed microscale clusters made of nanoscale wax flake.

In this work, we present a hierarchical hybrid nanocomposite of TiO2 nanoparticle encapsulated Aluminum (Al) flake clusters by mimicking the hierarchically grown flake clusters on the leaf of Mimosa pudica. These flake clusters formed by the aluminum hydrolysis process with TiO2 nanofluid could be fabricated not only on a flat substrate but also on the curved structures of a 3D printed leaf surface. When Al was immersed in heated TiO2 nanofluid with the 3D substrate, the Al source reacts with hydroxyl ion decomposed water in nanofluid to form flake-like AlOOH nanostructure during which TiO2 nanoparticles functions as the nucleus of a single AlOOH flake structure and the hierarchical flake cluster structures. The TiO2-Al based flake has long-term stability (more than two month) in superhydrophilicity due to dual scale roughness by AlOOH flake clusters as well as TiO2 effect while the Al base substrate showed mild hydrophilic but not lasted for a longer duration. Hierarchical structures with long-lasting superwetting properties were applied for the liquid collecting system by the 3D printed structures with fluid transport path, which were also mimicked from the leaf vein structure of Mimosa pudica.

MS03.06.04
Mechanical Response of Segmented Copolymer Coatings to the Growing Tin Whiskers under Harsh Environments Preeth Sivakumar1, John Daye2, Imani Ballard2, Surbhi Du2 and Junghyun Cho1,1; 1State University
Polymer conformal coating over the whisker-prone tin (Sn) surface significantly reduces the risk of electrical short circuits caused by tin whiskers. The choice of coating material and possible degradation with time/environmental exposure can impact the effectiveness of the coating. The conformal coating should be strong enough to buckle a metal whisker without being punctured through the coating but also sufficiently tough to avoid the cracking ahead of the tin whisker growth. In addition, the adhesion of the conformal coating should be high to avoid itself from being peeled from the tin surface during the vertical growth of the whiskers and nodules. In this study, polyurethane-based conformal coatings, which consist of the hard and soft segments, were prepared at various curing conditions to control the aggregation of the hard segments that result in the brittleness of the coating. In an effort to restore the toughness, a toughening agent was also added to the polymer to form the phase-separated domains. Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) were used to examine the degree of curing and its impact on the microstructure developments of the coating. Mechanical deformation of the microstructure-engineered coatings was evaluated by universal testing machine and indentation techniques that mimic the growing whisker. In particular, the contact mechanics between the growing tin whiskers and the protective polymer coating surface will be highlighted. Further, the effect of long-term high temperature and high humidity exposure on the adhesion of the coating and tin whisker mitigation behavior will be presented. This study provides a potential source of developing the effective copolymer microstructure and optimal mechanical properties that can well entrap the growth of tin whiskers and nodules beneath its coating.

**Interface Strengthened Carbon Fiber-Graphene Fiber Reinforced Polymer Hybrid Composite** Mingxin Li and Jie Lian; Rensselaer Polytechnic Institute, United States

Thanks to its superior specific strength to weight ratio, carbon fibers have been extensively used to reinforce polymers in composites for aerospace, automotive and construction uses since the 1970s. However, the atomic cross-linking that allows for the incredible strength of PAN-based carbon fibers comes at the price of increasing phonon scattering points, thus sacrificing thermal conductivity. Here, we report a new polymer composite reinforced with both PAN-based carbon fibers and highly thermal conductive (up to 1290 Wm⁻¹K⁻¹) graphene fibers. Heavily oxygenated graphene oxide is chemically grafted to the fibers to improve interfacial properties by increasing fiber-matrix contact area and introducing large amounts of hydrogen bonds between the carboxyl functional groups on the heavily oxygenated graphene oxide and the epoxide groups within the epoxy-based polymer matrix. Such a configuration provides ample mechanical strength and thermal conductivity for a comprehensive range of applications in the aerospace industry.

**MS03.06.06**

**Mechanical Behavior of Epoxy Composites in the Presence of Graphene-Based Core-Shell Nanoparticles as Toughening Agents** Radhika Wazalwar and Ashok M. Raichur; IISc, India

Aircraft grade tetra-functional epoxy, which is inherently strong but highly brittle, was reinforced with polystyrene-graphene oxide (PS-GO) core-shell nanoparticles to improve its mechanical properties with a focus on fracture toughness. PS-GO core-shell particles were synthesized by in situ emulsion polymerization of styrene in the presence of an aqueous dispersion of GO. The size of the core-shell particles was in the range of 300-600 nm. Scanning electron microscopy (SEM) images of the core-shell particles showed wrinkled spheres which indicated that the PS spheres have been well coated by the GO sheets. Epoxy composites were synthesized by adding 0.1, 0.5 and 1.0 wt.% of the core-shell nanoparticles to neat epoxy resin. The cured composites were tested for fracture toughness and compressive strength and maximum improvements of 25% and 21% respectively for the 0.5 wt.% and 0.1 wt.% PS-GO epoxy composites respectively were observed. At 1.0 wt.% loading, the mechanical properties were on the decline due to the plausible agglomeration of the nano-filler in the matrix. SEM images of the fractured surface showed that the modified epoxy samples had a rough surface while virgin epoxy had a smooth surface. Toughening occurred due to filler matrix debonding causing crack arrest. The thermal behavior of the composites was tested using dynamic mechanical and thermal analysis (DMTA). It was observed that there was a ≤ 2% change in the storage and tan modulus of the modified epoxy as compared to the unmodified epoxy. Hence, the desired improvement in fracture toughness and compressive strength of tetra-functional epoxy was achieved by reinforcement with PS-GO nanoparticles without compromising the thermal properties.
MS03.06.07
Tribological and Mechanical Behaviour of Cr$_3$C$_2$ Reinforced Tribaloy-T400 Hybrid Suspension-Powder Plasma Sprayed Coating
Moumita Mistri$^1$, Shrikant Joshi$^2$, Kamal K. Kar$^{1,1}$, and Kantesh Balani$^1$; $^1$Indian Institute of Technology Kanpur, India; $^2$University West, Sweden

Co superalloy Tribaloy T400 (CoCrMoSi: 8.5% Cr, 28.5% Mo, 2.6% Si, and Co as balance weight) is considered as a potential candidate in impeding the wear-assisted surface material loss from engineering modules such as combustion chamber gas engines, bearings, valves, etc. operating at a temperature as high as 800 °C. A hybrid suspension-powder plasma spray technique has been employed to deposit T400 (average powder size = ~10-45 µm) reinforced with Cr$_3$C$_2$ ($d_{50}$ = 3.8 µm) of high hardness (600-1200 HV) and adequate tribo-corrosion protection for such application. A uniform and adherent T400-Cr$_3$C$_2$ coating of thickness ~100 micrometer with 34.4% reduced 2D theoretical inter-lamellar porosity (ImageJ Pro) with respect to T400 revealed in microstructural analysis infer a favorable higher densification characteristic to suspension plasma spray. Dendritic laves' CoMoSi/Co$_3$Mo$_2$Si and hard intermetallic Co$_7$Mo$_6$/Co$_2$Mo$_7$ phases of T400 along with the corresponding Cr$_3$C$_2$ phases are confirmed in T400-Cr$_3$C$_2$ phase analysis. Synergistic reinforcement of Cr$_3$C$_2$ has further elicited an enhancement in elastic modulus (of ~188.5 GPa) by ~39.4%, and Vickers hardness (of ~10.6 GPa) by ~68.2% in comparison to that of T400 (~135.2 GPa, and ~6.3 GPa respectively); which unambiguously elucidates the consequent increase in plasticity index by ~15.7%, and a drop in maximum displacement amplitude ($h_{\text{max}}$) by ~21.2% in T400-Cr$_3$C$_2$. Correspondingly, an enhancement in COF from 0.37 to 0.43 at 40,000 fretting wear cycles with a 65% reduced experimental specific wear rate in fretting estimated from Hertzian contact theory is obtained for T400-Cr$_3$C$_2$. In conclusion, Cr$_3$C$_2$ reinforcement in T400 can cater heavy-duty load bearing application by providing substantially improved micro-hardness via retaining the smaller grain size, and a subsequent fretting wear augmentation through carbide phase strengthening.

MS03.06.08
Mechanical Properties and Failure Behavior of Layered Heterostructures of Two-Dimensional Nanomaterials
Govind Mallick; Army Research Laboratory, United States

2D nanomaterials have shown many unique and attractive properties of which mechanical properties play very significant roles in manufacturing, performance, coating, and integration in the development of their potential applications. In this work we study the mechanical properties of combinations of multi-layered heterostructures of 2D nanomaterials, including graphene and hexagonal boron nitride (hBN) by performing nano-indentation through atomistic molecular dynamic simulations. Different stacking order of the free-standing 2D films are chosen and simulated indentation analogous to indentation via atomic force microscopy (AFM) are performed. Elastic properties and intrinsic breaking strengths including Young's modulus, bending modulus, ultimate tensile strength, and fracture strain are measured through nanoindentation simulation and compared to monolayer and bilayer 2D nanostructures. Our results suggest the heterostructures are comparatively more robust than their mono- and bi-layer counterparts. However, the indented area of hBN is much smoother than graphene which had comparatively rough fractured area. The magnitude of strength and fracture strain of monolayer and bilayer graphene is marginally greater than their respective hBN layers whereas that of three layered heterostructures are substantially stronger than their counterpart homostructures. The computed results will be compared with the experimental results during the presentation.

MS03.06.09
Role of Grain Boundaries in Plasticity and Fracture of Nanocrystalline MgAl$_2$O$_4$
Jessica M. Maita$^1$, James Wollershausen$^2$, Edward Gorzkowski$^2$, Boris Feigelson$^2$ and Seok-Woo Lee$^1$; $^1$University of Connecticut, United States; $^2$U.S. Naval Research Laboratory, United States

Transparent materials are used extensively in vehicles, cameras, sensors, and displays due to their ability to transmit light and provide physical protection from external chemical and mechanical interactions. Currently, glass is the most commonly used transparent material, but its protection capability is inferior to metals or alloys due to its low toughness. Recently, transparent nanocrystalline ceramic, MgAl$_2$O$_4$, has been developed through environmentally controlled pressure-assisted sintering of ceramic nanopowders with grain sizes ranging from 3.7 nm to 80 nm, the smallest grain sizes currently reported. This nanocrystalline ceramic is regarded as an excellent candidate for transparent armor in military applications because mechanical properties of ceramics are usually better than those of
glasses. Due to the small size of sintered ceramics, however, the determination of its mechanical properties has not been thoroughly investigated. The nanocrystalline structure contains a high density of grain boundaries, so it is critical to understand how grain boundaries influence plasticity and fracture behavior.

In this study, therefore, we performed nanoindentation and in-situ micromechanical tests on nanocrystalline MgAl₂O₄ to elucidate the role of grain boundaries in plasticity and fracture. For nanoindentation, the Hall-Petch (H-P) relation was observed up to 10.5 nm grain size with a peak hardness of 25.7 GPa, after which an inverse H-P relation was observed with decreasing hardness. These results imply that under the confined deformation mode of nanoindentation, the plasticity mechanism resembles that of nanocrystalline metals, where the grain boundary sliding occurs below the Hall-Petch limit. However, micropillar compression showed entirely different results. In-situ uni-axial micropillar compression showed brittle fracture without any noticeable plasticity. The fracture strength increases monotonically as the grain size decreases. Thus, the inverse H-P relation does not appear in fracture strength. The larger and sharper grain boundaries of 80 nm grain size samples could act as stronger stress concentrators which result in a lower yield strength based on the Griffith criterion. Thus, the grain boundary plays completely different roles; as fracture initiators in uniaxial compressions and plasticity barrier (H-P) or plasticity carrier (inverse H-P) in nanoindentation. High-resolution transmission electron microscopy analysis will also be presented to describe the unique amorphous-crystalline hybrid structure along grain boundaries, which could also be the critical factor controlling both plasticity and fracture processes. These results help provide a better understanding of the mechanical behavior of nanocrystalline MgAl₂O₄ and eventually lead to an improved design of transparent armor with the superior protection capability.

MS03.06.10
**Effect of Nanoparticle Surface Modification on Magnetic and Mechanical Properties of Iron Oxide–Poly(ethylene oxide) Nanocomposites**

Donovan Weiblen¹,¹, Grace Gionta¹,¹, Deniz Rende¹, Pinar Akcora² and Rahmi Ozisik¹,¹; ¹Rensselaer Polytechnic Institute, United States; ²Stevens Institute of Technology, United States

Magnetically susceptible nanoparticles have shown promise in diverse application areas such as shape memory polymers, membrane technology, and drug delivery. In the current work, the impact of surface coating of iron oxide nanoparticles on the bulk magnetization properties of poly(ethylene oxide), PEO, nanocomposites as well as the structure of the nanocomposites were explored. PEO was chosen as the matrix polymer due to its wide use in the healthcare industry. Two coatings were investigated in addition to bare nanoparticles: poly(ethylene glycol), PEG, coated and amine coated 10–nm–diameter iron oxide nanoparticles. Nanoparticles were dispersed in concentrations varying from 0.010–0.750% by weight in PEO. A significant increase in temperature was observed in all samples when PEO/Fe₃O₄ nanocomposites were exposed to an alternating magnetic field. Analysis of magnetization curves revealed an unusual result. The uncoated nanoparticles showed a stronger magnetization than the PEG coated nanoparticles even though the PEG coated nanoparticle containing PEO/Fe₃O₄ nanocomposites showed a much more significant and rapid magnetic heating response. Shape retention properties of samples were also investigated as a function of alternating magnetic field process parameters and iron oxide surface chemistry.

MS03.06.11
**In Silico Nanoindentation of Calcium-Silicate-Hydrates**

Yuan Chiang and Shu-Wei Chang; National Taiwan University, Taiwan

Although cement as a durable and affordable building material that has been widely used in construction environments, it still remains unclear on how their microstructures and chemical compositions at the molecular level affect the mechanical properties and time-dependent behaviors. The multiscale heterogeneities in the cementitious materials hinder the scientist from comprehensively understanding the mechanisms of the macroscopic phenomenon. With various hydration extent, irregular porous void and impurities like ettringite, portlandite and sulfate hydrates in the OPC (Ordinary Portland Cement), the study of the cement paste structure with accurate morphology from the molecular level to macroscale becomes challenging. In the light of recently proposed reactive modeling techniques of Calcium-Silicate-Hydrate (C-S-H), the elastic modulus of cement paste at the atomic scale as well as the effect of random nanopores on strength and toughness performance has been explored. However, fast and massive production of the full atomistic model is constrained by speed and size in that the reactive model using ReaxFF is computational intensive. In this study, we focus on straightforward modeling approach based on NMR experiments to study how defects at the nanoscale, for example, the intrinsic defective attribute of calcium silicate...
chains, including the mean chain length and the calcium-to-silicon ratio (Ca/Si), could strongly affect the mechanical properties of cement paste at macroscale. The combinations of calcium silicate hydrates with various Ca/Si ratios ranging from 1.2 to 2.1 are established and analyzed. From the bottom-up perspective, molecular dynamics simulations are carried out to simulate nanoindentation. By analyzing atomic structures and response under different loading, we reveal the relationships between the mechanical properties and the atomistic structure of C-S-H. This method helps us to bridge the atomistic structures with the material properties of C-S-H at larger scale level.

**MS03.06.12**

Multifunctional Hybrid Sol-Gel Coatings for Marine Renewable Energy Applications—Synthesis, Characterization and Comparative Analysis with Organically Modified Silicon Precursor Coatings

Manasa M. Hegde\(^1\), Yvonne Kavanagh\(^1\), Brendan Duffy\(^2\) and Edmond F. Tobin\(^1\); \(^1\)Institute of Technology Carlow, Ireland; \(^2\)Technical University of Dublin, Ireland

Aluminium (Al) based marine equipment go through a natural degradation when exposed to corrosive and erosive conditions. The reliability and maintenance of these marine based objects is found to be a major problem due to cavitation erosion. In addition, marine biofouling which is caused due to the presence of hydrogen sulphide in the microbes leads to Microbially Induced Corrosion (MIC) in objects in the marine environment. Together, the synergistic effect of erosion, corrosion and fouling leads to reduced lifespan of the structural and operational components in the marine renewable industry. Given the sheer scale of the marine renewable industry which is estimated to reach around €9 billion by 2030, the effects of cavitation erosion, corrosion and biofouling can cause large losses to the industry which will further increase the significant costs in the operation of such offshore technology. Numerous approaches have been developed to withstand the corrosion of the Al metals. Due to environmental concerns with regard to hexavalent chromium, chromate based coatings are being phased out and the present focus is on the advancement of chromate free coating systems. Conventionally, biocides were used in the antifouling coatings to stop the accumulation of fouling organisms like bacteria, fungi, barnacles etc. Nevertheless, these biocides were found to be toxic to the environment. This is the main driver behind developing eco-friendly multi-functional sol-gel coatings for marine renewable applications. The sol-gel process has the capability to develop coatings with low temperatures and provides uniform coatings with consistence thicknesses and also suitable in developing low fouling surfaces.

The main aim of this work is to develop hybrid sol-gel coatings which act as protective layers for the Al metal. Baseline coatings were synthesized using organically modified silicon precursor 3-methacryloxypropyltrimethoxysilane (MAPTMS) mixed with zirconium (IV) propoxide. The newly synthesized hybrid coating formulations will be compared with the developed baseline coating in terms of their corrosion and cavitation erosion resistance properties. The hybrid coatings were synthesized with a zirconium/alkoxide precursor which were then deposited by dip coating on Al panels. Characterization of the developed coatings included evaluation of properties such as surface finish, chemical composition, morphology, wettability and anti-corrosion properties. The structural and functional, thermal and electrochemical properties of the coatings were evaluated using ATR-FTIR, Differential Scanning Calorimetry (DSC), Open Circuit Potential (OCP) and Potentiodynamic polarization techniques. Furthermore, other properties such as cross-cut adhesion, hardness and Water contact angle (WCA) were determined. The baseline coating were shown to have hydrophobicity with the water contact angle (WCA) of 82°. Thermal analysis revealed that the baseline coatings were stable up to 220°C. Open circuit potential and potentiodynamic polarization measurements indicated a considerable improvement in the corrosion resistance of the coated substrates. Cavitation erosion and abrasion tests were completed on all coatings and rankings of these were produced. Mass loss measurements and surface roughness were used to compare and evaluate the relative degradation of the coatings. The tested coatings will be developed further to improve their cavitation erosion, abrasion and anti-contamination properties.

**MS03.06.13**

Anodized Aluminum Oxide/Polydimethylsiloxane Hybrid Mold with Improved Mechanical Properties for Roll-to-Roll Nanoimprinting

Sanghoon Kim and Jin Kon Kim; Pohang University of Science and Technology, Korea (the Republic of)

Two types (hard and soft) of the molds have been used in nanoimprint lithography (NIL) for a high throughput in a large area, and high-resolution parallel patterning. Although hard molds have proven excellent resolutions and high temperature strength, cracks of mold often occur, and high pressure is needed. On the other hand, although soft
molds can operate at lower pressure without cracks, it has poor pattern resolution. Here, we introduced a novel hybrid mold of anodized aluminum oxide (AAO) template chemically connected with polydimethylsiloxane (PDMS) layer. Due to the flexible nature of PDMS, we could obtain various nanostructured polymers on not only flat substrate but also curved substrate under relatively lower pressure. Furthermore, the hybrid mold is successfully used for roll-to-roll imprinting for the fabrication of high density array of various nanostructured polymers in a large area.

MS03.06.14
Controlling the Meso-Scale Assembly of CNTs/PBI Interlayers for Toughening of Thermoplastic Composites
Kaan Yildiz¹, Beyza Bozali¹, Hulya Cebeci¹, Feyzi C Cebeci¹ and Elif Ozden-Yenigun²; ¹Istanbul Technical University, Turkey; ²Royal College of Art, United Kingdom

Thermoplastic resin-based laminated composites with remodeling/reshaping ability, recyclability, and multifunctionality, if combined with reinforcement agents, have drawn attention in the composite industry. However, incorporation problems of reinforcement agents such as carbon nanotubes (CNTs) into highly viscous thermoplastic matrices have been challenging due to the difficulties in processability at elevated temperatures and poor dispersion which leads to weak interfacial bonding with the polymer matrix. Utilizing the grown CNTs on nanofibers having high surface area provides an ability to tailor mechanical, electrical and thermal performance in various applications such as lithium-sulfur batteries, laminated composites, and supercapacitors. Hence, to effectively produce CNT-reinforced interleaves with a high CNT quality, it is required to propose an alternative method to overcome these implementation problems.

In this study, growth of radially aligned CNTs on curved polymeric nanofibrous substrates has been conducted for the first time to address one step CNTs synthesis on polybenzimidazole (PBI) nanofibers at high temperatures, which benefits from the synergetic effect of the nanofiber network and stiff and conductive CNTs. Additionally, direct synthesis of CNTs on polymeric nanofibers has the potential of being used as interleaves without tarnishing the quality of the CNTs, as delamination, collection, dispersion, and distribution steps would have been avoided, achieving a single-step approach. The growth of radially oriented CNTs on PBI nanofibrous substrates has successfully been achieved by chemical vapor deposition method (CVD) and these interleavers are used for toughening in CF/PEEK laminated composites.

PBI nanofibers were produced by firstly dissolving PBI solution (PBI Products, 26.2 wt.%) in N-dimethylacetamide (DMAc) solvent to prepare a 20 wt.% solution, followed by an electrospinning process (Argeteknolab). 10 mM catalyst solution (Fe(NO3)3,9H2O (404.0 g/molar, Emir Kimya) and iso-proponal (Sigma Aldrich)) were prepared to deposit Fe3+ ions onto nanofibers which acted as a catalyst for CNT growth. Then, nanofibers were kept at 50 °C for 5 hours in an oven. The growth of CNTs onto PBI nanofiber was achieved at 600 °C with 15 min. nucleation and 10 min. growth times. The morphology of the produced CNT/PBI nanocarpet was investigated by Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM).

After the production of CNT/PBI nanocarpet, compression molding was utilized to lay up CNT/PBI nanocarpets and Polylethersulphone (PES) films (GoodFellow, thickness 0.5 mm) with different sequences where CF/PEEK prepregs (Mir AR-GE) were used as top and bottom layers. The main reason for the integration of PES films into composites was to provide compatibility between the CF/PEEK prepregs and the CNT/PBI nanocarpet. Following the compression molding process, the samples were hot-pressed for 30 minutes at 320 °C under a pressure of 10 bars. The thickness of the final composite structures was measured to be 1.5±0.03 mm.

The mechanical performance of PES/PBI/PES and PES/CNT-PBI/PES integrated CF/PEEK composite samples under flexural loadings was investigated by a universal test machine (UTM, Shimadzu AG-X Plus) according to ASTM D790-18 standard. The initial results showed that the flexural strength of the neat PBI nanofiber integrated CF/PEEK laminated composite was 103.5±8 GPa, while CNT/PBI nanocarpet integrated laminated composite was around 144.3±10 GPa. In the final paper, to further investigate the effect of the CNT integration on the overall composite structure, a dynamic mechanical analyzer (DMA) (TA Instrument, Q850) will be used to determine storage and loss moduli and to evaluate their variation with frequency and temperature using a three-point bending fixture.

MS03.06.15
Large Scale Growth of SWCNT Forests for Advanced Structural Nanocomposites
Sei Jin Park, Eric R. Meshot, Steven F. Buchsbaum, Melinda L. Jue, Kuang Jen Wu and Francesco Fornasiero; Lawrence Livermore National Laboratory, United States
In this era of advanced manufacturing, a plethora of materials and methods have been developed to produce lightweight materials with unique mechanical properties. Record high strength/modulus to density ratios, flaw tolerance, flexibility of ceramic materials, and combination of seemingly conflicting properties (e.g. stiffness and damping) show the promise of nanoscale material architectures. Vertically-aligned single-walled carbon nanotube (SWCNT) forests is one of the best platforms to build these materials from, by the virtue of aligned, a-few-nanometer diameter, and long length (> 1 mm) struts with exceptional mechanical properties arising from strong C-C sp² hybridized bonds. However, mass production of SWCNT forests needed for their wider adoption is hampered by a poor understanding of how to scale CNT growth recipes from small benchtop reactors to larger scale systems. We sought to address the SWCNT forest growth scalability by gaining a deeper understanding of the CNT growth process. We first identify the limiting step in the SWCNT growth rate and determine the dependence of the reaction kinetics on chamber pressure, gas composition and flowrates. We then employ this knowledge in translating the CNT forest growth to successively larger areas, ranging from 1 × 1 cm² pieces to 6-in. wafers. We demonstrate synthesis of high-density (> 10¹² CNTs/cm²), small-diameter (~ 2 nm) SWCNT forests with structural characteristics and growth kinetics that are uniform over large areas, up to 4-in. diameter. Achieved carbon conversion efficiency far exceeds typical benchtop reactor processes and is on par with the best values reported in the literature. We also demonstrate that the carbon conversion efficiency increases with substrate area and decreases with total flow rate. This trend can be rationalized by accounting for the reactant gas flows in the showerhead CVD reactor, as shown by computational fluid dynamics simulations. We finally demonstrate that, by varying the gas mixture, flowrates, and chamber pressure, we can tune CNT growth kinetics as desired without affecting the forests’ structural properties. These results and insights gained from them will prove to be a valuable guideline for future scale up efforts of SWCNT forests for advanced mechanical/structural nanocomposites.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-XXX

MS03.06.16
Controlling Mechanical Behavior in Nanocrystal Films—How Layer and Substrate Properties Play a Role
Alborz Izadi, Mayank Sinha, Sara Roccabianca and Rebecca J. Anthony; Michigan State University, United States

Cutting-edge technology such as flexible electronics and displays, biocompatible health monitoring systems, novel photovoltaic devices, and functional coatings rely on novel behavior of thin-film materials such as nanocrystal layers. While the optoelectronic properties of semiconductor nanocrystals are well-studied, deploying these materials in flexible/stretchable devices requires an understanding of the mechanical behavior of the nanocrystal layers, which can be challenging to investigate in-situ. Nanoindentation experiments and other probe-based techniques can be used to evaluate single-nanocrystal elastic/plastic deformation – but are more difficult to employ as in-situ methods for layers of nanocrystals on elastomeric substrates. Recently, our group created a novel in-situ framework for evaluating the mechanical properties of thin layers of luminescent silicon nanocrystals (SiNCs) by measuring the onset of instabilities in the SiNC layers on polydimethylsiloxane (PDMS) under finite bending deformation. Our work revealed a neo-Hookean coefficient (µ, analogous to shear modulus at low stress/strain) of a 4.5 µm-thick SiNC film to be 345 ± 23 kPa, which is several orders of magnitude smaller than the shear modulus of a single SiNC. While we hypothesize that the reason for this property difference is due to the porosity of the SiNC layer, there are many other parameters that could influence the mechanical behavior of the SiNC layers including layer thickness, SiNC size and surface functionality, and mechanical properties of the PDMS substrate. Here we investigate these important parameters regarding their influence over the mechanical properties of SiNC layers on PDMS. We prepare the PDMS in-house using a Sylgard 184 elastomer kit. Next, we synthesize SiNCs using a low-pressure nonthermal plasma and then inertially impact them into thin layers onto the PDMS through a slit-shaped orifice. We control the SiNC size, surface functionality, and layer porosity using the gas flowrate, pressure, gas composition, and deposition stage parameters. The PDMS properties depend on the prepolymer/catalyst ratio and curing conditions during PDMS preparation. Our results indicate that the layer and PDMS parameters exert competing influences on the mechanical properties of the SiNC layer. For example, we found that reducing the stiffness (reducing µ) for PDMS leads to a decrease in µ for the SiNC layer. This change occurs simultaneously with a microstructural densification of the SiNC layer, although the relationship is not monotonic. Unraveling the interconnectedness of these parameters on the physical, mechanical, and optoelectronic
properties of the SiNCs will allow for predictive engineering of nanocrystal films for flexible devices and thin-film technology going forwards. While we use SiNCs on PDMS as our testing system, our discoveries are applicable across material types and realize a non-destructive, \textit{in-situ} approach for evaluating the mechanical properties of other multilayered architectures of elastomers and nanocrystals.

\textbf{Fabrication of Ductile Ceramic Foams by Anodization and Proton Irradiation} Jung Woo Kim, Heonyong Jeong, Naeun Lee and Sung Oh Cho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Zirconia is a representative example of ceramic materials that demonstrate outstanding strength and relatively high fracture toughness and is utilized engineering application. In addition to fields requiring physical and chemical stability, it has been considered a candidate fuel matrix and cladding material in the nuclear power sector because of its radiation tolerance when its crystal grain is reduced to the nano-scale level. Moreover, tetragonal stabilized zirconia has a crack-resistant mechanism so-called transformation toughening. This reversible phase transition is involved volume expansions (4-5\%) of tetragonal \textit{ZrO\textsubscript{2}} to monoclinic \textit{ZrO\textsubscript{2}} phases, and has been widely studied to apply to composite materials. However, despite its advantages, zirconia has a brittle nature that can easily be broken by external impacts. Ceramics perform high strength and stiffness compared to other metals and polymers. On the other hand, the lack of plasticity and sensitivity to flaws are actually weak in terms of structural stability and thus limited in its use. In brittle ceramic materials, it is generally accepted that pores are considered as a detrimental flaw because of serving an occurring point that higher stress is locally concentrated. On the other hand, an insight for suppressing brittle fracture has been proposed recently by applying uniform porous and hollow structures on the nano-scale level. In order to improve the mechanical properties of the ceramic material, not only the morphological aspects, a thoughtful microstructure design is also required in terms of constituent atomic arrangements.

In this study, through the anodization technique, the zirconia layer with nanoporous structure was fabricated. It is aimed to examine the mechanical responses of nanoporous ceramics when manipulated in atomic arrangements. The annealing treatment and proton beam process were utilized as an effective tool inducing the crystallization to the amorphous ceramic oxide layer. To observe the mechanical properties of the zirconia ceramic with nanoporous structures, the micro-pillars were prepared and uniaxially compressed. The deformed morphology of the compressed pillars was also characterized to analyze the mechanical behaviors of each condition.

The zirconium oxide layer with a honeycomb-like structure was fabricated by optimized anodization technique. The microstructure of zirconium oxide layer can be manipulated by utilizing the annealing and ion beam treatment. It was observed that as-fabricated nanoporous oxide layer with amorphous structure was experienced to be fully or locally crystallized. Through micro-compression tests, the plasticity without generating cracks was exhibited in both as-anodized and irradiated pillars with amorphous structure. This fracture tolerant response with large plasticity could be caused by that the compressed pillar has an amorphous structure. The mechanical properties of conventional ceramics manifest in the case of annealed pillar, implying that crystalline structure brings out the brittle feature. In proton irradiated condition, the increased free volume induced by ion bombardments made the ceramic layer more plastically responded. From the results of the mechanical behaviors, the occurrence of plasticity without brittle failure of the ceramic material implies the great potentials that the nanoporous oxide layer can be utilized for various engineering applications by securing the material stability. Especially in ion beam process, it is expected that the ideal characteristics for high strength with remarkable plasticity can be designed by controlling the degree of crystallization with varying the dose of the beam irradiation.

\textbf{MS03.06.18}
\textbf{Fabrication and Mechanical Properties of Functionalized Boron Nitride Nanoplatelets Reinforced Epoxy Matrix Nanocomposites} Joon Hui Kim, Sung Chan Yoo, Ho Jin Ryu and Soon Hyung Hong; Korea Institute of Science and Technology, Korea (the Republic of)

After publication of first 2D material, Graphene, numerous journals treating with 2D nanomaterials were published. Boron nitride (BN) is a synthetic material made from boric acid or boron trioxide and consists of the same number of boron (B) and nitrogen (N) atoms. BN has an isoelectronic structure similar to that of a carbon lattice and shares the same number of electrons between adjacent atoms. The mechanical properties of BNNPs are comparable to those of graphene. The elastic modulus of BNNPs ranges from \textasciitilde 800–850 GPa, depending on the degree of chirality. Like graphene, the mechanical properties and thermal conductivity of BN nanostructures make them attractive as nanofillers in composite materials.
The major applications of BNNP is the polymer nanocomposite. Unlike other polymer composites, polymer nanocomposites show superb property despite of low volume percent of reinforcement material. In addition, polymer nanocomposite is easier to fabricate than conventional consolidation process. The major fabrication factor of polymer nanocomposite is dispersibility of reinforcement material in polymer matrix. However, BNNP agglomerates among themselves due to van der Waals force, so this problem needs to be solved.

To solve agglomeration and dispersion problem, we adopted functionalization process to give BNNP proper dispersibility in solvent. BNNP was covalently functionalized using hydroxide-assisted ball-milling processes, which both induce chemical exfoliation and apply strong mechanical shear forces. This covalent functionalization resulted in more stable dispersion than was attainable with non-covalent functionalization.

In this research we functionalized BNNP to prevent agglomeration and increase own properties by using hydroxide functional group. This functionalization process exfoliates BNNPs via the synergetic effect of chemical peeling and mechanical shear forces to overcome the limitations of the previous approaches. After functionalization of BNNP, functionalized BNNP/Epoxy (BNNP/Epoxy) composite were fabricated by solvent mixing. Mechanical properties of BNNP/Epoxy composites were characterized by using Microforce testing machine.

Mechanical properties of BNNP/Epoxy composites showed 1.8 times enhanced elastic modulus and 2.7 times enhanced fracture toughness, compared to pure epoxy. These results could be explained by hydroxides stacked on surface of BNNP flakes, which hindered agglomeration among BNNP flakes. Furthermore, hydroxides on BNNP improved interfacial bonding with epoxy matrices. This result leads to homogeneous dispersion of BNNP in Epoxy and successfully optimized mechanical properties of nanocomposites. Our team wish that these results could provide useful property criteria of Boron nitride Nanoplatelet for structural materials as industrial applications.

MS03.06.19
Fabrication of High Recovery Ultralight Materials Using Carbon Nanotube and Low Molecular Weight Carboxymethylcellulose Kazuki Matsushima, Naoto Shioura, Tomonaga Ueno and Takahiro Segi; Nagoya University, Japan

Ultralight materials are expected to be applied to structural materials, heat insulating materials, and filters, etc. Various composite materials such as carbon nanotubes, graphene, and polymers have been proposed for the improvement of mechanical properties for ultralight materials. Recently, ultralight materials have been proposed which have high recovery rates for compression. Since carboxymethylcellulose (CMC) acts as a dispersant for carbon nanotubes, an ultralight material consisting of carbon nanotubes (CNT) and CMC has been reported, but a high recovery rate against compression at low density was not observed. In this study, we fabricated the ultralight materials with the apparent density of 1.25 mg/cm³ consisting of CNT and CMC, and showed that the material has a high compression recovery rate. In this case, the low molecular weight CMC is necessary for the ultralight material to show a high compression recovery rate.

