High entropy alloys (HEAs) is a relatively recently identified class of metallic alloys [1] which, in contrast to its conventional counterparts, have four or more elements mixed in near-equimolar composition to form a single-phase alloy [2]. High entropy alloys of refractory elements like Nb, Ni, Zr, Ta, Cr, Ti have reported exhibiting superior mechanical properties while having low-density [3]. In this work, we investigate the generalized fault energies of the BCC High Entropy Alloy system NbMoTaW using Density Functional Theory and compare the competing deformation mechanisms of slipping and twinning. A 23 layered (1-21) type plane structure was generated and systematically sheared along the [111] direction to get stacking faults and twins. Energy landscapes for twinning (Generalised Planar Fault Energy curve) and for slipping (Generalised Stacking Fault Energy curve) was calculated for NbMoTaW and compared with the component elements. These energy landscapes include parameters like unstable stacking fault energy for slipping and twinning, stable stacking fault energies, twin boundary migration energy, etc. It has been found that the stacking fault and planar fault energy values for the HEA are lower than that of all component elements. Twinnability, the ratio between Twin Boundary Migration energy and the difference in unstable stacking fault energies ($\gamma_{TBM}/\Delta\gamma_{us}$), of the HEA system was calculated from the simulated energy landscapes to investigate the competition between formation of full dislocation and emission of partial dislocations from subsequent atomic layers. This ratio was found to be 0.13 suggesting extensive deformation twinning can happen in the HEA system. Origin of low fault energies in NbMoTaW was investigated using Integrated Crystal Orbit Hamilton Population (ICOHP) which is the molecular bond order analog in solid state. For each pair of interactions in the HEA system, bond weighted Density of States was computed, integrated up to the Fermi level and then compared with the interactions (Nb-Nb, Mo-Mo, Ta-Ta, W-W) in pure component elements. Among the component element interactions, Nb-Nb has the highest ICOHP energy (weakest interaction) and lowest Stacking Fault Energy. W-W interaction is the strongest and it in-turn has the highest stacking fault energy. Except for W-Mo, W-Ta, interactions in NbMoTaW was found to be as weak as the Nb-Nb interactions which explain the reduced fault energies. As the interactions involving Tungsten are stronger than the other interactions, stacking fault and twin formation is less likely to happen near Tungsten rich regions of the alloy. Since deformation twinning is preferred as suggested by the twinnability parameter, the twins formed are likely to be Tungsten deficient due to these strong interactions.

Microstructure and Mechanical Properties of AlCoCuFeNi0.8 High Entropy Alloys Zhongwei Chen;
Northwestern Polytechnical University, China

Compared with traditional alloys, high entropy alloys have excellent properties such as simple phase composition, higher strength, higher hardness, better wear resistance, better corrosion resistance, and unique electromagnetism as a novel alloy. In this work, Effects of Al and Cu content on the microstructure and properties in AlxCoCu1-xFeNi0.8 alloys were investigated by XRD, SEM, EDS, TEM, microhardness testing, tensile and compression testing. In AlxCoCu1-xFeNi0.8 (x=0.25, 0.3, 0.4, 0.5, 0.75) high-entropy alloys, the phase composition of alloys gradually changes from a single face-centered cubic (FCC) structure to a body centered cubic (BCC) structure and a little amount of FCC structure with the increase of Al content and the decrease of Cu content. Microstructure of the as-cast AlxCoCu1-xFeNi0.8 (x=0.25, 0.3, 0.4, 0.5) alloys presents the typical dendritic morphology, and microstructure of as-cast Al0.75CoCu0.25FeNi0.8 alloy presents the cellular crystal structure and the dendritic morphology. EDS results show that Cu element tends to be segregated in the inter-dendrites. Al0.75CoCu0.25FeNi0.8 alloy has the best comprehensive mechanical properties. The compressive yield strength and compressive strength are 1585MPa and 2049MPa, respectively. The fracture strain is 16.4%, and the hardness is 619.4HV. The heat treatment of AlxCoCu1-xFeNi0.8 (x=0.25, 0.3, 0.4, 0.5) alloys at 800°C for 0.5h, 6h, 12h were investigated, too. The inter-dendritic phase was obtained by eutectic reaction and grain boundary generated spinodal decomposition after heat treatment, forming a net structure. After 0.5h of heat treatment, the nano-sized precipitate phase is generated. With the increasing of heat treatment time, the nano-meter precipitate phase is dissolved, and the spinodal decomposition occurs in Al0.25CoCu0.75FeNi0.8 alloy. The highest yield strength is obtained at 0.5h heat treatment, and BCC phase is still the main phase of Al0.75CoCu0.25FeNi0.8 alloy. After heat treatment for 6h, the yield strength of Al0.75CoCu0.25FeNi0.8 alloy is as high as 1719MPa.

Combinatorial Screening and Identification of Non-Equiatomic High Entropy Alloys for Improved Mechanical Properties John Balk; University of Kentucky, United States

The largely unexplored phase space of high entropy alloys (HEAs) offers potential for transformative enhancement of metallic material properties, but the breadth of this phase space also invites an approach for high-throughput evaluation of candidate alloys. One possibility is combinatorial thin film screening. Different combinations of CrMnFeCoNiCu and VNbMoTaW thin film samples were prepared by simultaneous magnetron sputtering of the elements (all 6, or subsets of 5) onto silicon wafer substrates, to identify potential FCC and BCC HEAs, respectively. Due to the arrangement of the sputtering targets, a wide chemical composition gradient was achieved in the films. The various areas of these films exhibited different phases, some of which were non-equiatomic single-phase regions. In order to screen the crystal structure and chemical composition of these potential HEAs, multiple characterization techniques were used: scanning electron microscopy, energy dispersive x-ray spectroscopy, X-ray diffraction and electron backscattered diffraction analysis. Based on the results of this combinatorial method, potential single-phase HEAs were identified and successfully produced in bulk form via arc-melting followed by thermomechanical processing. A second possibility for high-throughput evaluation of candidate alloys is slow cooling from the melt, which allows the alloy system to find its stable composition(s). Equiatomic CrMnFeCoNiCu was melted and then cooled at a slow, controlled rate, resulting in a multiphase microstructure consisting of Cr-rich needles inside a matrix that was itself an HEA. This matrix was used as the basis for fabricating new alloys with similar composition. These approaches yielded bulk alloys that exhibited improved mechanical properties in comparison to their equiatomic counterparts. This presentation will describe the identification of candidate HEAs with desired microstructure (stable single-phase alloy), their fabrication in bulk form, thermomechanical processing, and mechanical testing with a focus on tensile properties.

Quinary TWIP-TRIP High-Entropy Alloys—Design, Microstructure, Mechanical Behaviour and Magnetism
Xiaoxiang Wu1, Zhiming Li1,2, Yuji Ikeda1, Biswanath Dutta1, Fritz Körmann1,3, Jörg Neugebauer1 and Dierk Raabe1; 1Max-Planck-Institut für Eisenforschung, Germany; 2Central South University, China; 3Delft University of Technology, Netherlands

The effect of magnetic ordering on stacking fault energy (SFE) is of great interest and significance for designing high entropy alloys (HEA) with targeted mechanical properties. To reveal the influence of magnetic ordering on SFE and correspondingly its influence on the deformation mechanisms and mechanical properties, we designed a class of novel non-equiatomic quinary HEAs by a combination of ab initio simulation and experimental validation. A wide compositional space of Cr20MnxFe10Co20Ni2 (x + y + z = 60, at. %) was probed by density functional theory (DFT) calculations to search for potential alloys displaying the TWIP (twinning induced plasticity) /TRIP (transformation induced plasticity) effects. Several representative HEA compositions with low computed SFEs were metallurgically synthesized, processed, and probed for microstructure, deformation mechanism and mechanical property evaluation. It is found that the Mn content plays a key role in the stabilization of antiferromagnetic configurations which strongly contribute to the SFEs and eventually lead to the prevalent deformation behaviour observed. The impact of valence electron concentration (VEC) on TWIP/TRIP behaviour in Mn-containing HEAs is also probed and discussed.

High-Entropy Ceramic Thin Films Synthesized by Magnetron Sputtering Alexander Kirnbauer and Paul H. Mayrhofer; TU Wien, Thin Film Materials Science Division, Austria

The demand on materials for various applications is growing continuously, especially in the field of ceramic coatings used to protect various components or tools for hard-to-machine materials. The development of materials that can withstand high thermal and mechanical loads is therefore in focus of many materials science activities. In this respective, a relatively new class of materials, so-called high-entropy materials, gained enormous attraction. These alloys consist of multiple principal elements (more than 5), which lead to a high configurational entropy (> 1.5R, R being the universal gas constant) if single-phased. Typically, these high-entropy materials exhibit four core effects: 1) The high-entropy effect, which significantly reduces the overall Gibbs free-energy (especially with increasing temperature); 2) the severe lattice distortion, stemming from the different atom radii forming the solid solution; 3) the sluggish diffusion, due to the increased activation energy for diffusion as the individual atomic neighbourhood is different; and 4) the so-called cocktail effect, allowing to combine the individual properties. More recently as for metallic bulk materials, this concept was also introduced to ceramics and especially hard coatings and ceramic thin films.

Here we show the beneficial effect of the high-entropy concept applied to several thin film material systems including nitrides, borides, and oxides. The study focuses on their preparation with physical vapor deposition, their (non)sensitivity to deposition parameters, their thermal stability and mechanical properties. All coatings investigated exhibit outstanding thermal stability and significantly decelerated decomposition and softening processes, outperforming their commonly-used binary or ternary constituents.

Development of High-Entropy Aluminum Alloys (HEA-Al) Mohammad Asadikiya, Libo Wang, Diran Apelian and Yu Zhong; Worcester Polytechnic Institute, United States

High entropy alloys (HEAs) have been investigated in recent years due to their superior properties such as high strength, high hardness, and high temperature softening resistance. Meanwhile, the traditional aluminum alloys possess attractive properties including light weight, high corrosion resistance, and high thermal conductivity. In this project, the ICME approach (Integrated Computational Materials Engineering) is applied to design a new alloy by combining high-entropy alloys and traditional aluminum alloys. In other words, the “high entropy” concept will be utilized in this new alloy with the aluminum FCC matrix. Combining the “high entropy” concept borrowed from HEAs and aluminum FCC matrix shows a totally new composition region, which has higher entropy of mixing.
comparing with the traditional aluminum alloys. After manufacturing the samples based on the simulation guidance and experimental characterizations, it was found that the designed alloys show promising ultimate tensile strength and elongation.

Equiatomic and Non-Equiatomic Refractory High Entropy Alloys That Exhibit Tensile Ductility Cem Tasan¹, Shaolou Wei¹, SangJun Kim², Eun Soo Park², Yongjie Zhang³ and Tadashi Furuhara³; ¹Massachusetts Institute of Technology, United States; ²Seoul National University, Korea (the Republic of); ³Tohoku University, Japan

After the recognition that conventional superalloys have reached their limits in high-temperature applications, there has been growing interest in developing alternative metallic-based structural alloys. Owing to their unique characteristics such as high melting point and excellent softening resistance, refractory metals have attracted significant focus in high-entropy alloys (HEAs) design. However, the investigation of novel refractory HEAs is largely retarded by the traditional trial-and-error alloy design framework, particularly within the non-equiaxial composition regime. To this end, here we present that by making use of the natural thermodynamic mixing characteristics, a series of non-equiaxial refractory HEAs can be developed. We show that these non-equiaxial HEAs exhibit desirable strength-ductility synergy and promising high-temperature performances.

The International Space Station U.S. National Laboratory—Opportunities for Improved High-Entropy Alloys via Microgravity Solidification Ryan D. Reeves, Etop Esen and Michael S. Roberts; International Space Station U.S. National Laboratory, United States

High-entropy alloys exhibit many desirable mechanical properties, including high fracture toughness, wear resistance, and crack resistance. However, the large atomic mass differential between constituent elements can lead to undesired compositional segregation and inhomogeneity. Gravitational effects (e.g., convection and sedimentation) during the melt cause density-driven phase segregation leading to inhomogeneity in the composition of the alloy. This causes reduced mechanical strength and toughness.

The International Space Station (ISS) U.S. National Laboratory offers a unique environment of persistent microgravity and, if desired, exposure to the harsh space environment in low Earth orbit. Microgravity mitigates gravitational phenomena such as buoyancy-driven convection, density-driven sedimentation and segregation, and heterogeneous nucleation at surface interfaces. Early studies of the solidification of high-entropy alloys in microgravity have demonstrated a higher degree of compositional homogeneity compared with terrestrial solidification. In addition, microgravity provides the opportunity to decouple the effects of Stokes sedimentation from Marangoni flow in order to better understand the heat and mass transfer dynamics in the melt and during solidification.

We will introduce the underlying phenomena directing the physics of the high-entropy alloy melt in persistent microgravity and will present the roles of Stokes sedimentation, Marangoni flow, and buoyancy-driven convection during the melt and solidification of high-entropy alloys. Additionally, we will present case studies of high-entropy alloy solidification in microgravity and compare the results with terrestrial experiments. We will also discuss translational lessons learned from microgravity experiments that inform and direct terrestrial research and manufacturing. Finally, we will present opportunities for future microgravity experiments and access to ISS facilities through the ISS National Laboratory.

11:45 AM MS04.09.09
Strengthen Mechanical Property of a Novel FeMnCoCrNiSi Medium Entropy Alloy by Deformation Induced FCC To HCP Phase Transformation Kaifan Lin, Shih-Che Chen, Hung-Wei Yen and Hsin-Chih Lin; National Taiwan University, Taiwan

High entropy alloy (HEA) or Medium entropy alloy (MEA) have attracted extraordinary attention since the single faced-center-cubic (FCC) Cantor alloy with excellent mechanical properties in a cryogenic environment was observed. Based on the cantor alloy, equal-atomic CoCrFeMnNi, nemours Cantor-like alloy systems have been widely studied in the past decade. Adding external elements and adjusting operational element contents, all of the alloy design strategies were to enhance the mechanical performance through different strengthen mechanism. In this work, a FeMnSi-based MEA containing 10% Cobalt, 12.5% Chromium and 5% Nickel (at atomic%) was achieved to be a single FCC crystal structure through vacuum argon melting furnace, and it is realized the improvement in the
mechanical properties through tensile test comparing with those of Cantor alloy. By reduction of valuable contents, such as cobalt and nickel, the cost of the novel MEA has been cheapened, and the addition of Silicon into this system has diminished the stacking fault energy (SFE) in order to trigger the deform-induced ε martensite phase transformation over a tensile test. Under the transmission electron micrograph (TEM) observation, various hexagonal close-packed (HCP) martensite phases were investigated among the deformed microstructure. The result from cryogenic tensile under the liquid nitrogen environment illustrated two series of interwoven ε martensite phases that behave both slat-shaped and needle-shaped sizes, which contribute the ultimate tensile strength (UTS) to a value over 1.2GPa. To further study the effect of microstructure evolution on the mechanical property among the elongation process, X-ray diffraction (XRD), electron backscatter diffraction (EBSD) technique have applied in this work.

Thermal Shock Synthesis of High-Entropy-Alloy Nanoparticles Liangbing Hu; University of Maryland, United States

The controllable incorporation of multiple immiscible elements into a single nanoparticle merits untold scientific and technological potential, yet remains a challenge using conventional synthetic techniques. We present a general route for alloying up to eight dissimilar elements into single-phase solid-solution nanoparticles, referred to as high-entropy-alloy nanoparticles (HEA-NPs), by thermally shocking precursor metal salt mixtures loaded onto carbon supports [temperature ~2000 kelvin (K), 55-millisecond duration]. We synthesized a wide range of multicomponent nanoparticles with a desired chemistry (composition), size, and phase (solid solution, phase-separated) by controlling the thermal shock parameters (substrate, temperature, shock duration, and heating/cooling rate). To prove utility, we synthesized quinary HEA-NPs as ammonia oxidation catalysts with ~100% conversion and >99% nitrogen oxide selectivity over prolonged operations. The unique shock synthesis enables high-entropy mixing and non-equilibrium processing to create HEA-NPs, and shows generality, tunability, and potential scalability. The successful synthesis of HEA-NPs opens a new research area for materials discovery and optimization, where the elemental composition and mixing entropy of nanoparticles can be carefully designed and controlled.

The Synthesis of Bi-Sr-Fe-Zr-Y-O High Entropy Oxide Cheng-Hao Lin and Jyh Ming Wu; National Tsing Hua University, Taiwan

High entropy oxide composed of Bi, Sr, Fe, Zr, and Y is synthesized by sol-gel method. Using nitrate-based compound including 4Bi(NO3)(OH)2-Bi(OH), Sr(NO3)2, Fe(NO3)3-9H2O, N2O7Zr-xH2O and Y(NO3)3-6H2O to synthesize the Bi-Sr-Fe-Zr-Y-O. First, all compounds are poured in a beaker with water and stir it for 1 hour. Then, adding the citric acid to as the chelating agent that catches all metal atoms rotates for half an hour. Next, the solution is adjusted to PH=7 by adding ammonia solution and put it into the oven that is at 90 degree Celsius for 48 hours. After that, it is sintered at 900 degree Celsius for 12 hours in the furnace. Finally, the High Entropy Oxide, Bi-Sr-Fe-Zr-Y-O is formed as nanoparticle.

2:15 PM MS04.10.03
Softening by Room Temperature Aging in High Entropy Alloys Norihiko L. Okamoto1, Tokujiro Yamamoto2, Martin Luckbauer1, Hiromu Watanabe1, Kouichi Hayashi1, Hidemi Kato1 and Tetsu Ichitsubo1; 1Tohoku University, Japan; 2Utsunomiya University, Japan; 3Twente University, Netherlands; 4Nagoya Institute of Technology, Japan

Although solid-solution strengthening (SSS) is one of the most important mechanisms that dominate the mechanical strength of high entropy alloys (HEAs), the classical theories of SSS, which were established mostly for dilute
binary solid solutions, cannot be applied to HEAs, because the definition of “solvent” or “solute” in HEAs is difficult and also because the “solute” concentration is as high as ~20 at.%. It has recently been proposed, however, that the mean-square atomic displacement (MSAD) averaged over the constituent elements can be a good scaling parameter to predict the degree of SSS in HEAs [1]; the MSAD is a measure of the local lattice strain that acts as obstacles for moving dislocations. In the course of investigating atomic environment of each of the constituent species in the Al$_{0.3}$CrFeCoNi HEA by X-ray fluorescence holography (XFH), some of the authors (TY & KH) have found that the holograms and reconstructed atomic images drastically change after room-temperature (RT) aging for 18 months, which invokes that certain diffusionless structural relaxation occurs at room temperature in the HEA. The RT structural relaxation will have an impact on the MSAD value, resulting in change in strength/hardness. In the present study, we have investigated the resonant frequencies, internal friction, Vickers hardness, and MSAD value in Al$_{0.3}$CrFeCoNi as a function of RT-aging time after casting, in order to elucidate what kind of structural relaxation occurs during RT aging. The resonant frequencies/internal friction measured by electromagnetic acoustic resonant spectroscopy monotonically increase/decreases with the aging time whereas the Vickers hardness decreases by approximately 5%. These phenomena can be understood by considering a situation where atoms located at unfavorable (metastable) positions just after casting, which are largely displaced from the average lattice points (ALPs), are shifted to more stable positions closer to ALPs with the aid of thermal energy during RT aging. In other words, just after casting the atoms are somewhat loosely bonded to each other with large MSAD, consequently, to exhibit a relatively low elastic modulus (low resonant frequencies) and high hardness, but they become more tightly and regularly arranged with small MSAD during RT aging, resultingly exhibiting higher elastic stiffness (higher resonant frequencies) and lower hardness. The decrease in the MSAD value after RT aging has been exemplified by single crystal X-ray diffraction analysis. This softening behavior observed in the hardness is opposite to the age hardening observed in some aluminum alloys and should be taken into consideration for the practical usage of HEAs as structural materials.

Atypical Phase Separations in High-Entropy, Lanthanide Oxides Kuo-Pin Tseng$^{1,2}$, Ming-Hung Tsai$^2$, Qun Yang$^2$ and Waltraud M. Kriven$^1$; $^1$University of Illinois at Urbana-Champaign, United States; $^2$Pacific Northwest National Laboratory, United States; $^3$National Chung Hsing University, Taiwan; $^4$ShanghaiTech University, China

The increase of temperature typically facilitates the mixing of materials because it enhances the effect of entropy. However, a series of high-entropy, lanthanide oxides, with nine different five-component high-entropy oxides involved, has shown the opposite behavior. Those nine candidates exhibit single-phase, high-entropy crystal structures below 1100 °C, but experience phase separations as well as multiple phase transformations at high temperature, up to 2200 °C. In this study, in-situ, high temperature synchrotron data of this high-entropy lanthanide system was collected. Atomic resolution, high angle annular dark-field (HAADF) imaging and energy-dispersive X-ray mapping (STEM-EDS) were performed on our candidates before and after phase separations. Another five-component, high-entropy, lanthanide oxides system, with similar cation radii differences ($\delta$) compared to the prior system, has been studied. Those candidates remained structurally stable without phase transformation from room temperature to melt. By comparing these two systems, a hypothesis has been made based on their crystal structures, oxidation states and difference in constituent cation radii. This research introduces that the single-phase oxide could possibly be transformed to multi-phases under thermal treatments. Therefore, the possible structural transformation(s) of the constituent mono-cation ceramic (e.g. oxide) need to be considered in the design of high-entropy ceramics.

2:45 PM MS04.10.05
Single Crystal High Entropy Perovskite Oxides—Functional Properties Beyond Structural Purposes Yogesh Sharma$^{1,2}$, Alessandro Mazza$^1$, Aiping Chen$^2$ and T. Zac Ward$^1$; $^1$Oak Ridge National Laboratory, United States; $^2$Los Alamos National Laboratory, United States

High-entropy alloys (HEAs) have proven to exhibit remarkable mechanical and structural properties. Beyond HEAs, the high entropy oxides (HEOs) have been proposed as a promising material system, where configurational disorder due to the random distribution of constituent elements into the cation sublattice can act as a driving force to tailor physical properties as well as stabilize new material phases and functionalities. In this talk, we will present on
growth and functional properties of single-crystal epitaxial thin films of extremely configurationally disordered ABO$_3$ perovskites; Ba(Zr$_{0.2}$Sn$_{0.2}$Ti$_{0.2}$Hf$_{0.2}$Nb$_{0.2}$)O$_3$, La(Cr$_{0.2}$Mn$_{0.2}$Fe$_{0.2}$Co$_{0.2}$Ni$_{0.2}$)O$_3$ and (La$_{0.2}$Nd$_{0.2}$Sm$_{0.2}$Gd$_{0.2}$Y$_{0.2}$)(Cr$_{0.2}$Mn$_{0.2}$Fe$_{0.2}$Co$_{0.2}$Ni$_{0.2}$)O$_3$. These new materials conform to standard tolerance factor considerations where multicomponent on A or B-site can be simply being treated as the average ionic radii value. A first investigation on the crystal, magnetic, relaxor-ferroelectric, and thermal properties of these high-entropy perovskite oxide thin films grown by pulsed laser epitaxy will be presented. X-ray diffraction and scanning transmission electron microscopy show single phase growth of these films with excellent crystallinity and atomically abrupt interfaces to the underlying substrates. Atomically resolved chemical mapping confirms a uniform and random distribution of all B-site cations. We will close by discussing how “Entropy-Stabilization” approach provides an ideal opportunity to design materials from a much broader combinatorial cation pallet for fundamental studies in strongly correlated materials where local disorder can play a critical role in determining macroscopic properties.

This work was supported by the U. S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Division.

Can Thin Films be Used to Study High-Temperature Oxidation of Refractory High-Entropy Alloys? A Study of the Effect of Film Thickness on Oxygen Penetration Howie Joress$^1$, Daniel B. Miracle$^2$, Todd M. Butler$^2$ and Jason R. Hattrick-Simpers$^1$; $^1$National Institute of Standards and Technology, United States; $^2$Air Force Research Laboratory, United States

The large composition-processing space for high-entropy alloys (HEAs) makes study of them using high-throughput screening methodologies advantageous. The most common method of rapid synthesis is to create combinatorial thin film libraries. For refractory HEAs, an important and necessary property is high-temperature oxidation resistance. Currently it is unknown if high-temperature oxidation in HEAs can be studied in thin films as there is some question as to whether the finite thickness of the film, on the scale of a couple of microns, will affect the ability to measure oxygen penetration and oxide thickness compared to semi-infinite bulk samples. An answer to such question is necessary to justify the translation of thin-film high-throughput refractory HEA oxidation resistance to bulk alloys. In this work we create NbTiTa thin films with a range of thicknesses and subject them to oxidation at varying times and temperatures. As a function of thickness, we look at oxygen penetration depth and oxide thickness to determine the limits of time and temperature at which the thin film becomes bulk-like and no longer exhibits finite size effects.

4:15 PM MS04.10.08
Development of CoCrFeMnNi-0.18Ti High Entropy Alloy via Mixed Powders and Electron Beam Melting Mehmet Cagirici$^{1,2}$, Pan Wang$^1$, Mui Ling Sharon Nai$^1$, Chun Yee Aaron Ong$^2$, Jun Ding$^2$ and Jun Wei$^1$; $^1$Singapore Institute of Manufacturing Technology, Singapore; $^2$National University of Singapore, Singapore

High entropy alloys (HEAs) have great potential to combine numerous properties for structural applications. Here, mechanical mixing of pre-alloyed CoCrFeMnNi and pure Ti powders are employed to reduce the complexity of powder fabrication and the cost of synthesizing high-purity pre-alloyed powder. The CoCrFeMnNi-0.18Ti HEA is successfully fabricated with homogenous chemical compositions via electron beam melting (EBM), which is one of popular powder bed fusion additive manufacturing technologies. It is revealed that EBM is a promising method to develop new alloy using mixed powder. A detailed investigation on microstructural evolutions through the building direction is conducted by a transmission electron microscope, a scanning electron microscope with energy dispersive spectroscopy and electron backscattered diffraction. Besides of FCC phase, three precipitates, Cr-rich γ, Ni-rich D0$_{22}$, and σ (CrFe) are identified. The formation of these precipitates and their evolution are discussed based on the rapid cooling and subsequence in situ heat treatment during the EBM process. In addition, the tensile and compressive mechanical properties are also revealed based on the size and distribution of the precipitate.

4:30 PM MS04.10.09
Exceptional Mechanical Properties of BCC Structured Zr-Based Medium Entropy Alloys Designed by High-Throughput Screening Xuehui Yan and Yong Zhang; University of Science and Technology Beijing, China

Zr-based alloys are considered as the most promising materials in the biomedical application fields because of its excellent in vivo performance, acceptable mechanical properties, and great corrosion resistance. However, due to the complexity of composition and nonlinear relationship between the performance and mixing-entropy, efficienctive screening of Zr-based alloy with ideal phase structure and properties is a huge challenge.

In this work, a high-throughput method combining co-sputtering and physical mask, was used to prepare the compositional gradient films, which will be used to screen in Zr-based medium entropy alloys with BCC structure. Based on the screening results, the formation, structure and mechanical properties of bulk Zr-based medium entropy alloys were further discussed in detail. This work not only offers novel BCC structured Zr-based medium entropy alloys with prominent properties for practical applications, but also shed light on development of high-throughput preparation technology in general.

4:45 PM MS04.10.10
Development of Novel High Entropy Alloys of AlCoCrFeTi0.5Ni x with Enhanced Strength and Plasticity Lin Liu; Huazhong University of Science and Technology, China

Abstract
The improvement in plasticity is usually compensated by the reduction of strength in structural materials, which is a long-standing conflict referred as the strength- plasticity trade-off. In recent years, a new type of structural materials of high-entropy alloys (HEAs) with equiatomic or near-equatomic concentrations has attracted increasing attention due to their unique mechanical properties. However, HEAs with BCC structure normally exhibit high strength but low plasticity, while the HEAs with FCC structure show inversely high plasticity and low strength. The formation of the mixing structures (i.e, FCC+BCC) is an approach to solve the problem. In this work, a BCC-based AlCoCrFeTi0.5 high-entropy alloy (HEA) was modified by the addition of Ni to improve the plasticity. The new HEAs have the composition of AlCoCrFeTi0.5Ni x (x=0~3 mol%), which were prepared by arc melting following by copper mold casting. The effect of Ni concentration on the microstructures and mechanical properties of AlCoCrFeTi0.5Ni x alloys were systematically studied. It was found that the phase transformation follows the following sequences with the increase of Ni concentration: BCC1 (disordered)→BCC1+BCC2 (ordered)→BCC1+BCC2(ordered) +FCC(ordered). FCC phase appeared at Ni=1.5 mol% and then increased in amount with further increase of Ni content. Consequently, the mechanical properties changed drastically due to the phase transformations. A good combination of strength and plasticity was achieved at Ni=2.5 mol%, in which the proportion of FCC phase and BCC phases (BCC1+BCC2) are nearly equivalent. This high entropy alloy exhibits yield strength of 1.41 GPa, compressive plastic strain of 31.8% and fracture toughness Kq of 64.3MPa *m^1/2. The toughening mechanism of the HEAs are discussed on the basis of the microstructure evolutions associated with Ni addition.

**Braiding Nanoscale and Microscale Fibers Using Repulsive Capillary Forces** Cheng Zeng, John M. Faaborg, Ming Xiao, Yohai B. Sinai, Martin Falk, Rozhin Hajian, Michael P. Brenner and Vinothan N. Manoharan; Harvard University, United States

Braids have been used for centuries to enhance the material properties of fibers. However, although nanoscale and microscale braids are expected to show interesting mechanical and electric properties, braiding them remains challenging. Such thin fibers suffer from easy breakage when handled by mechanical braiding machines. Moreover, the complexity of braid topologies makes it extremely difficult to self-assemble braids. Here we demonstrate a gentle yet robust method to programmatically assemble nanoscale and microscale fibers into arbitrary braid topologies. This method relies on repulsive capillary forces to effectively trap and move small floating objects (“floats”) at the air/water interface inside designated channels of our devices. We designed the channels to change shape along the vertical axis. As a result, when a device is moved through the air/water interface, the shape of the meniscus and thus the capillary forces change. This change in force causes lateral motions of floats at the interface. Thus, we can steer the floats around simply by moving the device into or out of water. To braid wires, we attach them to the floats and operate the device such that the floats switch positions in a desired order to drive braid formation. Capillary forces are gentle enough to ensure wires don’t break during braiding. We show that it’s possible to translate, rotate, switch, and separate floats with capillary forces. We also demonstrate methods based on geometry or contact line pinning to repeatedly braid fibers without disassembly. Lastly, we show that any arbitrary braid can be fabricated with our method.

**Rational Design Strategies for Tough Self-Healing Materials** Christopher B. Cooper, Jiheong Kang and Zhenan Bao; Stanford University, United States

The design of robust wearable technologies (e.g. e-skin) and soft robotics requires a combination of highly conformal mechanical properties and long-term durability to withstand repeated damage from daily use. Self-healing materials offer a promising solution as they continuously and autonomously heal after experiencing damage, however improving self-healing abilities often results in materials with low toughness or large hysteresis. While a range of self-healing materials have been reported in the literature, limited understanding exists on the specific structure-function relationships between molecular design of the polymer and optimizing its resulting macroscopic properties such as toughness, elasticity, and self-healing speed and efficiency.

Here, we present our work to address this gap in knowledge and allow for the more intelligent design of self-healing materials. Using a model system with precise, tunable properties, we simultaneously study the effects of molecular design on the temporal characteristics and spatial morphology of the polymers and relate these changes to their macroscopic properties. Using small-angle x-ray scattering (SAXS), we examine how the molecular design of the polymers affects their resulting microstructure. In addition, through in-situ monitoring via SAXS under dynamic mechanical loading, we investigate how these microstructures evolve via distinct mechanisms after strain and over time as the networks relax. By combining the insights from these analyses and other characterization methods, we propose new rational strategies for the molecular design of self-healing materials, which will be highlighted in this talk. This work aims to provide a better understanding of the underlying molecular mechanisms driving the observed macroscopic properties of self-healing materials and is essential for more efficient design and integration of these
materials into advanced multifunctional materials and adaptive structures.

Biomimetic Fully Autonomous Self-Reporting and Self-Healing Strategies with In Situ Generated Ferromagnetic Particles
Ying Zhao and Jinglei Yang; Hong Kong University of Science & Technology, Hong Kong

Polymer materials are susceptible to small damages at micron level during service life, which is difficult to detect and further repair, yet can significantly propagate into larger one and subsequently compromise the integrity and functionality of the polymeric materials if left unattended at the early stage. Previously, efforts put on this issue have demonstrated some smart systems, like incorporation of AIEgens, pH indicators, or dyes. However, most of them either needed human intervention, like UV irradiation, or could only tackle the visual detection matter whereas the repairing solution still needed to be dealt with. To develop materials with in-situ autonomous visual indication and simultaneous repair functionalities towards the mechanical damages is a promising yet challenging task, due to difficulties in integrating different functional elements for packaging and lack of suitable vehicles to carry multirole triggers with high reactivity.

Herein, inspired by biomimetic external wound healing and internal bone fracture healing process, a genuinely fully autonomous smart composite material capable of self-reporting and self-healing was designed via simply incorporating the triple microcapsules containing Fe-ion solution, strong basic hardener and isocyanate/epoxy, respectively, as prepared by the versatile interfacial or in-situ polymerization methods. Microcapsule concentration and relative ratios were optimized.

Damage-triggered visualization, magnetization and healing can be accomplished by the delivery of core healants that precipitate magnetic nanoparticles and form new polymer networks upon mixing. Both ‘subcutaneous’ damage and macroscopic surface damage can be warned by the sharp color change from light yellow to conspicuous black, not only rapidly upon occurrence but also permanently even after repaired. Despite of black color visible to naked eyes, the magnetism of the precipitated ferromagnetic particles allows multiple methods for further detecting the damage shape, like magnetic sensor, and thermal imagery. Assisted with the Fe-ion/-OH/isocyanate combinations, the coating showed superior anti-corrosion and sealing performance. Also, a sharp color contrast occurred exactly where the crack is. Interestingly, by applying an alternating magnetic field, the ferromagnetic particles answered with heating effect, which could be utilized for thermal imagery, or as heat source (up to 60 degrees Celsius) intrinsic self-healing of thermal plastics coatings, while avoiding heating the non-damaged regions. On the other hand, the combination of Fe-ion/-OH/epoxy showed high healing efficiency up to 100% for both fracture toughness and dynamic impact strength. The magnetic detection and thermal imagery here enabled a detailed understanding of the damage shape and scale, which is beneficial for evaluation of the damages and consideration for further solutions.

One-Step Polymerization Induced Self-Assembly of Synthetic Biomimetic Vesicles with Photo/Chemo-Responsive Permeability
Gong Cheng and Juan Perez-Mercader; Harvard University, United States

The design and self-assembly of membrane-bounded cell-like artificial vesicles not only offers new inspiration for technology and applications in many fields, but also has the potential to help uncover the mechanisms for compartmentation that may have occurred in the origin of life. In natural cells, the out-of-equilibrium self-assembly of their membrane is a critical process that eventually results in the control of cell behaviors such as vesicular transport, cell motion or division. An intriguing aspect of the cell membrane in extant living systems is their dynamic permeability. It is selectively permeable to small molecules but blocks the passage of certain macromolecules, and, at the end of their lifetime, it would be disassembled by the degradation of the lipid amphiphiles to lead to burst release of all cellular contents. Despite the advance in the assembly of various vesicular structures (e.g. liposomes, fatty-acid vesicles, colloidosomes, polymersomes), to date, little progress has been made in the construction of biomimetic vesicles with such a similar dynamic membrane and application potential to many areas in chemistry and engineering.

To address this challenge, we designed and synthesized biomimetic vesicles with a photo/chemo programmable synthetic membrane using a one-step polymerization induced self-assembly (PISA) strategy. These polymeric vesicles can realize either release of small molecules only by light-induced selective permeability, or burst release of all contents from their lumen by chemo-induced degradation of the amphiphiles and the vesicular structure. Notably, the cell-like dynamic permeability is realized by installing a single azobenzene to bridge the hydrophilic block and
hydrophobic blocks of the amphiphiles. Specifically, light-induced isomerization of the azobenzene module in the membrane enables the full system to direct dissipative energy into functional pathways as a form of dynamic membrane permeability. Our work not only exemplifies a new strategy and easily implementable at the laboratory and industrial scales for the construction of cell-like active vesicular structures, but also opens new avenues to engineer synthetic material structures with spatially controllable functionalities.

9:15 AM SB01.01.05
Liquid-Free, Non-Faradaic and Stretchable Ionoelastomer Devices for Electro-Adhesion and Electro-Mechanical Transduction
Hyeong Jun Kim¹, Baohong Chen², Zhigang Suo² and Ryan Hayward¹; ¹UMass Amherst, United States; ²Harvard University, United States

Soft solids capable of conducting ions offer promise for the design of entirely new classes of highly deformable and bio-inspired devices. While resistive and capacitive ionic circuit elements are well established, next generation ionotronics will require advanced elements that can control and switch ion flow. Here, we introduce ‘ionoelastomers’—soft polymer networks capable of selectively conducting either anions or cations—to demonstrate liquid-free, elastic, and stretchable ionic diodes and transistors that operate entirely via non-Faradaic processes. We show that the junction of two oppositely charged ionoelastomers yields an ‘ionic double layer’, analogous to the depletion layer in a semiconducting p-n junction. This enables the design of ionic devices for rectifying and switching non-Faradaic ionic currents. Further, soft and stretchable ionoelastomer junctions provide fundamentally new functionalities including: 1) low voltage reversible electro-adhesion and 2) electro-mechanical transduction, i.e., the conversion of mechanical deformation into electrical signals. Our studies provide new fundamental insight on the interface between two oppositely charged ionoelastomers and open opportunities for the application of these soft ion-conducting devices.

9:30 AM *SB01.01.06
Self-Organization of Electrostatically and Sterically Stabilized Colloidal Nanocrystals—The Roles of Topology, Image Charges and Non-Classical Nucleation
Dmitri V. Talapin, Igor Coropceanu, Erik Janke and Michael A. Boles; University of Chicago, United States

Colloidal nanocrystals offer a route toward engineering new classes of materials by acting as discrete units that can be assembled to construct composite solids. The self-assembly of two sizes of spherical nanocrystals has revealed a surprisingly diverse library of structures. To date, at least fifteen distinct binary nanocrystal superlattice (BNSL) structures have been documented. BNSLs naturally represent a powerful platform for practical implementations of multifunctional materials. However, the stability of the observed binary phases cannot be fully explained using the traditional conceptual framework treating the assembly process as entropy-driven crystallization of rigid spherical particles. We evaluate new theoretical models treating the co-crystallization of deformable spheres and to formulate new hypotheses about the factors affecting the nucleation and growth of the binary superlattices. The deviation from hard sphere behavior can be explained by specific topological textures developed within deformable layers of surface ligands. Our results also suggest that the relative abundance of BNSL phases is determined not only by their thermodynamic phase stability but also by a postulated pre-ordering of the binary fluid into local structures with icosahedral or polytetrahedral structures prior to nucleation.

Strong electronic coupling between individual nanocrystals within a superlattice is an important prerequisite for the emergence of non-additive physical properties. However, a simultaneous realization of strong electronic coupling and dense ordered packing of nanocrystal solids has remained elusive. We report a method for growing all-inorganic highly ordered solids of electrostatically-stabilized nanocrystals with the interstitial space filled with a glassy metal chalcogenide matrix which, combined with the short separation between particles leads to very strong electronic coupling. Temperature-dependent conductivity measurements show metallic transport across our supercrystals. The formation of strongly-coupled all-inorganic nanocrystal assemblies represents an important step toward the bottom-up design of functional nanostructured composites.

Nanoscale Magneto-electric Nanostructures for Cell Trapping Applications
Christopher Lynch¹,², Auni Kundu² and Yu-Ching Hsiao²; ¹University of California Riverside, United States; ²University of California, Los Angeles,
Magnetoelectric cell sorting offers the potential to sort large numbers of cells quickly. Cells can be tagged with fluorescent markers that identify cell type. They can also be tagged with magnetic micron or smaller magnetic beads. These beads experience a translational force in the presence of a magnetic field gradient. Macro scale cell sorting magnetically tags cells that are to be captured, making it possible to hold those cells and remove the unwanted cells. Magnetoelectric devices offer the ability to control magnetism at the sub-micron scale. There are multiple challenges faced when applying magnetoelectric devices to cell sorting. In an envisioned device, the magnetically tagged cell is in a fluid bath that flows across a nanomagnet. The magnet traps the cell. Ideally, when voltage is applied, the cell is released. Some of the challenges include: the design of nanomagnets to produce the right force to trap and hold a cell in a flow field, and the ability to alter the magnetization in a way that enables releasing the cell. Ideally, an applied voltage would turn the magnetization off completely. The approach taken to developing a voltage-controlled magnet was to produce magnetostrictive structures on a piezoelectric substrate. At small length scales this approach can be used to produce single domain magnets with the magnetization in-plane. In certain systems like a NiCo layered structure, when the layers are thin enough, interface effects dominate and the magnetization shifts to an out-of-plane orientation. The work that will be presented describes the design of the nanomagnets to produce the desired capture force, the fabrication and characterization of an array of nanomagnets under an applied magnetic field to produce M-H curves, and the effect of strain on those M-H curves. Although the ability to switch these magnetic structures from a state of perpendicular magnetic anisotropy to an in-plane magnetic state has not yet been demonstrated, sufficient progress has been made to suggest that the approach may ultimately be successful.

11:00 AM SB01.01.08
Ferromagnetic Soft Continuum Robots—Towards Next-Generation Medical Robots Yoonho Kim and Xuanhe Zhao, Massachusetts Institute of Technology, United States

Enabling access to hard-to-reach areas in a remotely controllable manner, small-scale soft continuum robots capable of active steering and navigation through complex and constrained environments hold great promise for medical applications in diverse areas across the human body. Several concepts of continuum robots have been commercialized so far, offering a range of new therapeutic and diagnostic procedures that are safer for patients owing to their minimally invasive nature. However, existing continuum robots are often limited to relatively large scale due to miniaturization challenges inherent in their conventional actuation mechanisms such as pulling mechanical wires. Such miniaturization challenges have rendered even the most advanced form of commercialized continuum robots, mostly used for cardiac interventions, substantially unsuited for neuro-surgical applications due to the considerably small and tortuous vascular structures.