In this study, single-walled CNT (SWCNT) with diameter of 2nm was used. Then, two kinds of CMC with different molecular weights were prepared. The viscosity of low molecular weight CMC (l-CMC) and high molecular weight CMC (h-CMC) solutions at 1 wt% was 50 mPa s and 1734 mPa s, respectively. SWCNT was added to an aqueous solution in which CMC was dissolved, and subjected to ultrasonic treatment to prepare a CNT dispersion. The CNT dispersion was frozen while controlling the temperature with a heat insulating material, and freeze-drying was performed to produce a CNT/CMC ultralight material. The upper surface is controlled to −80 ° C, and the bottom surface is thermally insulated by a heat insulating material, whereby the hexagonal ice crystal structure formed on the upper surface reaches the lower portion, and vertical gaps are arranged. Structural observation was performed by a scanning electron microscope, and mechanical properties were evaluated by a compression test.

Samples were made with an apparent density of 5 mg/cm³, 2.5 mg/cm³ and 1.25 mg/cm³ as the target. No recovery after compression was observed in the composite materials with an apparent density of 5 mg/cm³, 2.5 mg/cm³, and 1.25 mg/cm³ regardless of the two kinds of CMC. However, in the density of 1.25 mg/cm³, the clear difference of mechanical properties was observed between h-CMC and l-CMC. In CNT/h-CMC, no recovery was observed. On the other hand, in the CNT/l-CMC ultralight material, the drastic recovery was observed. The recovery rate was 60% against 80% compression. Then, it has low compressive stress even in high strain range. The compressive stress was 0.0014 MPa for 80% strain. Moreover, the compression recovery rate was kept when the compression test was repeated.

In high density of CNT/CMC materials over 2.5 mg/cm³, hydrogen bonds are formed between adjacent CMC. In this range, the recovery rate is lowered because the hydrogen bond force is greater than the resilience by CNT. The low density of CNT/l-CMC materials shows a higher recovery rate than the other samples because the resilience by CNT was greater than the attraction of hydrogen bonds between CMC molecules.
**MS03.06.20**

**Improvement of Mechanical Properties of Porous Silica Insulator by Nano Fiber Addition**

Naoto Shioura1, Kazuki Matsushima1, Tomoki Osato2, Tomonaga Ueno3, Norifumi Isu3, Takeshi Hashimoto4 and Takumi Yana4; 1Nagoya University, Japan; 2IHI Corp., Japan; 3LIXIL Corp., Japan; 4Meijo Nano Carbon Co., Ltd., Japan

Effective use of heat by heat insulation attracts attention from the aspect of energy saving. Insulating materials are used widely in homes, automobiles, and space transport aircraft. In recent years, development of silica aerogel has been promoted as an ultimate heat insulating material. Silica aerogel is a porous silica body that has both a high porosity (90% or more) and a pore structure with an average diameter of 20 to 40 nm. Heat transfer is generated by three mechanisms of convective heat transfer of gas, heat transfer of solid, and radiative heat transfer. Silica aerogel with low density and fine void structure can greatly suppress convective heat transfer of gas and heat conduction of solid, and achieve extremely low thermal conductivity of 0.02 W / (m K) or less at room temperature. However, the low mechanical properties due to the low density, and the need for high pressure processes such as supercritical drying are problems. In this study, we focused on porous silica. Porous silica is an aggregate of silica particles, and has fine voids of several nm to several tens of nm, which is a powder material. Porous silica has very high thermal insulation performance due to its bulky, fine void structure. Furthermore, since porous silica is a powder, if it can be aligned sparsely in the material as much as possible, it has lower density than silica aerogel and high heat insulation performance is expected. However, as in the case of the silica aerogel, the low mechanical properties, and the poor formability due to the powder are problems. Therefore, we attempted to improve mechanical properties and formability by combining carbon nanotube (CNT), for which high mechanical properties are reported, with porous silica. The high thermal conductivity of CNT may increase the thermal conductivity of the heat insulating material, but in this study, this was suppressed by the coating of CNT with a polymer. Furthermore, since CNT are nanomaterials having a diameter of several nm to several tens of nm, there are extremely many interfaces and interface contact points. As a result, the thermal conductivity of the bulked actual material becomes significantly lower than the theoretical value due to the thermal resistance of the interface. Porous silica has a high transmittance in the infrared region and radiation heat transfer is not suppressed. The carbon material has a high absorption rate of radiation, and the addition of CNT is also expected to shield the radiation. Using Carboxymethyl cellulose (CMC) as a dispersing agent, CNT was dispersed in water by ultrasonication. This liquid was mixed with porous silica and freeze-dried to obtain a CNT / CMC / SiO2 composite material. The structure of the material was observed by an optical microscope and a scanning electron microscope (SEM). The mechanical properties were measured by uniaxial compression test and three-point bending test. Thermal conductivity was measured as a measurement of adiabatic performance.

In the case where no CNT was added, the material was largely shrunk by freeze drying, and it was not possible to form a compact. However, the addition of CNT made it possible to produce a high porosity (90% or more) CNT / CMC / SiO2 composite material with almost no shrinkage. This material is composed of voids of several tens of μm derived from ice crystals upon freeze drying, and these fine voids are expected to suppress the convection of gas. In addition, the mechanical property was improved by the increase of the added amount of CNT. By increasing the amount of CNT added from 0.5 mg / cm³ to 2 mg / cm³, the bending strength is from 0.01 MPa to 0.02 MPa, and the strain until the material breaks is increased 4.1% to 8.5%. The increase of CNTs confirmed the improvement of the flexibility of the material.

**Understanding Self-Healing in Nanocomposite Materials**

Christopher B. Cooper, Jiheong Kang and Zhenan Bao; Stanford University, United States

Self-healing materials offer a promising mechanism to create wearable electronics and soft robotics with high stretchability and durability, due to their intrinsic ability to recover after damage. Embedding different self-healing materials with distinct nanomaterials can impart different functionalities (e.g., conductors, semiconductors, insulators) to a self-healing polymer. Recently, researchers have designed composite systems in which healing restores not only the mechanical integrity of the device but also its electrical functionality. However, the mechanism for the self-healing of nanocomposites is not well understood, and a variety of factors including size, shape, and chemical interactions of the embedded particles can influence the rate of healing in a composite self-heaving device. In this poster, we present different examples of self-healing composite systems and discuss how the self-healing
properties of the composite change based both on the polymer matrix and the embedded nanomaterials. This work highlights potential insights into the design of self-healing composites with improved properties and their potential to be integrated into robust wearable electronics.

**MS03.06.22**

**Manufacture of Al₂O₃-Composites by the Combination of RBAO and SPS Processes** Enrique Rocha-Rangel¹, Jose A. Rodriguez-García¹, Ruth P. Alvarez-Carrizal¹ and Yoshikazu Todaka²; ¹Universidad Politecnica de Victoria, Mexico; ²Toyohashi University of Technology, Japan

In this work, the effect of additions of silver or titanium nanoparticles on the microstructure and mechanical properties of Al₂O₃-based composites was studied. The processing method for the manufacturing of alumina-based composites was a combination of RBAO and SPS processes. After milling stage, carried out in a high energy mill, we have that approximately 90% of the powders have a particle size less than 0.5 μm. After SPS process well densified bodies with almost full density were obtained. The microstructure observed by OM, shows that the reinforcement metal (silver or titanium) occupies intergranular positions and the grain size is very fine and homogenous. On the other hand, with respect to mechanical properties, addition of metals on alumina increases significantly its fracture toughness, being more significant the effect of silver, because K<sub>IC</sub> rises from 3.2 MPam<sup>0.5</sup> for monolithic Al₂O₃ to 6.9 MPam<sup>0.5</sup> for Al₂O₃/1wt%Ag composite, whereas, for the Al₂O₃/1wt%Ti composite, the value of K<sub>IC</sub> was of 5.7 MPam<sup>0.5</sup>.

**Bio-Inspired High Tough Carbon Nanotube Yarn** Hyunsoo Kim and Seon Jeong Kim; Hanyang Univ, Korea (the Republic of)

A carbon nanotube (CNT) yarn is attracting as strong and lightweight yarn because of impressive mechanical properties. Especially, among their yarns, tough performance, which is the ability to absorb mechanical energy before fracture, is considered an important mechanical property for the protection of damage to external force. We described high tough carbon nanotube yarn by inspired a muscle structure of nature, which called myofibrils. The muscle inspired CNT yarn is dramatically improved both tensile strength and strain, and yarn provides a high-energy absorption, which is higher than spider dragline silk (165 J/g) and Kevlar (78 J/g). Additionally, not only demonstrates high tough performance in the wetting and high temperature conditions but also shows ease in shape change by using water. This sewable, wearable, and shape controllable tough yarn has a potential for various applications such as bulletproof material, wearable device, stretchable electrode, aerospace industry, and artificial muscle.

**MS03.06.24**

**Development of “Paper Actuator” Using Carbon-Nanotube-Composite Papers** Takahiro Ampo and Takahide Oya; Yokohama National University, Japan

In this study, we propose a unique actuator based on a polymer type actuator and carbon-nanotube (CNT)-composite papers. The polymer actuators have different features from existing actuators. These are low voltage operation, light weight, flexible and molecular level movement. For the above reasons, energy saving is possible and more complex operation can be realized. In addition, other actuators using bucky gel that consists of CNTs and ionic liquid have been also developed.

CNTs are substance consisting of carbon and have many excellent properties such as high electrical conductivity, light weight, high strength and flexibility. Since CNTs have these properties, CNTs are expected to be used for various things. In contrast, CNTs are nanoscale powdery substance. Therefore, we may contrive to use it or develop the way for applications such as combining with other materials. Thus, we focus on “papers” as the material which is able to change shape easily and is a familiar material of our daily life. We made a paper mixed with CNTs. This material had many excellent properties based on CNTs. We have called this material “CNT-composite papers”.

Recently, development of a lightweight and flexible polymer actuator has been required for medical use, interior design, and so on. Here, the paper can be cut and pasted. So, if the polymer actuator made of CNT-composite papers can be developed, it can be used in various situations. And more complex movements can be performed than existing mechanical actuators. For the above reasons, we aim to develop the “paper actuator” using CNT-composite papers.
One of the polymer actuators contains ions and harnesses the force generated by the movement of ions for operation. We here focused on this type of the actuator in this time. This actuator composes of two types of layers, i.e., the electrode layer and the electrolyte layer. The electrolyte layer is sandwiched between the electrode layers and generally contains ionic liquids. Both the electrode layers and electrolyte layer contain the electrolyte. And the electrode layer contains CNTs. When a voltage is applied to the actuator, cations are attracted to the cathode and anions are attracted to the anode. In ionic liquids, there is a difference in the size of the cations and anions. If cations are bigger than anions, the cathode will be extended and the anode will be shrunk. From this process this device operates as an actuator.

Here our device has a three-layer structure, we designed. The outer layers consist of the CNT-composite papers as the electrode. And the inner layer bases on an ordinary paper containing no CNTs as the electrolyte layer. The ionic liquid was included in this device as the electrolyte.

The production method of the CNT-composite papers is based on Japanese washi papermaking method. First, we prepare the pulp dispersion by stirring pulp fibers in water and prepare the CNT dispersion by mixing CNTs and dispersants with ultrasonication in water. Next, we mix the pulp dispersion and the CNT dispersion. And then, we pour the mixture dispersion in the mold on the net, and scoop up the mixture by the net and dry it by heat pressing. Then, we can fabricate CNT-composite papers by this process. Then an ordinary paper containing no CNTs is sandwiched between CNT-composite papers. We layer the papers by heat pressing in this state. After that, we drip the ionic liquid. When voltage was applied this sample, we confirmed that our sample showed the operation as the actuator, as a result.

We believe our CNT-composite paper will be used as actuators in near future.

MS03.06.25
Mechanical Durability of Slippery Liquid-Infused Porous Surface with Silica Aerosol Dispersed PDMS
Youngeok Kim1, Jin Hwan Kim2 and Byungsu Lee2; 1Korea Electronics Technology Institute, Korea (the Republic of); 2Kangnam Jevisco Co., LTD, Korea (the Republic of)

Slippery liquid-infused porous surface (SLIPS) technology provides unique capabilities that are unmatched by any other surface technologies. SLIPS comprises a smooth and slippery lubricating surface, where lubricant is trapped within the pores of a solid material to repel various substances, such as water and ice. Thanks to their ultralow ice adhesion strength, SLIPS materials have actively investigated in the field of icephobic coatings where the ice accreted on the coating is passively detached by ice’s own weight. The SLIPS coatings however are still far from being employed in the real environment because of limited durability of the slippery liquid that can be removed together with the detached ice.

Here, we investigate icephobicity of a SLIPS coating based on oil-infused polydimethylsiloxane (PDMS). In order to improve the durability, porous silica aerogel (specific surface area of 600 ~ 800 m²/g, porosity above 90%) is used as the oil container. The different viscous oils (viscosity of 6, 100, and 350cst)-infused aerogel and PDMS are mixed and bar-coated, and the hardened films are followed by additional swelling of the oils.

We setup the reliable measuring instrument for icephobicity and characterize oil content, surface topography, ice adhesion strength during repeated icing/deicing cycles of the SLIPS films with different aerogel content. Finally, the inclusion of aerogel container is confirmed to increase the total oil content of the film, which results in more durable icephobicity.

MS03.06.26
Experimental Mechanics of Pure MXenes (Ti3C2Tx) and MXene (Ti3C2Tx) /Polymer Nanocomposites
Shreyas Srivatsa1, Krzysztof Grabowski1, Leon Mishnaevsky2 and Tadeusz Uhl1; 1AGH University of Science and Technology, Poland; 2Technical University of Denmark, Denmark

Titanium Carbide (Ti3C2 - MXene) with surface termination (Ti3C2Tx; Tx: -F, -OH, -O) have created a lot of interest for applications in electro-mechanical engineering domain apart from material science investigations. This interest is primarily due to unique conductivity and hydrophilic behavior exhibited by MXenes which are useful for fabricating nanocomposites for multifunctional sensing applications. The investigation of mechanical properties of a single layer (flake) or few-layer pure (free-standing) Ti3C2Tx and Ti3C2Tx nanocomposites reported in the literature are limited to the estimation of elastic properties like Young’s modulus and tensile strength. Experimental identification of structural parameters of pure MXenes and MXene/Polymer nanocomposites from the point of view of mechanics is necessary for the design and development of smart structures for Structural Health Monitoring (SHM).

The focus of this paper is on the modeling of pure MXenes (Ti3C2Tx) and MXene nanocomposites. Characterization
of Ti$_3$C$_2$Tx and Ti$_3$C$_2$Tx nanocomposites along with experimental validation of the models are performed. The characterization tests discussed in this paper are conducted with Scanning Electron Microscope (SEM), Transmission Electron Microscope (TEM) and X-ray Diffraction (XRD). MXene flakes are modeled as thin plates in microscale while the macroscale samples subjected to testing are modeled as one-dimensional and two-dimensional structures. These models help in studying the mechanics of the samples and determining the mechanical tests to be performed. Nanocomposites with MXenes as fillers in polymer matrices like epoxy, polydimethylsiloxane (PDMS) and polyvinyl alcohol (PVA) are fabricated and subjected to mechanical loads. The flexible films formed by PDMS and PVA and rigid films formed by epoxy are subjected to tensile and bending tests. Results of these tests are compiled and discussed. The paper concludes with the discussion on the possibility of using MXenes for smart structure and smart coating for SHM.

MS03.06.27
Microstructure-Electrochemical Behaviour Correlation for NiCo-MWCNTs and NiCo-Graphene Oxide Composite Coatings Sweety Arora and Chandan Srivastava; Indian Institute of Science, India

The magnetic behaviour of NiCo coatings along with high hardness, corrosion resistance and excellent wear resistance makes them a suitable candidate for applications in sensors, actuators and protective coatings. Addition of foreign particles into NiCo matrix is known to promote grain refinement and randomization leading to enhanced corrosion resistance behaviour. In the present work, varying amount of multi-walled carbon nanotubes (MWCNTs) and graphene oxide (GO) was incorporated separately into the NiCo coating matrix which was electrodeposited over mild steel substrate. The formed composite coatings were characterized using scanning electron microscopy (SEM), x-ray diffraction (XRD) and energy dispersive x-ray spectroscopy (EDS) techniques for morphology, phase identification and composition of the coatings respectively. Electrochemical impedance spectroscopy and potentiodynamic polarization studies in 3.5 wt.% NaCl solution revealed that the corrosion behaviour of the coatings was sensitive to the amount of graphene oxide and CNTs present in the coatings. With the continued addition of CNTs and GO the corrosion rate of the composite coatings first decreased to the lowest corrosion rate value and then increased to values higher than that of pristine NiCo coatings. This indicated towards the existence of optimum concentration of CNT or GO for achieving highest corrosion resistance performance. Addition of optimum CNT concentration provided hydrophobicity to the coatings and promoted growth along low energy (111) direction. Electron backscatter diffraction (EBSD) analysis of the coating cross-section prepared using SEM-FIB revealed that samples exhibiting maximum corrosion resistance (for optimum CNT/GO concentrations) also had the highest fraction of low angle grain boundaries (LAGBs) with no additional strain in the matrix.

MS03.06.28
Brittle to Ductile Transition via Ultrastructural Design of Single Crystalline Silicon Nitride Nanoporous Membrane Ali Khourshaei Shargh and Niaz Abdolrahim; University of Rochester, United States

In this work we use molecular dynamics simulations to investigate mechanical behavior of silicon nitride nanoporous membranes upon tensile loading. We show that pore arrangement pattern, pore size, as well as pore separation distance play an important role in mechanical behavior of the nanostructure with hexagonal pore shape. A brittle to ductile fracture mechanism criterion is successfully developed for hexagonal pore pattern via introducing a new ultrastructure based parameter. For ductile fracture, it was found that von-Mises shear strain is localized into a network of narrow bands within the ligaments that connect the pores. In consequence, a compressive stress is produced within the nodes that connect ligaments and cause suppression of crack propagation and enhances the ductility. In contrast, the accumulation of tensile stress in nodes leads to brittle fracture.

MS03.06.29
Mechanical Properties of Diamond Schwarzites—From Atomistic Models to 3D-Printed Structures Levi C. Felix$^1$, Vladimir Gaal$^1$, Cristiano F. Woellner$^2$, Varlei Rodrigues$^1$ and Douglas S. Galvão$^1$; $^1$State University of Campinas, Brazil; $^2$Federal University of Paraná, Brazil

In the recent years, 3D printing has been employed as an effective tool to study hierarchical structures that are difficult or elusive to be synthesized on atomic scale, such as the Schwarzites [1]. Schwarzites [2,3] are 3D carbon nanostructures with their shapes resembling triply periodic minimal surfaces (TPMS), which are porous structures possessing negative Gaussian curvature. In this work we investigated the mechanical properties of diamond Schwarzites through fully atomistic molecular dynamics (MD) and 3D printing techniques. The geometrically
optimized atomic models were used to create macroscale models that were then 3D printed (cm size) in home-made device using PLA (polyactic acid) and ABS (acrylonitrile butadiene styrene) polymers. Interestingly, as it was also observed for other Schwarzite families (gyroid and primitive) [1], some qualitative trends of the mechanical behavior (in particular with relation to compressive/tensile deformations and energy absorption/dissipation mechanisms) are present at nano and macroscale. This is especially evident when the ratio between the number of octagons to hexagons (‘flatness’) increases. Another interesting feature is that they exhibit negative (auxetic) [4] and zero Poisson’s ratio regimes. Considering that our multiscale approach is completely general (to use atomic models to create macro models that can be 3D printed), it can be very useful to create new or to improve Schwarzite-based engineering functional materials.

MS03.06.30
Improved Mechanical Properties of Graphene/Carbon Fibre/Epoxy Hybrid Composites through Silanization
Xudan Yao, Mark A. Bissett and Ian Kinloch; The University of Manchester, United Kingdom

Carbon fibre reinforced polymer (CFRP) composites have been widely used owing to their superior specific strength and modulus. Meanwhile, graphene-based composites have drawn much attention since it’s discovered with exceptional mechanical, electrical and thermal properties. More recently, interest in hybrid composites combining continuous fibres with nanomaterials has grown for achieving ideal properties. For these hybrid composites, the nanomaterial dispersion as well as the interfacial bonding raise the challenges.

In this work, graphene/carbon fibre/epoxy hybrid composites were investigated. The graphene was achieved through in lab electrochemical exfoliation, followed by filtration, washing and drying. The obtained graphene has adequate in-situ oxygen groups, i.e. hydroxyl and carboxyl groups, which makes the dispersion easier as it could stay stable in either water or ethanol. On the other hand, in order to improve the interfacial bonding, silanization was introduced with the 3-Aminopropyl)triethoxysilane (APTES) as the coupling agent. The APTES could react with both oxygen groups of the graphene and amine groups of the hardener, thus build the bridge between them. After the surface modification, the graphene was dispersed in ethanol then sprayed on to carbon fibres, followed with vacuum assisted resin infusion to manufacture the composites. During the mechanical testing, compared with the sample without functionalization, the delamination was largely removed after the silanization. As a result, the mechanical properties, especially for the tensile and flexural strength, improved by more than 60%.

MS03.06.31
Rapid and Energy-Efficient 3D Printing of Continuous Carbon Fiber/Thermosetting Composites Kun Fu; University of Delaware, United States

Additive manufacturing of continuous carbon fiber composites using thermosetting polymers is a challenge and so far very few work has been reported. Recently, we developed a novel 3D printing system allowing one-step manufacturing of continuous carbon fiber/thermosetting composites in a rapid and energy-efficient way. Our 3D printing system has good compatibility with commercial carbon tow and bundles, and most of epoxy resins. Our 3D printed composites exhibit high fiber volume fraction (>60%) and high tensile strength (>800 MPa). In this oral presentation, I will talk about our 3D printing technology, including the fundamentals and applications. In addition to carbon fiber, our 3D printing technology can also be extended to other high performance fiber composite manufacturing, including kevlar/thermosetting, and glass fiber/thermosetting.

MS03.06.32
Synergistic Effect of Cellulose Nanocrystals and Carbon Nanotubes on Interfacial Properties of Carbon Fiber Epoxy Composite Ozge Kaynan and Amir Asadi; Texas A&M University, United States

Load bearing capability and lifetime of the epoxy composites can be enhanced by improving interfacial adhesion fiber and epoxy. In this paper, we aim to elucidate the mechanisms that create the interface of cellulose nanocrystals
(CNCs)-bonded carbon nanotubes (CNTs)- carbon fiber reinforced polymer (CFRP) composites. Particularly, we will articulate the CNTs/CNCs’ synergistic effect on the interfacial strength of carbon fiber epoxy composite. To date, several approaches have been proposed to improve interfacial bonding of epoxy composites including sizing of reinforcing fiber [1], nanofiller coating [2, 3] and nanoparticle growth on the surface of fibers [4]. Among these, coating of fibers as a thin layer of polymeric components or nanoparticles is a widely adopted strategy for interfacial enhancement. However, the main challenge is still to develop scalable techniques to incorporate well-dispersed nanoparticle in polymer matrix composites to create a strong bonding between the matrix and reinforcing fiber to enhance interfacial properties. We have introduced a novel processing technique in which CNCs are exploited to control the dispersion and deposition of pristine CNTs onto carbon fibers. CNCs are spindle-shaped nanocrystals having 3-5 nm width and 5-500 nm length [2] with high mechanical properties (130 GPa modulus and 7 GPa strength). Our results show that the integrating 0.2 wt % CNC and 0.2 wt % synergistically increase the flexural and interlaminar properties of CFRP composites by 44%. The CNC-CNT suspension was prepared by sonication in deionized water and the suspension was used to coat the carbon fabrics prior to infusion of resin in a vacuum assisted resin transfer molding (VaRTM) process. To investigate the interfacial properties of CNC-CNT coated carbon fiber/epoxy, in-situ single fiber fragmentation test under an optical microscope is performed. Furthermore, AFM-nano-IR characterization will be used to correlate the chemical composition (with 200 nm resolution) and surface topology of the interphase to its mechanical properties such as strength and modulus.

Interfacial Analysis on Functionalization Exfoliated Graphene in Polyamide 66 Under Novel High Shear Elongational Flow Justin W. Hendrix1,2, Thomas Nosker1, Thomas Emge1 and Jennifer Lynch-Branzoi1; 1Rutgers, The State University of New Jersey, United States; 2Naval Surface Warfare Center, United States

Graphene is publicized as the game changing material of this millennium. As research continues to expand our knowledge of this 2D semimetal, interfacial properties are increasingly becoming an important characteristic for an idealized graphene integrated composites system. Our research suggest translating graphene’s properties at the nanoscale to the macroscale is best achieved by forming primary or secondary chemical bonds from the matrix to a graphene flake. In our previous work, we have invented a method of creating a graphene reinforced polymer matrix composite (G-PMC) from flake mineral graphite and PA66 in-situ, using high shear elongational flow. Due to our process, we were able to identify chemical bonding at graphene’s surface and edge by XPS and Raman Spectroscopy. By electron microscopy, our results shed light on the mechanism to the formation of graphene functionalities and the creation of unique modified nanostructured morphologies. This work highlights a method to green chemical routes for manufacturing scalable graphene composites.

Highly Compressible, Porous Ethylenediamine-Reduced Graphene Oxide Aerogels with Enhanced Structural and Restorative Properties Benjamin Zimmerli and Junjun Ding; New York State College of Ceramics at Alfred University, United States

Graphene oxide (GO) and reduced graphene oxide (rGO) aerogels have been studied intensively over the past decade for their immense potential speculated by the highly desirable mechanical, electrical, and physiochemical properties. Herein, we report the fabrication of an ethylenediamine (EDA)-reduced GO aerogel via lyophilization freeze-drying method from prepared rGO/EDA hydrogels. EDA is added to the GO solution to act as a partial reducing agent, in addition to serving as a crosslinker during the formation of the hydrogel. The resulting structures exhibited extremely high compressibility and structural stability, while additionally exhibiting significant compressive elasticity. Aerogel samples were reported to hold up to 3000x the sample mass, while simultaneously
compressing less than 40% of the total volume. In addition, fabricated aerogel samples were measured to exhibit extremely little, even negligible fatigue over several testing cycles, which further describes the extent of the aerogel’s structural integrity. This gives rise to the potential of EDA/rGO aerogels towards mechanical applications such as shock absorbance or impact resistance.

**Modification of Interlaminar Fracture Toughness and Through-Thickness Conductivity in PANI-GNP Reinforced CFRP**
Dilli Dhakal, Pralhad Lamichhane, Kunal Mishra and Ranji Vaidyanathan; Oklahoma State University, United States

Carbon fiber-reinforced polymer (CFRP) are lightweight composites and have massive potential towards aerospace and automobile component application. However, the delamination cracks of CFRP are still a challenging topic for the researcher. Numerous works have been done by adding nano-fillers to modify the polymer and improve the mechanical, electrical, and thermal properties. Understanding and minimizing the delamination cracks in CFRP are extremely valuable to reduce the failure in aerospace and automobile parts. Also, CFRP has very low through-thickness conductivity in comparison to conductivity in the fiber direction due to limited the fiber contact surface. The study of through-thickness conductivity is essential because delamination activity in CFRP can be monitored with a change in electrical resistance in through-thickness direction. Investigation and improvement in through-thickness conductivity of CFRP will lead to understanding and reducing the delamination of CFRP during the catastrophic event like lightning strike.

In this present investigation, Polyaniline (PANI) doped graphene nanosheets (GNS) are used as nano-filler, and its effect on fracture toughness and through-thickness conductivity has been studied. The impact of variation in GNS (0, 0.2, 0.5, and one wt %) with respect to PANI is investigated. A double cantilever beam (ASTM D5528) experiment is carried out to characterize the interlaminar fracture toughness. Through-thickness conductivity is measured by impedance spectroscopy. Scanning Electron Microscopy (SEM) is used to study the cross-section of the laminate. Also, viscoelastic properties have been studied in DMA.

**MS03.06.36**

**In Situ Growth of Si$_3$N$_4$ Nanofibers on BN Surface to Enhance the Thermal Conductivity of the Polymer Composites**
Tong Yao, Ke Chen, Yigang Yang and Ying Yang; Tsinghua University, China

Thermally conductive but electrically insulating materials become more and more important for the thermal management. However, the traditional high filler loading to build a thermally conductive network usually leads to significant increase in the viscosity of the precursor mixtures and mechanical deterioration of the polymer composites. Therefore, it is necessary to increase the thermal conductivity of the composites with as little filler as possible. In this work, the surface of BN was firstly coated by SiO$_2$ via hydrolysis and condensation reactions with tetraethyloxyorthosilicate (TEOS). Then, atomic layer deposition (ALD) technique was used to coat alumina (Al$_2$O$_3$), which would play a catalytic role in the subsequent reaction, on the surface of BN coated by SiO$_2$ (BN@SiO$_2$). After that, the BN@SiO$_2$ treated by ALD (BN@SiO$_2$-Al$_2$O$_3$) was mixed with a certain proportion of super P. Si$_3$N$_4$ nanofibers grown in situ on BN can be obtained through reduction and nitridation heat treatment in a nitrogen (N$_2$) atmosphere. In this structure, which Si$_3$N$_4$ nanofibers grown on the surface of BN (BN/Si$_3$N$_4$), BN can form the main thermally conductive paths and the Si$_3$N$_4$ nanofibers can connect the neighboring BN like “bridges” to construct phonon transmission pathways. This special structure can be used to enhance the thermal conductivity of the polymer composites.
Diego, United States

Photoactive deformable polymers have drawn a significant amount of attention due to their distinct advantages such as fast responsiveness, local and wireless control, and environmentally-friendly actuation. Photo-responsive polymers (PRPs) can convert the light energy into the mechanical work. Accordingly, these functional soft materials have been utilized as the bio-mimetic devices and light-responsive soft robots. Among them, the liquid crystalline polymer (LCP) doped with the azobenzene molecules exhibits large and reversible mechanical deformation in response to the UV/visible light irradiation. When the 365 nm-light ray is illuminated, the rod-like trans-moieties are excited and then, isomerized into bent cis-molecules. The photo-chemical reaction induces the collapse of the initial symmetry of the LCP network, which results in the macroscopic deformation. In order to analyze and design the deformation of the PRPs, the multiscale simulation framework, which integrates the mesoscopic light-triggered response and macroscopic mechanical behavior, is systematically developed. Especially, we consider the effects of the diverse design parameters such as the initial LC phase, morphology of the polymer network, and geometry of the specimen to carry out multiscale simulation-based design of the photo-mechanical deformations. First, the coarse-grained molecular dynamics (CG MD) simulation is performed to investigate the changes in properties of the macromolecular network in response to the photo-isomerization reaction. The mesoscale photo-switching potential is firstly developed by using the iterative Boltzmann inversion (IBI) technique to reflect the light-induced molecular shape change and LC phase transition. As a result, we successfully reproduced the light-activated transition between 3 phases (Smectic A (Sm A) – Nematic (N) – Isotropic (I)) and corresponding mesoscale deformations. The light-induced polymeric shape change and softening effect on the elastic properties are parameterized by the photo-isomerization ratio, which represents the extent of the photo-chemical reactions. Then, the mesoscale parameters are upscaled to the continuum scale stress-strain relationship, which is derived from the neo-classical elastic free energy of the LCPs. In order to efficiently reflect the light-induced rotation of the LC mesogens and geometric nonlinearity, a co-rotational formulation is implemented to the finite element (FE) shell model. The presented multiscale analysis efficiently realizes the exotic 3D deformations as well as the simple bending behavior. In addition to these deformation prediction capability, the instability of the snap-through deformations are systematically investigated in terms of the material parameters. We expect that the present scale-bridging computational study can help to practically design the deformed topographies of the photo-responsive mechanical actuators and light-stimuli soft robot components.

Rational Design of Polymer Nanocomposites to Advance Their Thermomechanical Performance via Predictive Multiscale Modeling Wenjie Xia; North Dakota State University, United States

Understanding and predicting the thermomechanical behaviors of polymer nanocomposites are challenging as they are greatly influenced by many factors, such as interfacial energy and filler volume fraction, giving rise to the presence of nanoscale interfaces. To better design of polymer nanocomposites, we have recently developed a predictive multiscale modeling approach, namely the energy-renormalization method, to examine how the nanoscale interfaces and molecular characteristics influence the mechanical and glass transition properties of polymer nanocomposites. Taking nanofiller reinforced glassy polymer as a model system, I will present a multiscale modeling framework based on coarse-grained modeling, in conjunction with machine learning, to achieve improved and tunable performance of nanocomposites.

9:15 AM MS03.07.03
Peeling of Composite Membranes Daniele Liprandi1, Federico Bosia2 and Nicola M. Pugno1,3,4; 1Università degli Studi di Trento, Italy; 2Università degli Studi di Torino, Italy; 3Queen Mary University, United Kingdom; 4KET Lab, Italy

Biological and bio-inspired materials are an example of composite materials with superior mechanical properties. Nature can provide inspiration for mechanical optimization of artificial matrix-reinforcement systems, often involving high tunability and synergetic properties. One of the emerging topics of interest in this respect is the study
of the mechanical behaviour of composite adhesive structures. This involves the full characterization of the interaction between complex surfaces, a problem that remains to be fully understood in three-dimensional cases, with adhesive and frictional properties emerging from effects from the nano- to the macro-scale. Indeed, unless specific symmetries or simplifying conditions are considered, it is almost impossible to exactly predict the interaction between generic composite surfaces, due to the large number of parameters involved, including geometrical features, mechanical properties of the materials, substrate properties and the adhesive potentials determining the contact properties. If composite materials are considered, the complexity of the mechanics involved is further increased. To tackle this problem, we have developed a theoretical-numerical approach to simulate the behaviour of a heterogeneous composite adhesive membrane-like structure interacting with a rigid substrate. The model is based the framework method to discretise continuous bodies using structured spring lattices. An in-house developed C++ code has been developed, which allows the model to have a great portability and versatility. As an example, the model is applied to simulate the peeling behaviour of a composite spider disc attachment, composed by a stiff tread fused with a softer silk plaque. The adhesive interface is described using a 3D cohesive law, validating the solutions with analytically predictions for symmetrical problems. Results show how the geometrical properties of the membrane determine the maximal pull-off force and extensibility of the system, and how tearing phenomena and the heterogeneity of the structure change the overall behaviour of the spider disc attachment. Numerical predictions are compared with experimental results from collaborating groups.