Recently, burgeoning efforts have been made to utilize fully soft-bodied robots in medical applications with great expectations that their inherent compliance would lead to enhanced safety. Despite the purported advantage, the field of soft robots is still faced with a set of key challenges. First, existing soft robots based on pneumatic or hydraulic actuations are mostly heavily tethered, which limits their use in realistic medical applications that typically require tether-free actuation. Second, most soft robots are difficult to accurately control based on quantitative models, largely because their actuation mechanisms often rely on highly nonlinear deformation or instabilities. Third, conventional soft robots are difficult to miniaturize below millimeter scales, because their actuation mechanisms and associated fabrication methods are often unfavorable to such small size.

Here we present a submillimeter-scale, self-lubricating soft continuum robot with omnidirectional steering and navigating capabilities based on magnetic actuation, which are enabled by programming ferromagnetic domains in its soft body while growing hydrogel skin on its surface. The robot’s body composed of soft polymer matrices with embedded ferromagnetic microparticles can be miniaturized below a few hundreds of microns in diameter. To cope with the significant friction experienced by the robot while navigating through highly unstructured environments, we grow hydrogel skin, a thin layer of hydrated crosslinked polymers, onto the robot’s surface. This hydrogel skin substantially decreases the surface friction due to its high water content.

Elaborating on our recent progress in magnetic soft materials towards untethered soft machines and robots, we present novel material systems and fabrication schemes to realize ferromagnetic soft continuum robots at submillimeter scale. We also present our model-based material design strategies to optimize the actuation parameters.
performance of our soft continuum robots. Combining all these features, we demonstrate the capability of navigating through complex and constrained environments with close relevance to clinical challenges, such as tortuous phantom neurovasculature with cerebral aneurysms, which are difficult to navigate with bulky robotic catheters or manually controlled passive instruments. Incorporating a functional core, such as an optical fiber, in the robot’s body, we further demonstrate additional functionalities such as steerable laser delivery for potential clinical applications in laser atherectomy. Given their compact, self-contained actuation and intuitive manipulation, our ferromagnetic soft continuum robots may open new avenues to minimally invasive robotic surgery for previously inaccessible lesions, thereby addressing challenges and unmet needs in healthcare.

11:15 AM SB01.01.09
Designing Magnetorheological Fluids for Soft Robotics Abigail L. Rendos, Kevin McDonald, Tommaso Ranzani and Keith A. Brown; Boston University, United States

Smart fluids are suspensions of functional particles in which an applied field drastically changes the fluid’s properties. For example, ferromagnetic microparticles in solution form magnetorheological (MR) fluids in which an applied magnetic field causes the liquid to solidify through the formation of rigid columns of particles. This field-driven transition enables the fluid to change reversibly from a viscous state to an elastic state that can be described as a Bingham plastic. As a result of this unique property, MR fluids have been widely used in a variety of systems such as brakes, dampers, and clutches. We propose to leverage MR fluids to realize novel classes of soft robotic systems in which magnetic fields interact with fluid flow to actuate systems in novel ways. However, there are two major barriers to this vision, (1) new architectures of actuation need to be developed and (2) more generally, sedimentation of the magnetic particles is a common issue hindering the use of MR fluids. We address the sedimentation challenge through the detailed exploration of MR fluid performance with different thixotropic agents in novel water-based MR fluid formulations. Controlling the formulation allows us to realize low sedimentation, low off-state viscosity, and high on-state viscosity. By mapping their response to magnetic fields, we ensure a predictable, variable resistance caused by increased thickening of the fluid enabling users to design a variety of systems from one MR fluid recipe. These materials innovations allow us to explore novel soft actuation architectures based upon MR fluids.

11:30 AM SB01.01.10
Tunable Silver Nanofilament Formation Dynamics in Polymer-Ionic Liquid Electrolyte Composites by Direct-Write Zhongmou Chao and Susan Fullerton; University of Pittsburgh, United States

Direct-write is a bottom-up fabrication approach where material is added to a substrate in well-defined locations. With the advent of 3D printing and the need for inexpensive, printable and flexible electronics, direct-write patterning is attracting more attention for its ease to use for fewer processing steps. In this work we demonstrated a direct-write, electrochemical approach to the formation and dissolution of silver filaments through a new type of multifunction polymer electrolyte consisting of a UV-crosslinkable polymer, polyethylene glycol diacrylate (PEGDA), and an ionic liquid (IL), 1-butyl-3-methylimadazolium hexafluorophosphate ([BMIM]PF₆). A conductive atomic force microscope (C-AFM) is used to form and dissolve the filaments at pre-programmed locations using a custom script. Filament formation and dissolution kinetics are measured at various IL compositions and formation biases. The IL strongly impacts filament formation kinetics by controlling the local PEGDA structure. For example, in a highly crystalline PEGDA film with a low IL concentration (10 wt%), silver filament formation kinetics vary significantly with XY location and exhibit highly asymmetric formation time distribution; in contrast, when the IL concentration is increased to 30 wt%, PEGDA crystallization is suppressed and the filament formation times exhibit a normal (Gaussian) distribution with respect to XY location. In addition, we show that a competition between electric double layer (EDL) screening, ion transport, and electrochemical reactions gives rise to a non-monotonic dependence of formation time on applied voltage. Time-dependent analysis of formation current along with scanning electron microscope (SEM) characterizations suggest that filament structure is directly related to the magnitude of formation voltage, which can be tuned to improve the filament switching capability. Our results provide deeper understanding of the kinetics of filament formation through a crosslinkable polymer electrolyte, which is potentially useful for multiple material functionalities including the development of new metamaterials with reconfigurable optical properties, and non-volatile, on-board resistive random-access memory (ReRAM) for printable and flexible electronics.

11:45 AM SB01.01.11
Photocontrol of Structural Colors in Self-Organized Helical Superstructures Lang Qin and Yanlei Yu; Fudan University, China

Light-driven cholesteric liquid crystals (CLCs) exhibit unique selective reflection, originating from their inherent self-organized helical superstructures, and dynamic reflection tuning in response to light, which has unique advantages for remote, temporal, local, and spatial manipulation. Such elegant systems may represent ideal candidates for use as “photonic inks” to realize changeable information in color reflective displays, especially those providing paperlike viewability in sunlight where backlit devices perform poorly. To this end, phototunable reflection across the visible spectrum has been demonstrated for CLCs and was induced by photoresponsive chiral motors and switches with tetrahedral, axial, or planar chiralities. These triggers undergo photoisomerization, giving rise to both the variations in helical twisting power (HTP) and the color change.

In this report, we demonstrate several new strategies for manipulating the structural colors of CLCs. We design a tristable chiral switch by incorporating two different azobenzenes into one chiral structure. Three stable configurations of the chiral switch endow the CLC with two continuous and adjacent tuning periods of the reflection, covering not only entire visible spectrum, but also one more wide period within near-infrared region. The resultant CLCs are capable of creating images of RGB colors with a black background, which is realized based on piecewise reflection tuning. In addition, we proposed a novel tuning mechanism based on a partial photochemical phase transition to enable continuous patterning of photostationary RGB colors in a CLC system, which contains nonresponsive chiral dopants and o-fluoroazobenzenes (Fazo) to serve as the photoswitch. Distinct isomer ratios of Fazo result in precise light-directed RGB colors for the photostationary states, and, thus, a fixed relationship is established between the light stimulus and the reflection color. Accordingly, the RGB color patterns can be continuously erased and rewritten under light irradiation with different wavelengths.

SESSION SB01.02: Responsive Materials and Drug Delivery
Session Chairs: Pablo Valdivia y Alvarado and Christian Wischke
Monday Afternoon, December 2, 2019
Hynes, Level 3, Ballroom A

1:30 PM *SB01.02.01
Biomimetic Glucose-Responsive Smart Insulin Delivery Zhen Gu; University of California, Los Angeles, United States

Closed-loop drug delivery strategies have proven to be a practical tool for homeostatic regulation, by tuning drug release as a function of biosignals relevant to physiological and pathological processes. Among them, a glucose-responsive “closed-loop” insulin delivery system mimicking the function of pancreatic cells holds great promise to improve quality of life and health in people with diabetes. In this talk, I will introduce our ongoing efforts in developing formulations and related devices for glucose-responsive insulin delivery. I will first discuss the transdermal microneedle patches integrated with glucose-sensitive components for self-regulated insulin delivery tested on both mice and pigs. I will further introduce integration of beta cells and microneedle patch loaded with the synthetic “glucose-signal amplifier” for releasing insulin with a glucose-responsive manner. In addition, synthetic beta cells with vesicle fusion-mediated mechanism for glucose control will also be presented.

2:00 PM SB01.02.02
Instant Strong Adhesion of Wet Tissues and Devices for Biomedical Applications Hyunwoo Yuk and Xuanhe Zhao; Massachusetts Institute of Technology, United States
Two dry surfaces can be instantly adhered upon contact with each other by intermolecular forces such as hydrogen bonds, electrostatic and van der Waals interactions. However, it is extremely challenging to form such instant adhesion between wet surfaces such as biological tissues, because water separates molecules from the two surfaces to form instant interactions. Existing tissue adhesives, mostly in the form of liquids or gels, rely on diffusion of their molecules into the polymer networks of the tissues for bonding, which can take significant time and give weak adhesion. Consequently, these limitations have severely hampered the scope of applications of existing tissue adhesives and their efficacy in practice. In this talk, we introduce a new mechanism to realize instant strong adhesion of a broad range of wet tissues and devices, implemented in various form factors including double-sided tapes, tissue-mimicking patches, and injectable pastes. Our new tissue adhesives boast unprecedented capability of forming instant adhesion less than 5 s with superior adhesion performance over 1,000 J m$^{-2}$ interfacial toughness, 120 kPa shear and tensile strength, surpassing commercially-available solutions. This work not only reveals a new paradigm in wet adhesion but also provides new opportunities and solutions in applications as diverse as tissue adhesives and sealants, bioscaffolds, drug delivery, and wearable and implantable devices.

2:15 PM SB01.02.03
Supramolecular Hydrogels for Sustained Release and Enhanced Thermal Stability of Biotherapeutics
Catherine Meis, Anthony C. Yu, Anton A. Smith, Caitlin L. Maikawa and Eric A. Appel; Stanford University, United States

The emerging generation of drugs is dominated by biotherapeutics, such as antibodies, hormones, and other proteins, for critical treatment applications ranging from cancer to autoimmune diseases to vaccine development. However, many of these drugs suffer from short half-lives in vivo, leading to the need for frequent administrations in order to maintain their concentrations at therapeutic levels in the body. In addition, these large complex-structured macromolecules are inherently unstable in formulation, requiring cold-chain transportation and storage and limiting their long-term viability in in vivo depots. To address these challenges, we have developed a multifunctional, injectable delivery system utilizing supramolecular hydrogels that can sustain the release of these drugs over an extended period of time while simultaneously maintaining their stability, even at high loading concentrations. This work will focus on assessing the ability of these supramolecular polymer-nanoparticle hydrogels to improve the thermal stability of biotherapeutics. In vitro plate assays conducted under accelerated aging conditions are used to investigate how the hydrogel formulation influences the biostability of various model protein drugs, including hormones, enzymes, and antibodies. In addition, correlation between hydrogel mechanical properties and their ability to act as a stabilizing agent is explored. We demonstrate that these hydrogels are capable of extending the thermal stability of sensitive biotherapeutics at even at high concentrations, potentially enabling new drug formulation strategies.

2:30 PM SB01.02.04
Micromotor-Enabled Active Drug Delivery to Treat Gastrointestinal Diseases
Jinxing Li1,2, Liangfang Zhang2 and Joseph Wang2; 1Stanford University, United States; 2University of California, San Diego, United States

Advances in bioinspired design principles and nanomaterials have led to tremendous progress in autonomously moving synthetic nano/micromotors with diverse functionalities in different environments. However, a significant gap remains in moving nano/micromotors from test tubes to living organisms for treating diseases with high efficacy. Here we present the first, to our knowledge, in vivo therapeutic micromotors application for active drug delivery to treat gastric bacterial infection in a mouse model using clarithromycin as a model antibiotic and Helicobacter pylori infection as a model disease. The propulsion of drug-loaded magnesium micromotors in gastric media enables effective antibiotic delivery, leading to significant bacteria burden reduction in the mouse stomach compared with passive drug carriers, with no apparent toxicity. Moreover, while the drug-loaded micromotors reach similar therapeutic efficacy as the positive control of free drug plus proton pump inhibitor, the micromotors can function without proton pump inhibitors because of their built-in proton depletion function associated with their locomotion.

2:45 PM SB01.02.05
Novel Drug Eluting Soy Protein-Based Films
Lior M. Matsliah1, Daniella Goder1, Ariel Furier2 and Meital Zilberman1; 1Tel Aviv University, Israel; 2Israel Defense Forces, Israel

Bioresorbable structures can be used as drug eluting platforms in various biomedical applications. Soy protein is a
new natural material in the medical field with very promising properties. It has been used in our lab as basic material for wound dressings designed for pre-hospital treatment, mainly of burn injuries. Our dressing design consists two layers: a porous layer in contact with the skin, which allows better water permeability and accommodates newly developed tissue, and a top, dense layer, preventing pathogen penetration. In the current study the porous layer was loaded with the hemostatic agent tranexamic acid for bleeding control, and the dense layer was loaded with both an antibiotic drug (Cloxacillin) for infection prevention and with an analgesic drug (Bupivacaine). The whole soy protein structure was crosslinked by glyoxal and plasticized by glycerol.

A film containing higher crosslinking density achieved better strength and modulus, while a film with lower crosslinking density and higher plasticizer concentration exhibited a higher maximal strain. The water vapor permeability, the most important property of burn dressings, was also affected by the film’s formulation: increasing the crosslinking agent resulted in a lower water vapor transmission rate. The swelling ratio and weight loss were higher for the less crosslinked film as well.

A cytotoxicity test was performed with samples containing 3% Cloxacillin (w/w of dense layer). No significant difference was found between the drug loaded film and the neat film without drug. Both did not show any cytotoxic effect.

In conclusion, our novel wound dressing holds a promise to be a most effective measure for casualty pre-hospital treatment, as multi-drug releasing platform, which may also support tissue regeneration.

3:00 PM BREAK

Chemical Reactions as Active Elements in Multi-Responsive Materials and Devices Stephen Craig; Duke Univ, United States

The materials chosen for use in soft devices tend to be compliant elastomers whose function is to deform in a way that meets the mechanical requirements of the application. In recent years, a new idea has emerged: namely, that the strains that naturally occur during device function can be harvested to drive chemical changes and add function to the devices. One strategy toward capturing strain is to use tension in polymer molecules to trigger the covalent response of an embedded mechanophore. This talk will discuss structure-activity relationships in mechanophore design and their application in multi-responsive materials and devices.

4:00 PM SB01.02.07
Soft Magnetically Responsive Materials for the Manipulation of Stiffness, Friction and Adhesion Alexander Bennett1, Elise Corbin2, Brianna Messam1, Alexia Vite1, Kenneth Margulies1 and Kevin T. Turner1; 1University of Pennsylvania, United States; 2University of Delaware, United States

Smart materials with tunable properties have opened new avenues for studying the fundamental, dynamic behavior of cellular systems. The behavior of biological cells is strongly dependent on their mechanical micro-environment. To date, efforts to study this dependency have relied on the use of mechanically static materials with stiffness that can be changed through preparation. This approach provides only half the story though as cells and tissues are dynamic in nature. We have developed a composite extracellular matrix platform with dynamically tunable mechanical properties and have used it to assess the response of cardiomyocytes and fibroblasts to dynamic changes of their mechanical environment. The key material in this platform is a magnetorheological elastomers (MRE) that is composed of an elastomer (polydimethylsiloxane) and ferritic particles. This MRE is a soft (E~10-100 kPa) active material with mechanical properties that can be manipulated through the application of a magnetic field. We have characterized the change in modulus, friction, adhesion, and surface roughness of these MREs that occur due to an applied magnetic field. The effect of the magnitude of the field, the material composition, and material synthesis method on the response were characterized. The stiffness, friction, and adhesion changes were characterized via indentation and sliding tests at the millimeter scale. The results show that the magnetic-induced changes in viscoelastic modulus (up to ~5x) lead to changes in the tribological behavior (friction and adhesion) of the materials. Surface roughness and geometry changes resulting from the strong magnetostrictive response of these MREs to weak fields was also characterized. Finally, the severity, spatial uniformity, repeatability, and time-dependency of the MR effect were also examined. The knowledge gained through indentation and tribology experiments as well as through roughness characterization of these MREs will lead to the design of new stimuli responsive materials that enable more accurate study of dynamic, biological systems.
4:15 PM SB01.02.08
Twisted Shape Memory Nanocomposite Fibers Jinkai Yuan1, Wilfrid Neri1, Cécile Zakri1, Pascal Merzeau1, Karl Kratz2, Andreas Lendlein2,3 and Philippe Poulin1; 1Ctr de Recherch Paul Pascal, France; 2Institute of Biomaterial Science and Berlin-Brandenburg Center for Regenerative Therapies, Germany; 3University of Potsdam, Germany

Macroscopic rotating engines powered by electricity or fuel are very common devices that are generally used to produce mechanical energies. However, it is very difficult, to integrate them into microdevices. Making high-speed and strong miniaturized engines with simplicity, robustness and low cost is always very challenging. Up to now, the strongest rotary motors ever reported are based on the concept of twisted fibers. [1] The concept of twisted fiber can actually be used to develop rotary motors by involving several mechanisms, such as entropic elasticity of polymer chains, [2] solvent swelling in CNT yarns,[3] or the expansion/contraction of GO via water adsorption and desorption.[4] Here, we study the shape memory effect by twisting polymer fibers and explore their application for strong engines.

To make strong microengines, it is necessary to reinforce the torsional properties of polymer fibers by inclusion of nanoparticles. We prepared carbon nanotube (CNT)- or graphene oxide (GO)-doped polyvinyl alcohol (PVA) fibers by using wet-spinning method. As compared to pure PVA fiber, CNT and GO nanosheets have nearly the same reinforcement efficiency on the tensile properties. However, GO nanosheets have more significant effect on the improvement of torsional properties because of its unique two-dimension nanostructure. We used such strong GO fiber to prepare torsional motors. By measuring the recovered angle against an applied constant torque, we achieved a maximum generated energy density as high as 2800 J/kg. To our knowledge, this is actually the first report of the use of graphene to reinforce torsional properties of polymer composites and the greatest energy density observed in rotary motors.

4:30 PM SB01.02.09
Density Functional Theory Calculation Study of Two-Dimensional Electromechanical Actuation Materials
Zhe (Jefferson) Liu; The University of Melbourne, Australia

Miniaturization of electromechanical devices will bring a revolution to humanity in the coming decades synonymous with the effects of miniaturizing electronic devices in those previous [1]. They promise and deliver a myriad of applications within industry, including those within the automotive, electronics, aerospace, environmental, and defence. An electromechanical actuator — a device that converts electrical energy to mechanical deformation or motion — is the core component of many such devices. Consequently, research interrogating mili-, micro-, and nano-actuation has, and will continue to become increasingly essential.

In this talk, I will first present a quick overview of my team's density functional theory based computational materials design for high-performance two-dimension (2D) actuation materials [1-5]. 2D materials have a combination of several desirable properties for actuation at a small scale, e.g., atomistic thickness, excellent mechanical strength and flexibility, superior electronic properties, and excellent tunability [6,7]. Various actuation mechanisms are explored in our studies, such as piezoelectricity, electroactive, quantum mechanical effect, and shape memory effect. We will use several material systems to demonstrate these different actuation mechanisms briefly.

My presentation will focus on the shape memory effect (SME) of 2D materials [2-3]. Shape memory materials (SMM) have a unique feature of programmability. This stimulates novel device design concept, so-called material-as-machine, in which SMM can be programmed for actuation/motion following a pre-determined sequence, just like machines but with higher intelligence and flexibility whereby the materials can sense and react accordingly. This concept is particularly appealing at small length scale. However, the conventional shape memory alloy will lose its reversible martensitic phase transformation (origin of the shape memory effect) below a critical size (4 – 60 nm).
Our recent study discovered a set of promising 2D shape memory materials. The physical mechanisms of their SME are fundamentally different from conventional SMMs. The external stimuli to trigger the shape memory behaviour are also different from conventional SMMs, i.e., electric field, charge doping, and mechanical force, versus the thermal field. These new stimuli will enable quick response (up to GHz) and precise control (down to nm), which are highly desirable for actuation devices at small length scale.

Monolayer Studies on the Interplay between Cross-Linking and the Degradation Kinetics of Biomaterials
Rainhard Machatschek1, Burkhard Schulz1,2 and Andreas Lendlein1,2; 1Helmholtz Zentrum Geesthacht, Germany; 2University of Potsdam, Germany

Improving the state of the art of treatments in regenerative medicine demands for materials that are capable of accomplishing multiple tasks, e.g. providing mechanical support while releasing a drug and then vanishing from the body. Such highly multifunctional materials require distinct properties which are achieved by tailored molecular architectures. Mechanical properties and thermal transitions are adjusted by e.g. joining different building blocks. Cell recognition motifs can be provided by grafting functional side chains or modifying chain-ends, drug loading capability enhanced by strategically placing functional groups to optimize the binding energy between drug and matrix. Cross-linking is a common approach to create polymer networks capable of forming hydrogels or to obtain rubber-like materials. However, while the material properties are a result of the synthesis and the processing of the material, functionalities arise from its interaction with the environment. For example, a hydrogel requires the presence of water and a cell binding motif is useless without cells. Quite often, the different functions are also not orthogonal in a sense that one environmental interaction can trigger multiple functionalities. For example, the swelling of a material in water triggers both drug release and degradation. Ensuring that all material functions are executed as intended therefore requires an understanding and a holistic prediction of the material behavior when responding to a stimulus. Especially predicting material degradation, which has a drastic impact on all material properties and therefore also functions, remains a great challenge. Without such a prediction, designing a biodegradable multifunctional material with a specified lifetime is only possible on an empirical basis.

To support the predictive design of multifunctional materials, a theoretical model for the interplay of cross-linking and molecular degradation kinetics is presented. It is elaborated how the degree of crosslinking affects the degradation kinetics of macromolecules. This model also predicts the decrease of the degree of cross-linking with proceeding degradation in dependence on the molecular fragmentation mechanism, which could be e.g. a random fragmentation or a preferential cleavage of certain bonds. Using the established theories of rubber elasticity, the evolution of the material’s mechanical properties can be deduced from the degradation models. Such an analytical model provides a qualitative understanding for the impact of cross-linking related molecular parameters on the material behavior during degradation. Taking into account the inhomogeneous microstructure of processed, real-world materials and the complex geometries of medical implants, a lifetime prediction of multifunctional medical devices will require multiscale computational simulations. Moreover, all models rely on
input parameters such as reaction rate constants, which have to be determined experimentally. The Langmuir monolayer degradation technique is an established way to determine these parameters for materials degrading in aqueous environments in experiments that take only a few hours\(^1\). Here, it is presented how the technique was used to verify the analytical models and to determine the kinetic parameters for poly(ε-caprolactone) based networks which were prepared \textit{in-situ} on the Langmuir trough. In such a system, the cross-linking density can be varied by compressing the layer, and the decrease of the cross-linking density during degradation is registered as a decrease of the storage modulus by means of interfacial rheology.

A Dual-Function Collagen-Based Scaffold with On-Demand Drug Delivery for Diabetic Wound Healing

Tauseef Ahmad\(^1\), Ronaldo do Amaral\(^{1,2}\), Renuka Sitram\(^1\), Brenton Cavanagh\(^1\), Fergal J. O’Brien\(^1,2,3\) and Cathal J. Kearney\(^1,3\); \(^1\)Royal College of Surgeons in Ireland, Ireland; \(^2\)National University of Ireland Galway, Ireland; \(^3\)Trinity College Dublin, Ireland

About 20% of the over 400 million diabetic patients will develop diabetic foot ulcers (DFUs) in their lifetimes. DFUs are associated with high incidences of morbidity and mortality that includes higher lower-limb amputations rates, and worse post-amputation survival rates than breast and prostate cancers. A reason for the recalcitrant nature of these wounds is that sequential physiological healing is absent in DFUs. By restoring the normal temporal healing profile using signalling factors, we aim to reinstate co-ordination of biological processes to drive enhanced healing. To achieve this, we are developing a tissue engineering device with dual functionality: (1) ultrasound-responsive alginate microparticles for on-demand delivery and (2) a collagen-glycosaminoglycan (CG) scaffold that houses these particles and acts as a regenerative template for the cells. This device would be capable of delivering bioactive agents on-demand and by mimicking nature’s temporal profile for angiogenesis (e.g., sustained vascular endothelial growth factor (VEGF) and delayed platelet-derived growth factor (PDGF) signalling), we hypothesise that sequential healing of DFUs can be effectively driven.

To develop the system, PEGylated gold nanoparticles (PEG-AuNP) were incorporated into combinations of high (~250kDa; 0 – 1%) and low (~70kDa; 0 – 1.5%) molecular weight alginate. Alginate microparticles were generated by electrospaying (11kV) and ionically crosslinking using CaCl\(_2\) (30mins, 100mM). A CG slurry was blended using type I bovine collagen (5 mg/ml) and chondroitin-6-sulfate (0.44 mg/ml) in 0.05 M acetic acid solution. The microparticles (20% final volume) were mixed with the CG slurry and cast in steel trays for freeze-drying. SEM images revealed local disruption of pore structure neighbouring the microparticles but an open interconnected porous structure in the remainder of the scaffold. Scaffolds were crosslinked (by UV, dehydrothermally or by carbodiimide chemistry). Ultrasound was applied (0 – 35% amplitude) to trigger AuNP release. Up to 50% AuNPs was released in <5 min using ultrasound; baseline release of AuNPs was negligible. With the proof-of-concept confirmed using model nanoparticles, we next tested a bioactive nanoparticle in the device. PDGF conjugated PEG-AuNPs were developed and their bioactivity confirmed using a mesenchymal stem cell (MSC) and fibroblast proliferation assay. PDGF-AuNPs enhanced cell proliferation by 30%. Optimum PDGF dose and timing was assessed using a suite of \textit{in vitro} vascularisation assays (e.g., vessel formation in the CG scaffolds). When added at delayed time-points, 25ng/ml PDGF stabilised vessels in CG scaffolds; however, vessels regressed when PDGF was not added or when added at earlier time-point. Finally, PDGF-PEG-AuNP doped CG scaffolds were fabricated and subjected to ultrasound. PDGF functionalised AuNPs could be successfully released from within the scaffolds and retained their bioactivity (cell proliferation assay). To protect the structural integrity and regenerative potential of the CG scaffolds from ultrasound, a bilayered system was fabricated with alginate-PDGF-AuNPs doped into a
sacrificial CG scaffold annealed to a main regenerative CG scaffold. These results demonstrate the ability of this alginate-doped collagen-GAG scaffold to facilitate cell seeding and to locally deliver drugs on-demand. Future work will demonstrate the devices’ full potential to coordinate angiogenesis and direct healing.

Personal Thermal Management via Engineered Optical and Evaporation Phenomena 
Matteo Alberghini¹, Matteo Fasano¹, Yi Huang², Luis M. Lozano², Francesco Signorato¹, Eliodoro Chiavazzo¹, Gang Chen², Pietro Asinari¹ and Svetlana V. Boriskina²; ¹Politecnico di Torino, Italy; ²Massachusetts Institute of Technology, United States

The increasing energy demand worldwide must be addressed with sustainable technologies to mitigate further climate change. In particular, the energy employed for heating and cooling covers 79% of the total energy consumed in the European households. Both reducing the cooling demand and improving the efficiency of the energy conversion processes could limit the environmental impact of building cooling. On the one hand, novel materials for personal thermal management can be adopted to shift upwards by few degrees the set-point of room temperature, therefore reducing the cooling load at fixed thermal comfort. On the other hand, the energy consumption of traditional vapour-compression systems can be significantly reduced by achieving sub-ambient temperatures in the condenser thanks to passive coolers.

Recent developments in materials science allowed to reinvent two long-standing passive cooling technologies, namely radiative and evaporative cooling, thus increasing their performances and expanding their application field. We combine the complementary evaporative and radiative cooling features to overcome the intrinsic limitations of conventional polymeric textiles for personal thermal management. Polymeric films and fabrics with tailored optical properties have already been proposed for daytime radiative cooling, reaching a specific cooling capacity up to 100 W m⁻² and acceptable wearability. These composite organic-inorganic nanoparticle-filled polymer materials combine strong spectral selectivity of nano-particles with unique lateral heat-spreading capability of semi-crystalline polyethylene films and textiles. However, their radiative cooling potential is strongly limited by the ambient humidity; additionally, these textiles are not yet optimised to favour the typical skin cooling by sweat evaporation.

We optimize the material, sizes and plot of the fabric to enhance both radiative and evaporative cooling performance via multi-physical modelling, which considers water wicking and evaporation, vapour permeation and spectrally selective optical properties. The optimized multi-functional textiles, including dual-mode, reversible or ambient-responsive materials, could be employed for more effective personal thermal management, thus allowing a substantial reduction of the economic costs and environmental footprint of building cooling.

Hierarchical Mushroom-Like Re-Entrant Arrays for Superomniphobic Surfaces
Joon Hyung An, Jiseong Choi and Seongmin Kang; Chungnam National University, Korea (the Republic of)

In this work, we present a robust hierarchical mushroom-like structured surfaces by using novel and low-expertise fabrication method. The microscale re-entrant mushroom-shaped structures were fabricated on a substrate by a replica molding technique using a polydimethylsiloxane (PDMS) and an ultraviolet (UV)-curable polyurethane acrylate (PUA) containing inorganic nanoparticles. The tiny inorganic particles were used to make nanoroughness on the top of the re-entrant structures by using plasma polymer etching process. Finally, we have successfully obtained hierarchical mushroom-shaped structures without any structural failure, and the nano/micro multiscale re-entrant features demonstrated remarkable superomniphobic properties repelling water and oil. It is expected that the hierarchical structures are to be applied in a wide range of applications requiring self-cleaning and antifouling surfaces.

SB01.03.05
Multifunctional Ultra-Thin Crosslinked PEDOT:PSS Films for EMI Shielding and Organic Electronics
Pritom J. Bora, Amith G. Anil, Praveen C. Ramamurthy and Sankaran Subramanian; Indian Institute of Science,
PEDOT:PSS conducting polymer films have found numerous application in organic electronic systems, as sensors, hole transport materials, transparent conducting electrodes, flexible electronics, thermoelectric systems etc. However, stability of the thin films against moisture remains a bottleneck for extending their application potential. Researchers have adopted crosslinking as one of the strategies to improve moisture stability and mechanical strength, although in many cases this adversely affects the conductivity of the obtained films. Recently, a crosslinking method was reported to make moisture stable PEDOT:PSS films wherein the crosslinker also acts as a dopant, improving the electronic properties of the film. In this work, a similar system with simpler composition is reported to produce highly flexible, free standing, water resistant, ultra-thin (12 \pm 1 \, \mu m) films of PEDOT:PSS exhibiting a superior electrical conductivity of 59300 \, S\, m^{-1} compared to pristine PEDOT:PSS film(18 \, S\, m^{-1}) . These films also displayed excellent electromagnetic interference (EMI) shielding behaviour as opposed to pristine PEDOT:PSS films. A 12\pm 1 \, \mu m thick crosslinked PEDOT:PSS film exhibited an average EMI shielding efficiency (SE) of 40 \, dB which is adequate for commercial applications. On the contrary, EMI shielding efficiency of pristine PEDOT:PSS films is only 20 \, dB. The absolute SE of crosslinked PEDOT:PSS film is calculated to be 51480 \, dB\, \text{cm}^2\, \text{g}^{-1}, highest ever reported for an all polymer EMI shielding system. The absorption predominant SE originates from the coarser morphology and interpenetrating layers generated by cross-linking. Tensile strength testing with a micro UTM revealed that crosslinked films could bear double the amount of stress compared to pristine films. The outstanding moisture stability combined with high electrical conductivity of the crosslinked films makes them potential candidates for encapsulant and back electrode of organic photovoltaic systems. Moisture stability and transmission characteristics of these films are currently being investigated. In addition, their higher electrical conductivity also makes them suitable for active electrode materials in sensor applications for environmental monitoring, wherein their stability in water also plays a crucial role. Application potential of the films in these avenues are currently under scrutiny.

**Non-Destructive Investigation of Dispersion, Bonding and Thermal Properties of Emerging Polymer Nanocomposites Using Close-Up Lens Assisted Infrared Thermography**

Ali Ashraf, Nikhil Jani, Francis Farmer and Jennifer Lynch-Branzoi; Rutgers, The State University of New Jersey, United States

Polymer nanocomposites possess unique sets of properties that make them suitable for applications, including structural materials, aerospace, flame retardant material, electromagnetic wave reflector, strain/solvent sensor, thin film transistor, flexible display, and many more.\(^1\) The properties of these nanocomposite are dependent on nanofiller dispersion and bonding with polymer matrix (i.e. particle-matrix interaction). Thermal imaging is a non-destructive method that may be used to gain insight into dispersion and particle-matrix interaction.\(^2\) Infrared (IR) radiation emitted from these nanomaterial polymer composite depends on the emissivity of the individual components. In addition, during flash heating and cooling, thermal conductivity of components in the nanocomposite can influence IR radiation being emitted. Moreover, during in-situ incorporation of filler with polymer and during curing of thermostet nanocomposites, exothermic and endothermic reactions representing bond formation can be investigated with IR camera\(^3\). Even for nanoscale phenomenon as electron transport and energy dissipation, nanomaterials like graphene can be characterized by IR imaging\(^4\). We have used an economical mid wavelength IR camera Fluke RSE600 equipped with a close up macro lens and algorithm based on MATLAB image processing toolbox to analyze dispersion, voids, thermal diffusivity and energy dissipation of patented graphene polymer nanocomposite materials (G-PMC)\(^5\) in micron scale. These G-PMCs can act as a standard material to determine the potential of our IR thermography technique due to their homogeneity and lack of impurity due to unique fabrication process. Thermal diffusivity and dispersion of nanoparticles in our G-PMCs was estimated after irradiation with a xenon flash lamp by spatially mapping transient IR radiations with time from different G-PMCs using a Fluke RSE600 thermal imager. Our thermography technique was used to study nanomaterial agglomeration, energy dissipation or thermal transport during sensing application of G-PMCs. Interpretation of the thermal image will be verified by performing scanning electron microscope (SEM), Rheometry, Raman spectroscopy and X-ray photoelectron spectroscopy (XPS). We believe this low cost, fast, non-destructive technique will provide valuable insight into functional polymer nanocomposite fabrication and corresponding mechanical, electrical, and thermal properties.

**Effective Thermal/Electrical Conductivities of Three-Dimensional Cellular Architectures Based on Triply Periodic Minimal Surfaces**

Juveiriah M. Ashraf, Dong-Wook Lee, Oraib Al-Ketan, Aliaa Abou-Ali, Kin Liao and
Cellular structures based on Triply Periodic Minimal Surfaces (TPMS) are structures in three-dimensional (3D) space with a locally net zero curvature and a unique architecture that locally minimizes the surface area. They can be divided into two main categories; solid and sheet networks. The special morphology of TPMS, along with their low density and yet high surface area has led them to demonstrate enhanced electrical, thermal, and mechanical properties. The objective of this paper is to computationally evaluate the effective electrical and thermal conductivity of three cubically symmetric TPMS cellular structures – namely Gyroid, IWP and Diamond over a range of relative densities and morphological parameters using the Finite Element Method (FEM). Particularly, it compares the solid cellular structures with each other and investigates the inter-relation between the solid and sheet networks. Results show the effective conductivity to vary linearly with increasing relative density for the three shapes, with the sheet networks demonstrating higher conductivities than the solid networks at all relative densities. The IWP and Gyroid exhibit similar trends while the Diamond shows a lower conductivity for the same values of relative density. Among all the structures, the IWP presented the highest value of 0.17 for the sheet networks and 0.13 for the solid networks, both at a relative density of 25%. The second parameter that is investigated in this study is varying the morphological parameter c-value, which changes the ratio of the two volumes divided by the minimal surface, and at a critical value, alters the geometry such that TPMS-based tube-networks are formed. As observed for the Gyroid, at the same relative density, increasing the c parameter decreases the effective conductivity of the structures due to a decreased surface area available for heat transfer. The effect of varying the c value for the Diamond and IWP tube-networks show similar trends to the Gyroid. The findings of this work are to be used as a validation for measuring the thermal and electrical conductivities of TPMS-based graphene 3D lattices synthesized experimentally where the minimal surfaces of polymer material will be fabricated using additive manufacturing, coated with graphene oxide and subsequently etched via thermal methods to obtain pure 3D graphene architectures.
engineering due to the possibility of allying, through the appropriate choice of a polymer matrix and inorganic filler, biocompatibility, bioabsorption and mechanical resistance properties to be compatible with bone structures. The rapid prototyping technique (3D printing), via fused deposition modelling, enables the fabrication of bone implant structures with complex shapes at a suitable scale. The aim of this work was to obtain nanocomposites filaments, composed by PLA (poly (lactic acid) and nanohydroxyapatite (nHA). PLA is a polymer of low density, great biocompatibility and biodegradability, compatible to be applied for bone reconstruction strategies. nHA is toxicless, non-inflammatory ceramic, with high osteointegration capacity due to the Ca-P composition, similar to bones. PLA2003D (NatureWorks) were cryogenically ground and mixed with powder nanohydroxyapatite (Sigma-Aldrich) at proportion PLA:HA 70:30. The powder mix were extruded at 180°C to obtain filaments with 1.75 mm diameter. A Clever CL1 printer was used for fused deposition modeling (FDM) of samples at 175°C. Compression strength samples geometry were settled at H:20 W:10 and T:10 mm and for Scanning Electron Microscopy (JEOL microscope running at 15 kV) the geometry were 4 mm of diameter and H:1mm, which was cryogenically fractured. The hydroxyapatite was distributed homogeneously with effective interaction between the polymer matrix and ceramic material. The compression behavior was similar to those reported in the literature on bionanocomposites. However, the bionanocomposite demonstrated higher mechanical properties in comparison with pure PLA.

Titanium Aluminide (MAX Phase) Thin Films for Optoelectronic Applications Abhijit Biswas, Sachin Kumar Singh, Swati Parmar, Arundhati Sengupta and Satishchandra B. Ogale; IISER Pune, India

Recently, research in layered ternary carbides has attracted immense interest as the materials show both ceramic and metallic properties. Here, we have grown hexagonal layered Ti₃AlC₂ (MAX) thin films on structurally compatible c-Al₂O₃ substrates by pulsed laser deposition (PLD) and studied their physical properties and potential applicability. Structural and morphological characterizations by x-ray diffraction (XRD), atomic force microscopy (AFM), x-ray photoelectron spectroscopy (XPS) and Raman spectroscopy confirm the high crystallinity with low surface roughness of < 1 nm. We have elucidated the strain in the films as a function of layer thickness using Raman spectroscopy. Resistivity (ρ) of bulk 80 nm film is found to be ~50 µΩ-cm at T = 300 K, which increases only to a bit higher value of ~60 µΩ-cm at T = 5 K. The incredibly low temperature coefficient of resistance (TCR) indicates that the electronic transport in this unique system is marginal between metallic and semiconducting modes of transport. Moreover, the bulk film is nonmagnetic with a positive magnetoresistance (MR) ∝ B², attributed to the Lorentz contribution. Surprisingly, with reducing the film thickness, even the ultrathin 2 nm film shows sheet resistance (Rₛ) only of ~700 Ω/square sheet at T = 300 K. Importantly, this highly conducting ultrathin 2 nm film transmits ~75% light in the visible wavelength range, making it suitable as an excellent transparent conducting bottom electrode for several optoelectronic applications. Furthermore, when tested for Triboelectric Nano-generator (TENG) device application, the bulk Ti₃AlC₂ films show an open circuit voltage (Vₒc) ~30 V when grown on c-Al₂O₃ and ~80 V, when grown on flexible Kapton substrate.

SB01.03.11
Programmable Soft Matter—From Active Membranes to Self-Replication Alexander Boeker; Fraunhofer Institute for Applied Polymer Research - IAP, Germany

This contribution discusses various approaches to create programmable soft matter either by directly incorporating functional biomolecules into polymeric materials or by transferring concepts conceived by nature to fully artificial materials.

The first approach involves the synthesis of polymer-protein conjugates and their self-assembly to form biofunctional membranes [1-3]. We introduce a new strategy using engineered natural protein channels decorated with polymer chains followed by self-assembly at a fluid interface to form ultrathin, permeable and highly selective membranes. A similar strategy can be used to incorporate sensitive enzymes into a fluid-like polymer membrane environment, thus allowing to almost completely retaining their initial activity after immobilization and even boosting their temperature stability.

The second example is aiming towards creating artificial materials systems that are able to self-replicate. To achieve this, an indispensable prerequisite is the multi-directional control of interactions between the building blocks of materials. Thus, we aim to create a new class of multi-patch colloidal particles via an advanced micro-contact printing technique yielding patches of different chemical or physical functionalities. The new production process
allows precise control over the patch location and chemistry and thus also gives particles that go well beyond known ABA- or ABC-type Janus particles [4-7].