Mechanics of Cellulose Nanomaterials Using a Coarse-Grained Modeling Scheme  Upamanyu Ray, Zhenqian Pang and Teng Li; University of Maryland College Park, United States

The quest for alternative biodegradable materials such as cellulose to replace plastics is attracting tremendous attention among the materials science community in addition to being directly aligned with the public interest. Most cellulose nanomaterials comprise of a combination of small (~nm) but strong nanofibers and long (~ μm) but weak microfibers. We investigate the role of interactions of such fibers, spanning across different length-scales, in improving the mechanical properties of the nanocomposite. To qualitatively understand the interface mechanics in the composite material, we devise a three-tier multi-scale coarse-grained (CG) modeling scheme. The levels of the CG scheme are as described: (a) Cellulose molecular chain level (~ Å); (b) Elementary fibril level (~ nm); and (c) fiber level (~μm). We characterize the length and diameter of the fibers using Atomic Force Microscopy and thereby choose the 2nd and the 3rd level of the CG scheme to model the nano and the microfibers respectively to reproduce analogous experimental conditions. We construct hybrid models by mixing the nano and microfiber models. Changing the mass % of the separate nanofibers help explore the fundamental reason behind why the hybrid show greater strength and toughness than the material separately fabricated using only nano or microfibers. From the quantitative aspect, we obtain that the fracture resistance enhances efficiently by around 57 times when the nanofiber content is about 85.7%. Independent molecular simulations of inter-fiber sliding in the nano-, micro- and hybrid fibers elucidate the formation and breaking of hydrogen bonds and clearly explain the role of hydrogen bonding across their interfaces which directly imparts superior mechanistic properties in the hybrids. Implementing the above CG scheme, we also study the interaction between two neighboring fibers (nano & micro) shedding fundamental insight on the mechanical response of cellulose nanomaterials under various representative loads. Such multi-scale modeling investigations, in addition to being very timely, can also be extended to other fundamental building blocks and directly influence the material design of novel hybrid materials having tunable interfacial properties.

Three-Dimensional Transformation of Membrane-Type Electronics Based on Plastic Framework and Plasticization Heungcho Ko; Gwangju Institute of Science and Technology, Korea (the Republic of)

Recent technology of developing membrane-type electronic devices which can deform without losing electrical performance enables stick-and-play system. Because thinner structure is more bendable, a number of researchers tend to make tremendous efforts to develop printable electric devices thinnest possible and transfer printing process. Most efforts work well by thin structure directly when the target applications require mechanically high flexibility but confront some problems of the lack of rigidity to realize three dimensional (3D) electronics devices such as omnidirectional sensory or display system. Here, we report the reliable strategy of handling membrane-type electronic devices, which can deform easily but cannot maintain the shapes by themselves. The method uses linear thermal plastic frameworks that can mechanically support the thin device and also undergo transition from glassy
state to rubbery state, in which their Young’s moduli generally decrease from several GPa to several MPa and migration of polymer chains are also possible. We carried out solvent- or heat-assisted plasticization to allow traveling into the rubbery state temporarily for controlled transformation. The strong advantage of this method is the possibility for positioning membrane-type electronics not only neutral mechanical plane but the top or bottom of the plastic frameworks, which is not available without plasticization. Using this method, we successfully developed bezel-less tetrahedral image sensors or curvilinear arrays of IGZO transistors with nonzero Gaussian curvature from planar forms.

Materials by Design Using Artificial Intelligence Markus J. Buehler; Massachusetts Institute of Technology, United States

What if we could design materials that integrate powerful concepts of living organisms – self-organization, the ability to self-heal, and an amazing flexibility to create astounding material properties from abundant and inexpensive raw materials? This talk will present a review of bottom-up analysis and design of materials for various purposes – as structural materials such as bone in our body or for lightweight, strong and resilient composites, for applications as coatings, and as multifunctional sensors to measure small changes in humidity, temperature or stress. These new materials are designed from the bottom up and through a close coupling of experiment and powerful computation as we assemble structures, atom by atom. Materiomics investigates the material properties of natural and synthetic materials by examining fundamental links between processes, structures and properties at multiple scales, from nano to macro, by using systematic experimental, theoretical and computational methods. We review case studies of joint experimental-computational work of biomimetic materials design, manufacturing and testing for the development of strong, tough and mutable materials for applications as protective coatings, cables and structural materials. We outline challenges and opportunities for technological innovation for materials and beyond, exploiting the use of artificial intelligence as a way to complement conventional physics-based modeling and simulation methods. Altogether, the use of a new paradigm to design materials from the bottom up plays a critical role in advanced manufacturing, providing flexibility, tailorability and efficiency.

11:00 AM MS03.07.07
Using Machine Learning Techniques to Predict Mechanical Properties of Composites beyond the Elastic Limit Youngsoo Kim1, Charles Yang2, Yongtae Kim1, Grace Gu2 and Seunghwa Ryu1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2University of California, Berkeley, United States

Composites with superior mechanical properties are widely used in advanced engineering applications. In the hopes of designing high-performance composites, various analytical, numerical, and experimental methods are used to predict the mechanical properties of composites in terms of reinforcement arrangement and external shape. However, the vast design space of composites, limited accuracy of analytical and numerical approaches in fracture, and time-consuming nature of experimental methods make the rational optimization of composite properties almost infeasible, especially when considering the entire failure mechanism. In this presentation, we introduce two representative works on composite design problems where we utilize machine learning techniques to predict material properties and use the trained models for optimization. First, we use convolutional neural network (CNN) to predict and optimize the stiffness, strength, and toughness of a model composite system consisting of two different linear elastic-perfectly brittle materials, with a reasonable amount of training data (full stress-strain curves of 100,000 random configurations obtained by crack phase field simulation). Despite the astronomically larger combinatorial design space, CNN’s fast inference speed enables the prediction and the optimization of composite design with acceptable accuracy. Second, we leverage Gaussian process regression (GPR) for the design of bio-inspired composites with relatively periodic and regular arrangements with a small training set (full stress-strain curves of 3D-printed samples with 50 different configurations obtained by experiments). The GPR-based design strategy provides a route for strength and toughness optimization when analytical or numerical approach is limited due to the nonlinearity of constituent materials and the uncertainty in manufacturing processes. Our studies demonstrate the potential for machine learning techniques to accelerate the composite design optimization process considering inelastic properties.

11:15 AM MS03.07.08
"In Situ, Multiparametric Nanocharacterization of Composite Materials Using Combined AFM/SEM/FIB"

Georg E. Fantner\textsuperscript{1}, Santiago Andany\textsuperscript{1} and Jason Killgore\textsuperscript{2}; \textsuperscript{1}École Polytechnique Fédérale de Lausanne, Switzerland; \textsuperscript{2}National Institute of Standards and Technology, United States

The complexity of nanocomposites poses tremendous challenges for the quantitative characterization of the properties of the individual components within the composite. The need for multifaceted characterization of the nanocomposite (mechanically, chemically, electrically, magnetically, etc) requires a multitude of nanoscale characterization methods to be applied to a single sample. While a myriad of excellent techniques exist that can provide information about specific aspects of the material, combining these individual techniques sequentially is particularly difficult for nanoscale composites for reasons of colocalization, contamination, and the hierarchical structures that can span several length scales (from nm to mm).

Combining multiple measurement techniques into one in-situ nanocharacterization instrument can solve these issues to enable multiparametric analysis of nanocomposites. For this purpose, we have developed a combined AFM/SEM/FIB instrument that combines the broad range of physical nanocharacterization methods of atomic force microscopy (mechanical, electrical, magnetic) with the chemical characterization capability of scanning electron microscopy and the micromachining capabilities of focused ion beam milling. Of particular interest for nanocomposites is the correlation of chemical composition, with structure and mechanical properties mapping. The vast differences in Young’s moduli between the individual components in many nanocomposites makes nanomechanical characterization particularly challenging. We therefore use advanced AFM based mechanical property measurement techniques (off resonance tapping in combination with contact resonance) to span three orders of magnitude in Young’s moduli.

In this presentation we will discuss examples of this in-situ nanocharacterization for 2D and 3D study of polymer blends, biological nanocomposites and high-performance self-healing synthetic materials.

11:30 AM MS03.07.09

Mapping Storage and Loss Modulus of Polymer Composites across Time and Temperature with AFM-Based Nano-DMA

Bede Pittenger, Sergey Osechinskiy, John Thornton, Sophie Loire and Thomas Mueller; Bruker Nano Surfaces, United States

For heterogeneous polymer samples like polymer composites and thin films, it is often of interest to understand the mechanical properties of microscopic domains within the material and near the boundaries between one component and another. Atomic Force Microscopy (AFM) has the nanometer level resolution and sensitivity needed to investigate these domains, but established AFM measurement modes do not yield results that allow direct comparison to established rheological techniques like Dynamic Mechanical Analysis (DMA). Contact resonance [1] provides mechanical property maps at well-defined frequencies, but cantilever resonances are many orders of magnitude higher than DMA, making comparisons indirect at best. Intermittent contact methods like TappingMode[2], force volume, and PeakForce Tapping [3, 4] face challenges in calculating intrinsic mechanical properties like storage and loss modulus (or tan delta) due to the non-linear process of making and breaking contact [5].

AFM based nano-DMA (AFM-nDMA) provides viscoelastic results that can be directly compared with bulk DMA. Like bulk DMA, it provides spectra of storage and loss modulus across frequency and temperature allowing construction of master curves through Time Temperature Superposition (TTS) [6]. In addition, it allows high resolution measurements of the microstructure of heterogeneous samples to allow better understanding of their properties and behavior. This presentation will examine the capabilities of this new mode with examples in a wide range of polymers and composites.

Coupled Electrical Resistance Measurement and IR Thermography Monitoring for Analysis of Damage Development and Fatigue Strength of Composite Materials  
Kundo Park¹, Seunghwa Ryu¹ and Flavia Libonati²;  
¹KAIST, Korea (the Republic of); ²Politecnico di Milano, Italy

Rooted from its heterogeneous microstructure, composite materials possess high strength to weight ratio and, therefore, they are applied in a wide range of industry. However, their complicated microstructure makes it difficult to predict the failure mechanism and residual material life. The in-situ health monitoring system has received much attention in recent years as one of the promising solutions for the aforementioned limitations of composite material. In this research, electrical resistance measurement and IR thermography is utilized simultaneously as a unified non-destructive testing system to monitor the initiation and evolution of damage inside the composite materials. Through the experiment where we combined our coupled NDT system and a uniaxial tensile test of GFRP, the deformation and failure timeline of GFRP under tensile test could be subdivided into three different levels and finally enabled us to identify a characteristic stress value called ‘Damage stress($\sigma_D$)’. In this research, we suggest that the Damage stress value, characterized by our coupled NDT system, can be a reasonable estimation of the fatigue strength of the studied material. In contrast with the conventional fatigue tests that requires tens of thousands of loading cycles, application of our coupled NDT system can effectively characterize the fatigue strength of composite materials in a single uniaxial tensile test. Series of analysis on the experiment result were carried out to understand how the damage stress value can be equivalent to the actual fatigue strength of the studied material. Furthermore, the correlation between the thermal, electrical and mechanical behavior of composite materials was thoroughly understood through multiphysics modeling study.

Bioinspired Fabrication of Complex Vascular Architectures in Polymers and Composites  
Nancy R. Sottos, Mayank Garg and Jeffrey Moore; University of Illinois at Urbana-Champaign, United States

The introduction of vasculature to polymers and composites enables adaptive and environmentally responsive materials with properties like self-healing, self-cooling, and electromagnetic reconfigurability. Previously, we demonstrated thermal degradation of sacrificial poly (lactic acid) (PLA) templates embedded in thermoset matrices to create multifunctional composites with interconnected vascular networks [1]. However, this vascularization method is a two-step process that requires significant energy input and time to first polymerize the thermoset matrix and then to depolymerize the PLA into volatile products at elevated temperatures (ca. 200 °C for 12 hours). Here, we introduce a biologically inspired, simultaneous depolymerization of sacrificial templates during frontal polymerization of the surrounding matrix [2]. As the reaction front propagates to polymerize the matrix, the released heat is sufficient to concurrently degrade and volatilize the sacrificial template. We explore sacrificial materials such as cyclic poly(phthalaldehyde) (cPPA) and poly(propylene carbonate) (PPC), which depolymerize at relatively low temperatures (~100°C). This new manufacturing process enables freeform fabrication of complex, porous vascular networks with potential for highly functionalized interfaces.

Uniaxial Extension of Ultra-Thin Freestanding Polymer Film

R K. Bay and Alfred J. Crosby; University of Massachusetts Amherst, United States

Recently, we developed a method for quantifying the complete uniaxial stress-strain relationship for ultra-thin polymer films. The key to this method is the use of liquids to help support ultra-thin, often fragile, films. Although this method has provided new insights into mechanical properties and deformation mechanisms for dimensionally-confined polymer systems, for some polymers the presence of a liquid may influence the ultra-thin properties. Here, we introduce a new method, freestanding tensile tester to directly measure the uniaxial stress-strain response of freestanding polymer thin films. Using polystyrene thin films, with thickness 15 nm-100 nm, we observe and quantify large strain deformation mechanisms, as well as yield stress and elastic moduli, and compare these results to the liquid supported measurements. We find that the liquid acts as a craze stabilizer for polystyrene thin films which leads to lower strains in the freestanding method compared to the liquid supported method. These results provide new fundamental insights into how the surface interactions can alter polymer behavior in thin confined polymer films.

Characterization of the Carbon Fiber/Matrix Interface in Frontally Polymerized Composites

Douglas Ivanoff, Clément Viers, Jaeuk Sung and Nancy R. Sottos; University of Illinois Urbana-Champaign, United States

Current manufacturing of carbon fiber reinforced polymers (CFRPs) consumes a significant amount of energy due to high temperature and pressure cure cycle requirements. Frontal ring opening metathesis polymerization (FROMP) reduces the total energy cost of manufacturing CFRPs by orders of magnitude while reducing the fabrication time. Using a resin system comprising of a ring-strained dicyclopentadiene (DCPD) monomer and a latent second-generation Grubbs catalyst, site-heating generates a self-propagating polymerization front that consumes the monomer and creates rigid, tough thermosets and composites with greater than 50% fiber volume fraction. pDCPD composites currently display suboptimal mechanical properties attributed to weak adhesion of the hydrocarbon matrix to the carbon fibers with commercially available surface chemistries. In this work, several olefinic sizing agents are synthesized and applied to carbon fibers to covalently bond the matrix and reinforcement for increased interfacial shear strength (IFSS). The IFSS, debond length, and fiber slippage at the interface are all characterized in single fiber fragmentation tests under cross-polarized light. Sizing agents applied to the carbon fiber increase the amount of norbornene moieties on the surface, resulting in a reduced critical fiber length. This improved surface functionality increases the IFSS by over 50% from the epoxy-sized fibers. Due to the high fracture toughness of the pDCPD matrix, fiber debonding along the weak interface occurs preferentially to matrix cracking. In addition, we investigate the impact of the unique thermal processing history during FROMP on interfacial properties and compare to conventionally cured samples.

New Deformation Modes in Three-Dimensional Liquid Crystal Elastomer Microstructures

Joanna Aizenberg; Harvard University, United States

Adaptive, responsive and self-regulated 2D and 3D materials hold promise for a variety of applications – from energy-efficient transducers and energy harvesting to autonomously moving devices and homeostatic systems. From a wide variety of designs that have been utilized to engineer such materials, a hybrid bioinspired system comprised of high-aspect-ratio skeletal elements embedded in a responsive gel “muscle” has proven very versatile. One limitation of this system is its reliance on the responsiveness of the gel, in order to achieve the macroscopic deformations provided by the movement of the skeletal elements. We will present several active temperature- and light-responsive systems where microstructures made of liquid crystal elastomers (LCEs) are themselves the responsive elements. By varying the molecular structure of the LCE precursors and cross-linkers and by predetermining nematic ordering of the resulting elastomers through choosing the orientation of the prepolymer samples in the external director – magnetic field – we have realized a wide range of systems capable of temperature- and light-induced deformations, many of which are unattainable in traditional gel-skeletal element responsive designs or in well-known cellular structures. We will demonstrate predetermined and self-regulated deformations in these LCEs, as well as designs capable of chirality generation and switch, and unprecedented nonmonotonic
responses to monotonic stimuli. We foresee that this platform can be widely applied in switchable adhesion, information encryption, autonomous antennae, energy harvesting, soft robotics, and smart buildings.

4:00 PM MS03.08.05
Size Effect of Freestanding Ultrathin Polymer Films Guorui Wang and Tobin Filleter; University of Toronto, Canada

The mechanical properties of thin polymer films are of scientific and technological interest to diverse communities of researchers. This interest is mainly driven by the development of flexible and stretchable electronics with a wide range of applications in flexible, wearable, and implantable devices. While the moduli of thin polymer films are known to deviate dramatically from their bulk values, the nature of such size effect still remains debatable. Specially, indentation technique gives rise to contradicting results from both buckling experiments and molecular dynamics calculations, which is claimed to result from the substrate effect. Herein, freestanding ultrathin polymethyl methacrylate (PMMA) films with thickness ranging from 6 nm to 129 nm were measured by atomic force microscope (AFM) based nanoindentation. Obvious plate-to-membrane transition is observed in the deformation characteristics with decreasing thickness. Combined with the classical plate theory and contact mechanics model, we demonstrate the great enhancement in both Young's moduli and yield strength even in the absence of substrate, which is further evidenced and interpreted by molecular dynamics (MD) simulations. Additionally, the broadening of the elastic strain range allows higher stretchability, which is anticipated to further advance the development of flexible and stretchable electronics.

4:15 PM MS03.08.06
High-Strain-Rate Plasticity of Block Copolymer Microspheres Correlating with Microphase Separation Ara Kim and Jae-Hwang Lee; UMASS Amherst, United States

In the use of advanced manufacturing, targeting certain mechanical performances by tailoring inherent material properties is a success factor, and material diversities are emphasized as the application area expands to non-metallic materials and mixed composites. Multi-phase polymers or phase-separated block copolymers (BCPs) consist of two or more mechanically distinctive nanoscale phases. The diverse nanostructures of BCPs, which can be tailored through thermal annealing process, cause obvious changes in mechanical properties. Moreover, the high-strain-rate deformation characteristics are generated and controlled by impact tests with different collision conditions. Polymers are emerging materials in additive manufacturing such as the cold spray technique, however, mechanical behaviors including extreme plastic deformations resulting from collisions have not been demonstrated thoroughly. In order to obtain insight into the novel phenomena of BCP’s mechanical behaviors with anisotropic nanostructures, single-particle impact experiments of polystyrene-block-polydimethylsiloxane (PS-b-PDMS) block copolymer (BCP) microparticles with different nanostructures were performed to demonstrate the effects of nanostructures of BCP microparticles before and after impact against rigid substrates. BCP particles with different volume fractions of PS and PDMS were annealed at diverse conditions to obtain different degrees of ordered nanostructures in two phases, such as cylinders and lamellae. Both annealed and non-annealed BCP particles were tested by using the laser-induced projectile impact test (LIPIT) method. A single BCP micro-particle was accelerated to a high velocity (70 – 600 m/s) and impacted onto a rigid substrate, and the collision was monitored with an ultrafast imaging system using femtosecond illumination pulses. Coefficients of restitution, critical velocity, acceleration-force-induced inelastic deformation and collision-induced extreme plastic deformation features of the BCP particles were investigated for different nanostructures and impact conditions. Electron microscopy and focused ion beam milling were used to demonstrate ordered nanostructures and impact-induced morphological changes of the BCPs before and after the collisions. Acceleration-force-induced inelastic deformation was investigated by analyzing dimension changes during acceleration and until the moment of impact. As critical velocities and coefficients of restitution of BCPs were changed depending on the status of the nanostructures, the morphologies of nanostructures were important factors in deciding the mechanical characteristics of BCP before and after impact. One of the most critical findings of this study was that nanoscale structural changes of BCP microparticles cause microscale changes in mechanical behaviors, and it furthers research into how BCPs can be tailored to satisfy target performances in additive manufacturing.

Complex-Shaped Cellulose Composites Made by Wet Densification of 3D Printed Scaffolds

Michael Hausmann\textsuperscript{1,2}, Gilberto Siqueira\textsuperscript{1,2}, Dimitri Kokkinis\textsuperscript{2}, Antonia Neels\textsuperscript{3}, Tanja Zimmermann\textsuperscript{1}, Rafael Libanori\textsuperscript{2} and André R. Studart\textsuperscript{2}; \textsuperscript{1}Swiss Federal Laboratories for Materials Science and Technology, Switzerland; \textsuperscript{2}ETH Zürich, Switzerland; \textsuperscript{3}Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Cellulose is an attractive material resource for the fabrication of sustainable functional products, but its processing into structures with complex architecture and high cellulose content remains challenging. Such limitation has prevented cellulose-based synthetic materials from reaching the level of structural control and mechanical properties observed in their biological counterparts, such as wood and plant tissues. To address this issue, we report a simple approach to manufacture complex-shaped cellulose-based composites, in which the shaping capabilities of 3D printing technologies are combined with a wet densification process that increases the concentration of cellulose in the final printed material. Complex-shaped composites with cellulose concentration up to 27.35 vol % can be created through the wet densification of 3D printed scaffolds. The densification process involves the exchange of the aqueous phase of the printed wet scaffold by a liquid mixture that works as a poor solvent for the cellulose particles. Because of their high cellulose concentration, composites obtained via infiltration of wet densified scaffolds with an organic phase show significantly higher fracture strength and stiffness compared to state-of-the-art 3D printed cellulose-based materials. This strengthening effect arises from the very high concentration of cellulose achieved in the final composite and is also partly affected by the strong alignment of the cellulose particles along the extrusion direction during the printing process. The high level of structural complexity and control achieved with this combined process opens the way to the fabrication of cellulose-based materials that capture some of the design principles of biological structures like wood and morphing plant structures. Since mechanical stability and high cellulose content are key to achieve long-term durability and to fully benefit from the sustainable nature of this material resource, the proposed manufacturing workflow is also expected to have a major impact in future cellulose-based structural, biomedical and energy-related products.

Direct Observation of Chain Adsorption Processes on to a Solid Surface

Yuma Morimitsu, Hisao Matsuno and Keiji Tanaka; Kyushu University, Japan

Polymer/inorganic filler composites have attracted a great deal of attention as a light-weight structural material with excellent mechanical properties. So far, it has been widely accepted that the interface between a polymer and a filler is a key to control the material performance. However, it is still open how the interfacial layer composed of adsorbed chains is formed. In this study, the direct observation of the formation processes for the interfacial adsorbed layer was performed by atomic force microscopy (AFM). As a model polymer, deoxyribonucleic acid (DNA) was selected because of its relatively-large molecular size, leading to observation with relative ease. Lambda phage DNA with 48.5k base pairs, hereafter referred to as DNA, was used. Basically, DNA molecules used take a random coil conformation in a solution state. The radius of gyration ($R_g$) and the persistence length determined by small-angle X-ray scattering measurement were 284 nm and 29.3 nm, respectively. DNA solutions at various concentrations were prepared by diluting a stock solution of DNA with 40 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffer solution containing 5 mM NiCl$_2$ (5Ni). Mica disks were incubated with the diluted DNA solutions for a given time and then washed with 40 mM HEPES containing 10 mM NiCl$_2$ (10Ni). To study the morphology of single chains, AFM observations for the sample incubated in 0.1 mg/mL DNA solution with 5 Ni for 2 min were carried out. A single chain of DNA adsorbed on a mica surface was clearly captured. It took a two-dimensional (2D) extended coil conformation. The radius of gyration estimated from the AFM image, defined as $R_{g,2D}$, was approximately 630 nm. This value was twice larger than the corresponding value in a solution state determined by SAXS. For statistical analyses, the wide AFM images, containing two or three DNA chains, were acquired. The $R_{g,2D}$ and the persistence length evaluated by fast Fourier transform (FFT) analysis were 796 nm and 362 nm, respectively, meaning that DNA chains were more extended onto the mica surface than in the solution. This is
probably due to create greater contact points between DNA and mica surface. To discuss the adsorption processes of DNA chains, AFM observations for the samples incubated in a 0.1 mg/mL DNA solution with 5 Ni for 5 - 45 min were carried out. With increasing incubation time, the amount of adsorbed DNA chains increased. Interestingly, DNA chains were inhomogeneously adsorbed, although there were a lot of empty sites on the mica surface. To obtain a better understanding of this finding, we focused on the distance between adsorbed DNA chains. First, the AFM-FFT analysis was made for the sample incubated for 2 min. Since DNA chains were highly isolated for one another, the power spectrum as a function of spatial frequency ($L^{-1}$) so obtained corresponds to the form factor spectrum. Then, the structure factor spectra for the samples incubated for several hours were obtained from each FFT spectrum after dividing it by the form factor spectrum. In these spectra, a peak corresponding to the distance between adsorbed DNA chains was observed at $L^{-1}$ of approximately $6 \times 10^{-4}$ nm$^{-1}$, namely 1.5 μm, which was slightly smaller than twice $R_g$ described above. This peak position was not dependent on the incubation time. This result means that DNA chains were inhomogeneously adsorbed since the earlier stage of adsorption process. Also, entanglements between two DNA chains were clearly observed. Taking into account that the concentration of the solution here used was much lower than the overlapping concentration of DNA, the results indicate that the entanglements between precedingly adsorbed chains and free chains occurred on the mica substrate, called “cooperative adsorption”. In our presentation, effects of molecular weight of DNA and ionic strength of DNA solutions on the adsorption process will be also discussed.

**MS03.09.02**  
*Influence of Graft Density on Dynamically Coupled Polymer Grafted Nanocomposites*  
Andrew Ehlers¹, Pinar Akcora² and Rahmi Ozisik¹; ¹Rensselaer Polytechnic Institute, United States; ²Stevens Institute of Technology, United States

The viscoelastic behavior of polymer grafted nanocomposites (PGNs) with significantly different glass transition temperatures ($T_g$) between the graft and matrix polymers is investigated with molecular dynamics simulations. These types of PGNs have been shown to have reversible and repeatable stiffening behavior upon heating (Senses, E.; Isherwood, A.; Akcora, P. *ACS Appl. Mater. Interfaces* 2015, 7, 14682). This unique thermal stiffening behavior was attributed to the dynamic coupling of the high-$T_g$ adsorbed chains and low-$T_g$ matrix chains. The PGN studied in the current work consists of a nanoparticle with grafted high-$T_g$ polymer chains in a low $T_g$ polymer matrix. The effect of the dynamic coupling of the grafted and matrix polymer chains is studied by molecular dynamics simulations. The influence of the graft density on viscoelastic properties is investigated to identify the mechanism of the observed stiffening in these types of PGNs.

**MS03.09.03**  
*Water-Triggered Evaporation of Fragrance Oil from Porous Particles Coated with Hydrophilic Polymers*  
Hesson Chung¹, Young Sim Song² and Jeongae Lee¹; ¹KIST, Korea (the Republic of); ²Cleani Co., Korea (the Republic of)

Fragrance oils were encapsulated in a variety of porous particles by preparing emulsion of fragrance oil/hydrophilic polymer and by kneading the emulsion with porous particles. Depending on the hydrophilic polymers, the evaporation rate was slowed down and was controlled by the addition of water. Corn starch, polyvinylalcohol, chitosan, carboxymethyl cellulose were effective because the evaporation rate of fragrance oil was low (lower than 20 %) in air and was high (higher than 80%) in water when the particles were stored at room temperature for 2 hours. The evaporation rate was similar in air and in water in case of sodium alginate, xanthan gum and carboxpol. Among the porous particles including activated carbon, powdered charcoal, zeolite, porous silica and magnesium aluminum metasilicate, powdered charcoal had the lowest evaporation rate of fragrance oils. However, the water-triggered evaporation was not observed since fragrance oil did not evaporate even in the presence of water. Choice of fragrance oils was also important in controlling the evaporation rate. In air, more than 50 % of limonene, citronella and peppermint oils evaporated when the particles were stored at room temperature for 2 hours. Only less than 20 % of lavender, tea tree and ylang-ylang oils were evaporated under the same experimental condition. When water was added to the magnesium aluminum metasilicate particles containing corn starch, 80 % of the lavender oil evaporated in 2 hours while 50 % was evaporate in 24 hours in air. The water absorbent particles retained absorbent power after the emulsion containing the fragrance oil and hydrophilic polymer. The prepared particles were mixed with superabsorbent polymers to be used in manufacturing the pet pads. The particles and the superabsorbent polymers had different densities and therefore had to be shaken from time to time to ensure the mixing.
Water-absorbent particles such as Syloids and Neusilins were effective in controlling the water-triggered evaporation of fragrance oils because the particles deprive water from the hydrophilic polymers and help form the outer protective polymer layer. When the particles were used with the superabsorbent polymers the urine odor was eliminated by absorbing the chemicals in the urine, by odor-masking of the evaporated fragrance oil, and by the antimicrobial activity of the fragrance oil.

**Hybrid Heat-Hydration Triple Shape Memory in Electrospun Polymer Blends** Emily Sharp, Michelle Pham, Melodie Lawton and Patrick T. Mather; Bucknell University, United States

Contemporary research based on electrospinning fabrication has continued to grow as this technique has proven to be an efficient and highly reproducible method for nanofiber production. Electrospinning is the process of forming nanofibers from viscous polymer solutions exposed to electrostatic forces that drive continuous jet formation as solvent is removed and the jet is stretched. The use of dual-electrospinning, involving a two-solution delivery system, in reducing fabrication time and fabricating composite fibrous mats has continued the advancement of electrospinning-based research. This study aims to utilize such advancements to demonstrate triple shape memory via two distinct stimuli that is possible in dual-electrospun poly(vinyl acetate) (PVAc) and poly(ε-caprolactone) (PCL) films.

The term shape memory (SM) refers to the ability of a material to form and recover from a secondary shape to its permanent shape through the application of an external stimuli. We have reported that isotropic PVAc:PCL blends prepared by electrospinning exhibit dual and triple SM, meaning that they can form two distinct temporary shapes. Hydration of the composite films was found to reduce the PVAc glass transition to a subambient level as water molecules disrupt intramolecular bonding and mobilize the network chains. This reduction produces a rubbery material that has a well-separated glass transition temperature (of PVAc) and melt temperature (of PCL), thus allowing this material to exhibit triple SM using two different external stimuli: heat and water.

We report on hybrid shape memory behavior involving both heat and mass transport for PVAc/PCL blends. Heating blends above the melting point of PCL, deforming the sample, and cooling will result in one temporary shape. Deforming the sample again in a water bath, followed by drying, forms a second temporary shape. Rehydration of the composite returns the sample to the first temporary shape and reheating the sample returns it to the original shape. Variables considered include the concentration of PCL, the overall sample geometry and thickness, and the extent of the shapes formed. This hybrid SM is quantified using a Dynamic Mechanical Analyzer (DMA) in conjunction with uniaxial tensile testing with a water immersion bath to separately quantify the SM response to heat and the response to water, respectively. Qualitative analysis is performed through image processing with visual confirmation through video documentation. This provides valuable information on a hybrid process of two well-defined and well understood phenomena, aiding in future research and product concepts that have the potential to revolutionize multiple different fields ranging from textiles to medicine.

**Melt Extrusion of Novel Nanocomposites with Thermal Stiffening Behavior** Chen Gong1,1, Pinar Akcora2 and Rahmi Ozisik1,1; 1Rensselaer Polytechnic Institute, United States; 2Stevens Institute of Technology, United States

A class of polymer-absorbed silica nanoparticle reinforced polymer nanocomposites were found to have a peculiar thermal stiffening response with increasing temperature that not only provides a new method to manipulate mechanical properties as a function of temperature but also offers the opportunity to develop new products based on thermal stiffening. The next step towards mass production requires testing these new class of materials’ processability via traditional polymer processing techniques such as extrusion. In the current work, a laboratory mixing extruder was used to evaluate the processability and the effect of processing conditions on thermal stiffening behavior. Polymers with different rigidities were absorbed on to silica nanoparticles before they were dispersed in a poly(ethylene oxide), PEO, matrix. Then these nanocomposites were melt extruded under various extrusion conditions. The resultant extrudates were characterized using Fourier-transform infrared spectroscopy (FTIR) and electron microscopy. Thermal stiffening behavior of the extrudates was characterized using a parallel plate rheometer. Systems with highly rigid adsorbed polymers, the storage modulus values dropped drastically after extrusion. Systems with less rigid adsorbed polymers recovered and even experienced a slight reinforcement in storage modulus after extrusion. The current work probes the processability of a novel nanocomposite system and also provides new insights towards its dynamics under complex deformation conditions.
Damage-Free and Selective Transfer of Ultra-Thin Films by Solvent-Assisted Adhesion Control

Sumin Kang, Boo Soo Ma, Taeshik Yoon, Min Sun Cho and Taek-Soo Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Interfacial adhesion has been regarded as a key factor for mechanical peeling and transfer of ultra-thin films which are necessary to fabricate next-generation electronics. Ultra-thin films have strong adhesion because their extreme flexibility enables conformal contact to the topography of a substrate. Whereas, strong interfacial adhesion between a film and a substrate causes both structural damage to the film during delamination process and difficulty of interfacial crack initiation. To reduce adhesion energy and structural damage, solvent assisted transfer methods have been developed by using water and ethanol recently. However, quantitative control of adhesion and its application to damage-free, selective transfer have not been demonstrated yet.

In this work, we show damage-free and selective transfer of ultra-thin films by solvent-assisted interfacial adhesion control. Double cantilever beam fracture testing is performed in various solvent environments including water, ethanol, diiodomethane to measure quantitative adhesion energy of graphene-Cu and Au-Si interfaces. Moreover, two-component surface energy analysis and Owen-Wendt method are exploited to calculate work of adhesion, which is required energy to separate an interface and create new surfaces. Various solvents introduce dramatic change of the interfacial adhesion energy owing to the surface energy difference in the crack-tip environments, and the variation is corresponded to the calculated work of adhesion. Accordingly, the interfacial adhesion can be controlled by modulating surface energy of solvents, and it can be estimated by work of adhesion.

Solvent-assisted adhesion control enables structural damage-free and selective transfer of ultra-thin films. Degree of structural damage in transferred graphene and Au nanofilm is investigated by Raman area mapping and optical images. The solvent environments allow effective mitigation of structural damage in the transferred films by reducing interfacial adhesion energy, and the transferred graphene electrodes with less damage have outstanding mechanical reliability due to uniform stress distribution. Furthermore, novel method for selective transfer of patterned thin films is developed by modulating wettability of thin films and utilizing surface tension of a solvent. Diverse patterns of Au nanofilm such as serpentine electrodes, thin film spiral inductors, and characters are achieved, and the patterned thin films are transferred onto a flexible substrate. We expect that this study will provide an advanced transfer technology to integrate a patterned ultra-thin film without damage onto an arbitrary substrate.