**SB01.03.12**

**Comparison of Experimental and Modeled EMI Shielding Properties of Periodic Porous Composites** Avi Bregman; University of Michigan, United States

With the advent of massive telecommunications networks and the expansive development of wireless electronics operating in the gigahertz range, “electromagnetic pollution” has risen to unprecedented levels. To mitigate the effects of electromagnetic interference (EMI) from spurious radiation, improved EMI shields are needed. Shields composed of solid metals or metal-based coatings oftentimes exhibit high shielding efficiency (SE) but have issues such as poor wear and corrosion resistance and high rigidity. Foaming of these materials has demonstrated higher broadband EMI absorption as compared to the non-foamed material due to minimization of the air-to-shield impedance mismatch. However, the pore morphology inside the foam is highly dependent on the specific foaming conditions and materials involved. The final pore morphology can drastically affect EMI shielding efficiency resulting in significant resources being spent on optimization of the foaming process. Herein we present an approach that relies on the introduction of periodically placed air-filled pores into conducting polymer composites in order to reduce material requirements and maximize microwave absorption. The presented research will demonstrate experimental validation of a novel route for the development of highly efficient EMI shields based on a magnetically functionalized graphene composite material. First, constitutive electromagnetic properties of bulk composite material are retrieved from scattering parameter measurements. The constitutive properties are manipulated through variable addition of magnetoelectric filler material. Second, electromagnetic properties are utilized in finite element method-based optimization to establish optimal periodic geometry that have high EMI shielding for a desired range of frequencies and incidence angles. Finally, optimized geometries are realized via compression molding. We demonstrate the validity of this approach using two different polymer systems, one of which includes a segregated conductive network.
In Vitro Antitumoral Activity of the Black-Tailed Rattlesnake (*Crotalus molossus*) Encapsulated in Chitosan-TPP-Alginate Nanoparticles
Alexel J. Burgara-Estrella, Jorge Jimenez-Canale, Jose A. Sarabia-Sainz, Daniel Fernandez-Quiroz and Martin R. Pedroza-Montero; Universidad de Sonora, Mexico

Cancer is one of the first causes of death within developed countries, and still on the rise. Nanomedicine offers novel tools to treat these types of diseases by implementing nanocarriers that diminish secondary noxious effects and enhance therapeutic properties. Herein, we prepared biocompatible and biodegradable polymeric nanoparticles (NPs) through the ionotropic gelation process in order to encapsulate crude venom from the Mexican Black-Tailed rattlesnake (*Crotalus molossus*). Low molecular weight (LMW) Chitosan (Cs) was used and Tripolyphosphate (TPP) alongside LMW sodium alginate (ALG) were utilized as crosslinking agents. Cs-TPP-Venom-ALG and Cs-NaCl-TPP-Venom-ALG NPs presented a size distribution of 1284 ± 80.23 nm and 504.7 ± 22.3 nm, with a surface charge of 61.6 ± 2.48 mV and 41.0 ± 1.66 mV, respectively. NPs Surface membrane interaction with T-47D breast cancer cells was demonstrated by fluorescence microscopy. T-47D treated with NPs without venom had no significant cytotoxicity effect, while cells treated with NPs with venom showed lower cell viability. This justifies pursuing the strategy of nanoencapsulating venom toxins, in order to follow new therapeutic strategies against various malignant cells.

Anti-Biofouling Coating for Orthopedic Implants through Lubricating Micro-Nano Structured Surface
Kyomin Chae1, Woo Young Jang2, Kijun Park1, Yeontaek Lee1, Jin Hyeok Lee2, C. K. Lee2 and Jungmok Seo1; 1Yonsei University, Korea (the Republic of); 2Korea University, Korea (the Republic of)

Orthopedic implants are widely used for diverse orthopedic treatments to sustain the broken bone and substitute for the worn joint. However, conventional implant materials are vulnerable to bio-contamination, which might cause the bacterial invasion into the wounded area and even lead to postoperative infection after the treatments. Inspired by the slippery surface of the Nepenthes pitcher plant, we have developed a durable anti-biofouling surface on the orthopedic implant [1]. To fabricate the anti-biofouling surface, we first etched the implant material in HF and HNO3 solutions to form the micro/nano roughness on the surface [2]. After that, perfluorocarbon-based self-assembly monolayer (SAM) coating was applied to the etched surface, which allows the surface to hold the thin film of medical-grade perfluorocarbon-based lubricant. The developed surface exhibited extreme liquid-repellency against diverse liquids from low surface tension liquids like alcohols to viscous liquids like blood. We further demonstrated that the developed surface prevented the formation of biofilm, and the attachment of biochemical substances and calcium on the implant in vitro. The developed surface shows less than 1% attachment of bacteria and all biochemicals in comparison to the untreated surface. In addition, we confirmed that the property of anti-biofouling is maintained even after repeated physical damages applied in a surgical operation. Moreover, even though bacteria exposed implant was used in orthopedic treatments in vivo, we confirmed that the developed surface showed no tendency to infection over 4 weeks experiment. However, treatments using the bare and superhydrophobic treated implant caused severe infection even delaying bone regeneration rates to less than 20% compared to the developed implant. We envision that the developed surfaces with extreme anti-biofouling property and mechanical durability can be applied to infection-free orthopedic treatments.

Liposome-Based Nanosensors for Biological Sensing
Rona Chandrawati; University of New South Wales (UNSW Sydney), Australia

The detection of target biological molecules in a specific and sensitive manner is critical for the development of
diagnostic devices. Nanoparticle biosensors have the potential to enhance or supersede current analytical techniques, and their introduction could have a great impact in clinical practice.\(^1\) Lipid assemblies in the form of spherical liposomes have played a key role in the design of biosensing assays.\(^2\) Liposomes offer advantageous physical and chemical properties as biosensors; they have a large internal cavity for encapsulation of signal markers and a high surface area for conjugation of recognition elements that allows for the detection of a wide variety of biomolecular analytes. This talk will describe a number of examples of liposomes used for biosensing applications. We recently developed an assay for the selective and sensitive detection of cancer biomarkers,\(^3\) influenza biomarkers (miRNA),\(^4\) and food spoilage indicator.\(^5\) This system does not require washing, amplification or separation steps, and present a unique sensing mechanism inspired by nature. By tuning the recognition elements, this platform may be used for sensing other biological targets, including proteins, drugs, and cells.

Scalable Fabrication of Resonant Sensors and Applications in Wireless Reporting of Soft Material Deformation Sadaf Charkhabi, Yee Jher Chan, Doh Gyu Hwang, Sean T. Frey, Michael D. Bartlett and Nigel F. Reuel; Iowa State University, United States

This work focuses on the development of kirigami-patterned, passive resonant sensors that operate in the short-wave radio frequency range (1-150 MHz) to wirelessly monitor the deformation of materials in closed systems. At first, the sensors are rapidly prototyped out of Pyralux\textsuperscript{©}, a copper-coated polyimide substrate. The Archimedean spiral design is masked by drawing on the copper with an indelible marker (using a craft XY plotter) and the unwanted copper is etched away with hydrochloric acid and hydrogen peroxide. The samples are then rinsed with acetone to release the mask, coated with polydimethylsiloxane (PDMS), and laser-cut to add the kirigami-inspired pattern to the sensor. The onion ring-shaped resonant sensor is wirelessly coupled to external, two-loop reader antennas to report the extent of material deformation. The reader antennas are connected to a benchtop vector network analyzer (VNA) which can capture both the reflection and transmission scattering parameter signals. We have defined the sensor response as the resonant frequency, which is the minimum of the sigmoidal feature in the transmission scattering signal (\(S_{21}\)). The resonant frequency of the sensor is modulated by changing the physical parameters of the resonator such as coil length and spiral pitch. The resonant frequency of the sensors are tracked over an extension range of 0-22 cm and a major shift in the resonant frequency is observed. For instance, a 90 MHz shift in the sensor response is observed by stretching the sensor to 10 cm. Moreover, the effect of the pitch size of the resonator on the sensor’s linear span and gain value (MHz cm\(^{-1}\)), which is defined as the linear slope of the resonant frequency-stretch curve, is studied. In order to confirm the repeatability of the gain of kirigami resonant sensor, a 96 cycle hysteresis experiment is conducted for sensors with different pitch sizes. Furthermore, the coated sensors are placed in a pipe to test the ability of kirigami resonators to wirelessly report different flow rates. The sensor with 1 mm PDMS coating exhibits the highest flow gain value (0.17 MHz.s mL\(^{-1}\)) and largest linear span (10–100 mL s\(^{-1}\)). Finally, since Pyralux\textsuperscript{©} is a relatively expensive substrate and the etching process produces unwanted waste, we demonstrate scalable, sustainable fabrication of resonant sensors with screen printing using conductive silver paste. The resonators are characterized in terms of their electrical and magnetic properties (e.g. resistance, quality factor) as well as their physical properties (using microscopy). Also, the quality of screen-printed resonators is compared to copper-etched and ink-jet printed resonators. We will also discuss current work to print on soft, compliant materials such as Tegaderm\textsuperscript{™} (3M product). In conclusion, flexible, passive, kirigami-patterned resonant sensors can be fabricated for many proposed applications in healthcare, motion and deformation tracking, virtual reality, and soft robotics.

Magnetic Field Driven Buckling in Architected Magnetoelastomers

Vincent Chen1,2, Artemii Goshkoderia3, Matthew Robinson1,2, Carson Willey1,2, Stephan Rudykh4, Abigail Juhl1 and Phil Buskohl1; 1Air Force Research Laboratory, United States; 2UES, Inc., United States; 3Technion–Israel Institute of Technology, Israel; 4University of Wisconsin–Madison, United States

Magneto-Active Elastomers (MAEs) are an important class of soft, shape-recoverable materials that exhibits a stiffness increase in response to an applied magnetic field. Using magnetic field to tune material stiffness is advantageous due to the fast, remote and reversible switching, which is relevant for applications in areas of soft actuators, adaptive vibration dampers and acoustic filters. 1D and 2D architected MAE composites, such as laminates and periodic inclusions, have been predicted to possess novel mechanical instabilities, due the spatial distribution of stiffness mismatch and the ability to dynamically tune the mismatch with magnetic field. We fabricated MAE composites using a commercial silicone as the non-responsive soft matrix and a silicone loaded with iron microparticles for the stiff, magnetoactive regions to experimentally demonstrate these concepts. The silicone matrix formulation was modified to increase the stiffness contrast between the soft encapsulating matrix and the stiff MAE regions, including tuning of the crosslinker to polymer ratio, and addition of silicone oil to further reduce crosslinking. 3D printed templates were used as molds to construct laminates and 2D periodic MAE architectures. Magnetic field induced stiffening was characterized using a custom compression test jig that was designed and 3D printed to systematically load the specimen within a 2 Tesla electromagnet. The study provides experimental feedback on the sensitivity of the buckling strain to experimental specimen sizing/edge effects and provides broader insight on the practical integration of MAE instabilities into functional devices.

Stretchable Solid-State Electrolytes Based on Butyl Rubber -Poly(ethylene oxide) Graft Copolymers

Yiting Chen1, John Trant1, Elizabeth Gillies2, R. Stephen Carmichael1 and Tricia B. Carmichael1; 1University of Windsor, Canada; 2Western University, Canada

The emergence of stretchable and wearable electronics raises a strong demand for stretchable electrolyte materials. Compared to the traditional liquid electrolyte, solid-state electrolytes (SSEs) are non-flammable and have improved mechanical and thermal stability, making them promising for applications in advanced stretchable electronics such as lithium batteries, supercapacitors, and light-emitting electrochemical cells (LEECs). Current research activities in SSEs have focused on improving the electrochemical stability and ionic conductivity of ceramic, polymeric or composite materials to replace flammable liquid electrolytes. Although ceramic electrolytes exhibit high ionic conductivities of the order of ~ 10-3 S/cm, they fracture easily and typically exhibit a high interfacial resistance. Polymeric electrolytes are often complexes of lithium salts and high-molecular-weight polymers such as polyethylene oxide (PEO). However, these polymers typically have low conductivities at room temperature, typically ~ 10-5 S/cm.1,2 Although adding plasticizers or liquid electrolyte into polymer electrolytes improves the ionic conductivity at room temperature, these composite electrolytes generally exhibit poor mechanical stretchability. For advanced stretchable electronics, mechanical performance becomes a critical performance consideration since SSEs need to tolerate repeated volume change during cycling and survive external forces during use. Thus, it remains challenging to fabricate SSE materials that have robust mechanical properties without sacrificing ionic conductivity. Here, we present a new stretchable SSE that shows both high mechanical performance and high ionic conductivity at room temperature using a mixture of an elastic graft copolymer and lithium triflate salt. This elastic graft copolymer has a butyl rubber backbone that provides mechanical flexibility, with PEO sides chains that complex lithium salts to provide ionic conductivity. The resulting SSE provides a superb stretchability of >100% with an ionic conductivity of 1.33 x 10-5 S/cm, which is comparable to that of PEO based SSEs. We demonstrate the application of this new stretchable SSE in iridium complex-based LEECs. LEECs fabricated using a composite blend of iridium complex and the SSE showed one order of magnitude faster light emission response to applied voltage compared to LEECs fabricated using the pristine iridium complex alone, highlighting the higher ionic conductivity of the composite. In addition, the high mechanical stretchability of the SSE provides stretchable and durable LEECs that exhibit a negligibly changed peak radiance under repetitive strain. This new copolymer SSE, with outstanding mechanical properties and ionic conductivity similar to state-of-the-art polymer-based
electrolytes, opens up a new opportunity in high-performance stretchable electronics.

**Design and Characterization of Zwitterionic Materials to Address Long-Standing Challenges at Biointerfaces**

Gang Cheng; University of Illinois at Chicago, United States

Material-associated biofilm, blood coagulation, foreign body response, and biofouling have significant impacts on a variety of applications, including biomedical devices, biosensing, marine industry, etc. To fill the needs of a broad spectrum of applications, materials with superior antifouling property and tunable properties, such as anti-microbial, conducting, mechanical, optical properties, are urgently needed. Countless efforts have been devoted to developing materials that can effectively address these long-lasting challenges. Among these emerging materials, zwitterionic materials have demonstrated superior anti-fouling properties resisting proteins, mammalian cells, and microbes, and better biocompatibility compared to other anti-fouling materials. Although existing zwitterionic polymers exhibit unseen antifouling property at the interface, current zwitterionic materials cannot provide all desired properties, such as electron conducting, antimicrobial, pH-responsive and mechanical properties, for biomedical applications. For example, zwitterionic materials lack electronic conductivity and suffer from weak mechanical properties and lack of elastic property to function as the structural materials. Over the past ten years, we conducted a set of studies to understand the structure-function relationships of zwitterionic polymers. In this presentation, I will show you how we use the design criteria that we learned from structure-property studies to design high-performance zwitterionic materials with superior antifouling/antibiofilm, tunable mechanical, conductive and degradation properties to address the unsolved complications at biointerfaces.

**Facile Electrochemical Routes for the Conformal Coating of PEDOT/Au Nanoparticles on Inverse Opals as Highly-Sensitive Biosensors**

Pei-Sung Hung, Guang-Ren Wang, Tze-Ting Chiang, Tsung-Eong Hsieh and Pu-Wei Wu; National Chiao Tung University, Taiwan

Conducting polymers have received considerable attention in various fields, including electronic devices, sensors, energy materials, anti-corrosion coatings, and biomedical applications. Not only through their tunable electronic properties, but also the soft organic material nature and facile functionalization process render these materials as versatile platforms. Via the hybridization with inorganic compounds, such as metal nanoparticles (NPs), a further enhanced electrochemical properties as well as synergistic effects, could be realized. With these improvements, they can be utilized in the rapid identification of certain biomarkers for early detection of various diseases. In this work, we report a single-step fabrication route, which exploiting the simple electrosynthesis process of conducting polymers, to construct composite sensors with metal NPs incorporation. In addition to their deposition on the planar electrodes, both the deposition bath recipe and processing parameters are explored and optimized for the conformal coating on metal-based inverse opals with flexible substrates support. The composite coating on such bio-inspired 3-D nano-scaffold as the sensing layer could fully utilize the increased specific surface area and improved mass transport brought by the intriguing honeycomb structure. Meanwhile, the enclosed metal inverse opal is employed as the current collector to ensure a highly conductive pathway for signal transduction. The sensing performance for these 3-D sensors is evaluated by the selective detection of ascorbic acid (AA), uric acid (UA), and dopamine (DA). Relevant structural and compositional characterizations are conducted by SEM, EDX, XPS, and Raman spectroscopy.

**SB01.03.21**

**Electrochemical and Thermal Properties of Polymer Gel Electrolytes Based on Ionic Liquid and Organic Solvents**

Dae Hyun Cho, Keun Hyung Lee and Jeonghui Kim; Inha University, Korea (the Republic of)

Ionic liquids (ILs), or room temperature molten salts, composed entirely of low molecular weight cations and anions, have attracted great attention in a broad range of electrochemical devices owing to their physicochemical and electrochemical properties such as non-flammability, non-volatility, high ionic conductivity, and large electrochemical stability windows. The use of highly viscous ILs in electrochemical devices often limits the performance of the IL-based devices due to slow ion transport. To enhance the mechanical integrity of the liquid electrolyte, structuring polymers are often blended to form a chemically or physically cross-linked network, resulting in solid polymer electrolytes known as ion gels. However, the addition of a polymer network in ILs even
lower the ionic motion, which leads to slow response of the ion-gel-based devices to an external signal. Mixing organic solvents with ILs is an effective strategy to alleviate the issue mentioned above. In this work, we blended the four different kinds of organic solvents with the ion gels and investigated the effect of the blend composition on the electrical and thermal properties of the solid electrolytes. The electrical properties depended on the viscosity and dielectric constant of the organic solvent, whereas the thermal properties depended on the vapor pressure of the component materials. When these mixed ion gels were applied in electrochemical thin-film device, the mixed ion gel-based devices showed superior performance to the pure ion gel without organic solvents owing to the enhanced ionic motion.

Stretchable Synesthetic Sound-in-Display Electronics Based on Strain-Insensitive Silver Nanowire Electrodes
Seungse Cho, Donghee Kang, Hyejin Lee and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

With increasing importance of human-machine interface along with the rapid growth of Internet of Things (IoT), integration of sound generation and visual display in a stretchable form of single sound-in-display device has attracted great attention to connect human with machines via a visualization of auditory system. Herein, synesthetic bimodal senses of sound and color is demonstrated by stretchable sound-in-display devices consisting of strain-insensitive silver nanowire electrodes and field-induced inorganic electroluminescent (EL) phosphor emissive layers. While sound-in-display devices embedding EL phosphors in a dielectric elastomer matrix produce the light emission under alternating-current (AC) bias, audible sound-wave is generated via an actuation of dielectric elastomer matrix along with input sound signals simultaneously. The stretchable sound-in-display devices show highly robust and reliable EL sound performance that can be repeatedly stretched and released without severe degradation due to the use of strain-insensitive silver nanowire electrodes. This study demonstrates stretchable electronics including light emission and acoustic system in a single device, which could be further expanded for the realization of sound-in-display electronics.

SB01.03.23
Thermoresponsive Smart Surfaces as Color- and Texture-Changing Sensors and Actuators
Ayoung Choe, Jeonghee Yeom and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Stimuli-responsive smart materials are promising for the detection of various stimuli, such as temperature, pH, or light intensity. Under the external stimuli, the smart materials abruptly change their physicochemical properties. Above all, colorimetric smart materials have great advantages in direct detection and real-time visualization of stimuli. Here, we present a thermoresponsive colorimetric sensor based on the hybrid structure of plasmonic gold nanoparticles and thermoresponsive poly(N-isopropylacrylamide) (PNIPAM) microgels. The color of smart hydrogel film shifts from ruby red to grayish violet with a large extinction peak shift of 176 nm in 1 second for the temperature change from 25 to 40°C. Through the analysis of color shift, the colorimetric sensor array shows a high thermal resolution of 0.2°C. Furthermore, the thermoresponsive colorimetric sensor can be stretchable up to 90% when the hybrid plasmonic microgels are embedded in a stretchable polyacrylamide. In addition, both color- and texture-tunable smart surfaces can be fabricated by using shape memory polymers (SMPs) and thermochromic dyes. We design a thermoresponsive color- and texture-changeable smart surface based on polylactic acid/polyurethane SMP and thermochromic dyes. Here, the pyramid-patterned SMPs (py-SMPs) with fluorinated silica nanoparticles exhibit thermoresponsive change of surface texture and wettability (water contact angle change from 98° to 144°), and thermochromic dye displays thermoresponsive color change. The suggested concept of smart surfaces can be extended to the fields of sensors, actuators, and smart coating by using various adaptive polymers.

SB01.03.24
Injectable Triblock Copolymer Hydrogel for Cryogenic Preservation Combined with Polymeric Dipole Interaction and Quadruple Hydrogen Bonding
Jewon Choi¹, Seyoung Kim¹, Soo-Hyung Choi² and Kookheon Chatt¹; ¹Seoul National University, Korea (the Republic of); ²Hongik University, Korea (the Republic of)

Hydrogel has been attracted great attention in biomedical field since this material resembles the feature of extracellular matrices (ECMs). For the successful application of hydrogel for cell culture or tissue engineering, not only providing the stable substrate but also considering the cryogenic preservation of cells or organs is essential to prevent unwanted cellular degeneration. In cryogenic preservation of cells, it is essential to make the water
molecules in hydrogel unfrozen during the freezing process. To this end, synthesized the triblock copolymer hydrogel composed with hydrophobic block, zwitterionic block and quadruple hydrogen bonding moiety was investigated in this research. Due to the synergistic effect of super-hydrophilic nature of zwitterionic polymer and nanoscale domain formation of hydrogen bonding moiety, the large amount of water in this hydrogel did not freeze below the temperature 223K. Furthermore, capitalizing on these dynamic bond, this triblock copolymer hydrogel shows injectable and self-healable property. In addition, it shows plateau modulus in the range of soft tissue. We hope that our basic finding give the design principle on hydrogel for biomedical application such as a tissue engineering.