Developing Advanced Manufactured Composite Polymer Filaments for Extreme Environments

Zachary Brounstein1,2, Jianchao Zhao1, Joseph H. Dumont1, Samantha J. Talley1, Eamonn C. Murphy1, Kwan-Soo Lee1 and Andrea Labouriau1; 1Los Alamos National Laboratory, United States; 2The University of New Mexico, United States

Extreme environments comprised of elevated temperatures, harsh chemical species such as acids and bases, mechanical stresses, and ionizing radiation are of serious concern in every industry relying on materials retaining their inherent properties throughout their lifetime. Furthermore, some industries or uses require these materials to protect its workers and instrumentation from such aggressive conditions. In the current aerospace, defense, and nuclear industries, commercial products are readily used as protective barriers, but there are circumstances when these are less than ideal at providing optimal shielding against extreme conditions, especially neutrons and gamma rays[1][2]. In addition, these non-optimized materials may not possess desired properties such as ideal topology and geometry and thus mechanical behavior. As innovations to aerospace, defense, and nuclear technologies continue to progress, developing new engineered materials and composites for extreme environments grows in importance and need.

In the present work, we used an advanced manufacturing (AM) technique known as Fused Filament Fabrication (FFF) to create novel feedstock composite materials for 3D printing. FFF is a layered AM process whereby thermoplastic filaments are heated up to their melting point and extruded into cross-sections of the end product[3][4]. Because FFF has the capability to create prototypes and end-use parts with fine resolution details and excellent strength-to-weight ratios, the technology is ubiquitous across many enterprises requiring enhanced manufacturability and unique features.

Difficulties in creating composite filaments for FFF arise from fabricating a homogenous wire that has uniform thickness and a smooth surface. If a filament does not have these initial properties, then either the FFF process will
not work or the end product will not be as desired. Creating a homogenous wire proves more difficult when different base and filler materials are used in the fabrication process, however, this can be solved if the organic materials are solvated in a liquid solution and then mixed with the inorganic phase. Creating a wire of uniform thickness relies heavily on the extrusion process, whereby the temperature and extrusion speed are controlled.

In this study, we have prepared homogenous composite filaments for AM from a variety of polymer bases and incorporated a high weight percent loading of metal fillers. Thermal, mechanical, chemical, and radiative properties were evaluated to determine the efficacy of this process of creating AM feedstock material for FFF technologies.

**Electrospun Nanofibrous Bilayer Fabrication Technique Based on Electrolyte-Assisted Electrical Discharge**

Hyeonseok Han¹, Sang Min Park¹,², Hyeonjun Hong¹ and Dong Sung Kim¹; ¹POSTECH, Korea (the Republic of); ²Pusan National University, Korea (the Republic of)

Due to the advantages of electrospinning process including facility, versatility, cost-efficiency, it has been widely used to fabricate a polymeric nanofiber mat in the engineering field. Especially, a wide range of material selectivity, high surface area to volume ratio and porosity of electrospun nanofibers have contributed to remarkable developments in tissue engineering by recapitulating the hierarchical architecture of the extracellular matrix (ECM).

Significant development of electrospun nanofibrous scaffold in tissue engineering has been associated with the alignment of electrospun nanofiber with respect to topographical effects on cellular activity of cell proliferation, migration, and differentiation. More specifically, the aligned nanofiber mat has been demonstrated to promote the regeneration or repair of various in vivo tissues (e.g. skin, cardiac muscle, and peripheral nerve) and to be used for medical applications.

To produce aligned nanofibers, a number of approaches including electric field-controlled technique (e.g. parallel ground electrodes) and mechanical technique (e.g. high speed rotation of mandrel) have been proposed previously. Among them, the electric field-controlled method can easily produce an aligned nanofiber mat without an additional motion control system of the mechanical method. Moreover, diverse configuration of the alignment, like uniaxial and radial alignments, could be achieved by arranging the ground electrodes. However, the aligned nanofiber mat fabricated by the electric field-controlled method is too mechanically weak to handle. In addition, the charge retention of as-spun nanofibers, which cause unstable electric field and repulsive force near the aligned nanofiber mat, impedes the fabrication of thick aligned nanofiber mat in the process. In order to resolve the limitations of mechanical weaknesses, electrospun nanofibrous bilayer which is composed of the aligned nanofiber layer (functional layer) and the random nanofiber layer (supporting layer) was introduced in previous studies. Though several methods such as transfer method and charge retention-based method have been suggested to generate the electrospun nanofibrous bilayer, the disadvantages (e.g. additional transferring process, misalignment, time-consuming, non-uniformity etc) of each method have not been improved.

In this study, overcoming the aforementioned disadvantages, we have developed a novel electrospinning process for the fabrication of electrospun nanofibrous bilayer based on electrolyte-assisted electrical discharge. Interestingly, the newly suggested electrospinning process enabled in situ fabrication of aligned and random nanofiber multilayer (e.g. triple, quadruple layer) by sequentially changing ground electrode from arranged metal electrodes to electrolyte with a simple liquid filling system and without additional transferring process to induce misalignment of the nanofiber. The adoption of the electrolyte was found to provide a stable electric field by an electrical discharge from the deposited nanofibers and allowed the focused electric field on upper surface area of electrolyte. Consequently, the fabrication time was reduced by 2.5 times compared to conventional method. In addition, more homogeneous
morphology of the deposited nanofibers was shown. The improved elastic modulus of 4.5 MPa due to the compactly deposited random nanofiber layer demonstrated the sufficient mechanical properties for handling compared with the elastic modulus of 2 MPa of conventional method. To examine its possible utilization in the field of regenerative medicine, biological \textit{in vitro} wound healing assay was proceeded with NIH3T3 fibroblasts. The accelerated fibroblasts on the aligned nanofibers suggest the potential of the electrospun nanofibrous bilayer as a wound healing patch and indicated the wound closed faster than the control.

An Investigation on Finding an Optimal Pore Structure in Porous Materials Using Finite Element Simulation

Dongmyung Jung and Yongwoo Kwon; Hongik University, Korea (the Republic of)

Effective properties of a porous material comprising solid and pore phases can be varied between upper and lower bounds at a given porosity by varying its pore structure. However, achieving low thermal conductivity and high Young’s modulus at the same time is difficult because there is a trade-off. Nevertheless, there must be an optimal pore structure. In this work, we try to find the optimal structure for a porous metal using finite element simulation. Relations between structural parameters and properties are characterized for several pore structures with porosity of 50%. The structural parameters are local curvatures of interfaces (morphology) and Euler characteristics (topology). Then, some rules will be extracted and applied to design an optimal structure.

**MS03.09.10**

Molecular Dynamics Simulations of Thermal Nanoimprint Lithography for Polymeric Materials

Jahlani I. Odujole and Salil Desai; North Carolina A&T State University, United States

Nanoimprint lithography (NIL) is a low-cost, high-throughput method used to manufacture products at the nanoscale. The benefits of nanoscale research are the improved physical characteristics of materials at smaller scales. Two of the most prominent methods of NIL are thermal (T-NIL) and UV. In general, T-NIL processes utilize a pre-fabricated rigid mold to imprint a pattern onto a substrate coated with a thermoplastic resist. This research focuses on the molecular dynamics (MD) simulations of T-NIL for four candidate polymers as resist materials: poly methyl methacrylate (PMMA), polyacrylic acid (PAA), polyethylene terephthalate (PET), and polycryliconitrile (PAN). This is a novel method that considers more than two polymers as possible resists. In order to make inferences about the effect of temperature, force, and pressure on the quality of T-NIL results, the polymers are operated upon using MD. The specific force field applied to this system is a modified version of the consistent valence force field (cvff). It is shown that PMMA yields the most consistent imprints given a certain set of simulation parameters. The simulation parameters were modified to produce changes in: penetration depth, imprint depth, and recovery behavior. The ability to manipulate multiple polymer materials for T-NIL processes is demonstrated by this research.

Amplified Photo-Actuation Performance in Azobenzene Incorporated Heterogeneous Polymer Network via Sequential Thiol-ene Reactions and Isomer Self-Interconnection

Chenzhe Li, Hyunsu Kim and M. Cho; Seoul National University, Korea (the Republic of)

Photo-actuation is of great interest because the light stimuli are capable of transferring remote controlling signals and high energy density power supply spontaneously with great spatial selectivity. Azobenzene, as one of the molecular scale photo-strain generator, offers direct light-mechanical responses with high energy conversion efficiency and fast responding kinetics. The direct utilization of this molecular-level photo-strain phenomenon is challenging. Conventionally, azobenzene monomers are homogeneously copolymerized with other host materials (such as liquid crystalline polymers), therefore by disturbing the local polymer network structure, the molecular-level photo-generated strain could be translated to mechanically applicable macro-scale actuation. While this strategy offers great optical efficiency, material selection feasibility and programmability, the translation of the molecular-level strain to mechanically applicable macro-scale is inefficient. In this study, we describe a versatile heterogeneous polymer fabrication strategy to achieve significant enhancement in the translation process, resulting in amplified the photo-actuation responses in azobenzene incorporated polymers. The strategy employs a facial two-step polymerization process based on the sequential orthogonal thiol-ene Michael addition (thiol-acryloyl) and free-radical (thiol-allyl) reactions. In the first step, a combination of di-acryloyl and AB-type allyl/acryloyl functionalized azobenzene moieties undergo thiol-acryloyl addition reaction in the presence...
of the catalyst. This step offers accurate size control of azobenzene interconnected oligomers with a wide molecular weight range (from 2,300 to 23,000 Da). In the second step, free radical polymerization was carried out for the embedment of the azobenzene oligomers with the host polymer matrix, which provides free-standing actuators with heterogeneous polymer networks. Because of the great chemoselectivity between thiol-acryloyl and thiol-ene reactions, one-pot synthesis scheme is implemented. To better understand the contribution of isomer interconnectivity for photo-actuation performances, free-standing polymer films with different azobenzene interconnectivity (2,300, 5,000, 7,000, 9,000 and 23,000 Da) are tested under various working conditions (irradiation parameters, external loadings, and strains). The power output limits are also measured and fairly compared with the homogenous cases. Results of our study show significant photo-actuation performance enhancement in the isomer-interconnected heterogeneous network comparing to the homogenous cases. In extreme cases (23,000 Da), the maximum power output performances enhancement is up to 500%. Studies within different azobenzene interconnectivity also suggest that the increase of the interconnectivity of isomer significantly benefit the photo-actuation performances. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIP) (No. 2012R1A3A2048841).

MS03.09.12
Toughening in Epoxy Nanocomposites by Nanoparticle Debonding and Cavitation Mithil Kamble, Nikhil Koratkar and Catalin Picu; Rensselaer Poly Institute, United States

In this study we investigate a toughening mechanism in epoxy filled with silica based on nanoparticle debonding and subsequent cavitation. The fractographic analysis suggests that such processes take place in the crack tip region due to the high localized hydrostatic stress, and support enhanced dissipation and enhanced toughness. We study the toughening mechanism using models of composites with stochastic microstructure, aiming to identify the distribution of nanofillers which produces the largest toughness enhancement. To this end, we consider composite microstructures with spatial fluctuations of porosity/nanofiller concentration and of elastic moduli, and explore the design space defined by the amplitude and spatial correlations of these stochastic parameters. Based on this combination of experimental and modeling results, we develop design rules for nanocomposites with non-uniform distributions of fillers.

MS03.09.13
Mechanical Characterization and Impact Behavior of Single Polymer Composite Made through Hybrid Yarn Technology Ashraf N. Khan, Ramasamy Alagirusamy, Apurba Das and Puneet Mahajan; Indian Institute of Technology Delhi, India

With the advancement in the technology, Composite materials are picking up paramountcy in its expansive overall application from Automobile structural material to Aerospace application, from Household to Marine application and several others like biotechnology, and so forth. Everywhere composite materials are finding its place by superseding conventional materials like metal, ceramic, etc. Low weight and high specific mechanical property make a composite material attractive for developing high load bearing-bridge, bulletproof armor, and high energy efficient process, etc.

In the present work, Composites have been fabricated with the same matrix and reinforcement material (i.e single polymer composite) having different molecular mass and degree of crystallinity. Purpose of choosing the same reinforcement and matrix material is to enhance its interface strength by increasing fiber and matrix compatibility because the same material has high affinity to make strong bonding in comparison to a different material (that is an increase in adhesive/cohesive force). Here, Composite material is chosen which is completely recyclable which makes it environment-friendly.

In this work, the main objective is to optimize mechanical and impact property of different composite flat-panel prepared by using the same matrix and reinforced material. So, By changing the internal architecture of reinforced material through different geometrical weaving like uni-directional and bi-directional fabric reinforcement structure. For the comparison purpose, the composites are produced having the same fiber/volume fraction. Composite’s mechanical and impact behavior keeps on changing as the fiber alignment changes. Mechanical strength and modulus have been calculated through prescribed ASTM standard.

Due to the high viscosity of thermoplastic material, it is difficult to obtain a uniform flow of a matrix during production time throughout the composite which leads to low load transfer from a matrix to the reinforcement material. To sort out this problem, Composite preform is prepared in such a way that melt flown distance of matrix is reduced to very small(through Hybrid yarn technology) which lead to a uniform flow of the matrix material which
in turn gave excellent quality (High interlaminar/intralaminar strength) of a composite. Detailed study of the specimens has been done after mechanical and impact testing. Mechanical testing has been performed using DIC software (Digital image correlation) and mechanical strain gauge. CT (computed tomography) scan has been performed for a thorough analysis of damage to different composites occurred during testing. XRD (X-Ray Diffraction) analysis has been performed to study the crystal structure of fiber to check the temperature sensitiveness on a crystal structure. SEM (Scanning electron microscope) images of the cross-section of different composites have been taken to view the interface between fiber and matrix and quality of the composites. Numerical Simulation has been performed through ANSYS software to validate the experimental results.

MS03.09.14
Characterization of a Nanocomposite of Polyurethane Reinforced with Fiberglass Additivated with TiO2
Danilo B. Janes1, Ana Paula de Moura1, Amanda P. da Costa1, Luís F. dos Santos2, Romeu R. da Costa1, Silvio R. Teixeira3 and Márcia R. Aouada3; 1Federal University of Technology, Brazil; 2São Paulo State University, Brazil

The increase in the consumption of plastic materials is currently one of the major environmental concerns worldwide. To minimize this environmental impact generated by the plastics has been developing polymers from plant sources. Among these biodegradable polymers, the development of polyurethane (PU) using renewable raw material is growing every year, since PU is one of the most versatile polymers in the world today [1]. Despite the advantages that biodegradable plastics can bring to the environment it is necessary that these plastics have adequate durability in their final application especially when exposed in outdoor environments. For this, it is necessary to use stabilizing additives of UV light [2]. In this context, the objective of this work was to synthesize and evaluate the structural, morphological and mechanical properties of a nanocomposite of plant origin PU reinforced with fiberglass (FG) and additivated with Titanium Dioxide (TiO2) nanoparticles. For the nanocomposite formulations, the micronized rutile TiO2 was used, whose particles are in the range of 10 to 25 nm, which ensures that these micropigments reflect the UV rays without reflecting any visible light. The rutile form is considered the crystalline form more photo-stable, besides having a refractive index greater than the anatase [2]. The synthesis of PU/FG/TiO2 specimens was performed by adding 0, 5 and 10% of TiO2 and 50% of FG to a certain amount of polyol and disocyanate in the ratio 1:1 stirring until completely homogeneous. The mixture was then placed in molds which were placed for 48 hours in a pressure vessel. The characterization of the nanocomposite was done by Differential Scanning Calorimetry (DSC), Scanning Electron Microscopy (SEM) and Tensile Tests, which were performed followed the ASTM D3039/D3039M 14 standard [3]. DSC analyses showed that, regardless of the amount of nanocarga used, there was an increase in the melting temperatures of the TiO2 materials compared to PU containing only FG, indicating that the doped materials appeared to have a higher thermal resistance. SEM images showed that the PU/FG samples containing TiO2 presented a surface with small agglomerates of small spherical particles which is indicative of the presence of TiO2. According to tensile tests, the TiO2 decreases the mechanical properties, like tensile strength and ultimate strain, of the composite.

MS03.09.15
Highly Stretchable, Self-Healable Radiation Shielding Hydrogel Composites Jinwoo Park and Jeong-Yun Sun; Seoul National University, Korea (the Republic of)

Radiation poisoning causes serious problems such as sterility, leukemia and death. Recently, radiation shield research has been in great need to prevent the danger of radiation exposure danger in various fields such space engineering, nuclear generation, and environmental engineering. Radiation shield is typically composed of metals, such as lead, tungsten, and tin which are high atomic numbers and densities to block the transmission rate of radiation. However, such heavy metals are too heavy, rigid and bulky to be used commercially. In this study, we fabricated a highly stretchable hydrogel shield which was fabricated from acrylamide polymer with PbO2 metal particles and crosslinked by clay. By utilizing metal nanoparticles and incorporating them into
hydrogels, the hydrogel nanocomposite exhibit attenuation coefficient (0.1343 cm\(^{-1}\)) and was stretched to 1400%. Furthermore, because hydrogel composite is physically crosslinked by clay, it has a self-healing property with a maximum self-healing efficiency value of 96.55% at 55°C for 2 hours. However, self-healing efficiency tended to decrease at high radiation dose. Accordingly, XRD, rheometer, GPC were used to investigate these tendency.

MS03.09.16
Mechanoactive Camouflage Systems with Main-Chain Chiral Liquid Crystalline Elastomers
Se-Um Kim, Young-Joo Lee, Dae Seok Kim, Rui Yin, Jiaqi Liu, Randall Kamien and Shu Yang; University of Pennsylvania, United States

Inspired by a variety of camouflage mechanisms in nature, much effort has been made to develop rapid and reversible color changing systems for smart windows, displays, sensors and biomimetic devices. However, current technologies largely depend on modulating the periodicity of photonic structures, thereby the degree of deformation, the magnitude of the spectrum shift, and the color-tuning range are innately restricted. Here we demonstrate a novel type of main-chain chiral liquid crystalline elastomers (MCLCEs) that exhibit outstanding color changing capabilities under mechanical strain. When subjected to a tensile strain perpendicular to the helical axis, MCLCEs contract along the helical axis with a Poisson's ratio greater than 1, causing the Bragg wavelength significantly moves across infrared, visible, and UV spectra. A camouflage system is assembled using an array of patterned MCLCE films that can be actuated by pneumatic inflation. This device applies a bi-axial transverse strain to lead a highly efficient change of structural colors in accordance with the background pattern. Our research will provide new insights for designing smart windows and camouflage systems based on CLCEs.

MS03.09.17
Finding the Ultimate Shape of Adhesive Fibril by Using Machine Learning Techniques
Yongtae Kim\(^1\), Youngsoo Kim\(^1\), Charles Yang\(^2\), Grace Gu\(^2\) and Seunghwa Ryu\(^1\); \(^1\)Korea Advanced Institute of Science and Technology, Korea (the Republic of); \(^2\)University of California, Berkeley, United States

Over the last decade, a significant attention has been paid to design the adhesive fibril with excellent adhesive properties, by searching for the geometry which give rise to flattened stress distribution because the detachment initiates at a location with high stress concentration. However, the previously optimized fibril geometries were obtained from a limited design space, and the stress distributions were significantly dissimilar with the optimal flat stress distribution. In this study, we introduce the ultimate adhesive fibril shape covering extensive design space by using machine learning technique, kernel support vector machine (SVM) and random forest repressor (RFR). To explore the vast design space, first, we conducted numerical simulation to obtain the stress distribution with 200,000 different fibril shapes defined on the grid. Using the numerical results as a training set, we trained kernel SVM to classify and exclude the geometry with stress singularity at the edge of adhered interface. We then define a score function that represents the similarity with the optimal flat stress distribution, and adapted RFR to predict the score of a given geometry. After establishing the machine learning model, we combine the genetic algorithm and the greedy algorithm to search for the optimized adhesive fibril shape with vast design space. The optimization is repeated until it converges, and the optimized results are compared with the optimized adhesive-fibril in previous studies. Our study demonstrates that the stress distribution at the adhered interface is highly sensitive to the subtle change of the shape, and provides a new strategy of optimizing the adhesive fibril geometry.

MS03.09.18
Dissipative Particle Dynamics Simulation of Poly(Urethane-Urea)-Based Nanocomposites—Microstructure and Mechanical Properties
Yelena Sliozberg, Jeffrey Gair, Alex Hsieh and Asha Hall; Combat Capabilities Development Command Army Research Laboratory, United States

Hierarchical polymer composite materials are used in numerous applications that require high stiffness and high specific strength. Poly(urethane urea) polymers are high performance segmented polyurethanes and polyureas elastomers, particularly attractive as matrix materials because of their versatile properties and high tailorability achieved by tuning their microstructure. To further enhance the properties of PUUs, nano-scale fillers such as carbon nanotubes (CNT) are incorporated into PUUs, which form polymer nanocomposites (PNCs). The mechanical properties of these materials are controlled by their complex morphology caused by association of the hard segments (urea segments), which serve as physical cross-link sites due to the inter-chain joining that reinforce the soft matrix (urethane segments). Morphology of PNCs also depends on the nanofiller loading and orientation. Supplementary to
experimental efforts, modeling approach provides a powerful means to investigate a broad range of parameters, which is challenging to explore experimentally. We employed dissipative particle dynamics simulations to systematically study impact of chemical and compositional variables on structural and mechanical properties of PUU-based composites. The effect of soft to hard blocks ratio, chemistry and molecular weight as well as CNT concentration and orientation were studied. Our results demonstrated that inclusion of nanofillers is able to alter morphology of PNCs from mixed-phase to interface-mediated microphase separation states, which alter the mechanical response of these materials. Our simulation results are in agreement with recent experimental data.

**MS03.09.19**

**Influence of Composition and Uni/Biaxial Stretching on the Evolution of Structure and Dielectric Properties of PBT/PEI and PET/PEI Blends**

Zeynep Mutlu and Mukerrem Cakmak; Purdue University, United States

Capacitors are two terminal devices for energy storage. Polymers like polyethylene (PE), biaxially oriented polypropylene (BOPP), polystyrene (PS), polyethylene terephthalate (PET) are widely used in capacitor applications because of their good film forming properties such as low cost, high dielectric strength and low loss. State of art of polymeric dielectric films are biaxially oriented polypropylene with breakdown strength of 600-700 V/µm (for 10 µm thickness) and with dielectric constant of ~2.21,2. Various strategies have been used to increase the dielectric constant and the dielectric strength of polymeric dielectrics. One of them is to orient crystalline domains of polymers to make a torturous path, by applying mechanical deformation in semi-molten state. However, it is challenging to understand the polymer responses under deformation. One way to characterize the microstructural morphology is to measure the birefringence during deformation. By also looking WAXS and SAXS patterns these findings can be supported.

In this research, two different blends are investigated; PBT (polyethylene terephthalate/PEI (polyether imide) and PET/PEI. PBT and PET which are semi crystalline thermoplastic polymers, blended with different ratios of PEI which is an amorphous thermoplastic polymer with Tg ~220°C for high temperature applications. By doing so, processability of PBT also increased. It is found that up to 30/70 (PBT/PEI) blend can still crystallize on the other hand for PET/PEI above 30 % PEI the blend disappears. In the absence of orientation, the increase of PEI fraction leads to decrease of crystallizability as expected from the dilution effect that spatially prevents the crystallizable polymer chains from coming together. Blends with high PBT & PET amount can be stretched more and during stretching in blends, amorphous orientation takes place rapidly, followed by crystallization. Stress optical behavior which exhibits a multi stage behavior that depends on process conditions is also investigated3. At low stretching temperatures and high rates the stress optical behavior was found to start with an initial glassy photoelastic behavior.

**MS03.09.21**

**High Throughput Quantification of Plasticity and Failure in Pixelated Polymer Nanocomposite Thin Films**

Anesia D. Auguste¹, Allen B. Schantz¹, Andrew S. Gillman¹, Andrew Tibbits¹,², Phil Buskohl¹ and Richard A. Vaia¹; ¹Air Force Research Laboratory, United States; ²UES, Inc., United States

Nanoscale thin films with improved toughness, stiffness, and fracture resistance are crucial to numerous technologies, ranging from devices for human-machine interfaces to soft robotics, medicine, energy storage, and smart separation membranes. However, techniques that rapidly quantify the plasticity and failure mechanisms of these thin films, especially in relevant environments, are limited; and thus, hinder development of structure-composition-processing-performance relationships. In this work, we will discuss a high throughput concept to measure the elastic moduli, plasticity and failure strain of thin polymer and nanocomposite films. Building from the Wrinkling-Crack method, we design and additively manufacture compliant lattices to replace the traditional elastomeric support. The geometry of the lattice transduces macroscopic, uniform, in-plane deformation into a wide range of local deformation fields at each lattice cell via differing Poisson’s ratios. By placing a thin film on top of the lattice structure, each cell acts as a unique deformation stage, allowing simultaneous mapping of the yield and...
fracture envelope. Combining this with optical techniques, automated image processing, and pixelated films with varying composition, thickness, or process history, enables statistically robust analysis of many different parameters in parallel. The use of polystyrene and associated nanocomposite thin films facilitate the identification of opportunities and challenges for this concept.

**MS03.09.22**

Investigating Interlayer Bonding Strength of FDM 3D-Printed PEEK through Design of Experiment (DOE) and Three-Point Flexural Test  
Chya-Yan Liaw, Andrew House and Murat Guvendiren; New Jersey Institute of Technology, United States

Poly-Ether-Ether Ketone (PEEK) is a high-performance thermoplastic with excellent chemical resistance and mechanical performance under high-temperature and high-pressure environments. Therefore, PEEK has been commonly used in severe conditions such as aerospace, automotive, oil and gas field. In addition, PEEK has good biocompatibility and is easy to sterilize, which makes it become an important group of biomaterials for medical applications and a strong candidate as an alternative to replace metal and ceramic implants [1]. In recent years, FDM (fused deposition modeling) 3D printing has offered a new manufacturing technology which is able to fabricate complex and customized PEEK products that are either impossible or too expensive with conventional methods. Despite the widespread use of FDM technology, very few studies have investigated the effect of process parameters on the interlayer bonding of PEEK printed objects [2], where the interlayer bonding is a critical factor in order to create strong functional parts.

To address this problem, we adopted a DOE (Design of Experiment) approach to investigate printing parameters on the interlayer bonding using a three-point bending test and the crystallinity in the polymers. In this research, the aim is to identify significant main effects among four independent factors, including nozzle temperature, layer height, print speed, and layer time for the 3D printed PEEK. A $2^{4-1}$ design (resolution IV) was chosen which include fewer runs than a full factorial design but is efficient enough for identifying key factors. The samples were printed in an upright position, and were loaded in the weakest direction (layers are perpendicular to the tensile stress in the convex side of the specimen) in the three-point bending fixture. Flexure strength, modulus, and strain at break were evaluated.

The results show that the nozzle temperature is the most important factor which affects the flexure strength, strain at break and crystallinity of the PEEK part greatly, but has very little effect on modulus. The flexure modulus mainly depends on layer height. In addition, wait time and layer height had a significant effect on the flexure strength and crystallinity respectively. The examination of fracture surface through scanning electronic microscopy (SEM) shows different fracture types for specimens printed under different conditions. Overall, the combination of DOE and three-point bending test offers a systematic and efficient paradigm to investigate the effect of printing parameters on the interlayer strength of 3D printed PEEK.

**MS03.09.23**

A Multiscale Investigation of Polydopamine and Polytetrafluoroethylene Adhesion and Wear Mechanisms  
Mathew Brownell and Arun K. Nair; University of Arkansas, United States

Polydopamine (PDA) is used as a surface modifier for a wide variety of applications. Many experimental and computational studies have investigated the use of PDA and its adhesive properties, and it is believed that hydrogen bonding and van der Waals forces contribute to the adhesion of polydopamine. The application of PDA between a substrate and a surface coating has dramatically increased the wear resistance of thin film coatings, specifically polytetrafluoroethylene (PTFE). PTFE has been studied as a low friction surface coating since its discovery; using an intermediate layer of PDA between stainless steel and PTFE produces an incredible improvement in wear rate of the PTFE film. While experiments have shown that PTFE and PDA adhere quite strongly, the adhesive mechanisms between the two polymers remains relatively unknown. In this study we investigate the adhesive properties of PDA.
and PTFE via density functional theory and molecular dynamics. Various PDA oligomers are used to investigate the adhesive forces between PDA and PDA, and PDA and PTFE. Indentation and scratch tests are then performed on PDA/PTFE models and the deformation and wear mechanisms are studied between the interfaces. This study will elucidate the cause of tenacious adhesion between PDA and PTFE, as well as observe the influence of PDA molecules on the friction and mechanical properties of PTFE thin films.

**Investigation of Polytetrafluoroethylene Microscale Deformation Mechanisms** Mathew Brownell and Arun K. Nair; University of Arkansas, United States

Polytetrafluoroethylene (PTFE) has a low coefficient of friction but also a high wear rate. Numerous experimental and computational studies have investigated wear and the deformation mechanisms of PTFE films, however, severe limitations exists which prevent the modeling of PTFE on length scales which experimentalists are able to investigate. In this work, a coarse-grained model is developed to enable the computational modeling of PTFE particles at the microscale. The coarse-grained potential parameters are derived from first principle based ReaxFF force field simulations, while the PTFE particles are modeled after experimental observations. Indentation and scratch tests are performed using the newly developed coarse-grained models; it was found that the indentation force is dependent on the density of PTFE, and a smooth surface topography decreased the coefficient of friction of the particle. The development and use of the coarse-grained model of PTFE will enable numerical modeling of PTFE on length scales similar to experimental PTFE thin films, thus allowing for a deeper understanding of the deformation, wear, and failure mechanisms of microscale PTFE particles and films.

**Improved Viscoelastic Analysis of GY70/339 Composite Materials Using an Enhanced First-Order Shear Deformation Theory in Laplace Domain** Jang-Woo Han¹, Jun-Sik Kim² and M. Cho³; ¹Korea Institute of Industrial Technology, Korea (the Republic of); ²Kumoh National Institute of Technology, Korea (the Republic of); ³Seoul National University, Korea (the Republic of)

Recently, advanced composite structures have been widely used in various engineering applications due to their light-weight and high-stiffness characteristics. With increasing utilization of laminated composite structures, there are many theories developed to accurately predict their elastic responses, such as the well-known conventional theories (FSDT; first-order shear deformation theory) and many other refined shear deformation theories (EHOPT; efficient higher order plate theory, EFSDT; enhanced first-order shear deformation theory).

Meanwhile, composite structures have viscoelastic characteristics such as creep strain, stress relaxation and time-dependent failure because composite material is composed of elastic fibers and viscoelastic matrix. Thus, viscoelastic effects of the laminated composite structures should be considered for the reliable analysis. This brings us to develop a new type of enhanced first-order shear deformation theory (EFSDT) by employing the concepts of the strain energy relationship and Laplace transformation. This will allow us to analyze accurately the viscoelastic behavior of laminated composite plates under mechanical loading and to investigate viscoelastic effects such as creep strain and stress relaxation.

In this paper, viscoelastic finite element implementation based on the EFSDT will be performed, and the results of the present theory will be compared to those reported in the open literature. The process of strain energy transformation in Laplace domain and finite element formulation will be described in detail.

**MS03.09.26**

**Engineered ‘Organic-Inorganic’ Nanocomposites Properties through Embedding of Smaller Nanoparticles in a Thermoset Polymer Matrix: Structure and Property Characterization** Sanju Gupta and Alex Henson; Western Kentucky University, United States

Organic and inorganic nanoparticle reinforcements have garnered widespread attention for polymer nanocomposites to yield properties enhancement useful for wide ranging modern and future technologies including photovoltaics, catalysis, optics, and renewable energy. Recent experiments and computational simulations revealed the macroscopic properties are governed by mesoscale structure and interfacial layer dynamics due to the interactions between the polymer matrix (host) and nanoparticle reinforcements (guest). However, a clear fundamental understanding of the role of size, shape, loading (volume fraction) in controlling the structure and dynamics of
polymer-nanoparticle interfacial layer is limited. Moreover, ‘forward’ engineered polymer-nanoparticle composites often require higher volumetric density and better dispersions remains a challenging task. We report on developing polymer nanocomposites engineered to minimize dielectric losses and investigating structure and dynamics of interfacial layer to predict macroscale properties. The nanocomposites consist of poly(2-vinylpyridine) (P2VP) polymer matrix with (1) spherical silsesquioxane molecule clusters (~2-5 nm diameter) and silica nanoparticles (~10-20 nm diameter) and (2) planar nitrogenated graphene nanoribbons (~20 nm wide), having dimensions comparable to polymer matrix characteristic length i.e. gyration radius (Rg ~5 nm). This approach will enable improved nanocomposites properties due to enhanced interfacial interactions and identify key molecular parameters governing non-linear dielectric loss mechanisms while studying structure and dynamics using broadband dielectric spectroscopy and small-angle X-ray scattering. The transmission electron microscopy will reveal microscopic structure and the lattice bonding, interfacial stress transfer and conjugation length will be determined from micro-Raman spectroscopy. The exact loading and glass transition temperature, Tg, will be obtained using thermogravimetric analysis and differential scanning calorimetry, respectively. We will gain fundamental insights into the interfacial layer and diffusion dynamics above and below Tg and establish quantitative microscopic structure-property correlations, while predicting macro-scale properties. KY NSF EPSCoR and KY NASA EPSCoR subaward Grants.

MS03.09.27
A Ferroconcrete-Like All-Organic Nanocomposite Exhibiting Improved Mechanical Property and High Breakdown Strength
Zhenkang Dan and Yang Shen; Tsinghua University, China

Polymer based nanocomposites with excellent mechanical property and high energy density are crucial enablers for numerous applications in modern electronic and electrical industry. The energy density of parallel plate capacitors is determined by breakdown strength and dielectric permittivity of the inner dielectrics. Poly(vinylidene fluoride-trifluoroethylene-chlorofluoroethylene) (P(VDF-TrFE-CFE)), with the highest permittivity among all the dielectric polymers, is promising candidate for high energy density capacitors. However, its poor mechanical property and relatively low breakdown strength restrict the applications. In this work, we propose a novel method combining combinatorial-electrospinning and hot-pressing to fabricate P(VDF-TrFE-CFE) based all-organic dielectrics with ferroconcrete-like structure. In this structure, continuous fibers of polysulfone (PSF) with high Young's modulus act as tough scaffold to improve the mechanical properties of nanocomposites, and an over 750% enhancement of Young's modulus is obtained. The enhanced mechanical properties bring about significant improvement in Weibull breakdown strength to 485 MV/m, more than 50% higher than neat terpolymer. Besides, the suppressed leakage current and conduction loss thus improved discharge energy efficiency under moderate electric field are achieved due to the high insulation of PSF and interface regions restricting the mobility of space charges.