SB01.03.25
Epoxy Toughening with Core-Shell Bottlebrush Polymer Jin Woong Choi, Joona Bang and Yoon Huh; Korea University, Korea (the Republic of)

Bottlebrush polymers (BBPs) consist of a linear backbone and grafted side-chains. The high branch-to-backbone ratio in these systems causes BBPs to adopt different conformational behavior compared to linear polymers, making them a topic of interest. The most widely used synthetic method for BBPs is the ring opening metathesis polymerization (ROMP) of macromonomers. Here, we synthesized diblock macromonomer via atom transfer radical polymerization and nitroxide radical coupling, and then synthesized core-shell bottlebrush polymer via ROMP. Our diblock macromonomers consist of poly n-butylacrylate (PBA) and poly ethylene oxide (PEO). Here, PBA acts as a rubbery core and PEO acts as an epoxy miscible shell. With only 3 wt% of BBPs addition, epoxy toughening effect of 200% was achieved. The results show that the application of BBPs to the epoxy toughening industry can be expected.

SB01.03.26
Effective Utilization of Moth-Eye Inspired Structures with Different Dimension and Materials Jiseong Choi, Joon Hyung An and Seongmin Kang; Chungnam National University, Korea (the Republic of)

Since the fabrication of flexible anti-reflective (AR) structures has great attention for application, such as solar cells, display, wearable devices and so on, various methods, especially moth-eye inspired technologies, have been developed in decades. However, there is limited study to explain difference of optical properties depending on structure dimensions and materials fabricating ultra-violet (UV) curable polymers or thermal curable polymers. In this works, we fabricated moth eye inspired conical structures with three different-sized dimension using various materials. To compare the dimension and material dependent AR properties, we successfully fabricated 300 nm, 500 nm and 1000 nm moth-eye structures by using UV curable and thermal curable polymers. As a result, we have demonstrated that the anti-reflection effect of the fabricated surfaces is improved depending on the structural dimension and consisting materials of the nanostructures.

SB01.03.27
Programmable Three-Dimensional Curvature of Glassy Polymer Sheet by Photo-Triggered Strain-Engineering Jun-Chan Choi1, Jong Hyeok Lee2, Sukyoung Won2, Jae-Won Lee1, Jeong Jae Wie2 and Hak-Rin Kim1; 1Kyungpook National University, Korea (the Republic of); 2Inha University, Korea (the Republic of)

Shape morphing from two-dimensional (2D) planar sheet to three-dimensional (3D) structure have been attracted great attention for the number of application including packaging, assembly, transport, and mechanical actuation. To obtain programmable 3D structure from a 2D polymer sheet, various types of external stimuli have been used including light, heat, electric/magnetic field, and chemicals. In particular, photo-triggered strain engineering used pre-strained thermoplastic polymer sheet has been widely researched due to its ability to local actuation by harmless near infrared (NIR) light with simple and low cost processes. Generally the ink patterns are printed on the polymer sheet for local heating over glass transition temperature (Tg) of polymer with inducing local shrinkage at the pattern regions.

To control the morphed shape of 3D structures, many kinds of pattern design strategies have been studied. For example, pattern width and spacing of hinge patterns were handled for adjusting the folding angle of 3D folding structures. Moreover, different color of hinge patterns was used with different light sources for sequential folding actuation. Recently, using the large size of hinge patterns, global curvatures were controlled according to pattern location, gradient, and its combinations. However, most of the previous works have limited to morphing the folding shapes or the global curvatures based on simple hinge pattern because they considered the deformation of the pattern.
To morphing the complicated 3D structures using photo-triggered strain engineering, the pattern design should be done in advanced considered the deformation of non-pattern regions as well as pattern regions. Furthermore, the analyzing of intermediate shapes at each time interval should be done because the final morphed 3D structure is defined according to an intermediate one.

In this study, we demonstrated the pattern design strategy for 3D shape morphing considering the deformation of the non-pattern region by localized shrinkage of pattern regions with employing radial hinge patterns and round facet on bi-axially pre-strained polystyrene (PS) sheet with a circular boundary condition. According to pre-designed radial pattern conditions and the existence of the round facet, photo-triggered 3D shape morphing was experimentally discussed. Furthermore, we introduced the finite element modeling (FEM) simulation with consideration on temporal/positional stress distribution and their stress competition effects. Interestingly, the hidden mechanisms of the strain re-distribution effect at the non-pattern regions, associated with the final 3D curvature structuring, could be experimentally visualized with polarizing optical transmittance images of the photo-triggered birefringent PS films and they also could be analytically computed. Based on systematic experimental results and computational analysis for pre-determined radial patterns, complex 3D shape morphing having bio-mimetic shapes of soft-turtle shell and sea shell shapes could be successfully implemented, where the PS sheet actuation behaviors at the non-pattern regions were as important as the photo-actuating pattern regions in the formation of final 3D structures. The results of local curving actuation with quantifiable stress imply to take applicability forward for self-folded architectures embodying curved and linear geometric surface coexist.

In Situ Magnetic Alignment and Cross-Linking of RGD-Modified Alginate-Coated Magnetic Microparticles into Macroscale Bundles for Efficient Cell Alignment Seung Woo Choi1, Youngjin Choi2 and Jaeyun Kim1,2,3; 1Samsung Advanced Institute for Health Sciences & Technology (SAIHST), Sungkyunkwan University (SKKU), Korea (the Republic of); 2Sungkyunkwan University (SKKU), Korea (the Republic of); 3Biomedical Institute for Convergence at SKKU (BICS), Sungkyunkwan University (SKKU), Korea (the Republic of)

Cell alignment is an important factor in the exertion of specific mechanical function originated from its anisotropic structure. Especially, myoblast alignment is critical to form paralleled and organized myotubes in muscle regeneration. Diverse approaches have been proposed in cell alignment based on photolithography, electrospinning, laser-guided cell micropatterning, microfluidic patterning, acoustic cell patterning, and 3D bioprinting. However, there is still a need for an easier method that does not require complicated equipment to increase the efficiency of cell alignment. Here, we propose a facile method for magnetic assembly of arginine-glycine-aspartic acid (RGD)-modified alginate-coated magnetic microparticles for cell alignment, in particular myoblast arrangement. The particles could be aligned along the direction of a weak external magnetic field and alginate chains on the surface of microparticles could be cross-linked via ionic cross-linking. By these effects, stable linear bundle structures of the particles in centimeter-scale could be formed even after removal of the magnetic field. In addition, incorporation of RGD into alginate chains on the surface of microparticles could lead to myoblast adhesion onto cross-linked, anisotropic bundles. The efficient myoblast alignment on the bundles was confirmed by filopodia detection followed by analysis of filopodia orientation. As a proof-of-concept, in vivo demonstration of the alignment of alginate-coated magnetic particles was performed without complicated surgery by subcutaneous injection of the particles followed by an additional injection of a calcium solution for in situ ionic cross-linking under the external magnetic field. In histologic examination, the anisotropic bundle structures of the particles in subcutaneous space were observed even after 1 day of injection. This facile process could be one of the options to fabricate aligned architecture, which could further supply an aligned microenvironment to the cells; for example, myoblasts for muscular system in regenerative medicine and tissue engineering. Moreover, the properties of being able to be simply injected through a needle without extra surgery and being in situ cross-linked can be strong points when this platform is applied to in vivo system.

SB01.03.29
Molecular Structure and Hydration Effect of Human Epithelial Keratin Protein Chia-Ching Chou; National Taiwan University, Taiwan

Epithelial keratin protein, a type of intermediate filament protein, is the key component of epidermis in skin which is
the largest organ in human body. The epithelial alpha-keratin intermediate filaments feature a hierarchical structure, ranging from alpha-helical protein, a dimer composed of alpha-helical coiled coils and two globular C- and N-terminal domains, to full-length intermediate filaments. Epithelial keratins dominate the structural stability and mechanical properties of the skin, also help lock in moisture and bear the external pressure. At the molecular level, the alpha-helical coiled coils are stabilized by clusters of hydrogen bonds. Here we report a study on building a bottom-up molecular based model of one epithelial keratin protein by using the full human keratin type K5 and K14 amino acid sequence. A detailed analysis of geometric and mechanical properties of the full-sequence epithelial protein at different water contents by fully atomistic simulation is presented. We analyze how the protein structure and its properties vary with hydration and investigate the role of water molecules in the epithelial protein. Our results suggest that water molecules play a significant role in achieving the characteristic molecular behaviors, including filament assembled arrangement and mechanical properties of this protein material. We further compare our results with the latest experimental measurements and discuss the opportunity of studying disease states associated with genetic mutations and other structural defects in keratin.

SB01.03.30
Ultra Stretchable and Conductive Electrospun Fibers via Electroplating Reinforcement for Strain Sensor Applications Marco Chu, Hani E. Naguib and Tianhao Chen; University of Toronto, Canada

Electrospinning fibers have allowed for the creation of nanoscale structures with high surface to volume ratio which are ideal for next generation wearable electronic and textile applications. Conductive electrospun films are typically constructed by incorporating conductive nanoparticles such as graphene nanoplatelets (GNP) and carbon nanotubes (CNT). Inherently conductive polymers such as polyaniline or polypyrrole have also been used to fabricate conductive electrospun fibers. However, these methods of creating conductive pathways are insufficient as their conductivity remains several orders of magnitudes lower than any metal. Recent developments have used electroplating to coat the fibers with a thin layer of metal. Herein, an alternative electroplating method has been developed that allows for a coating of copper to be uniformly electroplated throughout the entirety of a highly stretchable electrospun styrene-butadiene-styrene (SBS) film. SBS is a copolymer rubber that possesses high elasticity and durability. When made into an electrospun film, the high aspect ratio amplifies the material's elastic properties and can reach strain ratios greater than 1000% without breaking. In this study, various conductive nanoparticles were explored to identify their effects on electroplating coating properties. The SBS film was ultrasonicated in an aqueous solution of the nanoparticles at varying weight percent to prepare the film for electroplating. The ultrasonication process assisted the conductive fillers to diffuse through the thickness of the film and adhere to the individual fibers. This provided an initial conductive pathway for the copper to deposit onto the fibers. As the conductive fillers were evenly coated on each fiber, the copper was also uniformly coated onto the underlying nanoparticle layer. The resulting conductive electrospun film retains its high elasticity through the mechanical properties of SBS, while the conductive copper and nanoparticle layer provide relatively high conductivity to the film even at high strain ratios. These properties make the film suitable for use as large strain sensors in electronic skins and smart textiles.

SB01.03.31
Nature-Inspired Encapsulation Layers for Soft, Transient Electronics JinMook Chung, Gwan-Jin Ko and Suk-Won Hwang; Korea University, Korea (the Republic of)

Transient electronics is a different form of electronics that can physically disappear and bioresorbable when immersed in water or moisture condition. New options about treatments of transient electronics are essential to create potential applications. Especially, an encapsulation of transient electronics is very important to protect electric devices at prescribed times. However, it is difficult for flexible electronics with encapsulation layers to maintain a soft and protection properties. Therefore, selecting encapsulation layers of transient electronics is an important issue. Usually, soft polymers are used for the encapsulation of electronics. We report some artificial and nature polymers, which have soft, biodegradable and biocompatible properties. On these polymers, we can fabricate electric components and integrated circuits.

In previous studies, thick or multiple encapsulation layers are used for increasing lifetime of device. However, that methods cause film delamination and decrease of flexibility. Therefore, we feel the need for new form of encapsulation layer.

In nature, lotus leaves have a large contact angle through microstructures, which results in a hydrophobic surface. Microstructures of lotus leaves can be applied to encapsulation layers of transient electronics. By tuning surfaces of
encapsulation layers, hydrophobicity of surfaces increases and lifetime of electronics can be enhanced effectively. As a result, softness and lifetime of devices can be controlled by surface-tuned encapsulation layers. And then, it is expected that this research is applied to various applications like wearable, medical devices.

Inkjet-Printed High Efficiency Organic Solar Cells as Customizable Energy Harvesting Systems for Autonomous Applications Daniel A. Corzo, Eloise Bihar, Khulud Almasabi, Diego Rosas Villalva, Sahika Inal and Derya Baran; King Abdullah University of Science and Technology, Saudi Arabia

Emerging materials including low-bandgap donors and non-fullerene acceptors are leading organic solar cells (OSC) to reach efficiencies beyond the 16% mark. The increased performance of OSCs along with flexibility, stretchability, and the versatility and low costs associated with solution processing has rendered them attractive as energy harvesting devices for unconventional applications such as conformable and disposable electronics and autonomous sensing. Inkjet printing has proven to be a viable fabrication technique to exploit the advantages of solar cells and transition from laboratory-made devices into consumer-ready products due to its low material usage, customization through digital design, and high-resolution of printed features.

This work demonstrates the fabrication of fully inkjet-printed high efficiency solar cells based on the PCE10:4F and P3HT:O-IDTBR blends for autonomous micro-powered applications. The engineering of functional inks for the different functional layers is centered on tuning the rheological properties for proper jetting, the compatibility of surface energies between the ink and the underlying films, as well as controlling the drying behavior for optimized electronic properties.

The optimization of the printing process results in repeatable devices with efficiencies of up to 12.5%, comparable with that of laboratory coating techniques. Fully printing OSC’s encourages their integration as a power source in combination with other printable electronics as a customizable solution for a wide variety of applications. Fully printed devices allow end-users to design and integrate OSC’s as a power source in combination with other printable electronics throughout a wide range of applications.

SB01.03.33
Reprogrammable Nanomagnets for Shape-Morphing Micromachines Jizhai Cui1,2, Tian-Yun Huang1, Zhaochu Luo1,2, Paolo Testa1,2, Hongri Gu1, Xiang-Zhong Chen1, Bradley Nelson1 and Laura Heyderman1,2; 1ETH Zürich, Switzerland; 2Paul Scherrer Institut, Switzerland

Shape-morphing micromachines have demonstrated significant potential in drug delivery, minimally invasive surgery, cell manipulation, and stenting applications [1]. With current fabrication methods, most micromachines are limited to a single type of transformation determined by their geometric design, which cannot be altered once fabricated [2]. In this work, we have developed a strategy to encode multiple shape-morphing information into transformable micromachines making use of the magnetic configurations of single-domain nanomagnet arrays. Inspired by origami, our micromachines consist of rigid panels carrying the arrays of nanomagnets separated by structured soft creases. The nanomagnets have tailored magnetic switching fields and, by applying a sequence of magnetizing fields, the arrays can be set into a particular magnetic configuration. By customizing the micromachine designs, we can obtain micromachines that perform specific shape transformations in an applied magnetic field.

Based on this strategy, we have built a simple four-pad micromachine with 24 possible magnetic configurations, demonstrating four distinct conformations when actuated by a magnetic field. Further, multicomponent micromachines were constructed by assembling modular units and, by customizing each individual unit, we have engineered a micromachine that can transform between two alphabet letters. We have also created complex folding behaviors, such as bending and twisting, and have implemented these folding modes in a microscale ‘origami bird’ capable of several different flapping modes. This work paves the way for the development of future intelligent microsystems that are reconfigurable and reprogrammable, which is required for biomedical applications and is also of interest for 3D magnetic and optical metamaterials. [3]

Color-Changeable Soft Actuators based on Metal Nanowire Network Transparent Heaters and Anisotropic Polymer for Biomimetic Soft Robotics

Hyeonseok Kim¹, Habeom Lee² and Seunghwan Ko¹; ¹Seoul National University, Korea (the Republic of); ²Pusan National University, Korea (the Republic of)

To overcome lack of functionality and limitation in conventional soft robots, we demonstrate a highly anisotropic color changeable soft actuators for the first time. Due to the huge anisotropic thermal expansion mismatch, the suggested actuators has a highly anisotropic bending with very large curvature (2.5 cm⁻¹) at considerably low temperature (=40 °C) compared to the previous electrothermal soft actuators. Low temperature operating condition enables the remarkable long-term durability during more than 10000 times actuating at the maximum curvature. In addition, the optical transparency of metal nanowire network heaters and polymer bilayer allow the incorporation of the thermo-chromic dyes to fabricate color-changing actuators. We demonstrate various color-changing biomimetic soft robots such as color-changing blooming flower, flapping butterfly, and color-changing twining tendril. Along with high anisotropic behavior, large bending curvature with low temperature operating, long-term durability, color-changing function, the actuators offer tremendous possibility for biomimetic soft robotics.

Gels for Bioprinting—Finding, Functionalising, Formulating, Printing and Characterising Gordon Wallace; University of Wollongong, Australia

The ability to create 3D printed structures containing living cells is providing a route to the creation of "living" systems that might be useful for bench top drug testing or implantables that facilitate tissue regeneration.

However, the realisation of a useful printed structure based on hydrogels is not a simple task. While we can build on the extensive knowledge that has accrued through cell-gel interaction studies to date, there are a number of dimensions that add to the challenge.

Central to these is that the gel containing the cells must undergo a reasonably rapid phase transformation. In addition, with some applications multiple cells and other bioactive entities need to be strategically distributed in 3 dimensions. Sterilisation of the components and/or the final structure is also of critical importance and finally knowing what we have created without destroying it remains a challenge.

Returning to the start of this process we encounter perhaps the most neglected aspect - most of the emerging hydrogels finding use in bioprinting are naturally occurring. So where do we find them - how do we ensure a reliable high quality source?

8:30 AM SB01.04.02/SB04.04.02
Novel Hybrid Approach to 3D-Print Graphene/Polymer Composites Xuechen Shen, Taylor J. Morrison, Hani E. Naguib and Tianhao Chen; University of Toronto, Canada

Current 3D printing uses a wide range of plastic, metal, and ceramic materials, with no significant effort to integrate these techniques for multi-material fabrication. We previously developed a novel method to deposit non-viscous ink through a stable continuous jet formed by gearing-enhanced peristaltic pumping. This ink deposition technique was used to deposit graphene oxide (GO) ink in a binder jetting (BJ) process to fabricate GO/polyvinyl alcohol composites. In this technique, ink particles are accelerated to speeds of 2-10ms⁻¹ to overcome surface tension forces tending towards pendant drop formation. Gearing is applied to achieve mechanical advantage (MA)<1, enabling high pump velocity. Motor acceleration made up for the lost torque. In recognizing that gearing could be used to
increase torque with MA>1, we realized the potential to perform Direct Ink Writing (DIW) using our ink deposition system. To this end, we DIW-printed viscous graphene/nanocellulose inks. We also recognized that DIW and BJ shared similar layer change, material transport, and gantry motions, allowing the 2 techniques to be implemented in the same system. We designed and built the hybrid 3D printer, implementing transmission to switch gearing ratios. The hybrid printer was demonstrated to print Graphene/polymer composites using both DIW and BJ printing modes.

8:45 AM SB01.04.03/SB04.04.03
Three-Dimensional Printing with Silica Cages Jen-Yu Huang¹, Tangi Aubert¹,², Ulrich Wiesner¹ and Tobias Hanrath¹; ¹Cornell University, United States; ²Ghent University, Belgium

Material scientists have now developed an extensive library of nano-sized building blocks, offering a vast panel of properties (optic, magnetic, plasmonic, catalytic, etc.). Nevertheless, combining these building blocks for the realization of multifunctional materials while controlling their structure from the nano- to the micro- and all the way to the macroscale still remains an open challenge in order to fully exploit their potential. In parallel, new material processing techniques such as 3D printing technologies are emerging for the fabrication of macroscopically highly engineered parts and devices. In this work, newly discovered silica nanocages are combined with digital light processing 3D printing technique for the rapid fabrication of mesoporous parts with arbitrary shapes and tunable internal structures. Complementary strategies are then deployed for the implementation and deliberate positioning of various functionalities throughout 3D printed objects with high control on the microstructure and macroscopic architecture of the superstructures. This approach paves the road for innovative device concepts and designs, that will benefit from the unique properties of nanomaterials and from the micro- and macroscale manufacturing capability of 3D printers.

9:00 AM SB01.04.04/SB04.04.04
Magnetically Navigable 3D Printed Multifunctional Microdevices for Water Quality Control Roberto Bernasconi¹, Elena Carrara¹, Marcus Hoop², Fajer Mushtaq², Bradley Nelson², Salvador Pani², Caterina Credi¹, Marinella Levi¹ and Luca Magagnin¹; ¹Politecnico di Milano, Italy; ²ETH Zürich, Switzerland

Water contamination, either chemical or biological, is one of the main problems for public healthcare in many parts of the world. Contaminated water is a source of a great number of diseases caused by pathogens or by chemical agents. Many techniques are available to improve water quality, but in many cases these methods are not entirely environmentally friendly. Current research efforts are directed toward the use of harmless substances and safer methods. From the pathogens control point of view, silver is one of the most used non-antibiotic agents. Regarding chemical pollutants elimination, one of the most promising techniques is photodegradation mediated by titania (TiO₂). This material photocatalytically generates reactive radicals able to oxidize pollutants upon exposure to an electromagnetic radiation. Functional layers of silver and titania can therefore be used to provide efficient water remediation.

An interesting approach consists in manufacturing multifunctional materials that exhibit both antimicrobial and photocatalytic activities. A fabrication technique able to yield this type of materials is electrolytic codeposition of particles with metals or alloys [1]. For example, thanks to this wet deposition technique, a matrix of silver with embedded titania particles can be easily obtained. The final composite layer exhibits both antibacterial and photoactive properties. Water cleaning possibilities can be further expanded if the antibacterial and the photodegradation action is performed by microdevices covered with silver/titania composites. An example of such devices are the so-called microrobots [2], which can be wirelessly guided using magnetic field and placed exactly where the water decontamination action is needed. Examples of microrobots presenting photocatalytic [3] or antimicrobial activity [4] are available in literature, but none of them combines these two actions on the same device.