MS03.09.28
Mechanical Performance of Polymer-Derived Ceramic Nanocomposites
Patel Tulsi, Dayton Street, Lisa Rueschoff, Robert Wheeler, Joe Bowen, Michael Cinibulk and Matthew B. Dickerson; Air Force Research Laboratory, United States

Structural ceramics provide exceptional mechanical properties at elevated temperatures. The inherent drawback of ceramics is its brittle nature, which paves way for catastrophic failure and is therefore, undesired for practical applications. However, at the nanoscale, materials properties have the capability to be enhanced through careful control of structure and morphology. This talk will precisely focus on nanocomposites based on polymer-derived ceramic reinforcement with tailored architectures for improved mechanical strength. Various polymer/ceramic and ceramic/ceramic systems will be considered and its corresponding structural and mechanical properties will be discussed. Ultimately, these structure/processing/property relationships will provide key insight in the design and development of structural, aerospace components that experience extreme conditions, such as in hypersonic flight.
Supramolecular Engineering to Guide Biomolecules into Functional Hierarchical Biomaterials Alvaro Mata; Queen Mary University of London, United Kingdom

There is great interest to develop materials with properties that resemble those of biological systems such as hierarchical organization, high stiffness, and the capacity to grow or self-heal. While supramolecular chemistry offers an exciting opportunity to grow materials with nanoscale precision, the ability to transform molecular design into functional devices with enhanced utility at the macroscale remains a challenge.

To tackle this problem, our group is developing supramolecular fabrication tools that combine self-assembly with engineering principles to enable the design of materials with innovative properties. These approaches take advantage of phenomena such as the interplay between protein order and disorder, compartmentalization, diffusion-reaction processes, and host-guest interactions to guide assembly of multiple types of building blocks hierarchically and with molecular and supramolecular control. Some of these building blocks include ions, peptides, proteins, and other components such as graphene oxide.

The resulting materials exhibit properties such as hierarchical organization, the capacity to grow, tuneable mechanical properties, and anisotropic bioactivity and are being used for the regeneration of tissues such as enamel, bone, and blood vessels as well as the fabrication of more biologically relevant in vitro models.

Tissue-Like Hydrogels by Design Shaoting Lin and Xuanhe Zhao; Massachusetts Institute of Technology, United States

The majority of natural tissues in human body are elegantly structured to bear a range of functional loads in diverse conditions. Cartilage, ligament, tendon, and muscle, to name a few, possess a set of combinational mechanical properties, including high strength (~1 MPa), superior compliance (~100 kPa) and high toughness (~1000 J/m²), which are unmatched by their engineering counterparts (i.e., synthetic hydrogels). These unprecedented mechanical properties, particularly fatigue resistance, are highly desirable for emerging applications of synthetic hydrogels as diverse as tissue adhesives, gastro-retentive devices, hydrogel electronics, hydrogel robots, and optical fibers. The study of mechanics and design of tissue-like hydrogels are both scientifically interesting and technologically important.

This talk particularly focuses on one extreme property, i.e., fatigue resistance, which is rarely achieved in synthetic hydrogels. The reported fatigue threshold (i.e., the minimal fracture energy that crack does not propagate) for synthetic hydrogels is on the order of 1 to 100 J/m². We propose a general principle that introduction of high-energy nanostructures in hydrogels can substantially enhance their anti-fatigue-fracture properties by fracturing beyond amorphous chains. We demonstrate that the controlled introduction of crystalline domains (1) and/or aligned nanofibrils (2) can substantially enhance hydrogels’ fatigue threshold as high as 1000 J/m². We further show that the principle can be readily employed to achieve fatigue-resistant adhesion by bonding ordered nanocrystalline domains of synthetic hydrogels on engineering materials, which gives a world record high interfacial fatigue threshold of 800 J/m². The principle for achieving anti-fatigue-fracture properties in synthetic hydrogels can evoke a number of applications including ingestible gastro-retentive hydrogel devices (3), fatigue-resistant hydrogel coatings, and robust hydrogel robots (4).

**Bioinspired Routes to Damage Tolerant Materials—Unique Microstructure and Fracture Properties of Enamel in the Mammal-Like Grinding Dentition of the Hadrosaurid Dinosaur**

Sid Pathak, Brandon A. Krick, and Gregory M. Erickson; 1University of Nevada, Reno, United States; 2Lehigh University, United States; 3Florida State University, United States

The *enamel* of grazing animals represents one of Nature’s most remarkable biological materials — a ceramic-like composite showing exceptional strength, toughness, wear-resistance and controlled-crack propagation. In this work, we study these multi-functional, damage-tolerant biomaterial composites that preserve and ensure life-long reliability for survival (feeding). The goal of our interdisciplinary research is to understand the biomechanical form, function and performance of aprismatic wavy enamel present in hadrosauroid dinosaurs. We test the hypothesis that these wavy enamel structures in hadrosaurid dinosaurs served the same function as those of current grazing mammals through comparative fracture experimentation. Preservation of fracture properties in fossil enamels, many of which are not found in living animals, allows exploration of past form and function and provides a novel source for biomimetically inspired next-generation ceramics.

Hadrosaurid (duck-billed) dinosaurs are the only the only animals known that independently evolved a grinding dentition in the absence of prismatic enamel. Unlike mammals (such as grazing horses and bovids (mammals from cattle family)) hadrosaurids with grinding dentitions utilized undulating wavy enamel (= folded layers of parallel hydroxyapatite crystallites separated by thin layers of loosely aggregated inter-layer matrix), the most complex enamel known in any reptilian taxon.

Wavy enamel has a highly complex hierarchical internal structure and is a particularly challenging material to characterize mechanically, especially at the micron length scales where the mineral and voids once occupied by collagen components are closely intertwined and the available testing methods are limited. We utilized a suite of small scale testing techniques for this work, which involve (a) high throughput nanoindentation testing, to more-specialized FIB-fabricated (b) micro-pillar compression, and (c) micro-tensile loading scenarios. The mechanical data obtained from these tests is correlated with the structure information at complementary length scales using techniques such as BSE-SEM and Raman Spectroscopy.

Our indentation results show that the trends of both the elastic (indentation modulus) and plastic (yield strength) properties are highly complementary to each other and closely reflect the 2D optical profilometry map of the harder and softer enamel tissue layers. The structure-property maps reflect the unique morphology of the wavy enamel layering, where the periodic variations in properties between the layers, combined with the enamel layer undulations, is postulated to promote the remarkable fracture resistance, localized damage and strategically controlled crack directionality of this structure. More-specialized micro-pillar compression testing of the wavy enamel tissue shows clear differences between the fracture behavior under compression of the harder (higher compressive yield and fracture strength) vs. softer tissue layers in hadrosaurid wavy enamel. Intriguingly, the harder tissue layers show initiation of multiple cracks before fracture, suggesting another level of hierarchy where this layer could be composed of weaker interfaces and subsequent sub-layers.

Such insights are crucial for effective approaches to bio-mimetic designs originating from the wavy enamel structure. We utilize the knowledge gained from this work to incorporate the undulating architecture of the hadrosaurid wavy enamel on to a Cu-TiN multilayered nanolaminate structure, synthesized using physical vapor deposition techniques. Our initial results show that, similar to the enamel layer undulations in hadrosaurids, the addition of the waviness to the layering of the metal-ceramic multilayer is instrumental in undulating the crack propagation, thus robbing the crack tip of the required strain energy and controlling its propagation through the laminate.

**Characterization of a Cartilage-Like Hydrogel-Nanofiber Composite**

Jacob M. Ludwick and Michelle L. Oyen; East Carolina University, United States

Articular cartilage plays an important role in synovial joint function, but this function is diminished when cartilage breaks down in osteoarthritis. Tissue engineering is a promising approach for replacing failed cartilage, which has no blood supply or intrinsic capacity to heal. Here, a biomimetic composite scaffold is developed, composed of a
composite poly (vinyl alcohol) (PVA) and poly (acrylic acid) (PAA) hydrogel, reinforced with gelatin nanofibers. The PVA-PAA hydrogel is cross-linked by repeated freeze-thaw cycles and contains pH-activated charges, which increases the compressive stiffness of the hydrogel. The gelatin nanofibers provide reinforcement against tensile loads, mimicking the function of collagen fibrils in cartilage. Mechanical characterization of the novel composite includes indentation tests, tensile tests and trouser tear fracture tests to measure stiffness, time-dependent behavior, strength and toughness of the composite. Properties approach those of natural cartilage and exceed values obtained for single component hydrogels. By combining biomimicry and composite engineering practices, a better solution for osteoarthritis can be developed.

Modelling Self-Healing Behaviour in Biological Materials and Bioinspired Composites Federico Bosia¹, Gianluca Costagliola¹ and Nicola M. Pugno²³⁴; ¹University of Torino, Italy; ²University of Trento, Italy; ³Queen Mary University London, United Kingdom; ⁴Ket Lab, Edoardo Amaldi Foundation, Italy

Self-healing is a characteristic property of many biological materials, leading to enhanced mechanical strength and toughness. Various efforts have been devoted to emulating this property in composite materials for applications in structural engineering. Modelling approaches are essential for this goal, helping to understand how failure processes and global mechanical properties can be modified by self-healing processes and their parameters. We present various approaches developed recently using lattice spring or random fuse models with the addition of self-healing characteristics. We highlight how these influence the scaling of mechanical properties of the corresponding composites, identifying some characteristic signatures from a statistical mechanics point of view, focusing on observables like avalanche distributions, maximum strength and crack roughness. We show how some of these observables can be exploited as indicators of imminent failure and discuss the influence of self-healing parameters on the time evolution of damage in composites, e.g. in determining a transition from a more ductile to a more brittle fracture.

Negative Poisson’s Ratio of a Natural Nanocomposite Discovered by In Situ TEM Mechanical Testing Jin-Kyung Kim¹, Jinsol Seo¹, Jiwon Jeong¹, Jeehun Jeong¹, Zhen Wang¹, Yue Liu², Huajian Gao² and Sang Ho Oh¹; ¹Sungkyunkwan University, Korea (the Republic of); ²Brown University, United States

The teeth of limpets are reported to be the strongest natural material, with tensile strength values ranging from 3 to 6.5 GPa. However, the origin of ultrahigh strength of limpet teeth is still unknown. Limpets use conveyor belt-like radula to scrape rocks and extract algae during feeding. These processes require extremely strong teeth. Limpet teeth show characteristic composite nanostructures consisting of high volume fraction of reinforcing goethite crystals and softer amorphous hydrated silica matrix. The volume fraction and morphology of goethite crystals are heterogeneous at different locations of the tooth, which leads to site-specifically heterogeneous mechanical properties. The present work reports on the relationship between microstructures and deformation mechanisms of limpet teeth, using transmission electron microscopy (TEM) and in-situ TEM deformation. At the leading part of a limpet tooth, goethite crystals are mainly aligned along the principal direction of a tooth. The goethite crystals are rod-shaped, with approximately 30 nm in diameter and 300 nm in length. The volume fraction of the goethite crystals is approximately 50 %. TEM characterization of a longitudinal section at the tip of a limpet tooth shows both normally and laterally aligned goethite crystals, with some clusters of the normally aligned crystals. In addition, transition areas at the interfaces between goethite crystals and amorphous matrix are frequently observed. Atomic scale scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) analyses show that the transition areas have different atomic structures and chemical composition from the original goethite crystals. The trailing part of a limpet tooth shows larger goethite crystals, with lower volume fraction than the leading part. To understand deformation behavior of limpet teeth, in-situ TEM deformation experiments were conducted using the samples taken from the tip of a limpet tooth. Upon tension, the sample shows both positive tensile and transverse strain, which indicates negative Poisson’s’s ratio. Through a digital image correlation (DIC) analysis, the rotation of laterally-aligned goethite crystals appears to result in the observed negative Poisson’s ratio. Inspired by the observation on its structure and deformation pattern, we constructed a conceptual finite element model to mimic its behavior, which can be extended into the framework of micropolar elasticity. When the sample fractures, a crack propagates very fast right after its initiation. The ultrahigh strength of limpet teeth is expected to
delay initiation of cracks. The present work will discuss the relationship among microstructures, deformation/fracture behavior and mechanical properties of limpet teeth. This could provide an insight into design of bioinspired engineering composite materials with superior strength and toughness.

The Leonardo da Vinci's Legacy, 500 Years After His Death  Nicola M. Pugno; University of Trento, Italy

The Italian artist, inventor and scientist Leonardo da Vinci (1452–1519) can probably be considered the father of bio-inspired mechanical design, as illustrated by his artificial wings and flying machines, based on bird observation and dissection. Today, 500 years from his death, bioinspiration is attracting widespread attention worldwide, both in academia and industry. This lecture provides a short overview of my group's research activity at the University of Trento, Italy, in line with the Leonardo's legacy on bio-inspired nanomechanics, including nano (i) and bio-inspired materials (ii), as well as their natural evolution towards what we have defined as "bionocomposites" (iii).

11:15 AM MS03.10.08
Bio-Inspired Polymeric Heart Valves Exhibiting Valve-Like Mechanical and Hemodynamic Behavior Xing Zhang1,2, Feng Guo1,2, Rizheng Han1,2 and Yun Bai1,2; 1Institute of Metal Research, Chinese Academy of Sciences, China; 2University of Science and Technology of China, China

Heart valve disease with major symptoms of stenosis and regurgitation is prevalent worldwide. Surgical replacement of diseased heart valves at the end-stages has been widely performed with mechanical valves (MVs) or bioprosthetic heart valves (BHVs). All these current devices have significant limitations with risks of further morbidity and mortality. For example, MVs may cause hemorrhage and thromboembolism, and require anticoagulation for the lifetime of the patients. BHVs show better hemodynamic behavior due to the composition and structural similarity to native heart valves when compared to MVs, however, they do show limited durability because of calcification and progressive degeneration [1]. Thus, polymeric heart valve (PHV) prostheses combining the advantages of MVs and BHVs with long-term durability and no necessity for permanent anticoagulation are of great interest and also show potential applications in advanced transcatheter devices.

In this study, two types of silk fibroin (SF) fiber membranes with anisotropic (ASF) and isotropic (ISF) properties were prepared by electrospinning methods, and were further combined with poly(ethylene glycol) diacrylate (PEGDA) hydrogels to serve as polymeric heart valve (PHV) substitutes (PEGDA-ASF and PEGDA-ISF). The uniaxial tensile tests showed obvious anisotropy of PEGDA-ASF composites with elastic moduli of 10.95 ± 1.09 MPa and 3.55 ± 0.32 MPa, respectively, along the direction parallel and perpendicular to the fiber alignment, close to those of native aortic valve leaflets, while PEGDA-ISF processed isotropic property with elastic moduli of 4.54 ± 0.43 MPa. These novel PHVs consisted of polymeric fibers to mimic the fibrous networks in the fibrosa and ventricularis layers for stress bearing, as well as PEGDA hydrogels to improve anti-fouling function [2,3]. Furthermore, the presence of PEGDA hydrogels in the composites improved the resistance to progressive calcification of the embedded fibers in vitro, likely due to prevention of large-size hydrated ions to pass through by the polymeric networks of the hydrogels [3]. The non-fouling PEGDA hydrogels encapsulated the surfaces of the composites and prevented contact between platelets and the underlying fibers [4]. Pulse duplicator tests presented good hydrodynamic characteristics of these PHVs from PEGDA-ASF and PEGDA-ISF composites according to the ISO 5840-3 standard. Finite element analysis (FEA) revealed the PEGD-ISF valve with anisotropic property showed a lower peak maximum principle stress value (2.20 MPa) in commissures during diastole compared to that from the isotropic PEGD-ISF valve (2.37 MPa). In systole, the bending area of the PEGDA-ISF valve was close to free edges, however, which appeared in the belly portion and near the attachment line for the PEGDA-ASF valve. Hence, our results revealed that anisotropic properties played important roles not only in mechanical properties, but also in hydrodynamic performance of these artificial PHVs. These novel PHVs with good biocompatibility and hemodynamic property can likely be used for heart valve replacement in future.

Biomimetic Boron Nitride/Gelatin Artificial Nacre for Biomedical Applications
Sung Chan Yoo, Joon Hui Kim, Ho Jin Ryu and Soon Hyung Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Atomic thin hexagonal boron nitride (h-BN) nanosheet (BNNS), a structural analogue of graphene, has received great attention due to its remarkable properties, which includes which include superior mechanical, thermal conducting and electrical insulating properties, high surface area, excellent chemical stability, high oxidation resistance, and potential biocompatibility.

Regardless of the development of facile and scalable BNNS fabrication processes, the impressive properties of BNNSs have not been exploited at the industrial scale because of the challenges associated with assembling the 2D crystals into macroscopic materials that can leverage the excellent properties of the nanoscale building blocks. On other hand, in nature, nacre exhibits surprisingly high mechanical properties with elegant simplicity in structure consisting of a brick-and-mortar assembly of inorganic and organic constituents. Furthermore, recent developments in nanomaterials and bioinspired materials revealed that excellent mechanical and functional properties can be simultaneously achieved by assembling the nanomaterials into brick-and-mortar (B&M) structure from the nanocrystals. Herein, artificial nacre-like materials were fabricated using hyperbranched polyglycerol (HPG)-functionalized BNNS and gelatin through a vacuum filtration-induced self-assembly technique. The electrostatic interaction-induced self-assembly of BNNSs and gelatin resulted in the formation of a layered B&M nanocomposite structure resembling that of natural nacre. In contrast to previously reported traditional polymer nanocomposite materials, BNNSs constitute a major load bearing hard component in the nanocomposite material, similar to the brick phases in the nacre structure, while the soft gelatin phases bind the hard brick phases together. Alignment of the BNNSs into a B&M structure was achieved by linking interlayer bridges through electrostatic interactions between anionic hydroxyl functional groups on the BNNSs and cationic amine functional groups on gelatin. The resulting nacre-like nanocomposite exhibited a controllable nanoscale alignment and mechanical properties similar to those of human cortical bones; these properties could be tuned by changing the amount of BNNSs, and by using a functionalization process. Moreover, biological characterization of the nacre-like nanocomposite revealed excellent biocompatibility with signs of negligible cytotoxicity and cell differentiation induction. Furthermore, we believe that various drugs and bioactive molecules could adhere to the surface of BNNSs via a functionalization process to improve biological functionality. The excellent mechanical properties and high biocompatibility of the nacre-like BNNS/gelatin nanocomposite suggests biomedical applications, including in bone implants, bone fillers, and biocompatible biomaterial coatings.

MS03.11.02
Plant-Derived Nanocellulose as Structural and Mechanical Reinforcement of Freeze-Cast Chitosan Scaffolds for Biomedical Applications
Kaiyang Yin, Prajan Divakar and Ulrike G. Wegst; Dartmouth College, United States

Despite considerable recent interest in micro- and nanofibrillated cellulose as constituents of lightweight structures and scaffolds for applications that range from thermal insulation to filtration, few systematic studies have been reported to date on structure-property-processing correlations in freeze-cast nanocellulose-based composite scaffolds, in general, and their application in tissue regeneration, in particular. Reported in this study are the effects of the addition of plant-derived nanocellulose fibrils (CNF), crystals (CNC) or a blend of the two (CNB) to the biopolymer chitosan on structure and properties of the resulting composites. Nanocellulose-chitosan composite scaffolds were freeze cast at 10°C/min and 1°C/min, and their microstructures were quantified in both the dry and fully-hydrated states using scanning electron and confocal microscopy, respectively. The modulus, yield strength,
Anisotropic Freeze-Cast Collagen Scaffolds for Tissue Regeneration—How Processing Conditions Affect Structure and Properties in the Dry and Fully Hydrated States

Prajan Divakar, Kaiyang Yin and Ulrike G. Wegst; Dartmouth College, United States

Few systematic structure-property-processing correlations for directionally freeze-cast biopolymer scaffolds are reported. Such correlations are critical to enable scaffold design with attractive structural and mechanical cues in vivo. This study focuses on freeze-cast collagen scaffolds with three different applied cooling rates (10, 1, and 0.1 °C/min) and two freezing directions (longitudinal and radial). A semi-automated approach for the structural characterization of fully hydrated scaffolds by confocal microscopy is developed to facilitate an objective quantification and comparison of structural features. Additionally, scanning electron microscopy and compression testing are performed longitudinally and transversely. Structural and mechanical properties are determined on dry and fully hydrated scaffolds. Longitudinally frozen scaffolds have aligned and regular pores while those in radially frozen ones exhibit greater variations in pore geometry and alignment. Lamellar spacing, pore area, and cell wall thickness increase with decreasing cooling rate. Both longitudinally and radially frozen scaffolds possess higher mechanical property values, when loaded parallel rather than perpendicular to the ice-crystal growth direction. Systematic trends and correlations become useful, when they allow predictions of performance and thus, the custom-design of new materials and structures. Traditionally, in the freeze-casting community, structural features, such as the lamellar spacing, λ (which in our case is equivalent to the short pore axis), are correlated with the freezing front velocity, v, during processing. Since the accurate measurement of the freezing front velocity for a given mold design and freezing setup is an elaborate undertaking that either requires specialized molds or cryo-X-ray tomography, it is more practical and useful to obtain correlations between structural features and the applied cooling rate. This is what we propose and report, here, for the case of longitudinal solidification, which results in a particularly reproducible and regular pore architecture. Correlations between the short axis of the pore, the pore area, and the applied cooling rate, ċ, are presented as well as correlations between cell wall thickness, modulus and yield strength. Collated, these correlations enable the custom-design of freeze-cast collagen scaffolds, which are ideally suited for a large variety of tissue regeneration applications.

Overcoming the Disadvantages of Applying Bio-Inspired Wettability Controlled Surfaces Underwater Using Electrochemical Water Splitting

Yongjae Jeung and Kijung Yong; POSTECH, Korea (the Republic of)

The fouling and drag force are major issues in fluid transport systems because they cause additional costs for cleaning and fuel consumption, respectively. However, the biggest problem is drag force and anti-fouling ability have conflicting relations so it is difficult to find the surface which satisfies both. For example, a superhydrophobic surface shows drag-reducing effect due to the formation of air layer underwater but this empty air layer could easily collapse by air diffusion and hydraulic pressure. On the other hand, a superhydrophilic surface shows outstanding anti-oil fouling ability due to its high affinity to water but this causes the drag-enhancing effect. To overcome this conflicting relation, we suggest a unique method which is employing electrochemical gas generation system to both bio-inspired wettability controlled surfaces. A superhydrophilic surface has a great advantage for electrochemical water splitting (EWS) due to its large surface area and superaerophobicity underwater. Because of superaerophobicity underwater, a superhydrophilic surface generates the small air bubbles (~ 30 μm sizes) on the surface which form an air layer. This air bubble layer lowers the near surface fluid density which induces an almost
26.5% drag reduction efficiency compared to the flat surface. This value is comparable to the superhydrophobic surface which is the well-known drag reduction surface for fluid transport. In the case of superhydrophobic surface, when the air layer is collapsed the nanostructure could contact with water which means EWS could occur on the surface. Thus, the air bubble is generated on the surface which induces regeneration of the air layer. This study presents an idea that combines the bio-inspired wettability surfaces with EWS bubble generation system for drag-reduced superhydrophilic surface and long-term stability superhydrophobic surface which is useful for an application on the fluid transport system.

MS03.11.05
Dynamic Compressive Strength of Hydrated Lamellar Bone at the Microscale
Cinzia Peruzzi1, Johann Michler1, Edoardo Mazza2 and Jakob Schwiedrzik1; 1Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 2ETH Zürich, Switzerland

Bone is a hierarchically structured composite tissue spanning several length scales. It consists of collagen molecules, calcium phosphate minerals and water. Mineralized collagen fibrils (MCF) are embedded into an extracellular matrix and form lamellar bone. Lamellae are 3 to 7 µm thick layers of MCF’s arrays and constitute the majority of cortical bone. To better understand the mechanical properties of bone, it is necessary to characterize the material over several length scales, as well as under conditions resembling a physiological environment [1]. It is important to note that not only are bones subjected to various strain rates on a daily basis, but especially so upon impact, e.g. falling [2]. Therefore, we investigated the strain rate dependency of bone at the length scale of a single lamella via micropillar compressions under hydrated conditions. The micropillars were produced in ovine bone using focused-ion beam (FIB) in axial and transverse orientations, using a well-established procedure [3]. The pillars had diameters of 5.493 +/-0.158 µm and heights of 10.557 +/- 0.744µm. Compression experiments were performed under ambient pressure with a relative humidity of over 90% using a customized nanoindenter setup. Compression tests were carried out under displacement control at different strain rates, varying from 10^-3 to 10^2 1/s, to cover the mechanical response of bone over 6 orders of magnitude in strain rate. Within this range, the change in yield stress, as well as post-yield characteristics were assessed. The anisotropy of the strain rate sensitivity was investigated and post-test HRSEM analysis was performed to image the deformation and failure mechanisms and correlate them to the measured mechanical behaviour.

These experiments highlight the importance of physiological condition testing and the influence of strain rate dependency on bone yield stress and ductility. The generated data may enhance existing micro-finite element models for the clinical evaluation of fracture risk in osteoporotic patients in the future.

MS03.11.06
Optimization of Bacterial Nanocellulose Fermentation Using Lignocellulosic Residues and Development of Novel BNC-Starch Composites
Francisco G. Silva1, Ricardo Carvalho1, Fernando Dourado1, Eugénio C. Ferreira1, Fátima Poças2 and Miguel Gama1; 1University of Minho, Portugal; 2Centre for Biotechnology and Fine Chemistry, Portugal

In the papermaking industry, a significant fraction of fibres that cannot be re-utilized is wasted, which raise economic and environmental concerns. On the other hand, the development of renewable polymeric materials became a priority for the sustainability of several industries. Bacterial nanocellulose (BNC), a biopolymer extruded by Gluconacetobacter xylinus as a 3D nanofibrillar network, provide interesting properties as high porosity, high water retention, biocompatibility, non-toxicity and biodegradability. These properties have sustained promising applications in the biomedical field, pulp & paper, composites and foods. However, large-scale BNC production remains a challenge, due to the low productivities, ineffective fermentation systems and high operating costs. Therefore, the production of BNC through lignocellulosic residues has been studied. Recycled paper sludge (RPS) composed of small fibres with 40% of carbohydrates were hydrolysed and used as a carbon source in culture media formulation. Then, a Response Surface Methodology (RSM) optimization with RPS was assessed in order to maximize BNC production, through static fermentation with K. hansenii ATCC 53582. Overall, the results suggest that RPS had the potential to be an alternative carbon source for BNC production with a maximum BNC yield of 5 g/L. BNC produced as described above was then used for the development of novel green thermoplastic
nanocomposites, combined with starch. When mixed with water and glycerol (with heat and shear), starch undergoes spontaneous destructuring, forming thermoplastic starch (TPS). In particular to food packaging applications, BNC has remained unexploited in spite of being considered to have enormous potential. In this work, two approaches for composite production were assessed. Firstly, BNC 3D membrane was filled with biodegradable bio-based thermoplastic starch (TPS), where the production was achieved in a two-step process: impregnation of TPS in the BNC membrane, followed by drying. Different thicknesses of BNC membrane were studied (1-5 mm) as two impregnation time (24h;72h). The second approach consisted on the use of glycerol-TPS as a matrix, where different concentrations (0.05 -0.5% w/v) of cellulose (Plant (PC) and BNC) was added. TPS-BNC and TPS-PC films were prepared by solution casting method. All nanocomposites manufactured were then characterized in terms of mechanical properties, morphology and permeability to water vapour (WVT). Overall, enhanced mechanical and barrier properties were obtained with composites composed by BNC membrane filled with TPS. In comparison to TPS-BNC and TPS-PC films, higher young modulus and tensile strength were obtained with the BNC membrane filled with TPS. Being longer and thinner, the BNC fibres offer greater mechanical resistance than the ordinary TPS-cellulose composites. In addition, the elasticity remains similar to the TPS-cellulose composites, despite having a lower concentration of starch/glycerol. The authors gratefully thank funding through the project Multi-biorefinery PAC (SAICTPAC/0040/2015) and SkinShip with reference PTDC/BBB-BIO/1889/2014 (financiado pelo Fundo Europeu de Desenvolvimento Regional (FEDER) através do Programa Operacional Competitividade e Internacionalização - COMPETE 2020, do Programa Operacional Regional de Lisboa e por Fundos Nacionais através da FCT - Fundação para a Ciência e a Tecnologia no âmbito do projeto POCI-01-0145-FEDER-016595).

MS03.11.07
New Bioplastic Composites of Polycoumarate Copolymers with Polybutylene Succinate Maninder Singh and Tatsuo Kaneko; JAIST, Japan

Fabrication of environment-friendly polymers are in great demand as they are derived from naturally occurring molecules which degrade easily into the environment without causing any harm and can be useful for solving environmental problems. One such environmentally benign, high performance polymer poly(4HCA-co-DHCA) was synthesized using phenolic monomers (4-hydroxycinnamic acid (4HCA) and dihydroxycinnamic acid (DHCA)) has high thermal and mechanical strength than usual aliphatic polyesters such as poly(lactic acid) which makes the resulting polymer highly rigid in nature. Also, these polymers show liquid crystalline behavior which sometimes dramatically increases the mechanical strength. Because of the high rigidity, these polymers cannot be used in applications which require flexible polymers. Poly(4HCA-co-DHCA) is brownish in color and look alike wood but it is very rigid in nature. This polymer can be a good candidate to be explored further to obtain a flexible polymer. To increase the flexibility of poly(4HCA-co-DHCA), some aliphatic chain such as polybutylene succinate (PBS) can be introduced. PBS is also derived from biobased monomers and it is biodegradable as well. In this report, we will present the synthetic protocol for copolymerization of rigid poly(4HCA-co-DHCA) with PBS. Flexibility and toughness of composite can be controlled by changing the wt.% of the PBS chain. The results will be discussed using various characterization techniques using NMR, GPC, TGA and tensile measurements.

MS03.11.09
Biodegradable PCL-PLGA-Brushite Scaffolds for Bone Tissue Engineering Aneela Anwar1,2 and Xiaojun Yu1; 1Stevens Institute of Technology, United States; 2University of Engineering and Technology, Pakistan

Introduction: Every year more than 2.2 million bone graft procedures are performed to treat the bone defects worldwide, which costs approximately $2.5 billion. Recent approaches for segmental bone defect reconstruction are limited to autografts, which are considered as gold standard due to their osteoconductivity, osteogenicity and osteoinductivity properties. However, there are some restrictions and concerns of this procedure results in donor site morbidity, secondary infection, restricted availability, and surgical limitations. In this context, synthetic scaffolds have proved to be a potential candidate for the bone grafts due to their unlimited supply. However, the major challenge to repair the segmental bone defect is the development of synthetic porous scaffold using biodegradable biomaterial for proper cell adhesion and proliferation in abundance in order to get required porosity and better mechanical properties. A variety of techniques and scaffolds are being made for this engineering. The choice of material, mechanical properties, and porosity of the scaffold can affect the cell progression after implantation [1]. Therefore, we have developed a novel biodegradable biocomposite scaffold based on polycaprolactone-poly lactic-co-glycolic acid (PCL-PLGA)-Brushite by using compression molding methods. Its structural and biological properties have been assessed. Importantly, faster degradation of PLGA than PCL led to the creation of in situ pores
in the matrix of PCL, which can help in the neovascularization.

**Materials and Methods:** The biocomposite scaffolds were prepared by heating the mixture of PCL, PLGA and brushite at 150 °C in a PTFE mold, followed by compression. X-ray diffraction (XRD) and scanning electron microscopy (SEM) techniques were used for the phase analysis and surface characterization of the as-sintered samples. The energy dispersive spectroscopy (EDS) was used for the analysis of brushite distribution in the PCL-PLGA matrix. The percentage porosity and density were measured by using liquid displacement method. For the mechanical testing, cylindrical samples of 6 mm diameter and 12 mm height were tested at a speed of 1.3 mm/min using the universal testing machine. Furthermore, the samples were tested for its degradation behaviour in 1×PBS at 37 °C for 2, 4, 6, 8, 16, 24, and 48 weeks.

**Results and Discussion:**
As-sintered cylindrical-shaped scaffolds were characterized by a dense structure with density ~1.07 g/cm³, which is comparable to the cancellous bone (0.1–1.0 g/cm³). The SEM carried out in the secondary electron mode revealed a micro-rough surface. This rough surface is expected to play an important role in cell adhesion and proliferation. A comparison of XRD results confirmed the presence of the amorphous phase of PLGA and crystalline phases of PCL as well as brushite. The mechanical testing of scaffolds showed a significant effect of PCL and PLGA ratio on the yield strength and young’s modulus. Furthermore, the detailed SEM-EDS mapping confirmed the uniform distribution of brushite (Ca, P, and O). The mechanical testing of scaffolds showed a significant effect of PCL and PLGA ratio on the yield strength and young’s modulus.

**Conclusions:**
In this study, we have prepared a novel biodegradable scaffold composed of PCL, PLGA and brushite and investigated its structural and biological properties. Based on our findings, we believe that this biomimetic scaffolds are suitable for bone tissue engineering applications and could be used a promising material for future endeavors.

**Bioinspired Fatigue-Resistant Adhesion of Hydrogels** Ji Liu¹², Xinyue Liu¹, Shaiting Lin¹, Zhao Qin¹ and Xuanhe Zhao¹; ¹Massachusetts Institute of Technology, United States; ²Southern University of Science and Technology, China

The adhesion of soft connective tissues (tendons, ligaments, and cartilages) on bones in many animals can maintain high toughness (~ 800 J m-2) over millions of cycles of mechanical loads. Such fatigue-resistant adhesion has not been achieved between synthetic hydrogels and engineering materials, but is highly desirable for diverse applications such as artificial cartilages and tendons, robust antifouling coatings, and hydrogel robots. Inspired by the nanostructured interfaces between tendon/ligament/cartilage and bones, we report that bonding ordered nanocrystalline domains of synthetic hydrogels on engineering materials can give an extremely fatigue-resistant adhesion with a record-high interfacial fatigue threshold of 800 J m-2, since the fatigue-crack propagation at the interface requires a much higher energy to fracture the ordered nanostructures than amorphous polymer chains. Our method enables fatigue-resistant hydrogel coatings on diverse engineering materials with complex geometries. We further demonstrate that fatigue-resistant hydrogel coatings on metallic joint replacements can give lower friction and better wear-resistance against natural cartilages than the commonly used polyethylene coatings.

**Exploratory Study of Composite Materials with Diatoms Fillers** Izabela B. Zglobicka¹, Jürgen Gluch², Cathy Kilroy³, Ehrenfried Zschech² and Krzysztof Kurzydlowski¹; ¹Bialystok University of Technology, Faculty of Mechanical Engineering, Poland; ²Fraunhofer Institute for Ceramic Technologies and Systems IKTS, Germany; ³National Institute of Water & Atmospheric Research Ltd., New Zealand

Diatoms constitute the largest and the ecologically most significant group of organisms on Earth. The unique silicified cell structure as well as intricate morphology of these microorganisms attract scientists attention for over 100 years. The details of their structure and the functionalities are still under debate and applications of diatom shells are in progress.
One of the widely spread diatom species is a freshwater diatom - *Didymosphenia geminata*, composed of siliceous cells and extracellular polymeric fibrous stalks. The present paper [1] concerns the possibilities of using frustules of this diatoms as a novel filler in epoxy composites. Preliminary results of the research aiming at achieving this goal have been presented in [1,2].

The current study, extends earlier investigations on the possibility of using the diatom frustules in innovative composite materials with metallic matrix. The results are presented of the exploratory research on the properties of the composite, which show a great potential for the development of bio-based metallic matrix composites.

Hierarchically Cellulose Nanofiber/Titanium Dioxide Nanowire Film with Morphological Matching for Reusable Organic Pollutant Photodegradation

Ting-Han Lin, Yu-Han Liao, Yin-Hsuan Chang, Ying-Han Liao and Ming-Chung Wu; Chang Gung University, Taiwan

Cellulose is the most abundant natural polymer on earth and exists numerously in wood, crop, and cotton. It shows potential to be a candidate for the sustainable material in next generation due to its bio-compatibility, bio-degradation, chemical stability, non-toxicity, and renewable ability. Cellulose nanofiber (CNF) extracted from plants has been reported that it exhibits the unique optical properties, good mechanical strength, and high aspect ratio. TEMPO-oxidation is an effective way to separate the CNF in cellulose microfibril bundles due to the formation of the regioselective repulsive force between each nanofibrils by modification of C6 carboxylate. For extending the application, combining the photocatalysts might provide multi-functional properties with solvent-resistance and degradation capability of pollution. One-dimensional TiO$_2$ nanomaterials can achieve the network structure easily that provides an efficient charge transport path to inhibit the recombination of electron-hole pairs. Moreover, nanofiber-shaped materials can be probably combined with CNF to form the dense, flexible, and freestanding composite film because of the accordance size between each other. In this study, we proposed a simple way to prepare the TiO$_2$ NFs/CNF nanocomposite film with flexibility, solvent resistance, and photocatalytic performance. The relationship between the chemical, physical properties of the TiO$_2$/CNF film and the morphological-matching were discussed. CNF is fabricated by TEMPO-oxidation method and post-reduction by NaBH$_4$. Various TiO$_2$ based materials with different dimension and morphologies, such as P25 nanoparticles, anatase TiO$_2$ nanowires, microparticles, and Ag:TiO$_2$ nanowires were incorporated with cellulose nanofibers. To obtain the uniform and freestanding TiO$_2$/CNF film, the well-dispersion TiO$_2$/CNF mixture solution was activated by UV-ozone treatment to improve the TiO$_2$ hydrophilicity. After the drop-casting and drying, various TiO$_2$/CNF films with 10 mm-thickness were obtained. With the various TiO$_2$, the surface on two sides of film was totally different, which is caused by the TiO$_2$ distribution and dimension in CNF. From the cross-sectional FESEM images and EDS mapping, 1-D TiO$_2$ were entangled with CNF near the edge of film, but P25-TiO$_2$ NPs and TiO$_2$ MPs were embedded and assembled in the CNF hierarchical structure. The distribution of TiO$_2$ in the CNF matrix directly rearranged the CNF ordering stack. We also investigated the crystal structure as well as grazing-incidence wide-angle X-ray scattering (GIWAXS) for the detailed preferred orientation of cellulose nanofiber film. In particular, the TiO$_2$ nanowires entangled with CNF improved the hierarchical stack due to the similar morphology and stacking orientation. Therefore, the mechanical properties including tensile strength and young’s modulus can be improved and higher than that of TiO$_2$ particles/CNF. In the testing of solvent resistance for 30 days, these various TiO$_2$/CNF film showed the outstanding resistance and stable in the acetone and dimethylformamide (DMF). For the better photocatalytic activity, Ag:TiO$_2$ nanowires were employed. In the photodegradation of 1.0 ppm methyl orange in ethanol, Ag:TiO$_2$ NWs/CNF film presented the high degradation efficiency of 87% and showed the excellent stability of morphology and activity after 3 cycles. In addition, Ag:TiO$_2$ NWs/CNF film presented remarkable degradation behavior and stability toward the VOCs including methanol, n-butanol, and DMF with 5,000 ppm.

Clay Hybrid Nano-Layer Assembly, Structure and Mechanics at the Air-Water Interface

Paulo H. Michels Brito, Antônio Gasperini, Lina Mayr, Ximena Puentes-Martinez, Romulo Tenorio, Leide P. Cavalcanti, Koiti
We present a study on the structural organization and mechanical proprieties of clay colloidal particle films at the air-liquid interface. The film self-assembly and stability is monitored employing the Langmuir Trough (LT) method. Both pure clays and modified clays are studied in an LT using synchrotron X-ray Grazing Incidence techniques (GID and GIXOS). The Langmuir film thickness and in-plane organization are monitored in order to investigate mechanisms for control of adsorption on different interfaces. These results are important for particle coating studies and for the development of new routes for assembling clay colloidal particles on liquid surfaces/interfaces. Surface properties are particularly important in relation to Pickering emulsions where particle coatings on droplets effectively prevent droplet coalescence and produce mechanically very stable surfactant-free emulsions. The adsorption of colloidal particles at the surface of liquid droplets [1] has applications in several areas such as the food-, cosmetics-, pharmaceutics-, and the petroleum sector. [2]. Here we demonstrate how the ordering of clay nanoparticles on a confined two-dimensional aqueous surface can be investigated in detail. In particular, we recreate the process of Janus clay-platelets exfoliation and clay platelet re-assembly, using synthetic Fluorohectorite clays [3], in the interfacial confined environment provided by the LT.

Fracturing of the Polycrystalline MoS2 Nanofilms Marianna Sledzinska1, Gil Jumbert1,2, Marcel Placidi3, Alois Arrighi1,2, Peng Xiao1,2, Francesc Alzina1 and Clivia M. Sotomayor Torres1,4; 1ICN2, Spain; 2Universidad Autonoma de Barcelona, Spain; 3IREC, Spain; 4ICREA, Spain

In the recent years we have observed a fast increase in the demand for personal flexible and wearable devices, for sensing, health monitoring and leisure. With the raise of 2D materials, the pursuit of high-performance flexible devices seems even closer to realisation. 2D materials seem perfect candidates for flexible nanotechnology because of their unique physical and mechanical properties. One of the issues innately related to flexible electronics is the ability of the active components to handle reasonably high strain. Therefore over the years it has been crucial to exploit the properties of 2D materials for the proper function of the flexible devices. But, while single crystals of 2D materials possess outstanding elastic properties, point and line defects will play an important role in potential technological applications of large-area samples grown, for example, by chemical vapour deposition.

In this work we investigate the crack propagation on micro- and nanoscale in polycrystalline MoS2 films in a very small grain limit. The study is performed on two types of MoS2 samples differing in the grain orientation with respect to the film plane, i.e., horizontal (in plane)-vertical (out of plane) and purely horizontal, with thickness of 17 nm and 3 nm, respectively. Using electron microscopy techniques we determine critical uniaxial strain as approximately 5%, independently of the sample morphology and thickness. We also study the nanoscale crack propagation under the transmission electron microscope and show that they propagate along the grain boundaries as well as through the grains preferentially along van der Waals bonding. Our results provide an insight on the fracture of polycrystalline 2D materials as well as new means for tailoring the critical strain and nanofabrication of ultra-thin MoS2 devices, by using well-developed tools and of great interest of flexible electronics industry.

MS03.11.15
Synthesis of a Novel Flame-Retardant Hydrogel for Skin Protection Using Xanthan Gum and Resorcinol Bis(diphenyl phosphate)-Coated Starch Yuan Xue1, Mingkang Li2, Bole Pan3, Lisa Quinto1, Jalaj Mehta4, Lauren Stiefel1 and Miriam Rafailovich1; 1Stony Brook University, United States; 2Shanghai Star-river Bilingual School, China; 3Guangzhou Tianhe Foreign Language School, China; 4Hauppauge High School, United States; 5Yeshiva University High School for Girls, United States

Firefighters continually endanger their lives in order to rescue others. This can leave them with severe burns; in
2017 alone, 2,835 U.S. firefighters suffered from burn-related injuries. In this research, a flame retardant hydrogel was synthesized using biodegradable, non-toxic materials: xanthan gum (XG) and resorcinol bis(diphenyl phosphate) (RDP) and starch. RDP was first coated onto the xanthan gum and starch surface. Fourier-transform Infrared Spectroscopy confirmed the hydrogen bonding between RDP and XG/starch. To evaluate the protection of FR hydrogel, sheepskin was embedded in aluminum pans, covered with hydrogel, and burned continuously for 150s. Temperature change of the sheepskin was recorded during burning test. Results showed the formation of a uniform char layer from the FR hydrogel which protects the underlying gel layer and skin. The FR hydrogel sample outperformed its pure XG gel control sample by 29% in terms of the final temperature. The FR hydrogel helped to remain the skin temperature below 45 °C for over 50 seconds and below 55 °C for 114 seconds upon direct burning with a propane torch. TGA tests showed that the FR hydrogel had more residue after test which is in agreement to the char formation during the burning test. Data from the viscosity tests revealed that all samples displayed shear-thinning behavior. Thermal protective performance (TPP) tests were also done to evaluate heat transmission through the FR hydrogel when exposed to a continuous heat source, and result compared to the Stoll Curve which represent the heat level for causing second-degree burn. The TPP test result showed that the FR hydrogel provided a prolonged protection time comparing to the control sample.

**MS03.11.16**

**Mechanical Behavior and Applications of Nanocomposite Fibers and Scaffolds**

Panagiota Gkertsiou, Spyridon Kassavetis, Zoe Dardani, Christoforos Gravalidis, Stelios Karamanidis, Varvara Karagkiozaki and S. Logothetidis; Aristotle University of Thessaloniki, Greece

Nanocomposite fibers in the form of scaffolds are candidate materials for several applications such as tissue engineering, regenerative medicine, controlled drug release and multifunctional surfaces. The performance and service life of such scaffolds is significantly affected by the mechanical properties of the nanocomposite fibers and the adhesion to the surface of their substrate material. Thus the understanding of the mechanical behavior of the fibers and scaffolds is critical for potential applications.

In this work, we focus on the fabrication of nanocomposite polycaprolactone (PCL) fibers and scaffolds via electrospinning and on their structural and mechanical characterization using X-Rays Diffractions (XRD), Atomic Force Microscopy (AFM) and depth-sensing Nanoindentation (NI), respectively. The scope is to correlate the structure of the nanocomposite fibers and scaffolds with their mechanical behavior and their antibacterial properties in terms of cell / bacteria adhesion and colonization.

For the Electrospinning of the nanocomposite PCL fibers we used: a) ZnO nanoparticles (NPs) with 15 nm average diameter, developed by precipitation method using Zinc Acetate Dehydrate, Sodium Hydroxide and Polyvinylpyrrolidone (PVP) as a surfactant and b) drugs such as Curcumin and Vancomycin. X-ray diffraction characterization showed the addition of 1% w/v ZnO NPs results to more crystalline PCL fibers. The NI testing, using a Berkovich type indenter and penetration depth up to 1/10 (~ 100 nm) of the fibers thickness (> 1 μm), and analysis of the NI Load-Displacement curves showed that the Elastic Modulus values of the PCL:ZnO(NPs) nanocomposite fiber increases from 1.2 GPa (pristine PCL) to 1.7 GPa, whereas the Hardness values remains almost the same (0.7 GPa). In addition, the tip of the AFM cantilever was used to deform the nanocomposite fibers and to estimate the critical load (Pc) for the onset of the elastic/plastic deformation and the formation of a clear imprint on the PCL:ZnO(NPs) fibers surface. It was found that Pc decreases from 1.25 μN to 1.07 μN, after the addition of the ZnO NPs.

The adhesion of the nanocomposite PCL:ZnO(NPs) fibers to glass substrate was also tested by AFM and it was found that although the fibers are subjected to plastic deformation and cutting, they remained adhered to the glass substrate. In conclusion, the incorporation of ZnO NPs into PCL fibers was found to affect both the crystallinity and the mechanical behavior of the nanocomposite scaffolds and fibers.

**MS03.11.17**

**Evaporation-Driven 3D Scaffolds of Carbon Nanotubes for Composite Reinforcement**

Asaf Nissenbaum, Israel Greenfeld and H. Daniel Wagner; Weizmann Institute of Science, Israel

Many biological composites (e.g., bone, tendons, seashells) possess superior mechanical properties (e.g., strength, toughness) mostly due to their hierarchical organization. These structures grow through unique self-assembly processes, via a ‘bottom-up’ approach. Such an approach may inspire the synthesis of novel man-made multiscale composites, with enhanced mechanical properties. A key material for ‘bottom-up’ construction of multiscale composites is carbon nanotubes (CNT). However, up until today, the methods for assembling CNTs into hierarchical
structures have not led to sufficient improvement of the mechanical properties with respect to conventional composite materials. Here we introduce a method termed Evaporation Driven Self Assembly (EDSA) patterning, assisted by high surfactant concentration. This technique enables the deposition of thick, oriented CNT layers onto quartz fibers, which are then used as a reinforcing component in polymer-based composites. We describe a series of experiments that are intended to characterize the composites microstructure and assess the interfacial adhesion of the CNT-coated quartz fiber to the surrounding matrix. These experiments include visual analysis by light and electron microscopy, as well as μCT scanning, and fragmentation testing to evaluate the interfacial shear strength. The results reveal that, although the nanoscale deposition is random (i.e. single nanotubes do not show any preferred orientation), the composite microstructure exhibits a ribbon-like, thick coating (thicker by an order of magnitude compared to the quartz fiber) that is approximately oriented parallel to the fiber long axis. The mechanical tests reveal that when this layer is impregnated by epoxy, it adopts a 'fibrous' behavior, namely the layer undergoes sequential fragmentation much like classic single-filament composites. A modified Cottrell-Kelly-Tyson (CKT) model is used to assess the interfacial shear stress and the results exhibit a threefold increase in composite strength. This type of multiscale composites could further realize the high potential of CNT mechanical properties, mainly due to the EDSA deposition that solves, to some extent, fundamental issues such as CNTs dispersion and low volume fraction.

MS03.11.18
Reactive Molecular Dynamics Modeling of the Compression of Two-Phase Composites of Cement Paste at the Nanoscale
Ingrid M. Padilla Espinosa and Ram V. Mohan; North Carolina A&T State University, United States

A complete understanding of materials at nanoscale facilitates the possibility of nanomanipulation to improve the materials macroscale properties. Although cement paste is widely used and studied, due to its complexity as a hierarchical random composite, there are still several unknowns related to the effects of molecular features on its macroscopic behavior. Molecular dynamics modeling with a reactive force field was used to study one of these unknown features: the effect of cement paste phases interactions at molecular level on the response to loading conditions at macroscale. Tricalcium silicate (C₃S) and amorphous calcium silicate hydrate (CHS) are modeled as minerals nanolayers. Under compression, the calcium atoms in the C₃S interact with water molecules from the CHS at the interface. Also, the water in the CHS favors the displacement of silicate chains and the breaking of Ca-O bonds, therefore, the CHS phase is more compressible than the C₃S phase in the composite.

MS03.11.19
Engineering Ductile Acrylic Blends Using Biodegradable Copolymers
Robert Wong, Stephanie Silva, Nora Ruth, Ryan Davis and Miriam Rafailovich; Stony Brook University, United States

The goal of this study is to develop and characterize a polymer blend consisting of polymethyl methacrylate (PMMA) and polybutylene adipate terephthalate (PBAT) using graphene as a compatibilizer. A polymer blend of this nature has the potential to be utilized in many aspects of the medical field, including antimicrobial bone implants and provisional dental crowns, while offering the ease of customizable manufacturing through 3D printing. PMMA is a nonconductive material with low impact toughness and high modulus, while PBAT is biodegradable, ductile, and has antibacterial properties; so by blending the polymers we aim to form a high-modulus, ductile material that can easily decompose in the environment. It is, however, difficult to form such a blend due to PMMA and PBAT being immiscible with each other. To overcome this problem, graphene is added as a compatibilizer to decrease interfacial tension and increase polymer–polymer adhesion. Graphene is expected to work well as a compatibilizer due to it having a high aspect ratio, and its work function with PBAT and PMMA is higher than that of PMMA with PBAT, indicating that the graphene will, critically, align along the polymer interfaces. Furthermore, graphene has high electrical, tensile, and antibacterial properties, which are desirable traits for the bulk blend. Based on previous studies working with similar polymer blends, we will start with a 70/30 mixture of PBAT/PMMA that will be tested with varying concentrations of graphene. Thermal, mechanical, and electrical properties will be examined with an objective to find optimal polymer concentrations to maximize these traits. In addition, to determine enhanced properties of the composite for biological applications, we will be testing antibacterial efficacy.
using E. coli and S. aureus and biocompatibility by testing cell viability of dental pulp cells. This novel blend of common low cost polymer gives a unique edge in fulfilling applications held traditionally by PMMA while also being more environmentally conscientious.

Metastable High Entropy Alloys—Effects of Bulk and Low Dimensional Thermodynamics on Mechanical Properties Dierk R. Raabe, Z. Ming Li, Wenjun Lu, Christian Liebscher, Gerhard Dehm, Fritz Körmann, Blazej Grabowski and Jörg Neugebauer; Max Planck Institute for Iron Research, Germany

Most alloys are thermodynamically metastable during some stages of synthesis and service. Here we discuss scenarios where metastable phases are not coincidentally inherited from processing, but rather are engineered. Specifically, we present approaches to compositional (partitioning), thermal (kinetics), and microstructure (size effects and confinement) tuning of metastable phases so that they form stacking faults together with planar slip and can trigger athermal transformation effects such as TWIP and TRIP when mechanically or thermally loaded. Such concepts work both at the bulk scale and also at a spatially confined microstructure scale, such as at decorated lattice defects. In the latter case, local stability tuning works primarily through elemental partitioning to dislocation cores, stacking faults, interfaces, and precipitates. Depending on stability, spatial confinement, misfit, and dispersion, both bulk and local load-driven athermal transformations can equip metastable medium- and high-entropy alloys with substantial gain in strength, ductility, and damage tolerance. We explore and demonstrate these effects along three specific thermodynamic questions: First we study the roles of magnetic and vibrational entropy contributions for understanding bulk metastability. Second, grand-canonical effects arising from spatial confinement will be discussed. Third, we present alloy cases with extreme metastability, forming self-organized two-phase
Understanding the thermodynamics of multi-principal-element alloys (MPEA), also known as high entropy alloys (HEA) is crucial to addressing their synthesis, properties, stability, materials compatibility and technological applications. While the thermodynamics of binary and ternary alloys have been relatively well investigated both experimentally and theoretically over the last five decades, this is not the case for multicomponent (>4 element) alloys. The classical calorimetric methods (e.g., liquid metal bath, direct reaction, and flux calorimeter) used for binary and ternary alloys will often encounter difficulties for alloys with more than three elements. Thus, a more flexible and general calorimetric approach is needed.

The present work introduces a new methodology for measuring the enthalpy of formation and mixing of metals based on high temperature oxidative calorimetry. This technique is based on the well-developed oxide melt solution calorimetry (OMSC). Using this method, the heats of formation of four binary (AlNi, AlFe, AlCo, and AlFe₃), one quaternary CrFeCoNi and one quinary Al₀.₁₄Ti₀.₁₈V₀.₁₈Nb₀.₂₆Ta₀.₂₃ alloys were obtained. The values in kJ/(mol atom) are: AlNi, -60.11 ± 3.94; AlFe, -23.46 ± 2.39; AlCo, -51.80 ± 1.89; AlFe₃, -13.72 ± 2.39; CrFeCoNi, -3.24 ± 2.39; Al₀.₁₄Ti₀.₁₈V₀.₁₈Nb₀.₂₆Ta₀.₂₃ -11.93 ± 4.80. The results are compared with predicted values from the Miedema model and with available experimental data. The methodology is thus established to be generally useful for determining the thermodynamic properties of MPEA.

Al₀.₇₅CoCrFeNi high entropy alloys received excessive scientific attention due to their promising mechanical and corrosion resistance properties. These alloys may contain a mixture of FCC and BCC phases were the latest has an important role in its hardening. It was demonstrated that increasing the Al fraction in Al₀.₇₅CoCrFeNi alloy will lead to an increase in the volume fraction of the BCC phase in the alloy. This BCC phase is usually a mixture of a disordered BCC Fe-Cr rich (A2) and an ordered BCC (primitive cubic, B2) Al-Ni rich phases. Moreover, heat treatment history has a major impact on the microstructure and properties as well.

In the present talk, the metallurgy behavior of Al₀.₇₅CoCrFeNi will be discussed. The experimental results suggested that sluggish diffusion and high activation energy for precipitation of A2 phase (disordered BCC) from B2 (ordered simple cubic) phase play major rule on the alloy phase composition. Moreover, the morphology of A2 phase found to be sensitive to cooling rate and the soaking temperate during heat treatment. It was concluded that the lattice distortion dominates microstructure and composition of phases.

The plastic deformation behavior of single crystals of the FCC equiatomic CrMnFeCoNi high-entropy alloy and its derivative equiatomic quaternary and ternary medium-entropy alloys has been investigated in a temperature range of 10-1273 K, paying special attention to possible variations in mechanical properties with heat-treatment that may cause different short-range ordering of the constituent elements. Deformation occurs via slip of
the \{111\}\{<110>\} system exclusively in the whole temperature range for all alloys investigated. The CRSS values increase with decreasing temperature, especially below room temperature, so that the concept of ‘stress equivalence’ is obeyed for all alloys investigated. This is a clear indication that the strength of these alloys should be described by a mechanism based on solid-solution hardening. Dislocations are smoothly curved in the slip plane without any preferred line orientation, indicating no significant anisotropy in the mobility of edge and screw segments. Planar \(\frac{\sqrt{2}}{2}\{<110>\}\{111\}\) dislocations dissociate widely into Shockley partials for all alloys investigated, indicating their low stacking fault energies; 30 ± 5 and 11 ± 3 mJ/m² for CrMnFeCoNi and CrCoNi, respectively. The CRSS values extrapolated to 0 K for polycrystals of equiatomic quinary, quaternary and ternary alloys are reported to be well scaled with the mean-square atomic displacement from the regular FCC lattice points (calculated based on density-functional theory). This seems also the case for the CRSS values at 10 K for single crystals of the present three alloys, although some modifications are definitely needed. Deformation twinning occurs on the conjugate system in the form of the Lüders type deformation in the later stage of deformation at low temperatures in all of the three alloys. The variation of the CRSS values, twinning stress and the stacking-fault energy upon heat-treatment and its inter-correlation will be discussed.

**Enthalpic an Entropic Contribution to the Stability of High Entropy Alloys—An Ab Initio Perspective**

George Bokas¹, Wei Chen¹, Stéphane Gorse² and Geoffroy Hautier¹; ¹Université Catholique de Louvain, Belgium; ²Institut de Chimie de la Matière Condensée de Bordeaux, France

High entropy alloys (HEA) have attracted a lot of attention in the last decades mainly due to their good mechanical, and thermal properties. HEA includes five or more alloying elements forming random solid solution phases. Based on the existing phase diagrams, multicomponent alloys would expect to contain many different phases. However, it is assumed the high value of the configurational entropy promotes the formation of simple solid solution phases inside the multicomponent alloys. It is crucial to understand why some multicomponent alloys can be formed as a single phase whereas some others cannot. In order to answer this question, several methods using atomic descriptors, empirical rules, and thermodynamic modeling have been proposed. These approaches suffer however from insufficient experimental data. Therefore, the prediction of alloys that can form random solid solution phases remains a challenge hindering the discovery of novel HEA and the understanding of what is driving their phase stability. In this work, we use DFT calculations to shed light in the relative thermodynamic stability of BCC and FCC random solid solutions. Using a regular solution model fitted on DFT computation, we created a database of almost 80,000 FCC and BCC alloys up to the quinary. We will report on the technical challenges in building this database and on the understanding of what is driving phase stability in HEA that one can extract from such a large data set. A special focus will be given to how entropy and enthalpy competition behave as the number of components increase in alloys.

**Phase Stability, Microstructure and Mechanical Properties of Nanoeutectic CoCrFeNiTa\(_x\) (0.2 < \(x\) < 0.5) High Entropy Alloy**

Barnasree Chanda and Jayanta Das; Indian Institute of Technology Kharagpur, India

High entropy alloys are a new class of alloys which consists of five or more major element in the range of 5-35 at.%. The ever increasing demands for new structural applications, high entropy alloys (HEA) are transpire as a new paradigm shift in material society. Nano-eutectic HEAs exhibit superior mechanical properties over the single-phase high entropy alloys. The optimum combination of strength and ductility are the key features of eutectic HEAs. In this work, the novel CoCrFeNiTa\(_x\) (0.2 ≤ \(x\) ≤ 0.5) HEAs with eutectic microstructure were designed and cast by arc melting. The phase composition, mechanical properties and stability of these alloys were investigated. The evolved microstructure in all the HEAs consist of eutectic lamellae with alternating α (γ-Ni)-FCC phase and β (Co,Ta)-type Laves phase. It was observed that \(x=0.2\), and 0.5 alloys contains eutectic microstructure along with proeutectic phase and at \(x=0.4\) homogenous eutectic microstructure was obtained. The CoCrFeNiTa\(_{0.4}\) HEA with the eutectic microstructure exhibited a relatively high combination of yield strength (∼1820 MPa) and ductility (∼21 %). Further, analysis regarding the eutectic phase stability in terms of different thermodynamic and electronic parameters considering the synergistic effect atomic size difference (\(\delta_0\)), mixing enthalpy (\(\Delta H_{mix}\)) and valence electron concentration (VEC) were carried out. Also, from literature EHEAs comprising of FCC /BCC solid solution phases and intermetallic compound/topologically closed packed (TCP) phases have been surveyed thoroughly. The assessment predict the existence of stable eutectic/near eutectic phases in all surveyed and present EHEAs when \(-18 ≤ \Delta H_{mix} ≤ -6\), \(6 ≤ VEC ≤ 8.5\) and \(\delta_0 > 3\%\).

**Dual-TRIP Effect in Metastable High-Entropy Alloys** Shaolou Wei, Jinwoo Kim and Cem Tasan; Massachusetts Institute of Technology, United States

Microstructural metastability engineering, especially transformation-induced plasticity (TRIP) effect, is one of the most effective strategies to enhance strain hardenability in exploring advanced high-entropy alloys (HEAs). While appreciable effort including both compositional and microstructural optimization has been accomplished to modulate the TRIP effect, the resultant transformation product, martensite, still seriously impedes the property advancement: its extensive defect density and limited hardenability inevitably lead to local embrittlement and thereby failure. Here in this presentation, we will demonstrate that by manipulating the mechanical stability of the parent FCC phase in an Fe-Mn-rich HEA, the strain induced HCP-martensite can become further transformable, activating an FCC→HCP→FCC dual-TRIP effect. With the aid of in-situ synchrotron X-ray diffraction, SEM/EBSD, and microstructural-based strain mapping techniques we reveal the corresponding transformation kinetic, kinematic, and global-local strain evolution characteristics. We will show that this sort of dual-TRIP mechanism exhibits a desirable potential to overcome the inherent property improvement threshold of classical TRIP effect.

11:45 AM MS04.01.09  
**Origin of Antiferromagnetism in Entropy-Stabilized Oxides** Zsolt Rak and Donald Brenner; North Carolina State University, United States

The origin of antiferromagnetism in the entropy-stabilized oxide Mg$_{0.2}$Co$_{0.2}$Ni$_{0.2}$Cu$_{0.2}$Zn$_{0.2}$O has been investigated using first principles electronic structure calculations within the DFT. To characterize the magnetic structure of the entropic oxide, the total energy in the ferromagnetic (FM) as well as in the type-I and type-II antiferromagnetic (AFM) configurations are calculated. In agreement with the experimental findings, the most stable configuration corresponds to the type-II AFM order, where the ferromagnetically coupled (111) planes are stacked antiferromagnetically along the [111] direction. To characterize the magnetic interactions between the nearest neighbor (NN) and next nearest neighbor (NNN) magnetic ions (Co, Ni, and Cu), the calculated total energies are mapped onto the Heisenberg spin hamiltonian and the exchange coupling constants, $J_1$ and $J_2$, are evaluated. The strong antiferromagnetic NNN coupling and the weaker ferromagnetic NN coupling is consistent with the type-II AFM magnetic configuration. The relative strengths and the signs of the exchange coupling constants are analyzed in terms of the calculated electronic structure. The results are compared to recent experimental investigations of long-range magnetic ordering in high entropy oxides.

This work is supported by the U.S. Office of Naval Research MURI program (grant No. N00014-15- 1-2863).

1:30 PM *MS04.02.01  
**Short-Range Order and the Mechanical Properties of Medium/High-Entropy Alloys** Robert O. Ritchie$^{1,2}$, Andrew M. Minor$^{1,2}$, Mark Asta$^{1,2}$, Jun Ding$^2$, Ruopeng Zhang$^2$,$^1$, Shiteng Zhou$^{2,1}$ and Qin Yu$^2$; $^1$University of California, Berkeley, United States; $^2$Lawrence Berkeley National Laboratory, United States

CrCoNi-based medium/high-entropy alloys can display exceptional combinations of strength (~1 GPa), ductility (~60-90%) and toughness (>200 MPa√m), properties which are further enhanced at cryogenic temperatures. *In situ* TEM observations identify multiple deformation mechanisms, associated with their high friction stress yet low stacking-fault energy, that act synergistically to generate damage-tolerance. For example, studies on CrCoNi reveal a hierarchical twin network that generates substantial 3-D barriers to dislocation motion with marked strain hardening, while simultaneously providing pathways for easy dislocation motion. Here we focus on the effect of local chemical ordering which appears to be an important factor governing the exceptional mechanical properties of...
these alloys. Our DFT-based Monte-Carlo simulations on CrCoNi show that variations in local chemical order have a profound effect on the stacking-fault and twin-boundary energies, the TRIP effect, and the formation energy of point defects, all features that influence mechanical properties; these predictions have recently been further confirmed by MD calculations. Despite the clear evidence from atomistic simulation, the existence of such short-range order in medium/high-entropy alloys has lacked direct experimental confirmation, having only been indirectly detected using x-rays. Here using energy-filtered TEM techniques, we provide direct experimental evidence for the presence of short-range order in the CrCoNi MEA, and comment on its significant effect on elastic and plastic deformation properties. These results highlight the possibility of “tuning order in disorder” in the form of a science-based atomistic tailoring of multiple-principal-element alloys to achieve specifically desired macroscale mechanical performance.

2:00 PM MS04.02.02
Understanding Short-Range Ordering in Refractory High-Entropy Alloys Wei Chen1, George Kim1, Chanho Lee2 and Peter K. Liaw2; 1Illinois Institute of Technology, United States; 2The University of Tennessee, Knoxville, United States

The material-design strategy of combining multiple elements in near-equimolar ratios has spearheaded the emergence of high-entropy alloys (HEAs), an exciting class of materials with exceptional engineering properties. While random mixing has been widely assumed in multi-principal element solid solutions, both experimental and computational evidence suggests short-range ordering (SRO) exists in many solid-solution HEAs. We employed an integrated first-principles and experimental approach to understanding the thermodynamic effects of SRO in the refractory NbTaTiV and NbTaTiVZr HEA systems. Results are compared with predictions from Special Quasi-random Structures (SQS). The existence of SRO produces distinct lattice distortion features in these HEAs and affects their mechanical properties.

2:15 PM MS04.02.03
Revealing the Short-Range Order and Its Effects in the CrCoNi Medium Entropy Alloy Shiteng Zhao1, Ruopeng Zhang1, Jun Ding2, Mark Asta1,2, Robert O. Ritchie1,2 and Andrew M. Minor1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

The equiatomic ternary CrCoNi medium entropy alloy (MEA) exhibits an exceptional combination of high strength, ductility as well as fracture toughness. Although usually considered as a random solid solution, it has been suspected that short-range order (SRO), i.e. atomic scale correlation of elemental distribution, exists in this alloy, which may significantly affect the mechanical behavior. However, up to date, the direct observation of SRO by electron microscopy has not been possible due to their intrinsically small scale and lack of contrast. In this investigation, we confirm the existence of SRO in a thermal-mechanically treated MEA by deploying an in-column, energy-filtered transmission electron microscope. The inelastically scattered electrons can be effectively eliminated by the energy filter, dramatically increasing the signal-to-noise ratio, enabling the detection of SRO diffraction pattern. Using energy filtered dark field imaging, we show that these SRO domains are as small as several angstroms and distribute uniformly across the sample. The influence of the SRO on the mechanical behaviors of the MEA are evaluated by nanoindentation, bulk tensile testing as well as pulse-echo ultrasonic measurement. The deformation microstructure, especially the dislocation configuration is examined by diffraction-contrast STEM imaging. It was shown that SRO promotes the planarity of the dislocation slip and increases the stacking fault energy of the MEA; It also slightly improves both nanoindentation hardness and yield strength without sacrificing the ductility. These discoveries corroborate with DFT-based Monte-Carlo computation, suggesting that the degree of SRO is an intrinsic materials parameter that can be tuned to tailor the structure-property relationship. Strategies of obtaining different degrees of SRO by thermal-mechanical treatment will also be touched base in this talk.

2:30 PM MS04.02.04
Investigation of Defects in High Entropy Alloy HfNbTaTiZr by Positron Anihilation Spectroscopy Petr Hruska1, Jakub Cizek1, František Lukac1,2, Radek Musalek2, Oksana Melikhova1, Jan Kuriplach1, Miloslav Janecek1, Jiri Zyka1 and Jaroslav Malek3; 1Charles University, Faculty of Mathematics and Physics, Czechia; 2Institute of Plasma Physics of the Czech Academy of Sciences, Czechia; 3UJP PRAHA, Czechia

High entropy alloys (HEA) exhibit various combinations of interesting physical properties due to the formation of
solid solution stabilized by a high configurational entropy. HEAs with high melting point are promising candidates for low density refractory metals, e.g. HfNbTaTiZr alloy. Since conventional preparation by arc melting results in a dendritic structure of bcc phases, long term and high temperature annealing is necessary for homogenization of the structure [1]. On the contrary, powder metallurgy is a fast way of producing fine grained alloys. The HfNbTaTiZr powder prepared by gas atomization was processed by spark plasma sintering (SPS) at various sintering temperatures. By characterization of its microstructure, lattice defects and mechanical properties [2] the sintering conditions were optimized in order to obtain a fully dense single-phase material. Defects formed during the process of SPS were characterized by positron lifetime spectroscopy (LT). LT is a well established non-destructive experimental technique with high sensitivity to open-volume defects (e.g. vacancies and vacancy clusters, dislocations, grain and phase boundaries). Moreover, the experimental LT data can be directly compared with ab-initio theoretical calculations. Analysis of measured LT spectra enables both identification of the type of defects in the material as well as evaluation of their concentration. Since the concept of HEAs is inherently related to severe lattice distortions which affect also open volumes, any information on the defects in the bulk solid solution phases is invaluable. LT may be used also for monitoring of the remaining porosity at the very atomic level in alloys prepared by SPS.