The aim of this work is the realization of cylindrical shaped microrobots combining biokilling and photodegradation thank to the presence of a bifunctional composite on their surface. Such microrobots are produced using 3D printing, more specifically microstereolithography, and are subsequently metallized using wet techniques. Two functional layers are applied on the surface of the 3D printed device: a CoNiP magnetic alloy and an Ag/TiO₂ composite. The first makes possible the movement of the device under the influence of an external magnetic field, while the latter imparts the biocidal/catalytic activity to the device. We demonstrate that these devices exhibit antimicrobial activity toward methicillin resistant Staphylococcus aureus bacteria. Moreover, from the pollutants removal point of view,
we prove that they can efficiently photodegrade a model molecule like rhodamine B when exposed to ultraviolet radiation.

Macroscale Double Networks—A Universal Method for Improving the Strength and Toughness of Soft Materials Daniel R. King, Tsuyoshi Okumura, Riku Takahashi and Jian Ping Gong; Hokkaido University, Japan

The double network concept has been revolutionary in its ability to turn soft, brittle hydrogels into tough, robust materials with mechanical properties that match the best synthetic elastomers. Double network hydrogels consist of two interpenetrating networks, where each network has a specific mechanical response: the “first network” acts as a sacrificial network, consisting of a rigid, extended network, and the “second network” is a globally percolated, stretchable network. When a double network hydrogel is stretched, covalent bonds of the first network break, dissipating energy; this process continues with increasing strain, until the sacrificial network is completely broken and the second network ruptures. The goal of this research is to demonstrate that the “sacrificial bond concept” is applicable at length-scales beyond the molecular scale. We aim to incorporate this design concept universally for application in structural and medical devices.

Like double network hydrogels, our system consists of a rigid “first network,” 3d printed polyurethane/polyacrylate grids, embedded in a soft and stretchable “second network,” silicone rubber. We found that when the strength of the matrix exceeds the strength of the grid, local fracture occurs in the grid, and stretching is isolated to the rubber in the fractured region. As stretching increases, the force increases, and when the local force exceeds the global strength of the grid, fracture will occur elsewhere in the composite. This process continues sequentially throughout the sample until all grid fracture sites are exhausted, and the matrix ruptures. By tuning the stiffness of the grid, we can independently control the yield strength and fracture strain of the composite, until a point where the grid strength exceeds the matrix strength, and the multiple fracture process no longer occurs.

We also systematically studied the interfacial interactions between the matrix and the reinforcing grid. Both interfacial adhesion as well as topological interlocking are important towards developing a robust composite. By adhesive interactions alone, only minimal fracture of the reinforcing phase occurs; topological interlocking is required to maximize fracture. Based on this result, we systematically change the grid size to modify the number of fracture events. In the optimized form, an increase in work of extension of ~50% over the neat matrix was achieved, representing a ~70% toughening efficiency versus the calculated maximum toughness. These results demonstrate that macroscale double networks can dramatically increase the toughness of soft materials.

9:30 AM *SB01.04.06/SB04.04.06
4D Printing Thermoplastic Polyurethane Hydrogel-Elastomer Trilayers for Structural Applications Richard S. Trask; University of Bristol, United Kingdom

Hydrogels represent a class of engineering materials that have great promise for integration within the human body; particularly by optimising and functionally grading their biophysical and biochemical properties. The ability to construct complex architectures through 3D printing is now common place but introducing the ability to transform a planar architecture into a new configuration once manufactured opens up the potential to minimise manufacturing complexity but maximising the design potential. This presentation will detail our latest design thinking utilising a multifunctional materials design methodology and 4D printing research for producing a diverse range of complex architectures utilising thermoplastic and hydrogel trilayer constructs. This unique methodology permits the viable construction of dynamically robust and complex bilayer and trilayer origami architectures for a new generation of active structures. In our study the resulting creations transform from flat 2D parts to 3D structures through submersion in water and return to their original configuration through dehydration. This technique uses commercially available materials and printers to enable a controlled and predictable actuation method that is more accessible and affordable than previous examples of hydration triggered 4D printing. We show the ability to create tessellated origami patterns, such as the Miura-ori origami fold pattern and the waterbomb configuration; the latter
being a design that has not previously been realised with 4D printing. These new designs demonstrate how the integration of multiple trilayers into a single 3D print enables through-thickness control of actuation resulting in the formation of active structures with complexity beyond what has previously been achieved with 4D printing. The research will now be extended by the generation of curved-layer morphing origami architectures (i.e. individual layers with variable z-component actuation) to enable selective structural buckling; the generation of tubular bilayer/trilayer architectures; and, the generation of sequential actuation through the addition of porogens (i.e. dissolvable particles used to create porous hydrogel structures) such that the rate and magnitude of actuation can be further programmed in the design phase.

10:00 AM BREAK

10:30 AM *SB01.04.07/SB04.04.07
Extreme Hydrogel Technology Xuanhe Zhao; Massachusetts Institute of Technology, United States

While human tissues and organs are mostly soft, wet and bioactive; machines are commonly hard, dry and biologically inert. Bridging human-machine interfaces is of imminent importance in addressing grand societal challenges in health, security, sustainability, education, and joy of living. However, interfacing human and machines is extremely challenging due to their fundamentally contradictory properties. At MIT Zhao Lab, we propose to harness “extreme hydrogel technology” to form long-term, high-efficacy, compatible and seamless interfaces between humans and machines. In this talk, I will first discuss the fundamental mechanisms to design extreme properties for hydrogels, including extremely tough, resilient, adhesive and anti-fatigue, for long-term robust human-machine interfaces. Then I will discuss a set of novel hydrogel technologies, including i). hydrogel bioelectronics capable of electro-opto-fluidic interrogating single neurons and continuously monitoring gastric physiological conditions over the long term; ii). tissue double-sided tapes that give instant strong adhesion of wet tissues and devices. I will conclude the talk with a perspective on future human-machine convergence enabled by extreme hydrogel technology.

11:00 AM *SB01.04.08/SB04.04.08
Smart Hydrogels from Mechanistic Design to Practical Applications Jie Zheng; University of Akron, United States

Synthetic polymer hydrogels as soft-wet materials, consisting of three-dimensional cross-linked networks and a large amount of water (50–90%), possess many unique properties such as swelling/deswelling, stimuli-responsiveness, shock absorption, and low sliding friction, making them as potential excellent biomimetics for substitution of soft living materials. However, conventional hydrogels often suffer from weak mechanical properties, which greatly limit their extensive uses for many other applications. In this talk, we will present different design strategies to prepare tough and multifunctional hydrogels with unconventional polymer network architectures and extraordinary properties. Guided by our design principle, we will demonstrate different hydrogels with high mechanical properties, self-healing, actuation, antifouling, and/or wound healing to mimic cartilages, artificial muscles, and mussel-inspired glues. In parallel, molecular simulations will be presented to given atomic-details of structure-properties relationship. Finally, several unique aspects for future development of tough hydrogels will be suggested.

11:30 AM SB01.04.09/SB04.04.09
Design and Understanding Dynamic Hydrogel with Hydrazone Crosslinks for 3D Printing Junzhe Lou, Sean Friedowitz, Christopher Lindsay, Sarah C. Heilshorn, Jian Qin and Yan Xia; Stanford University, United States

Dynamically crosslinked hydrogels received increasing interest for their adaptive mechanical behaviors under stress and deformation and wide applications for cell scaffolding and delivery. We present a new concept of modulating the dynamics of hydrogel systems crosslinked by hydrazone bonds via a biocompatible organic catalyst. The catalyst accelerates the exchange kinetics of hydrazone bonds for over two orders of magnitude, resulting in identical network structure with widely tunable viscoelastic behavior. The catalyst control of network dynamics enabled quantitative and unambiguous correlation between the network parameters and mechanical properties of dynamic polymer networks, which can be generalized to provide design principles to engineer their viscoelastic properties.
We also applied this system for 3D bio-printing to modulate the dynamic properties of hydrogels at different time points of application to have both high injectability and high stability. The incorporated catalyst enhanced the exchange of dynamic crosslinks to achieve high injectability during printing process, but rapidly diffused away from the hydrogel after ejection to retard the exchange and improve the long-term stability for cell culture.

11:45 AM SB01.04.10/SB04.04.10

**Chemical Pumps for Soft Autonomous Robots** Junsoo Kim¹, Kai Luo² and Zhigang Suo¹; ¹Harvard University, United States; ²Beijing Institute of Technology, China

Soft robots can be untethered by carrying a chemical fuel of pneumatic actuators. However, it has a fundamental design restriction; the fuel pressure should be higher than the actuator pressure to transport the fuel. Given that the fuel part occupies most of the volume, the robot becomes pressurized as much as the actuating pressure and requires stiffer materials for the fuel part, making entire robots stiffer. Here, inspired by the pit in plants, we decouple the pressures of the fuel part and the actuator while providing a fuel against the pressure gradient by introducing an isolator between them, thereby liberating from the design constraint. This isolator consists of a hydrophilic nanoporous membrane made of a hydrogel and a micro-porous wall made of a nylon mesh, that correspond to the pit membrane and the cellulose wall at the pit respectively. The mechanical integrity of the structure according to the geometry is studied by finite-element analysis to establish a design rule and the pneumatic power is extensively characterized experimentally with various parameters. Finally, the isolator is implanted to the conceptual soft robots to demonstrate the merits of the isolator.

**SESSION SB01.05: Applications of Multifunctional Materials: From Design to Advanced Manufacturing**

Session Chairs: Michael Dickey and Pablo Valdivia y Alvarado
Tuesday Afternoon, December 3, 2019
Hynes, Level 3, Ballroom A

1:30 PM *SB01.05.01

**3D Printing of Soft (Hydrogels) and Hard (Surfboard Fins) Materials** Marc In het Panhuis; University of Wollongong, Australia

Surfing is an iconic sport that is extremely popular in coastal regions. Current surfboard fin manufacturers produce high end products using an expensive injection moulding process to create hydro-foil shaped fins. This process, however, does not allow for easy customisation or rapid prototyping.

Hydrogels are smart and multifunctional materials with a real potential for use novel applications including soft robotics, (edible) sensors and bionic implants. Consisting of a highly swollen polymer network, hydrogels are typically soft and brittle meaning they are not compatible with many traditional techniques used to process materials into structures.

I will demonstrate a variety of (extrusion-based) 3D and 4D printing techniques for processing soft materials (hydrogel inks) alongside other inks of structural polymers to create composite architectures including a smart valve, an artificial cartilage meniscus, an artificial tendon, brain-like structures, edible electronic circuits, stretchable devices, soft robotic devices and edible/living hydrogels.

I will discuss the development of surfboard fins (a hard material) using a performance feedback loop. This loop involves the unique combination of computational fluid dynamics, computer aided design, 3D printing of hard materials, stiffness/flex testing, ocean testing (surfing the waves), embedded sensors / wearables, the Internet-of-Things, and surfers’ perceptive experiences.

Time permitting I will finish my talk with our progress on measuring the mechanical flex behaviour of surfboards, including vibration analysis.

2:00 PM SB01.05.02
**Oxygen-Responsive 3D Printing Inspired by Insect Cuticle Sclerotization** Kyueui Lee¹, Patrick A. Ruehs², Phillip Messersmith¹,¹ and Haeshin Lee³; ¹University of California, Berkeley, United States; ²ETH Zürich, Switzerland; ³Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Insects adopt phenolic molecules as molecular cross-linkers that tether internal proteins and/or polysaccharides (such as chitin) to form mechanically strong cuticles functioning as protective armor. The tethering mechanism is triggered by ambient ‘oxygen’ which induces oxidative polymerization between the phenols and the amine-based polymers (proteins or chitin) at the air/water interface. Motivated by this mechanism, we designed a new type of 3D printing system that can be controlled by an unusual external stimulus, ‘oxygen’. The ink for 3D printing is a mixture of pyrogallol (representative phenol), polyethyleneimine (amine-rich polymer), and a scaffolding material. It is initially fluid but immediately hardened after extrusion. By adjusting the air/water interfacial rheology, we were able to control the ink to be cured in 1 second in ambient air conditions. This was a suitable condition for the material to be stacked without falling. The advantage of this 3D printing system is material independence. Activated carbon has been applied to the system to print conductive 3D objects for demonstration, but it can be applied virtually to any colloidal materials on demand.

**2:15 PM SB01.05.03**

**Development of Programmable, Multi-Functional Composite Materials through Additive Manufacturing Techniques to Produce Carbon Capture Devices for Space Travel** Jamie Thompson¹,²,³, Gregory L. Whiting¹ and Camille Petit²; ¹University of Colorado Boulder, United States; ²Imperial College London, United Kingdom; ³Xerox PARC, United States

Multi-material, layer-by-layer additive manufacturing approaches provide a route to the fabrication of complex, structured, and multi-functional composite materials. These composites can be applied in many spaces, including using biomaterials for tissue scaffolding, zeolites for reversible gas capture, and various stimuli-responsive materials for a range of sensing applications.

Here, we present examples of additively manufactured multi-functional materials, including co-printing of conductive and non-conductive adsorbent paste formulations using a direct-ink writing approach to produce devices capable of performing thermal-swing reversible CO₂ capture and release. These printable composites show gas adsorption characteristics in-line with what is expected from the bulk material. Additionally, when an external potential is applied, the printed composites resistively heat to sufficient temperature to desorb captured CO₂. This potentially enables reduced mass and complexity, as well as in-situ manufacture for life-support systems in remote, enclosed, off-planet environments. This approach is further extended beyond the two discrete materials described above through the integration of inline mixing hardware. Multiple pre-functionalized inks were combined within a print head to enable digitally controlled continuous gradient blending of several different functional materials in order to deposit a programmable multi-functional composite. Components of varied resistivity across a spatial region are demonstrated allowing a high degree of thermal control to be achieved post print. This enables the coupling of desired thermal effects to specific chemistries in the design phase to optimize devices for performance, as well as energy efficiency. This is a key step to unlocking the higher potentials of simulation and multiscale modeling approaches used in prototype design.

Finally, implementation of basic closed-loop analysis of the deposition of these multi-functional materials was studied, by including in-line electronic and optical metrology tools on the print platform. By taking account of the specific effects of additive manufacturing processes, such as spatial resolution and geometry, on-the-fly design optimization is achieved, allowing for the degree of ink functionality to be measured and calibrated. This technique should be applicable to a wide range of functional inks thus unlocking the ability to rapidly prototype parts optimizing for multiple complex physical/chemical properties.

**2:30 PM SB01.05.04**

**Low-Temperature Sintering of Inkjet Printed Metal Nano Particles for Additive Manufacturing—Chemical and Morphological Assessment** Gustavo F. Trindade, Yinfeng He, Feiran Wang, Christopher Tuck, Ricky Wildman, Clive Roberts and Richard Hague; University of Nottingham, United Kingdom

Additive Manufacturing (AM) is nowadays employed in a wide range of industries utilising various materials alongside constant developments in terms of geometrical complexity. However, in addition to exploiting geometry, a
multi institutional and multi industry project [1] seeks to augment these products three-dimensional functionality through the co-deposition of both functional and structural materials contemporaneously. Material jetting is key for developing such next generation multi-material/multi-functional AM due to their ability to jet a wide range of materials from polymers, to inks containing metal nano particles (MNPs). In recent years, the use of inks containing silver MNPs has been explored for printing multi-material 3D objects by means of contemporaneous in-situ curing of a polymer and sintering of MNPs using near infrared (NIR) or ultraviolet (UV) light that is absorbed by the NP, triggering their sintering process [2, 3]. As a consequence of their high surface-to-volume ratio, silver MNPs are sintered typically at 120–200 °C, which is as low as 20% of the melting temperature of the metal [3]. Such an advantage enables the printing of metal structures on flexible polymer substrates such as PET or polyimide [4]. A common problem involving low temperature inkjet printing of MNPs is poor conductivity of 3D printed structures and the reason for such problem may lie on the chemistry and morphology evolution during the low-temperature sintering process. Past works have reported conductivity change as a function of annealing temperature and related it to morphological changes [2, 3], however, none has carried out a thorough chemical characterisation of these printed materials. This work describes the development of a protocol for assessing, chemically and morphologically, the sintering process of 3D printed silver nano-particles under different sintering conditions and strategies. Single-layer silver samples were produced by inkjet printing a commercial MNP ink and sintering at different temperatures and high specificity, surface sensitive techniques (time-of-flight-orbitrap secondary ion mass spectrometry – ToF-Orbi-SIMS and X-ray photoelectron spectroscopy – XPS) were employed to track chemical changes. Ambient scanning electron microscopy (SEM) has also been carried out to track in-situ morphological changes in function of sintering temperature.

2:45 PM SB01.05.05
2D-Macromolecular Heterostructures Enabled Colloidal State Machines Albert T. Liu, Pingwei Liu, Daichi Kozawa, Jingfan Yang, Volodymyr Koman and Michael Strano; Massachusetts Institute of Technology, United States

Arming nanoelectronics with mobility and self-awareness opens new opportunities in macromolecular science. Originally referred to as electronics based on chemically synthesized nanostructures, nanoelectronics today can also be fabricated following conventional top-down approaches that scale with Moore’s law. Although the subject has been studied intensively for the past two decades and finds application in a variety of disciplines from computing to energy generation, examples of nanoelectronics with mobility and on-board logics remain elusive. As an emerging paradigm that calls for several scientific and engineering disciplines to work in unison, it is necessary to establish a strong narrative that sets the field apart from similar concepts with explicit, unambiguous functions. In this context, I will discuss how the growing library of 2D-soft material composites, with the suite of exotic properties they command, has facilitated the symbiotic engraftment of electronics onto mobile colloidal particles[1] thus paving the way towards next-generation microrobotics with both low energy consumptions as well as complex functions.[2]

I will focus on our recent efforts in synthesizing such 2D-macromolecular heterostructures, using a novel fabrication technique named autoperforation, owing to the spontaneous perforation of the grafted 2D materials around a pre-designed polymer template.[1] This method lay the foundation of building the proposed colloidal state machines. We have demonstrated, for the first time, that nanoelectronic devices can be grafted onto and/or embedded within colloidal microparticles, creating autonomous machines capable of complex operations in a particulate form.[1] The characteristic mobility of a colloidal system integrates seamlessly with the modularity that comes with modern digital electronics, enabling information collection and recording in enclosed spaces – such as the human gastrointestinal (GI) tract,[3] microfluidic channels, and chemical/biosynthetic reactors – as well as remote locations like oil and gas conduits, waterbodies, soil, or the atmosphere.[1] Ultimately, we envision an intelligent colloidal microrobot that collects, manipulates, and stores information autonomously, extending electronic systems into traditionally inaccessible environments.
Ferromagnetic Soft Robots—Multifunctionality Enabled by 3D Printing and AI

Xuanhe Zhao; Massachusetts Institute of Technology, United States

Soft materials capable of transforming between three-dimensional (3D) shapes in response to stimuli such as light, heat, solvent, electric and magnetic fields have applications in diverse areas such as flexible electronics, soft robotics and biomedicine. In particular, magnetic fields offer a safe and effective manipulation method for biomedical applications, which typically require remote actuation in enclosed and confined spaces. In this talk, we will present ferromagnetic soft robots capable of untethered remote actuation, model-guided design, and AI-based control. We fabricate the soft robots by 3D printing the soft-robot bodies together with programming ferromagnetic domains in the robots. We develop a physics-based model capable of quantitatively predicting the deformation of the robots under applied magnetic fields. Based on the model, we obtain a massive amount of simulation data of various applied magnetic fields and deformed configurations. By training deep neural networks with the simulation data, a machine-learning algorithm is further developed to autonomously navigate the soft robots in complicated environments such as vascular systems. We will demonstrate multiple previously-inaccessible functions of the ferromagnetic soft robots, such as autonomous minimally invasive surgeries, enabled by the synergy of 3D printing, quantitative model and AI.

Sequential Shape-Shifting Capability of 3D Printed Shape Memory Polymers with Broad Glass Transition

Nicoletta Inverardi1, Stefano Pandini1, Giulia Scalet2, Davide Battini1, Fabio Bignotti1, Stefania Marconi2 and Ferdinando Auricchio2; 1University of Brescia, Italy; 2University of Pavia, Italy

4D printing, i.e. the application of 3D printing technology to stimuli-responsive materials, and in particular to shape memory polymers (SMPs), is gathering large attention among the researches on smart materials. Such an approach would lead to important improvements towards design flexibility, allowing to achieve complex or customized 3D printed structures with externally-triggered shape evolutions. The behavior of SMP-based structures consists in significant dimensional variations occurring when the polymer, after being deformed and fixed in a given temporary shape, recovers its permanent shape thanks to an external stimulus, typically involving heating above specific temperatures [1]. Inspiring aims of 4D printing pioneering works were the realization of active structures based on origami theory and of mechanisms capable of sequential self-folding motions [2].