Modeling Co-Cr-Fe-Ni-Mo High Entropy Alloys—Structural and Mechanical Properties Michael Gao1,2, Zongrui Pei1,3, Jeffrey Hawk1 and David Alman1; 1National Energy Technology Laboratory, United States; 2Leidos Research Support Team, United States; 3ORISE, United States

It is well known that addition of molybdenum to steels and nickel-base alloys can increase the mechanical strength and the resistance to pitting corrosion. However, it is less known how Mo addition may impact the atomic structure and hence the intrinsic physical and mechanical properties of the alloys as a function of temperature and composition. In present work, the evolution of the atomic structure (including short range order, atomic occupations, or local lattice distortion) of Co-Cr-Fe-Ni-Mo high entropy alloys in liquid, in solid, and during solidification is first studied using density functional theory (DFT) methods, ab initio molecular dynamics, and Monte Carlo simulations. This information gives implications for the mechanical properties from a thermodynamic perspective. As the next step, the elastic constants and stacking fault energies of the model alloys are calculated using DFT, which further improve our understanding of the impact of Mo on the yield stresses.

3:45 PM MS04.02.06
Microstructure Simulations of Complex Concentrated Alloy HfNbTaTiZr Jan Kuriplach1, Jakub Cizek1, Oksana Melikhova1, Frantisek Lukac1,2, Jiri Zyka2 and Jaroslav Malek1; 1Charles University, Czechia; 2Institute of Plasma Physics, Czechia; 3UJP Praha a.s., Czechia

The HfNbTaTiZr refractory alloy is intended for high temperature applications and crystallizes in the bcc structure at high temperatures. The microstructure of this alloy is studied by means of the density functional theory using the supercell approach. It is first explained why HfNbTaTiZr is not a true high entropy alloy. The tendency of the alloy to short range ordering is then demonstrated for several partially ordered structures based on the bcc lattice. Next, the Metropolis Monte Carlo algorithm is employed in order to simulate the short range order in the HfNbTaTiZr alloy. The tendency to short range ordering increases with the decreasing temperature. This indicates that a phase separation could occur at lower temperatures, which is indeed detected experimentally. The question why the alloy could not have an hcp structure at lower temperatures is also addressed. Finally, the structure of a $\Sigma_5$ grain boundary in the HfNbTaTiZr alloy is investigated. Such a grain boundary exhibits quite low grain boundary energy and the segregation of Ti is detected. The results of the simulations are compared with other experimental data available.

4:00 PM MS04.02.07
Microstructure Evolution of Refractory Alloys During Powder-Based Dealloying Alyssa Chuang and Jonah Erlebacher; Johns Hopkins University, United States

A key consideration in designing high-performance materials with exceptional strength and toughness is tuning the
microstructure. Dealloying is a processing method for producing metallic materials with a unique bicontinuous microstructure, which has been shown to exhibit size-dependent improvements in mechanical properties. Previously, dealloying was limited to electrochemical systems, but the emergence of liquid metal dealloying and solid state dealloying has expanded the capabilities of this technique to include refractory alloys.

Powder-based dealloying is a novel approach to creating bulk quantities of refractory metal composites with a complex, interconnected network of ligaments. By mixing and pressing together powders of the parent alloy with powders of the metallic solvent into a bulk sample, we can create a material in which dealloying occurs uniformly throughout the bulk of the material, not just at the geometric surface. These experiments offer insight into the microstructural evolution of dealloyed refractory metal composites as a function of time, temperature, and composition. Here we present an assessment of the mechanical properties of these materials, in addition to a study of the dealloying kinetics between pressed powders. Studying the fundamental kinetics of powder-based processing is the first step to developing the high-temperature processing techniques necessary to apply dealloying to additive manufacturing of refractory alloy composites.

4:15 PM MS04.02.08
Microdistortions Correlate with Misfit Volumes in High Entropy Alloys Wolfram G. Nöhring\textsuperscript{1,2} and William A. Curtin\textsuperscript{1}; \textsuperscript{1}École Polytechnique Fédérale de Lausanne, Switzerland; \textsuperscript{2}University of Freiburg, Germany

The yield strengths of High Entropy Alloys (HEA) have been shown to correlate with picometer-scale lattice distortions. Therefore, distortion measurements could be used to estimate strengths. Alternatively, a predictive model of HEA strength based on solute misfit volumes is available. Here, the connection between lattice distortions and misfit volumes is examined for two model ternary alloy families, fcc Cr-Fe-Ni and bcc Nb-Mo-V. The root mean square lattice distortion is nearly proportional to the misfit volume parameter over a wide composition range. The reported correlation of yield strength with lattice distortion is thus a consequence of the correlation between lattice distortion and misfit parameter and the derived dependence of yield strength on the misfit parameter.

4:30 PM OPEN DISCUSSION

4:45 PM MS04.02.10
Microstructure Evolution and Orientation Relationships of CoCrFeNi Thin Films Grown on (0001) α-Al\textsubscript{2}O\textsubscript{3} Younes Addab\textsuperscript{1}, Maya Katapadi Kini\textsuperscript{2}, Blandine Courtois\textsuperscript{1}, Alan Savan\textsuperscript{3}, Alfred Ludwig\textsuperscript{3}, Nathalie Bozzolo\textsuperscript{4}, Christina Scheu\textsuperscript{2}, Gerhard Dehm\textsuperscript{2} and Dominique Chatain\textsuperscript{1}; \textsuperscript{1}Aix-Marseille Univ, CNRS, CINAM, France; \textsuperscript{2}Max-Planck-Institut für Eisenforschung GmbH, Germany; \textsuperscript{3}Ruhr University Bochum, Germany; \textsuperscript{4}MINES ParisTech, PSL, France

The study of HEA in the form of thin films aims at providing missing data on HEA phase stability. Indeed, the small bulk volume of a film, combined with the presence of grain boundaries and interfaces, helps in achieving thermodynamic equilibration of these complex alloys. In addition, polycrystalline films can be used to test the role of grain boundaries on the mechanical properties of HEAs. Here we present a study of the stability of polycrystalline CoCrFeNi thin films, grown on (0001) α-Al\textsubscript{2}O\textsubscript{3} (c-sapphire), with respect to annealing treatments. It has been found that extremely large grains can grow in the film depending on their orientation relationship to the c-sapphire substrate. Despite their complex chemistry, the grains in the 200 - 670 nm thick CoCrFeNi FCC films investigated, adopt the same orientation relationships as those of pure FCC metal films on c-sapphire. However, the grains in CoCrFeNi grow much larger at homologous annealing temperatures.

The films have been synthesized at room temperature, using magnetron sputtering from four pure element targets in a chamber with UHV base vacuum. They consist of 30-100 nm wide columnar FCC grains with a <111> texture. Upon annealing for 1 hour in the range 973 K to 1423 K under an Ar-H\textsubscript{2} atmosphere, grain growth and grain boundary grooving compete to either stabilize or break-up the film. The microstructure evolves into larger grains and/or islands, of four different orientation relationships: OR1 (Me(111)[1-10]//α-Al\textsubscript{2}O\textsubscript{3}(0001)[1-100] and OR2 (Me(111)[1-10]//α-Al\textsubscript{2}O\textsubscript{3}(0001)[1-10] and their twins (OR1t and OR2t). Thinner films and higher temperatures favor the dewetting of the film to form single-crystalline islands. Dewetting initiates from holes which nucleate at grain boundary triple junction grooves, and which have deepened sufficiently to reach the substrate. At the highest temperatures, the OR2 and OR2t grains grow to sizes exceeding 1000 times the film thickness. The migration of the grain boundaries of these grains is fast enough to overcome both grooving and the nucleation of dewetting holes.
An alternative route toward production of high entropy alloy nanoparticles (HEA-NPs) is demonstrated using metal carburization and subsequent precipitation of graphite inside carbon nanotubes. Nanoparticles exhibit barely seen structures, including coexistence of different crystal structures and multiple phases. Magnetic hardening is also observed with saturation magnetization much greater than ferromagnetic particles consisting of single and/or binary components. Calculations support experiments and further reveal carbide mediated HEA-NP formation to be thermodynamic favorable.

Effect of Deposition Power on the Microstructural Properties of Sputtered AlCoCrCu0.5FeNi High Entropy Alloy (HEA) Thin Films Naveed Aziz Khan, Behnam Akhavan, Marcela M. M. Bilek and Zongwen Liu; The University of Sydney, Australia

High entropy alloy (HEA) thin films are immensely studied in recent times due to their excellent mechanical and physical properties having high hardness, superior corrosion resistance, and high electrical resistivity. This study reports the findings of radio frequency (RF) magnetron sputtered HEA thin films of AlCoCrCu0.5FeNi from a single stoichiometric target on Si (100) substrate in presence of argon with a substrate heating of 250 °C at three different powers of 200 W, 250 W, and 300 W. The argon flowrate was maintained at 15 sccm with a deposition pressure of 10 mTorr for all the films grown at three different powers. The characterization results reveal that the increase in deposition power from 200 to 300 W increases the average grain size roughly from 27 to 80 nm as well as the surface roughness of the films from 2.64 to 25.2 nm observed from the Scanning Electron Microscope (SEM) and Atomic Force Microscope (AFM) micrographs, respectively. X-ray diffraction (XRD) indicates that all the films are polycrystalline in nature with a mixture of FCC and BCC having a lattice parameter of 3.61 Å and 2.87 Å, respectively. The surface chemistry analysis from the X-ray Photoelectron Spectroscopy (XPS) confirms the presence of Al2O3 and Cr2O3 on the surface of all the HEA thin films grown at different deposition powers, acting as surface protective layers for superior oxidation and corrosion resistance. Energy Dispersive Spectroscopy (EDS) mapping confirms the homogeneous distribution of all the elements throughout the films grown at three different powers. The hardness data measured from the nanoindentation test shows a significant decrease in hardness from 15.95 GPa (200 W) to 4.84 GPa (300 W) with the increase in deposition power. The HEA films grown at various deposition powers were quite resistive and the highest resistivity of 945.13 µΩ·cm was obtained for the film grown at 250 W measured using the four-point probe method. The above characterization results show that the variation in deposition power is an important parameter to tune the microstructural properties of AlCoCrCu0.5FeNi HEA thin films during the sputtering process which intern governs the chemical and physical properties of the sputtered HEA thin films having potential applications as hard and protective coatings suitable for the energy and aerospace industry.

Predicting Properties of High Entropy Carbides from Their Respective Binaries Mina Lim1, Pranab Sarker2, Christina Rost3 and Donald Brenner1; 1North Carolina State University, United States; 2Duke University, United States; 3University of Virginia, United States

Recently, High Entropy Carbides (HECs) have been predicted the selection of candidate compositions with the phase stability from an entropy-forming-ability (EFA) descriptor from first principle. The predicted compositions are applied to disordered refractory five metal carbides, experimentally synthesized as rocksalt structure and
measured their mechanical properties. We report in this work the results of DFT calculations that were carried out to explore the degree to which properties of high entropy carbides containing different five-atom combinations from the elements Nb, Ta, Mo, W, Ti, Zr, Hf and V can be related to the properties of their respective binary compounds. Cohesive energy, bulk modulus and lattice constants from the Density Functional Theory (DFT) calculations were studied and compared between HECs composition and averaging the values from the binaries. These properties from the binary averages are either matched or slightly under-over estimated the DFT results. For the carbon vacancy formation energy (CVFE), the majority of HECs are distributed roughly within defined upper and lower limit CVFEs of the constituent binary carbides. Mixing multiple metal compositions in HECs still introduces the similar properties from the respective binaries and indicates more energetically stable in structures.

We also investigate the effect of carbon stoichiometry on thermal conductivity of high entropy carbide and its influence on the electrical contribution to thermal conductivity using DFT calculations together with semi-classical Boltzmann transport theory. The energy and electrical conductivity of the fully stoichiometric system, as well as systems containing carbon vacancies and interstitials were calculated. Both the vacancy and interstitial formation energies are positive, however, the energy for creating interstitial carbon is considerably larger than that for creating a vacancy such that the formation of a second carbon phase is highly favorable when excess carbon is introduced into the system. These results are consistent with experiment, where carbon indicative of a second phase is measured for high methane flow rates.

MS04.03.04

In Situ TEM Characterization of Segregation Kinetics of Quinary Solutes V-Nb-Mo-Ta-W in Cu(V,Nb,Mo,Ta,W) Alloy Yu-Ting Hsiao and Shou-Yi Chang; National Tsing Hua University, Taiwan

A robust ultrathin diffusion barrier layer is demanded for the Cu interconnects of integrated circuits to inhibit the rapid diffusion of Cu atoms and to prevent Si devices from failure. In recent years, based on the large positive mixing enthalpy between Cu and refractory metals and the thermodynamically-driven solute segregation, a “self-forming” technique was developed to generate a thin layer of refractory metal from a Cu alloy film doped with refractory solutes, for use as a diffusion barrier. Accordingly and additionally attributed to the high mixing entropy of multiple components, for the first time in our recent study, an ultrathin solid-solution layer of quinary V-Nb-Mo-Ta-W refractory alloy was self-formed from a Cu(V,Nb,Mo,Ta,W) alloy film. As confirmed by high-resolution TEM observations and elemental mappings, the doped solutes segregated to the Cu/Si interface and formed a continuous quinary alloy layer of only 1.5 nm thick. Because of the sluggish diffusion in high-entropy alloys, the quinary alloy layer was found to resist the interdiffusion of Cu and Si at 700 degree C, higher than the resisting temperature (< 600 degree C) of unitary metal layer. In-situ TEM characterization of the segregation of the quinary solutes V-Nb-Mo-Ta-W in a Cu(V,Nb,Mo,Ta,W) alloy foil was further conducted, and the diffusion kinetics of the solute elements in Cu were estimated. Elemental mappings indicated the entropy-stabilized incorporative diffusion of the five solute elements at an average rate of about 50 nm/h at 400 degree C. Mo and W segregated at a higher rate owing to the higher mixing enthalpies with Cu for 19 and 22 kJ/mol, respectively, while V, Nb and Ta segregated at a lower rate due to the lower enthalpies for only 2 to 5 kJ/mol.

MS04.03.05

Lattice Distortion Effect on Elastic Anisotropy of High Entropy Alloys Chao-Chun Yen1, Guan-Rong Huang2, Yun-Cheng Tan3, Han-Wen Yeh1, Shou-Yi Chang2 and Yu-Chieh Lo3; 1National Tsing Hua University, Taiwan; 2National Center for Theoretical Sciences, Taiwan; 3National Chiao Tung University, Taiwan

High-entropy alloys (HEAs) are at the hot topics of metallic materials research because of their outstanding mechanical properties, e.g. high fracture toughness in extreme temperature conditions. Currently, most researches focus on examining their plasticity instead of the elasticity. Compared with conventional alloys, HEAs may perform superior elastic properties because of the uneven local lattice strain. It is difficult for experimentalists to clarify the effect of severe lattice distortion on their mechanical properties. In order to investigate the elastic anisotropy, we conducted molecular dynamic simulations, composed of 1 ~ 5 atomic types containing Ni, Ni60W20, Ni60W40, FeCrNi, and CoCrFeMnNi under the Lennard-Jones potential, embedded-atom method (EAM) potential, and modified EAM potential. We analyzed Young's modulus E (h k l) and Poisson's ratio ν (h k l,θ) along [100], [110], and [111] loading direction for FCC crystals, and explored the performance of the elastic properties for each element type in HEAs. Our results suggest that electron density inconsistency among atomic elements dominates the elastic anisotropy of HEAs rather than the atomic radius difference.
Investigation of Laser Shock Peening Effect on Mechanical Behavior in CrMnFeCoNi High Entropy Alloy
Yanghoo Kim, Hyo Jae Jeong, Jae Hyang Lee and Jiyong Park; Korea Institute of Industrial Technology, Korea (the Republic of)

Laser shock peening process is a well-developed surface enhancement method which enhance fatigue life and damage tolerance of metallic materials by introducing a beneficial residual compressive stress. In this study, the laser shock peening effect on microstructure and mechanical behavior in face centered cubic CrMnFeCoNi high entropy alloy, known as Cantor alloy, was investigated. Three specimens with different thermomechanical condition, or recrystallized, cold rolled and laser shock peened after recrystallization, were subjected to hardness and sliding wear test to quantify the laser peening effect. Clear improvement of hardness and wear resistance was confirmed with comparable level to the rolled condition as well as residual stress reached several hundred MPa near the surface.

Efficient Mass Transport Calculations Using a Variational Principle Dallas R. Trinkle; University of Illinois at Urbana-Champaign, United States

While first-principles methods can compute activated state energies using the nudged-elastic band method, upscaling to mesoscale mobilities requires the solution of the master equation. The general solution for mass transport coefficients involves the inversion of rate matrix: the Green function. However, while the rate matrix is typically sparse, its inverse is not; moreover, numerical algorithms for the Green function are currently only available for cases of dilute defect concentration. By recasting the calculation of transport coefficients as a variational problem, we can compute transport coefficients from thermal average quantities instead of trajectory-based calculations. The variational principle also ensures that our diffusivity calculations are upper bounds of the true diffusivities. Replacing kinetic Monte Carlo calculations with Monte Carlo averages, or approximations for thermal averages, also increases the efficiency of mass transport calculations. We showcase this approach for random multicomponent systems.

Computational Modelling of Interdiffusion in CoCrFeMnNi High Entropy Alloys Mohammad Afikuzzaman, Irina Belova and Graeme Murch; Newcastle University, Australia

High-entropy alloy (HEAs) are a class of multicomponent alloy made with equal or near equal quantities of five or more principal elements. In this study, the problem of interdiffusion in HEAs is addressed. Detailed studying of the diffusion composition profiles in several interdiffusion couples in CoCrFeMnNi is performed. A constant as well as a composition dependent interdiffusion matrix was used for investigating the diffusion behaviour in CoCrFeMnNi HEAs. These composition dependent interdiffusion matrices are calculated according to the Darken and the Manning formalisms. MATLAB programing language is used as the main tool for generating composition profiles using an explicit finite difference method (EFDM). The simulated composition profiles are found to be in a very good agreement with the available experimental results [1, 2]. The ultimate purpose of this modelling is to systematically investigate interdiffusion in CoCrFeMnNi alloys in diffusion couples with substantial changes in composition.

Keywords: Interdiffusion, High entropy alloy (HEAs), Manning approach, Darken approach

High-entropy alloys, or complex concentrated alloys, are currently of significant attention in materials science owing to their exceptional mechanical properties that include the considerable cryogenic ductility of FCC-type alloys and the superior elevated-temperature strength of BCC-type alloys. It has been proposed that, in single-phase high-entropy alloys, the intrinsic atomic-level complexity causes a severe lattice distortion and an atomic-level pressure variation, which further affects the dynamic behavior of crystalline defects. However, the atomic-level formation mechanism of crystalline defects and the interaction of these defects with the intrinsic distorted and heterogeneous environment in high-entropy alloys remain unclear. In our previous in-situ microscopic experiments of micro- and nano-pillar compression in several crystalline systems of high-entropy alloys, the gum-like uniform barrel-deformation accompanied with the abundant nucleation sites of plastic regions was clearly observed. With the aid of atomistic simulations, the soft spots identified by the spatial distributions of low-frequency vibration modes have been further found to serve as the precursors of atomic-level rearrangement in solid-solution alloys. In high-entropy alloys, the successive defect growth exhibits a chain-like manner which relies on the coupling of local shear transformations and vortex-like atomic motion. This formation and growth mechanism resembles the reported nucleation mechanism of shear transformation zone in metallic glasses, which is different from the dislocation slip-induced planer fault growth in dilute solution alloys. In addition, the extremely short correlation length of mechanical heterogeneity in high-entropy alloys suppresses the synchronized motions of dislocation line, which impedes the long-range dislocation slip and contributes toward a strong strain hardenability. The critical defect formation mechanism at the atomic level provides the theoretical description of various-signature mechanical properties of high-entropy alloys.

High entropy alloy (HEA, also known as compositionally complex alloy) refers to simple-phase solid solution alloy that contains multiple principal components in equimolar or near-equimolar ratios. To computationally address the complexities of this type of high-order alloy systems, we have performed atomistic simulations to predicte the solid-solution stability as well as the short-range ordering in CoCrFeNi and AlCoCrFeNi bulk alloys and CoNiRuRh nanoparticles. In our simulations, the interatomic interactions were described using a set of modified embedded atom method (MEAM) interatomic potentials for these alloy systems. First, we used atomistic simulation methods to examine solid-solution phase formation rules for CoCrFeNi high entropy alloy. Using the Monte Carlo (MC) simulations based on the developed MEAM potentials, we sampled the thermodynamically equilibrium structures of the CoCrFeNi alloy and further predicted that the CoCrFeNi alloy could form a solid solution phase with high configurational entropy of 1.329R at 1373 K. Then, we examined the stability of this solid solution phase of the CoCrFeNi alloy against the well-recognized solid-solution phase formation rules by varying the MEAM potentials and thus tuning the atom size and mixing enthalpy in the alloy. Our simulation results revealed that it required atom size difference effect and mixing enthalpy effect -10 kJ/mol < ΔH < 0 kJ/mol for the modeled CoCrFeNi alloy to remain a single solid solution phase. Furthermore, we studied the stability of solid-solution phase of AlxCoCrFeNi HEAs using the developed MEAM potentials and the atomistic MC simulation method. In our MC simulations, different constituent elements were allowed to exchange their positions and thus the modelled HEAs were relaxed to their thermodynamic equilibrium states after several millions MC steps at 1300 K. The mixing Gibbs free energy of the HEAs was calculated using adiabatic switching thermodynamic integration method. We predicted that the AlxCoCrFeNi HEAs would form a single fcc solid-solution phase when x<0.21, a single bcc solid solution phase when x>1.08, whereas a mixture of fcc and bcc phases when 0.21<x<1.08. Our theoretical results are quite consistent with experimental observation. Moreover, we investigated the formation of solid solution phase in Co_{0.12}Ni_{0.14}Ru_{0.43}Rh_{0.30} nanoparticles with size ranging from 2 to 5 nm through a combined molecular dynamics (MD) and MC approach. Our simulation results indicated that the local severe lattice distortion could block the diffusion of atoms and hence lead to a stable solid solution phase during a carbothermal shock synthesis procedure. Consequently, we have demonstrated that atomistic simulation techniques as useful methods for understanding the composition-structure-property relation of novel high entropy alloys.
Correlated Multimodal In Situ Analysis of Oxidation of High Temperature Alloys

Arun Devaraj1, Bharat Gwalani1, Elizabeth J. Kautz1, Sten Lambeets2, Libor Kovarik2, Daniel Perea2, Daniel Schreiber1, Swapup Chena2, Yi-Sheng Liu3 and Sutharampillai Thevuthasan2; 1Pacific Northwest National Laboratory, United States; 2Env Molecular Science, United States; 3Lawrence Berkeley National Laboratory, United States

Metallic alloy surface oxidation process at high temperature remains inadequately understood. The early stages of this complex process involve structural and chemical transformations that require to be observed and described at the atomic scale. When it comes to high temperature alloys with complex composition such as high entropy alloys, the possibility of multiple oxide product phases further complicates the oxidation mechanisms. Hence, we employed in situ transmission electron microscopy, an environmental reaction chamber attached to an atom probe tomography and synchrotron based x-ray absorption near edge spectroscopy, in order to reveal the structural, compositional and chemical state transformations occurring during early stages of metallic alloy oxidation at high temperatures. This multimodal approach was used to analyze oxidation of selected model and commercial Zirconium alloys, Titanium alloys and high entropy alloys at high temperatures. We demonstrate the atomic scale changes to the composition of oxide layers, formation of polycrystalline structure of oxides, and presence of metastable phases in the early stages of oxidation. The time dependent variation of structure, composition and chemical state of the oxide layers can be correlated to corresponding alloys mechanical properties and thus can guide the development of accurate predictive mechanistic models.

Calculating Thermal Conductivity from the Electron and Phonon Subsystems in High Entropy Alloys

Michael J. Abere, Christopher B. Saltonstall, Nicolas Argibay and Andrew B. Kustas; Sandia National Laboratories, United States

The thermal conductivity of high entropy alloys does not follow typical trends in metals. Not only are they an order of magnitude less conductive than what rule of mixtures would predict, but their conductivities are also known to increase with temperature between 300-550K. Here, transport is calculated in an analytical model as the sum of contributions from the electron and phonon subsystems. For the lattice subsystem, conductivity is treated with the Leibfried and Schlömann formulation with perturbations for both electron-phonon interactions and point defect scattering. The electron subsystem is dominated by alloy scattering, which is calculated based on a virtual crystal approximation derived from each constituent’s Lennard-Jones potential. The model predictions are then compared to time domain thermoreflectance measurements in the Al0.5CoCrFeNiCu as well as previously published measurements of the Al0.37CoCrFeNi alloy.

Utilizing AI Algorithms for High Speed, High Temperature, Correlative Characterization of AlxFeCrNiMn (x=0, 0.3, 1) Alloys

Eric Hintsala1, Youxing Chen2, Bernard Becker1, Nan Li3, Nathan Mara4 and Douglas D. Stauffer1; 1Bruker Nano Surfaces, United States; 2University of North Carolina at Charlotte, United States; 3Los Alamos National Laboratory, United States; 4University of Minnesota Twin Cities, United States

Development of new structural materials for service under extreme conditions is slowed by the lack of high-throughput test protocols for investigating properties under relevant operating conditions. Here we demonstrate a method that integrates high-throughput nanoindentation mapping with precise temperature control under vacuum atmosphere. AlxFeCrNiMn (x=0, 0.3, 1) high entropy alloys (HEAs), which may possess the strength and stability...
required for high-temperature structural materials for nuclear applications, are investigated here. These alloys have distinct microstructural morphologies, and nanoindentation mapping reveals the mechanical behavior of the distinct phases as a function of temperature up to 400°C. The complexity of the microstructure, investigated under correlative conditions, allows the determination of specific phase properties. The FeCrNiMn consists of a FCC matrix with BCC precipitates exhibits significant softening in both phases at elevated temperature. In contrast, both the FCC phase and FCC-BCC phases present in Al_{0.3}FeCrNiMn show approximately 90% retention of the room temperature hardness at 400°C, and AlFeCrNiMn with BCC and B2 structures show a similar, 85%, retention of hardness.

Artificial intelligence algorithms, e.g. clustering, allow the for the relatively fast binning of structure and property into statistical forms without losing the location information required for the reproduction of maps. Experimental techniques and a brief discussion of what is required to validate the AI clustering is presented.

Mechanical Performance of Irradiated Refractory High Entropy Alloys at Elevated Temperatures Bo-Shiuan Li, Anna Kareer, Angus J. Wilkinson and David Armstrong; University of Oxford, United Kingdom

Refractory high-entropy alloys (RHEAs) are an alternative type of HEAs that possess BCC matrix and superior high-temperature strength compared to their FCC predecessors, making them ideal structural materials for extreme nuclear environment. The mechanical properties of a single-phase quaternary TiVCrTa alloy were investigated after ion-irradiation, using advanced micromechanical tests and high-resolution electron microscopy (HR-EBSD, TEM). Nanoindentation results of the as-cast sample irradiated to 3.5 dpa showed no irradiation hardening and TEM confirms negligible defect accumulation. Deformation mapping around the nanoindents via HR-EBSD were also carried out to provide mechanistic understanding of the irradiation resistance in term of change in strain localisation and GND density. Future experiments will apply high-temperature nanoindentation on the irradiated samples so the mechanical performance under relevant reactor operating conditions can be measured.

A Molecular Dynamics Approach after Burnup and Its Integrity in the Interim of Irradiation Willie Ahli¹, Zhao Hongtao² and Li Zhongyu³; ¹Harbin Engineering University (HEU), China; ²Harbin Engineering Uni, China

High Burnups can cause major structural changes in the edge of the fuel rod and a general degradation of the thermal conductivity. In irradiated oxide fuels of UO₂ and PuO₂, several fission products (FP) are produced and they take various chemical states depending on the conditions of the fuel. This work, based on the energy of the specified metallic fuels predominantly has some passive safety features during core off-normal events. During the structural and mechanical property changes, dissolved fission gases as well as thermal expansion cause the fuel to expand and swell to the cladding, where the fuel at the interface will transform to the molten phase, reducing reactivity in the reactor and helping to prevent the core from going supercritical. Uranium in particular has a low melting point; however, by alloying to metals that are also in BCC phase at high temperatures, the melting point can be increased. Lattice parameter, Burnups and the thermal conductivity were calculated for specified UO₂ and PuO₂. This calculations relate the degradation of thermal conductivity with a number of pores and increasing temperature. Finally, the migration energy barrier and the recovery energies of the obstruction type defects were calculated by molecular dynamics and molecular statics simulation.

Crack Propagation in Metallic Glass TEM Samples Xilei Bian, Gang Wang, Haijian Chu and Tong-Yi Zhang; Shanghai University, China
The present presentation reports experimental observations of crack propagation in both tough and brittle metallic glasses (MGs) via in situ high-resolution transmission electron microscopy (HRTEM) tensile tests, illustrating the cracking behavior of MGs is governed by an intrinsic cavitation mechanism ahead of the crack tip. Based on the experimental results, we proposed a model of surface diffusion induced cavitation in the strained region ahead of a crack tip and conducted numerical simulations to verify the proposed model. The simulation results catch the main and essential features of the cavitation mediated cracking behavior observed in situ HRTEM tensile tests. In addition, we also observed in situ HRTEM tensile tests that introducing nanocrystals in the front of the crack can effectively blunt the crack tips and retard the crack propagation. The in situ HRTEM observations and numerical simulations validate the proposed model of surface diffusion induced cavitation and cracking in MGs, thereby offering new insights into the deformation and cracking mechanism and paving a novel way for the design of MGs with high toughness.

3D Characterization of Nano-Scale Precipitates in Shape-Memory Alloys Dexin Zhao, Tejas Umale, Jobin Joy, Dimitris Lagoudas, Ibrahim Karaman and Kelvin Y. Xie; Texas A&M University, United States

Shape-memory alloys (SMAs) have wide aerospace and biomedical applications due to the capability to recover from large deformations via solid-to-solid transformations from martensitic to austenitic phases. Recently, Ni-Ti-Hf SMAs have attracted tremendous research interests because their phase transformation temperature is higher than that of traditional Ni-Ti counterparts. This expands their applications in high-temperature environments. Our previous research has indicated that the presence of nano-scale precipitates could further improve the cyclic transformation response in the Ni-Ti-Hf system. However, there lacks a detailed understanding of these precipitates, including crystal structure, chemistry, size, distribution and volume fraction. Moreover, the precipitate evolution as a function of heat treatment temperature and time is also not well understood. In this work, we combine STEM with TEM tomography to construct 3D models for these nano-scale precipitates to characterize and understand why nano-scale precipitates in SMAs could lead to even more consistent actuation responses in Ni-Ti-Hf SMAs.

Role of Advanced Characterization in Novel Alloys Design Yufeng Zheng¹, Stoichko Antonov², Qiang Feng² and Hamish L. Fraser³; ¹University of Nevada, United States; ²University of Science and Technology Beijing, China; ³The Ohio State University, United States

In order to reduce the fossil fuel consumption and greenhouse gas emissions, there is a continued demand for the new generation high temperature materials and lightweight materials for better performance. Integrated Computational Materials Engineering (ICME) has the capability to replace the time-consuming and labor-intensive traditional trial-and-error approach to expedite the design of novel materials and predict the microstructure and performance of materials produced by advanced manufacturing. However, the physics-based or data-based models in ICME highly rely on the accurate understanding of microstructure in materials during processing and service. For example, in order to produce shaped products that possess consistent and high-quality property performance using additive manufacturing, it requires the provision of solutions to problems, such as coarse columnar microstructures, porosity and residual stresses, which requires rapid and reliable microstructure determination using multi-scale ex-situ and in-situ characterization techniques. This presentation is mainly focused on the use of analytical microscopy techniques to explore the fundamental mechanisms in the development of novel metallic materials. Two studies about designing high temperature used Ni based superalloys and high strength lightweight titanium alloys for aerospace application via microstructure engineering utilizing advanced characterization will be introduced. The effect of Re on the long-term creep behavior and microstructural evolution in Ni-based single crystal superalloys have been systemically studied via multiscale electron microscopy, atom probe tomography and synchrotron XRD. The results show that Re is an effective creep strengthening element for Ni-based single crystal superalloys and long-term creep life of the alloys can be significantly improved by the addition of small amount of Re. Ultra-high strength metastable beta titanium alloys, via precipitation strengthening through the omega phase assisted alpha precipitation mechanism, have been realized by coupling the atomic resolution aberration-corrected S/TEM with phase field modeling. The pre-formed nano-scaled omega phase particles can alter the local structure and composition in the parent phase matrix and therefore provide additional driving force and nucleation sites for the formation of super-refined scale alpha phase precipitates.

Solute-Dislocation Interactions in bcc Refractory Alloys and Resulting Effects on Mechanical Properties
Yong-Jie Hu1,2, Michael Fellinger3, Brady Butler4, Laszlo Kecskes5, Dallas R. Trinkle3, Liang Qi2 and Zi-Kui Liu1;
1The Pennsylvania State University, United States; 2University of Michigan, United States; 3University of Illinois at Urbana-Champaign, United States; 4U.S. Army Research Office—Materials Science Division, United States; 5Johns Hopkins University, United States

The solute-induced softening and hardening effects in bcc W for twenty-one substitutional alloying elements (Al, Co, Cr, Fe, Hf, Ir, Mn, Mo, Nb, Ni, Os, Pd, Pt, Re, Rh, Ru, Ta, Tc, Ti, V and Zr) are examined to search for a similar softening effect as that observed with Re. The changes in energy barriers of dislocation motion caused by solute-dislocation interactions are directly computed via a first-principles approach with flexible boundary conditions. The effect of solutes on the critical resolved shear stress of the $\frac{1}{2} <111>$ screw dislocation in bcc W at room temperature is quantitatively predicted, as a function of alloy concentration, via a mesoscopic solid-solution model using the first-principles results as input. Al and Mn are proposed to be promising substitutes for Re as these two elements introduce similar softening effects as Re in bcc W. In addition, the trends of the solute-dislocation interactions, and their correlations to the dislocation core structure geometries are discussed.

Thermal Processes and Mechanisms in Refractory Nanomultilayers Andrea M. Hodge; University of Southern California, United States

The potential of nanomultilayers (NMMs) as a route to synthesize nanostructures is explored by examining the microstructural evolution of refractory Mo-Au, Hf-Ti and Ta-Hf NMMs through differential scanning calorimetry (DSC) and heat-treatments at different temperatures. Transitions occurring between room temperature and 1000°C are identified using DSC scans. The microstructural evolution of these materials and the nanostructures that develop after annealing are not well understood but can provide insight of active thermal processes and stabilization mechanisms. A wide range of characterization techniques including TEM and APT were utilized to examine compositional changes and gain insight into thermally activated events such as layer roughening, solute grain boundary segregation and phase separation. Understanding the evolution of these NMMs will allow tailoring nanomaterials with enhanced thermal stability.

Enhancing High Temperature Performance of Titanium Matrix Composites by Constructing Network Microstructure Lujun Huang; Harbin Institute of Technology, China

The improvement of mechanical properties must be achieved by designing and constructing more suitable microstructure, such as hierarchical microstructure and nano microstructure. In order to significantly enhance the creep resistance of titanium alloys, one two-level hierarchical microstructure with micro-TiB whiskers (TiBw) and nano Ti5Si3 reinforcements were constructed to form the modified composites by powder metallurgy combining with in-situ synthesis and precipitation. The micro TiBw reinforcement were in-situ synthesized around titanium matrix particles, which formed the first scale network microstructure. The nano Ti5Si3 particle were precipitated and distributed in the beta phase around alpha phase which formed the second network microstructure. The results showed that the high temperature strength has been significantly enhanced. The tensile strength at 550oC for Ti6Al4V matrix composites is increased to 1050MPa. Moreover, the creep rate of the modified Ti6Al4V matrix composites was remarkably reduced by an order of magnitude compared with the conventional Ti6Al4V alloys at 550 oC, 600 oC, 650 oC under the stresses between 100 MPa and 350 MPa. Moreover, the rupture time of the composites increased by 20 times, compared with Ti6Al4V alloys at 550 oC/300 MPa. The superior creep resistance can be attributed to the two-level hierarchical microstructures and the two-scale reinforcements. The micro-TiBw reinforcement in the first network boundary contributed to creep resistance primarily by blocking grain boundary sliding, while the nano-Ti5Si3 particles in the second network boundary mainly by hindering phase boundary sliding. In addition, the nano-Ti5Si3 particles were dissolved to smaller-sized Ti5Si3 particles during creep deformation due to high temperature and external stress, which can further continually enhance the creep resistance. Finally, the creep rate during steady-state stage was unprecedentedly decreased, not stable or increased, which
manifested superior creep resistance of the composites. The calculated results indicated that the dislocation climb is the dominant mechanism for the composites tested at 550 oC/(250-350) MPa and 650 oC/(100-250) MPa.

First Principles High-Throughput Screening to Enhance the Ductility of Lightweight Magnesium Alloys Qi An, Yidi Shen, Hongwei Wang and Bin Li; University of Nevada, Reno, United States

Magnesium (Mg) and its alloys are the lightest structural metals, but the low ductility at low temperature prevents them from massive manufacture process and extended engineering applications. Therefore, it is urgent to improve the ductility of Mg. Here, to provide guidelines of accelerating this improvement, we proposed a hierarchical high-throughput screening (HHTS) approach for alloy design that is based on full general stacking fault (GSF) energy surface (γ-surface) derived from density functional theory. We simplify the HHTS approach by examining only the unstable stacking fault energy (γus) on γ-surface. We applied this approach to determine the promising dopant elements in Mg-X binary alloys which may activate the pyramidal dislocations by decreasing GSF energy and thus improve the ductility of Mg. From our HHTS approach we sifted out ten promising elements, including Hg, Tl, Sn, Sb, Bi, Te, As, Pb, In and Ca. Particularly, Mg-Te alloy has the lowest γus of 156 mJ/m² among all binary alloys, which is 25% lower than that of Mg (209 mJ/m²), suggesting that it is the most promising alloy to enhance the ductility of Mg.

4:45 PM MS04.05.09
Role of Five-Fold Symmetry in Undercooling of Aluminium Based Alloys Noel Jakse; Grenoble institute of Technology, France

Understanding evolutions of transport properties in undercooled liquids and their interplay with their structural features represents an important issue for solidification processes of metallic alloys, such as crystallization and formation of quasi-crystalline or amorphous phases [1–4]. In the present work, we focus on various classes of Aluminum alloys such as Al-Ni [5], Al-Cu [6], Al-Cr [7] and Al-Zn-Cr [8] that are important for many automotive and aeronautic applications due to their light weight, good forgeability, high thermal conductivity, and low corrosion. Using ab initio molecular dynamics, we simulate the undercooling process of these alloys during which we monitor the structural and atomic transport properties. We find that diffusion, viscosity and structural relaxation time undergo a crossover between an Arrhenius and non-Arrhenius behavior at a temperature T_X during the slowing down, which corresponds to an onset of dynamic heterogeneities (DHs) that develop. The structural features display characteristics compatible with the occurrence of the icosahedral short-range order (ISRO) as well as the development of a medium range order (MRO) upon cooling. The interplay between the ISRO and MRO and the dynamic heterogeneities is examined. The differences and similarities between these alloys is also discussed.

Investigation of Stacking Fault and Antiphase Boundary Segregation in Ni-Based Superalloys Using Density
**Functional Theory** Brian S. Good and Timothy M. Smith; NASA Glenn Research Center, United States

Ni-base superalloys have a long history of use in jet turbine engines, and efforts to improve their performance in that application are ongoing. It is known that the precipitation of the Ni$_3$Al gamma prime phase within the disordered FCC gamma phase strengthens the overall material. However, in the high-temperature environment found inside a turbine engine, creep can cause the gamma prime phase to transform to different, weaker phases along stacking faults, which leads to a deterioration of performance. In the gamma prime phase, one mode of creep deformation is the formation of stacking fault ribbons, which consist of intrinsic stacking faults further shearing into antiphase boundaries (APBs). It is also known that certain alloying additions exhibit segregation to gamma prime stacking faults. If elements that segregate to the intrinsic stacking fault but not to the APB could be identified, the inclusion of such elements could lead to improved creep strength in these alloys.

To investigate this possibility, a density functional investigation was performed on the segregation of W, Mo and Cr to both a superlattice intrinsic stacking fault (SISF) and an APB. It was found that W, Mo and Cr all exhibit segregation to the SISF. In contrast, for the APB, Cr was either energy-neutral or segregated, depending on the presence of additional nearby Cr or on the specific lattice site on which it was placed. However, Mo and W did not segregate to the APB. Due to the segregation of W and Mo to the SISF but not to the APB, the inclusion of these elements could provide a degree of protection against creep-related deterioration.

**MS04.06.02**

**On the Segregation of Re at Defects in the γ’ Phase of Ni-Based Single Crystal Superalloys** Xiaoxiang Wu$^1$, Surendra Kumar Makineni$^1$, Jaber Rezaei Mianroodi$^{1,2}$, Pratheek Shanthraj$^{1,3}$, Bob Svendsen$^{1,2}$, Christian Liebscher$^1$, Gerhard Dehm$^1$, Paraskevas Kontis$^1$, Dierk Raabe$^1$, Baptiste Gault$^{1,4}$ and Gunther Eggeler$^1$; 1Max-Planck-Institut für Eisenforschung GmbH, Germany; 2RWTH Aachen University, Germany; 3The University of Manchester, United Kingdom; 4Imperial College London, United Kingdom; 5Ruhr-Universität Bochum, Germany

Single crystal Ni-based superalloys are an essential material for application in gas turbines in aero engines and power plants due to their outstanding high temperature creep, fatigue and oxidation resistance. These properties originate from their typical γ/γ’ microstructure, and by manipulating different alloying elements, the γ/γ’ morphology, misfit and corresponding properties will change significantly. A turning point was the addition of 3 wt.% Re in the 2nd generation of single crystal Ni-based superalloys, which doubled its creep life. Despite the significance of this improvement, the reasons for the so-called ‘Re effect’ continue to be debated in the field of superalloys. It is of great scientific and economic interest to understand the role of Re in extending the lifetime of single crystal Ni-based superalloys, and for the development of new superalloys. Here, we show direct evidence of Re, as well as Cr and Co, segregating to crystalline defects (dislocations and stacking faults) formed during creep deformation inside γ’, using combined transmission electron microscopy and atom probe tomography. Phase field modelling is employed to support our interpretation of the effect of Re on dislocations and stacking faults. The new observations and understanding regarding the ‘Re effect’ will help design future Ni-based and Co-based superalloys.

**MS04.06.03**

**The Effect of Solutionizing and Ageing Temperature on the Microstructural Evolution and the Mechanical Properties of Allvac 718Plus** Geeta Kumari$^{1,2}$, Carl Boehlert$^1$, M Sundararaman$^2$ and S Sankaran$^2$; 1Michigan State University, United States; 2Indian Institute of Technology Madras, India

Alloy Allvac 718Plus is a relatively new superalloy developed to improve the properties of the widely-used superalloy Inconel 718 (IN 718). The strength of IN 718 significantly decreases at temperatures of 650°C and above due to the transformation of the metastable, γ” (tetragonal, D022 structure) phase into the δ phase (orthorhombic, D0a structure). Allvac 718Plus, which was designed to address this issue, exhibits service temperature up to 704°C (55°C more than that for IN 718 and close to Waspaloy) and its formability is similar to IN 718 and better than that for Waspaloy. The major changes in chemistry for Allvac 718Plus include a three times increase in aluminum (Al) content and the substitution of 18wt.% iron (Fe) with 9wt.% cobalt (Co) and 10wt.% Fe. The change in the (Al+Ti)/Nb ratio favors the formation of the γ’ as the major strengthening phase in Allvac 718Plus. Another significant phase in Allvac 718Plus is the Nb-rich phase δ, which preferentially forms at grain boundaries. The δ phase plays a major role in controlling the grain growth during processing and fabrication. The volume fraction of the γ’ and the δ phase can be controlled by solutionizing followed by aging. In the present work, the effect of
solutionizing and aging on the resulting microstructure and the corresponding mechanical strength of Allvac718Plus was examined. Samples were solutionized at two different temperatures, 1000°C and 954°C, and then aged. To study the effect of aging temperature on solutionized samples, three different aging treatments were performed as follows: 1) one-step aging at 788°C for 16 h followed by faster cooling, 2) one-step aging at 704°C for 16 h followed by faster cooling, 3) Two-step aging at 788°C for 8 h followed by cooling to 704°C for 8 h then air cooling. Metallographic samples of the as-received and heat-treated samples were prepared to identify different phases using optical microscopy and scanning electron microscopy. Electron backscatter diffraction and energy dispersive spectroscopy was performed to investigate the composition of the various phases. Room temperature and elevated-temperature tensile and hardness testing will be performed on the aged samples to investigate the effect of the microstructure on the strength. The data obtained will be compared with the existing data and will help in understanding the dependency of time and temperature on the microstructural changes and mechanical properties.

MS04.06.04
Estimation of High-Temperature Properties of Structure Alloy by Molecular Dynamics Simulation Kenso Ueno and Yasushi Shibuta; The University of Tokyo, Japan

We proposed new methodology for estimation of high-temperature properties of structure alloy by molecular dynamics simulation. Using this method, solid-liquid interfacial properties of Fe-Cr alloy are investigated with an EAM potential (Bonny et al., Philo. Mag. 91 (2011) 1724). After estimating melting points of pure Fe and Cr of the EAM potential, solidus and liquidus compositions with respect to temperature were estimated as follows. The solid-liquid coexisting system with the same concentration (X_S = X_L) as the initial state was relaxed under the constant pressure and temperature (NPT) condition. Calculations were carried out until the propagation of the solid-liquid interface due to solidification and solute partition did not proceed. It is considered that converged concentrations in solid and liquid phases correspond to the equilibrium concentration at the set temperature. Therefore, the same calculations were performed for various temperatures. By connecting solidus and liquidus concentrations with respect to temperature, the phase diagram for the Fe-Cr alloy for the EAM potential was successfully derived.

Next, a solid-liquid coexisting system with equilibrium concentrations in the obtained phase diagram are relaxed at equilibrium temperatures to investigate the temperature dependence of the solid-liquid interfacial energy. The capillary fluctuation method (Hoyt et al., Phys. Rev. Lett. 86 (2001) 5530) is employed to estimate the solid-liquid interfacial energy including its anisotropy. The solid-liquid interfacial energy increases with increasing equilibrium temperature. On the other hand, regarding the anisotropy effect, the interfacial energy of solid-liquid interface with (100) orientation is larger than those of (110) and (111) orientations at all temperatures. In summary, the methodology proposed in this study can be easily applied to other novel high-temperature structural alloys including refractory alloys and Co-based superalloys.

MS04.06.05
Dislocation Mobility in BCC Multicomponent Solid Solution Alloys Han-Wen Yeh1, Chao-Chun Yen2,1 and Yu-Chieh Lo1; 1National Chiao Tung University, Taiwan; 2National Tsing Hua University, Taiwan

Multicomponent solid solution alloys (e.g., high entropy alloys) are at the cutting edge of metals research due to their outstanding mechanical properties such as the refractory characteristic in BCC HfNbTaTiZr alloys. At high temperature, the major deformation mechanism of BCC is dislocation creep, and it is directly related to the dislocation mobility. However, until now, studies have been most devoted to kink-pair nucleation and kink migration mechanism in multicomponent BCC alloys, and seldom discussed the dislocation mobility in them. Therefore, we conducted large scale molecular dynamics to study dislocation mobility in multicomponent BCC alloys including AlCoNiFe and AlCoNiFeTi by applying embedded-atom method (EAM) potential. To look into the dislocation mobility, we measured the dislocation velocities of multicomponent BCC alloys under different stresses, components, and temperatures. By this work, we could figure out the influence to the dislocation mobility and further affect the creep.

Modeling and Simulation of Defect and Defect Behavior in High Entropy Alloys Shigenobu Ogata¹², Junping Du¹, Peijun Yu¹, Shuhei Shinzato¹, Tomohito Tsuru¹, Tomotsugu Shimokawa³, Koretaka Yuge², Yoshiteru Aoyagi² and Momoji Kubo⁵; ¹Osaka University, Japan; ²Kyoto University, Japan; ³City University of Hong Kong, Hong Kong; ⁴Japan Atomic Energy Agency, Japan; ⁵Kanazawa University, Japan; ⁶Tohoku University, Japan

High-entropy alloys (HEAs), are multi-component random solid solution alloys with nearly an equiatomic composition, have been receiving tremendous attention due to the excellent cryogenic temperature ductility, superior mechanical strength and good wear resistance, exceptional damage tolerance. These excellent and distinguishing mechanical properties originates the curious properties of the lattice defects, such as vacancy, dislocation, twin, grain boundary, and so on, owing to the characteristic non-equilibrium quasi-random / short-range ordered atomic arrangement. To reveal the fundamentals of the mechanical properties, we studied the relation between the local atomic arrangement and the defect behavior and properties, such as vacancy diffusion, dislocation motion, deformation twinning and phase transformation, and grain boundary stability, using first-principles, molecular dynamics and Monte Carlo methods. We show that the local atomic arrangement, which is specified by the short-range order parameter and the local atomic strain, strongly correlated with the defect behavior in HEA.

Effect of Atom Propotions to Co-Cr-Mn-Fe-Ni High-Entropy Alloys Mechanical Behaviors—Molecular Dynamics Investigation Satoshi Takemori and Toshihiro Kameda; University of Tsukuba, Japan

High entropy alloys (HEAs) are solid solution materials composed of a large number of components (five and more) available in equiatomic or nearly equiatomic proportions. HEAs are considered to show “high entropy effect, severe lattice distortion effect, sluggish diffusion effect and cocktail effect”(B.S. Murty (2014), M.C. Gao(2016)). Since the proportion of each elements in HEAs changes those mechanical behavior, the most suitable assortment can be chosen for each objectives as a structural material by investigation.

Molecular dynamics(MD) simulation is the powerful tool to investigate those atomic effects and the influence of proportion because proportions of each atoms are easily decided for comparison of mechanical behaviors. The second nearest neighbour(2NN) modified embedded atom method(MEAM) potential is used to our MD simulation. Each parameters of 2NN-MEAM potentials of five elements Co, Cr, Fe, Mn and Ni pure and binary systems are taken from published literature.

In this study, influences of Cr proportion for mechanical behaviors at non-equiatomic Co-Cr-Fe-Mn-Ni high-entropy alloy were observed. Models are monocrystals and fcc structures. Six models with different Cr proportions were set to 5, 10, 15, 20, 25, and 30 percents as Co, Fe and Mn proportions were set to 20 percents. As a result, increase of Cr proportion rised monocrystal young module at each models. Moreover, Seven models with different Cr proportions were set to 5, 10, 15, 20, 25, 30 and 35 percents as Co, Ni and Mn proportions were set to 20 percents. Increase of Cr proportion rises young module at models less than Cr 25 percents. Increase of Cr proportion also rised ultimate tensile strength at models less than 25 Cr percents. The highest value of ultimate tensile strength is 20.6 GPa at the equiatomic model. At models more than 20 Cr percents, decrease of Cr proportion brought down each young moduli and each ultimate tensile strengths. In the future work, influences of other components for mechanical behaviors will be revealed as well as Cr. We are also planning to invstigate relationship between atomic proportions and dislocation activities.

Nanomechanical Behavior of Body-Centered Cubic VNbTaMoW Alloy Hicham Zaid, Jacob Stremfel, Koichi Tanaka, Angel Aleman, Jenn-Ming Yang and Suneel Kodambabka; University of California, Los Angeles, United States

We report on microstructural and mechanical characterization of a commercially-available V₀.2Nb₀.2Mo₀.2Ta₀.2W₀.2 bulk alloy. w-2θ X-ray diffraction spectra revealed multiple reflections corresponding to a single-phase, body-centered cubic polycrystal with a lattice constant of 0.319 ± 0.001 nm composed of nanoscale grains. Spatially-resolved energy dispersive X-ray spectra acquired from the sample indicated that the alloy is compositionally homogeneous (heterogeneous) elemental composition at millimeter (micrometer) length scales. Nanoindentation tests carried out using Berkovich diamond indenter yielded hardness and elastic modulus values of 9 ± 1.4 GPa and
207 ± 19 GPa, respectively. In situ scanning electron microscopy based uniaxial compression tests conducted at room-temperature on cylindrical pillars of sizes \( d \) between 0.3 µm and 1 µm revealed that all the pillars undergo plastic deformation. From the load-displacement data, we find that the yield strengths of the pillars increase with decreasing \( d \) from 3.3 GPa at \( d = 1 \) µm to 9.0 GPa at \( d = 0.3 \) µm. Work hardening exponents increase over two-fold with increasing \( d \) from ~0.3 at \( d = 0.3 \) µm to ~0.8 at \( d = 1 \) µm. We attribute the observed behavior to size-dependent variations in displacement burst frequency and slip events. We expect that our results provide new insights into the nanomechanical response of body-centered cubic alloys.

Theory for Yield Strength of BCC HEAs William A. Curtin and Francesco Maresca; 1Ecole Polytechnique Federale Lausanne, Switzerland, Switzerland; 2University of Groningen, Netherlands

BCC High Entropy Alloys (HEAs) consist of many elements distributed at random on the BCC lattice. The collective fluctuations in solute/dislocation interaction energies, even in dilute binary BCC alloys, lead to the spontaneous energy-lowering formation of a kinked/wavy structure for both screw and edge dislocations, respectively, over characteristic lengths \( \zeta_{\text{screw}} \) and \( \zeta_{\text{edge}} \). Dislocation motion starting from the kinked/wavy structure is determined by the energetics at scale \( \zeta \). New general theories for both screw and edge motion in BCC alloys starting from this basic phenomenon are presented. The screw theory is sketched briefly, and shown to accurately predict strength versus composition and temperature in Nb-Mo and Nb-W binary alloys. As for BCC elements, the necessary inputs are difficult to establish, especially in more complex alloys. Key comparisons to simulations help demonstrate major features of the theory. More importantly, the edge theory shows that edge strengthening can be sufficient to compete with screw strengthening. Moreover, edges can control strengthening, especially at high temperatures, in some BCC HEAs. The edge theory, for which all inputs can be computed easily, explains (i) the exceptional retention of strength measured in MoNbTaW and MoNbTaVW at temperatures up to 1900K, and (ii) why the V-containing alloy is stronger. The edge theory can be reduced to a simplified analytic form that enables efficient computationally-guided design of new alloy compositions predicted to have high retained strengths and strength-to-weight ratios. Several new compositions are proposed. The combination of both screw and edge theories enables assessment of strengthening versus composition and temperature across the entire domain of Cr-Mo-Nb-Ta-V-W-Hf-Ti-Zr BCC HEAs.

From First-Principles toward Atomistic Understanding of Mechanical Properties and Strength in High-Entropy Alloys Peter A. Schultz, Julien Tranchida, Michael Chandross and Aidan P. Thompson; Sandia National Laboratories, United States

Refractory high-entropy alloys (HEA) show great potential for high-temperature structural applications, particularly involving additive manufacturing. It is important to gain improved understanding of their mechanical properties. Valuable insights and predictions can be gleaned from atomistic simulations, but these are hampered by both the physical complexity of HEA (mandating numerous simulations with large models) and computational cost (driven by the need for accurate quantum-based density functional theory (DFT) to obtain reasonable accuracy). Using a simplified Al-Nb-Ti equi-composition metal alloy (bcc) as our examplar, we present a systematic approach to investigate mechanical strength, beginning with DFT to compute converged elastic properties in random composition alloys, and then using DFT data and machine-learning methods to generate SNAP (Spectral Neighbor Analysis Potentials) interatomic potentials for accurate finite-temperature molecular dynamics simulations of hardness and tensile strength of complex multi-component systems. We refine and assess DFT supercell-based approaches, using the SeqQuest code and PBE functional. The Al-Nb-Ti alloy proves to be physically different than its constituent species, and numerically more robust in calculations than elemental or crystalline (B2) alloys. For instance, the AlNbTi random bcc alloy is much stiffer in shear compared to crystalline sub-alloys. Computed properties of the equi-composition alloy are well converged with small (54-atom) random occupancy cells, are insensitive to the particular assignment of elements to sites in the cells, are robust to modest deviations from equi-composition, and (notably the shear moduli) converge much more rapidly against crucial aspects such as k-point sampling. This advantageous numerical behavior makes these modest supercell models ideal for generating the large training database needed for SNAP potential development. Each DFT model takes just a couple minutes to compute,
and collectively encompass an accurate converged description of shear behavior crucial to predictive atomistic simulations of strength. — Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

11:00 AM *MS04.07.07
Atomic-Scale Deformation Mechanisms in FCC High-Entropy Alloys Maryam Ghazisaeidi and Carlyn LaRosa; Ohio State University, United States

We present a phase transformation strengthening mechanism in CrCoNi, a ternary derivative of the CrMnFeCoNi high entropy alloy. CrCoNi alloy exhibits a remarkable combination of strength and plastic deformation, even superior to the CrMnFeCoNi high-entropy alloy. We connect the magnetic and mechanical properties of CrCoNi, via a magnetically tunable phase transformation. While both alloys crystallize as single-phase face-centered-cubic (fcc) solid solutions, we find a distinctly lower-energy phase in CrCoNi alloy with a hexagonal close-packed (hcp) structure. Comparing the magnetic configurations of CrCoNi with those of other equiatomic ternary derivatives of CrMnFeCoNi confirms that magnetically frustrated Mn eliminates the fcc- hcp energy difference. This highlights the unique combination of chemistry and magnetic properties in CrCoNi, leading to a fcc-hcp phase transformation that occurs only in this alloy, and is triggered by dislocation slip and interaction with internal boundaries. In addition, we discuss the importance of average stacking fault energies (SFE) on deformation mechanisms in alloys of various compositions. The average SFE will be compared against the change in local bonding environment and the implication on competing deformation mechanisms will be discussed.

11:30 AM MS04.07.08
Exploring Solid Solution Strengthening of High and Medium Entropy Alloys through Experiments and Modelling Mathilde Laurent-Brocq1, Guillaume Bracq1, Céline Varvenne2, Loïc Perrière1, Jean-Marc Joubert1 and Ivan Guillot1; 1Université Paris Est, ICMPE (UMR 7182), CNRS, UPEC, France; 2CINaM, UMR 7325, Aix-Marseille Univ., CNRS, France

In 2004, the face-centered-cubic (fcc) single-phased CoCrFeMnNi was discovered and very promising mechanical properties were demonstrated. Since then, new interesting compositions of high and medium entropy alloys (HEA and MEA) were tested, some of them having superior mechanical properties compared to the CoCrFeMnNi alloy such as CoCrNi but also similar or even lower properties. Through thermodynamic calculations, it was shown that the fcc solid solution is stable for a large range of compositions in the quinary Co-Cr-Fe-Mn-Ni system [1]. These studies motivate a more systematic and comprehensive exploration of this multi-component system. This remains complex because the composition domain to explore is very large and because the mechanical properties are due to several strengthening mechanisms (e.g. : due to solute or Hall&Petch effect), which are difficult to separate.

In this context, the objective of this study is both to explore the mechanical properties due to solid solution strengthening (SSS) within the fcc domain of Co-Cr-Fe-Mn-Ni system, and to provide physical understanding of their evolution with alloy composition. To do so, based on thermodynamic simulations, 24 compositions were selected within the fcc domain to cover as much as possible the quinary system and subsequently processed with a simplified and reproducible metallurgical route. The lattice parameter was measured by X-ray diffraction and nanoindentation was selected as an efficient tool to measure only the SSS. Then, using a recently developed model for SSS in HEA [2], yield strength predictions were performed using as inputs only experimental data, including the lattice parameters measured here. The sensitivity of the predictions to the inputs will be exposed. Afterwards, experimental nanohardness and predicted yield strength will be compared. Then, the trends of evolution of SSS with composition will be connected to physical quantities such as elastic constants and lattice misfit. Finally, the different strategies for exploring solid solution strengthening of HEA will be discussed.

Mesoscopic Dislocation Dynamics and Its Structural Origin in High Entropy Alloys Jian-Min Zuo\(^1,2\), Hu Yang\(^1\), Yu-Tsun Shao\(^1\), Haw-Wen Hsiao\(^1\) and Qun Yang\(^2\); \(^1\)University of Illinois at Urbana-Champaign, United States; \(^2\)ShanghaiTech University, China

High entropy alloys (HEAs) are composed of five or more elements of a near-equal molar percentage in solid solutions. This contrasts with most metallic alloys that are designed based on the addition of a small amount of impurities, or alloying elements, to improve the properties of pure metals. A major character of HEAs is severe lattice distortion. The elements that make up the HEAs have different atomic sizes. These size differences inevitably lead to distortion of the lattice. Lattice distortions contribute to the free energy and impede dislocation movements and lead to pronounced solid solution strengthening.

Here we show that the impedance of dislocation motion by lattice distortion in the HEAs lead to mesoscopic dislocation interactions inside nanopillars of hundreds nm in diameter. The manifestation of mesoscopic dislocation dynamics enables their observation by transmission electron microscopy (TEM), and thus provide an unprecedented opportunity for studying dislocations and dislocation dynamics. To demonstrate the above effect, we investigated the nature of lattice distortions in both fcc and bcc HEAs, and we performed correlation studies of dislocation dynamics with mesoscopic mechanical properties of the HEA nanopillars.

An example of correlative structure-property study is the observation of dislocation avalanches inside nanopillars of a HEA, Al\(_{0.1}\)CoCrFeNi. Our results show that the avalanches start with dislocation accumulations and the formation of dislocation bands in the HEA. Dislocation pileups form in front of the dislocation bands, whose giveaway triggs the avalanche. The experimental technique employed for the study is based on electron imaging, while a nanoindenter is used to exact the applied force and pillar displacement. Using this approach, we have observed and determined the conditions for the multiplication of dislocations, dislocation pinning, as well as a broad range of dislocation motions from nm/s to mm/s.[1]

To determine the nature of lattice distortions, we used electron nanodiffraction. Information about crystal symmetry, lattice strain and atomic distortion are data-mined and mapped from many (~10\(^4\)) diffraction patterns. Application to the HEA reveals two embodiments of distortion, nm-sized mosaic blocks of paracrystals and strained nano-clusters. Their interaction gives rise to fractal strain field across nanoscopic to mesoscopic scales.[2][3]

Real-Time Insight into the Cyclic Deformation Behavior of a High-Entropy Alloy Rui Feng\(^1\), Xie Xie\(^1\), Dunji Yu\(^2\), Yan Chen\(^2\), Ke An\(^2\), Tamas Ungar\(^3,4\) and Peter K. Liaw\(^1\); \(^1\)The University of Tennessee, Knoxville, United States; \(^2\)Oak Ridge National Laboratory, United States; \(^3\)E"otv"os University, Hungary; \(^4\)The University of Manchester, United Kingdom

Recently, high-entropy alloys (HEAs) attract worldwide attention due to their outstanding properties, showing a huge potential as engineering structural materials. In practical engineering applications, materials are usually subjected to cyclic loading during service, leading to fatigue fracture. However, few low-cycle fatigue (LCF) studies have been reported on HEAs so far. In this study, the LCF behavior of a multiphase HEA, are systematically studied
by integrated experiments and fatigue-life prediction models. Real-time in-situ neutron diffraction was employed to dynamically monitor the cyclic-deformation behavior of this HEA. Advanced microscopy techniques, such as transmission-electron microscopy (TEM), electron-backscattered diffraction (EBSD), and scanning-electron microscopy (SEM), were used to characterize the microstructural evolution during LCF. The in-situ real-time insight into the cyclic-deformation behavior of this HEA will pave the way to design innovative HEAs with outstanding fatigue resistance.

2:15 PM MS04.08.03
Fatigue Behavior of Equimolar HfNbTaTiZr Refractory High-Entropy Alloy at Room Temperature
Benjamin Guennec1, Vasuki Kentheswaran2, Loïc Perrière3, Akira Ueno4, Norio Horikawa1, Ivan Guillot5, Jean-Philippe Couzinié3 and Guy Dirras2; 1Toyama Prefectural University, Japan; 2Université Paris 13, France; 3Université Paris-Est, France; 4Ritsumeikan University, Japan

Concentrated complex alloys (CCAs), also usually referred as high-entropy alloys (HEAs) emerges as a deep paradigm shift in conventional metallurgy. Such solid solution phases are based on multi-element combination, instead of the regular one accepting a unique base element. Recent investigations have recently emphasized promising mechanical such as high yield stress, excellent resistance to wear, corrosion or creep. Among this new family of metallic materials, the refractory HEAs are focusing a lot of interest due to its good ability to retained high strength at elevated temperature, making potential unprecedented structural applications accessible. Nevertheless, the viability of HEAs as structural material requires to assess their mechanical properties under typical loading, such as fatigue one.

In the present work, the fatigue resistance of equimolar HfNbTaTiZr HEA is investigated in air and at room temperature. An outstanding fatigue strength is obtained under four-point bending fatigue, such as fatigue limit at $10^7$ cycles exceeding the uniaxial yield stress is found. Further investigations are also carried out in axial loading. An intergranular fatigue crack initiation and transgranular crystallographic crack propagation mechanisms occur. Analysis of the crack path in terms of crystallographic planes is also included, revealing that the crack spreads along both {011} and {112} slip planes. This particularity implies singularities in the crack propagation phenomenon in comparison with other metallic materials prone to similar crystallographic crack propagation.

3:30 PM *MS04.08.04
In Situ Transmission Electron Microscopy on Twinning vs Dislocation Hardening Process in High Entropy Alloys Scott X. Mao1, Qian Yu2, Easo P. George3 and Robert O. Ritchie4; 1University of Pittsburgh, United States; 2Zhejiang University, China; 3Oak Ridge National Laboratory and the University of Tennessee, United States; 4University of California, Berkeley, United States

In situ transmission electron microscopy is carried out to investigate deformation mechanisms in the medium- and high entropy alloys (CrCoNi and CrMnFeCoNi), which exhibit very high hardening behavior after plastic yielding, leading to high strength and toughness. With the deformation of CrCoNi, we find that a three-dimensional (3D) hierarchical twin network forms from the activation of three twinning systems. This serves a dual function: conventional twin-boundary (TB) strengthening from the interaction of dislocations impinging on TBs, coupled with the 3D twin network which offers pathways for dislocation glide along, and cross-slip between, intersecting TB-matrix interfaces. The stable twin architecture is not disrupted by interfacial dislocation glide. While, for CrMnFeCoNi, we found attacking faults and full dislocation process are dominating the plastic deformation, which serves the hardening process for the alloy.

4:00 PM MS04.08.05
Plasticity in the Precious Metal Based High-Entropy Alloy AuCuNiPdPt Felix Thiel1,2, David Geissler1, Dirk Seifert1, Kornelius Nielsch1,2, Alexander Kauffmann1, Sascha Seils3, Martin Heilmaier3 and Jens Freudenberg1,4; 1Leibniz Institute for Solid State and Materials Research Dresden, Germany; 2Technische Universität Dresden, Germany; 3Karlsruhe Institute of Technology–Institute for Applied Materials, Germany; 4Technische Universität Bergakademie Freiberg, Germany

High-Entropy Alloys (HEA) show outstanding mechanical and physical properties, which would not have been expected regarding their simple crystal structure and the fact that they are single phased. Despite, there are already
many systems known exhibiting this behavior, the mechanisms, responsible for their exceptional properties, were not completely clarified yet. In this study we report on the novel precious metal based HEA: AuCuNiPdPt, which crystallizes in the Cu-type face-centered cubic structure (fcc) and is single phase without chemical ordering after homogenization and recrystallization treatments. This alloy can be cold worked up to a logarithmic deformation degree of $\phi=2.4$ applying rotary swaging. During compression tests it further deforms homogeneously up to an engineering strain of $\varepsilon=30\%$. The yield strength ranges from 820 MPa in the recrystallized state to 1170 MPa when prior strain hardened by cold work with a logarithmic deformation degree of $\phi>0.6$. The texture with almost random orientation distribution in the recrystallized state develops towards a mixture of $<111>/ <001>$ fiber components during cold work. This is a similar behavior like what has been seen for conventional fcc alloys, such as Cu-based alloys or austenitic steels. Further, AuCuNiPdPt shows localized dislocation slip in the majority of all grains at low strains, leading to pronounced stacking faults and slip bands. In grains with a (near-) $<111>$ orientation, extended stacking faults develop towards deformation twins even with higher order causing significant grain refinement and finally to the aforementioned work hardening behavior. The results from mechanical testing are verifiably correlated to the microstructure by means of APT, SEM (EBSD, EDX), TEM as well as XRD analysis.