In order to obtain sequentially moving structures, i.e. structures in which different parts undergo dimensional changes at different times upon the application of the same external stimulus, various approaches may be adopted. Research efforts were mainly based on technological and design tools, as the employ of multi-material 3D printing techniques and the realization of functionally-graded structures [3]. An interesting alternative approach to achieve sequential motions is based only on the material, by employing specific SMP families, as in the case of multiple shape memory polymers (i.e. polymers possessing more than one glass transition or melting temperature) or of polymers featuring the so-called temperature-memory effect. These latter systems, thanks to a broad distribution of the glass transition or melting region, are able to “memorize” not only a shape but also the temperature at which the deformation of the temporary shape was performed, so as to trigger the recovery of the permanent shape at a temperature strictly correlated to the deformation temperature [4,5].

In this work the temperature-memory effect, displayed by a commercial resin, featuring an inherent broad glass transition region, was investigated, with particular interest towards the characterization of the effect and its exploitation for sequential motions of 3D printed geometries. A comprehensive experimental characterization is carried out on simple material specimens and on more complex structures (bars; cubes; self-locking mechanism; reverse-honeycomb auxetic structures) printed by stereolithography. In particular, their shape memory behavior was studied after thermo-mechanical deformation history (or “programming”) properly designed to investigate the material response in case of different deformation temperatures and of multi-step deformation histories. Multiple
deformations performed at different parts of a same specimen/structure and at different deformation temperatures enabled in fact the achievement of a controlled recovery process with the presence of distinct and sequential motions. The shape memory response was studied as a function of temperature and in isothermal conditions, these latter being employed to attempt, through the application of a time-temperature superposition scheme, a master curve full description of the time-dependent shape recovery process. The aim is to depict the dependence of the recovery on the deformation temperature both on the temperature and time scales in order to identify best conditions for multiple deformations allowing sequential recovery motions. As a final proof-of-concept and application example, a self-locking clamp was realized and properly “programmed”, so that locking motions were triggered on distinct time scales by the same thermal stimulus applied.

**Thermal and Laser Sintering of Liquid Metal Nanoparticles for Stretchable Electronics**  Shanliangzi Liu¹² and Rebecca Kramer-Bottiglio²; ¹Purdue University, United States; ²Yale University, United States

Gallium-based liquid metal nanoparticle inks have shown great potential in creating printed soft and stretchable electronics. Despite their metallic composition, as-printed liquid metal nanoparticles form a nonconductive film because the liquid metal cores of each particle are surrounded by a nonconductive metal oxide shell. Hence, these films require a sintering process to recover their conductivity. Our group previously demonstrated mechanical sintering of liquid metal nanoparticles, although this sintering process put a lower bound on both the size of the particles and softness of the substrate that may be utilized. In this work, we present two thermally involved sintering methods - laser and thermal sintering - to attain conductive liquid metal nanoparticle films. By comparing laser and thermally sintered films with respect to electrical conductivity, surface morphology and elemental composition, crystallinity and surface composition, we reveal the oxide rupture-induced mechanisms that enable electrical conductivity of liquid metal nanoparticles using both methods. We show that thermal and laser sintering under different conditions generate highly conductive liquid, solid or solid-liquid composite films with desired properties that can be used for different applications such as soft robotics, wearable electronics, or broader semiconductor and electronics applications. We also demonstrate high-resolution laser sintered patterns that can be implemented to create high-density electronic devices on soft substrates.

4:30 PM  SB01.05.09  
**3D Printed Objects with Functional Coatings**  Bhavana Deore, Chantal Paquet, Nathan Kredentser, Thomas Lacelle and Patrick Malenfant; National Research Council Canada, Canada

3D printing is an emerging additive manufacturing technology poised to transform both design and manufacturing due to its ability to customize design and generate structural complexity not possible using traditional manufacturing processes. Commercial examples of 3D printed objects using monolithic materials, such as GE’s fuel nozzle, illustrate early success of this technology by enabling new designs and significantly reducing the number of parts and supply chain required for manufacturing. However, only marginal progress has been made to demonstrate multi-material printing and as such it remains a low technology readiness level research endeavour at the moment with enormous potential for innovation and commercial impact. Multi-material 3D printing would increase the complexity and functionality of printed objects and pave the way for 3D structural electronics. The challenge is that most 3D printing techniques cannot print multiple disparate materials into one object. For instance, 3D printing techniques of stereolithography (SLA) and digital light processing (DLP) can generate 3D printed objects with high resolution, high quality surface finish and dimensional accuracy, and it does so using photo-active polymerizable resins as precursor material. However printing objects with functional coatings that are distinct from the core of the object has not been developed. Examples of multi-material 3D structures made from SLA and DLP have been made but the approaches typically result in a composite structure throughout the object and if functional surfaces are desired, this typically involves coating the objects post-printing with functional materials. The drawback of coating
post-printing is that it requires multiple steps with different coating apparatus and does not consistently yield coatings with the desired function or robustness, which will depend greatly on adhesion. In this presentation, we demonstrate multi-material printing using SLA 3D printing yielding an object with a functional coating.

4:45 PM SB01.05.10
Additive Manufacturing of 3D Architected Multifunctional Metal Oxides Daryl Yee, Michael Citrin, Max Lifson, Bryce Edwards and Julia R. Greer; California Institute of Technology, United States

Multifunctional metal oxides represent an important class of materials used in modern society. These materials exhibit unique properties such as piezoelectricity, superconductivity, and semiconductivity, rendering them useful in virtually every type of micro/nanosystem device technology. Most current device designs utilize metal oxides as thin film stacks because patterning these materials have mostly been limited to using traditional planar lithography, or various casting methods, which substantially limits the geometries that can be achieved. However, in recent years, 3D printing of these multifunctional metal oxides has become a significant area of interest as new experimental devices that have been able to utilize these 3D materials have demonstrated substantial improvements in performance. While many different techniques have been developed to achieve these architected materials, additive manufacturing (AM) has recently emerged as a frontrunner for the fabrication of three-dimensional metal oxide structures with almost arbitrary geometries.

In particular, additive manufacturing processes involving photolithography have emerged as one of the most promising ones due to the high resolution and small feature sizes achievable. These photolithography systems typically consist of photosensitive slurries, where metal oxide nanoparticles are dispersed in a photosensitive organic binder. The slurry is then patterned using a variety of lithography techniques to create 3D nanocomposite structures, which are then calcined to burn off the organic matrix and to sinter the metal oxide particles together. The advantages of these systems are that it’s simple and versatile – as long as the desired metal oxide nanoparticles can be obtained, the slurry can be made and the part 3D printed. However, the high loading of nanoparticles needed results in a host of other issues, such as increased viscosity, homogenous dispersion of the nanoparticles, and light scattering. To circumvent these, hybrid inorganic-organic photoresins, which contain polymers with metal heteroatoms in their backbone, have been developed. These photoresins can be patterned and then calcined in the same way to produce 3D metal oxide structures, but without the challenges associated with the inclusion of nanoparticles. A key disadvantage of this approach is that these photoresists are often not commercially available and sometimes require a complex multi-step synthesis. To fabricate arbitrarily shaped 3D metal oxide structures, a process that combines the beneficial aspects of existing approaches: (1) the simplicity and versatility of the slurry method and (2) the high resolution afforded by the organic-inorganic photoresists, has to be developed.

In this presentation, a new photopolymer system that circumvents the problems of both existing techniques is demonstrated. The photopolymer system is facile to prepare and can be easily modified to fabricate various multifunctional metal oxides. As an example of this technique, we demonstrate the printing of a few different metal oxides at a variety of scales by fabricating zinc oxide (ZnO) and lithium cobalt oxide (LCO) architected structures with sub-micron and sub-millimetre features respectively. Characterization of these structures using X-ray diffraction, energy-dispersive spectroscopy and transmission electron microscopy indicate that the structures are indeed comprised of the appropriate material. Compression of the ZnO structures results in a voltage response, exhibiting the piezoelectric behaviour of these structures. Electrochemical cycling of the LCO structures showed efficient performance as a lithium ion battery cathode over greater than 100 cycles. This ability to fabricate these multifunctional 3D materials could open up the field of smart devices and change how we design them.
SB01.06.01 Matrix- and Morphology-Dependent Electronic Responses of Nanocarbon-Polymer Composites
Chen Chi¹, Toshiyuki Sato², Yoshitaka Kamata², Daisuke Hashimoto², Pawel Czubarow³ and Howard E. Katz¹; ¹Johns Hopkins University, United States; ²NAMICS Corporation, Japan; ³eM-TECH Inc., United States

Nanocarbon-polymer composites offer the advantages of functional electronic response combined with facile processing, thermal stability, and mechanical flexibility. In this presentation, we consider two nanocarbon morphologies, carbon nanotubes and nano-carbon spherical particles, and four polymer matrices, two of which are entirely aliphatic and two of which are rich in aromatic rings. We find that simple current-voltage curves, thermoelectric responses, and perturbations by the oxidizing vapor NO₂ are consistent with the best interconnection and greatest responsiveness associated with carbon nanotubes in aliphatic matrices. In particular, these latter composite types using poly(methyl methacrylate) (PMMA) matrix showed bulk conductivities >1 S/cm and small, concentration-independent Seebeck coefficients <5 µV/K at or below the percolation threshold <5%. At <1% incorporation in epoxy, conductivity was injection-limited rather than bulk-limited, with currents consistent with a 1 S/cm conductivity. Exposure of 1% carbon nanotube-in-PMMA samples to 10 ppm NO₂ resulted in a steady, cumulative p-doping response of about 2% per hour. No such response was observed from nano-carbon spherical particles mixed into PMMA at the same concentration. Insulating polystyrene and semiconducting poly(bisdecylquaterthiophene) (PQT12) matrices resulted in much lower conductivities with carbon nanotubes, with the polystyrene samples essentially insulating with 1% carbon nanotubes, and PQT12 showing moderate conductivities and increased Seebeck coefficients consistent with significant traps, barriers, and aggregates formed by the carbon nanotubes. The results taken together suggest that moderately polar but nonaromatic matrices yield the highest and best controlled environmental responses from nanocarbon composites.

SB01.06.02 3D Reconfigurable Liquid Crystal Elastomers via Dynamic Bond Exchange
Emily C. Davidson, Arda Kotikian and Jennifer A. Lewis; Harvard University, United States

We report a method to create 3D liquid crystal elastomers (LCEs) that exhibit programmed shape morphing capabilities which can be ‘locked-in’ on demand via dynamic bond exchange. Specifically, we have created printable inks composed of oligomer-based LCEs with main-chain rigid mesogens and allyl dithiol chain extenders. Their programmed director alignment, which is uniquely defined by print path, gives rise to a reversible actuation response when thermally cycled above and below their nematic-to-isotropic transition temperature, TNI. By incorporating light-activated dynamic bonds, we ensure that the external stimulus for bond exchange is orthogonal to that required for their reversible actuation. When actuated above TNI, UV light can be used to “trigger” allyl disulfide bond exchange within these printed LCEs in response to the pre-programmed internal stress to “lock-in” their actuated state. Our results offer a pathway towards reconfigurable, adaptive actuators with controlled shape-morphing capabilities and high specific energy density.

SB01.06.03 Simultaneous 3D Printing and Frontal Polymerization for Rapid Manufacturing of Multifunctional Nanocomposites
Leon Dean, Jia En Aw, Allen Guo, Douglas Ivanoff, Samya Sen, Randy Ewoldt and Nancy R. Sottos; University of Illinois at Urbana-Champaign, United States

Thermoset polymers and composites exhibit excellent specific stiffness and strength, thermal stability, and chemical resistance. However, the manufacturing of high-performance thermosets and composites typically requires lengthy cure times at elevated temperatures, which presents significant challenges for 3D printing. Recently, we demonstrated a technique that combines frontal polymerization (FP) with extrusion-based direct ink writing to simultaneously print and cure neat polymer parts with minimal energy input. This system relies on the ring-opening metathesis polymerization (ROMP) of partially cured endo-dicyclopentadiene (DCPD). Here we expand this approach from the printing of neat polymers to the printing of nanocomposites. We investigate the shear and extensional rheology of nano-inks composed of DCPD monomer and either carbon or silica nanoparticles. From
these data, we define a suitable window for direct ink writing in terms of monomer degree of cure and nanoparticle loading. We also use thermal imaging to characterize the FP of printed nano-inks, including front velocity and front temperature, in a variety of printing conditions. Finally, we report on the multifunctional properties of printed nanocomposites, including enhanced mechanical and electrical properties, as well as potential applications based on their multifunctionality.

SB01.06.04  
**Multi-Dimensional and Multi-Length Scale Assembly of Functional Biomaterial**  
Pu Deng and Xiaocheng Jiang; Tufts University, United States

Electrochemically active bacteria (EAB) such as *Shewanella* and *Geobacter* are capable of performing long-range charge transport through a variety of evolutionally developed electron pathways. While these biodevived electroactive systems represent intriguing building blocks for a range of bioelectronic applications, their applications to date are still limited by the lack of effective structural and functional integration at meaningful scales. Here we present our recent effort toward the multi-dimensional assembly of these living materials. Core-shell, EAB-encapsulated hydrogel fibers were manufactured by the multi-inlet coaxial microfluidic devices for 1D assembly. Inside these core-shell fibers, the cellular interactions and microenvironments can be precisely modulated to engineer the developments of the protein-based conductive materials. Based on the results, closely contacted bacteria promote the development of high-density, sub-micron protein structures at cellular interfaces which can be directly translated to the increase of conductivity (16.2 mS/cm) as compared with low-density, micrometer long protein structures generated by the isolated bacteria (6.4 mS/cm). Furthermore, bioprinting was applied to assemble these bacterial cables into functional bioelectrochemical systems, where the 3D structure, including xx, yy and zz, can be programmed and optimized to overcome the intrinsic charge and mass transport limits in native biofilms. The current work represents an important strategy to achieve spatial organization of electroactive living materials with precisely engineered functions and could open up new possibilities to design and construct a biosynthetic functional system from the bottom-up.

SB01.06.05  
**Microfluidic Manufacture and Use of 3D Multi-Material Microparticles for Uniform Fluid Compartmentalization and Bioassays**  
Ghulam Destgeer, Mengxing Ouyang, Chueh-Yu Wu and Dino Di Carlo; University of California, Los Angeles, United States

Biosensing accuracy suffers from low signal above background at low analyte levels and random variations in sensor performance at higher analyte levels which limit quantitation. Conventional detection schemes, e.g. enzyme-linked immunosorbsent assays (ELISA), overcome low analyte level challenges through enzymatic signal amplification, however these assays typically measure the bulk signal from a single or few reactions, leading to compromised detection sensitivity and accuracy. Microfluidics has provided promising tools for uniform compartmentalization of a sample fluid volume into many smaller reactions, however skilled users or specialized and costly commercial instruments are required for implementation. Here, we present a versatile platform to compartmentalize and perform reactions in uniform nanoliter-scale volumes based on the fabrication of microscale multi-material particles (e.g. hydrophobic outer layer and hydrophilic inner layer ring-shaped particles) that form a single droplet per particle with design flexibility of particle structure and droplet shape. Our “dropicle” system provides uniform compartmentalization, customizable shape-coded particle for multiplexing, flexibility to be scaled up, and ease of implementation with existing amplified assay workflows, enabling hundreds to thousands of parallel reactions.

We manufacture the multi-material particles using a 3D printed device to run a hydrodynamically stable co-flow of four different streams of fluids including polymer precursors. The inlet ports of the device are connected using intricate channels such that the outlet flow streams take a cylindrical co-axial shape. Density-matched flow streams consist of Poly(propylene glycol) diacrylate (PPGDA), PPGDA and photo-initiator (PI), Poly(ethylene glycol) diacrylate (PEGDA) and PI, and PEGDA, from the outermost to the innermost stream, respectively. At the device outlet, a square glass capillary is attached to provide a region where fluid streams are exposed to UV source through a patterned mask when the flow is stopped. The two streams with PI are cured into ring-shaped multi-material particles with the inner and outer layers made of PEGDA and PPGDA, respectively. The size of particles are readily controlled by adjusting the fluid-flow rate ratios at the inlets and mask design; whereas the shapes are altered by customization of 3D printed device and mask design for UV exposure.
We have fabricated particles with four distinct cross-sectional shapes and different thickness. These particles with a hydrophilic inner hollow layer and hydrophobic outer layer provide a versatile and scalable platform to form highly uniform aqueous droplets in the center of the particles suspended in an oil phase holding a volume of 1-6 nL depending on the particle design. Capture antibodies for target analyte or other immobilization anchors such as biotin are added to the PEGDA layer during the fabrication process. We successfully implemented an HRP-based fluorescent immunoassay using the dropicle system and demonstrated a limit-of-detection of 10 pg/ml (i.e., 100 fM) with a dynamic range of at least 3 orders of magnitude. Fluorescent-based imaging of the droplets after reaction enabled both end-point measurements and real-time amplification with simultaneous tracking of large numbers of single particles over time. Furthermore, multiplexing was shown without crosstalk, where two types of particles with different outer polymer shapes and inner droplet shapes maintained their individual fluorescent signals. In addition to be used as a “swarm” of analog assays by correlating fluorescent intensity with target analyte concentrations, our dropicle system is also promising to serve as a digital platform by scaling up the number of particles and reducing their size. Finally, signal readout using a portable imager are being explored to extend assay capability to point-of-care settings without relying on expensive instrumentation.

SB01.06.06
Controlling the Perception of Softness in Haptic Interfaces—The Role of Indentation Depth and Contact Area Charles Dhong1 and Darren J. Lipomi2; 1University of Delaware, United States; 2University of California, San Diego, United States

In contrast to sight and hearing, we are relatively weak at recreating the sense of touch. To address this gap, we have conducted several studies to decompose tactile (touch) sensations into their fundamental components, with the goal of recreating arbitrary tactile sensations. Using micropatterned elastomeric slabs of precise thicknesses and psychophysical testing with human subjects, we systematically investigated the role of indentation depth and contact area on the human perception of softness.1 By decoupling the indentation depth from the contact area, we developed explicit equations to design and tune the perceived softness of haptic interfaces so that, for example, one object feels twice as soft as another. We provide strategies such as designing materials to feel “softer”, while keeping the Young’s modulus constant. These findings provide specifications for designing new materials to interface with the sense of touch and how these materials can be actuated to reproduce tactile sensations.

SB01.06.07
Lattice Fluidics—A New 3D Microfluidic Platform for Tuning of Multiphase Interfaces Nikola Dudukovic, Joshua DeOtte, Hawi Gemeda, Maira H. Ceron, Sarah Baker and E.B. Duoss; Lawrence Livermore National Laboratory, United States

Conventional microfluidic devices are often limited to enclosed channels and planar geometries, which hinders their usefulness in multiphase reaction or transport processes. We present a novel platform based on capillary fluid flow in three-dimensional open-cell lattices. Using deterministic cell and lattice design and additive manufacturing, we fabricate complex 3D structures with tuned porosity. This approach enables selective placement and direction of liquid flow into predetermined continuous paths through the structure, as well as optimizing the occurrence of gas-liquid or gas-liquid-solid interfaces. We demonstrate the application of lattice fluidics for CO2 capture by incorporating a liquid sorbent into a 3D lattice with high gas-liquid interfacial area. ***This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 within the LDRD program 19-SI-005. LLNL-ABS-778327.

SB01.06.08
Exploring Natural Photonic Crystals in Prawn Exoskeletons as a Template Material Fiona Sander1, Dominic Melvin1, Adrian Ting Ho2, Stefano Angioletti-Umberti1 and Ahu Gumrah Dumanli2,1; 1Imperial College London, United Kingdom; 2University of Manchester, United Kingdom

Chitin structures can be found in a variety of organisms in nature and show unique mechanical and optical properties in combination with biodegradability and nontoxicity. One of those species is Penaeus setiferus (King Prawn) with
an exoskeleton made of chitin which is conformed into a bouligand/helical structure that is a photonic crystal. *Penaeus setiferus* uses this structure mainly to form a strong network as a part of exoskeleton and the optical appearance of the shrimp seems to do not reveal the interesting chiral optics of such organisation. However, when the proteins and calcium minerals were removed from the shrimp exoskeleton, the residual chitin film show quite remarkable iridescent appearance with strong circular polarization. This isolated helicoidal framework is much more porous than the starting material and provides an exciting foundation as a template for exploring chiral photonics using different deposition methods. With the goal of transferring this intricate network, the iridescent chitin shell is used in this study to decorate with metal nanoparticles using wet chemical methods and in a separate study conformally coated with TiO$_2$ using atomic layer deposition techniques. It is shown that the helicoidal organization of the iridescent shrimp shells can be conformed and transferred in to higher refractive index materials with distinctive macroscopic combination of optical effects.

**SB01.06.09**  
*Water-Processable and Biodegradable Bioplastic from Engineered Microbes* Anna Duraj-Thatte$^{1,2}$, Avinash Manjula Basavanna$^{1,2}$ and Neel Joshi$^{1,2}$; $^1$Harvard University, United States; $^2$Wyss Institute for Biologically Inspired Engineering, United States

Over 335 million tons of plastic is produced globally every year and nearly 80% of it have accumulated in landfills and water-bodies. Contamination of non-biodegradable plastics and microplastics (<5 mm fragmented particles) are causing potentially irreversible damage to our ecosystems and global health, including that of humans. Herein, we report a new class of microbialy produced biodegradable bioplastic that is water-processable. *E. coli* was genetically engineered to produce biopolymers under ambient conditions to produce bioplastic that can withstand strong acid/base and organic solvents. In addition, our bioplastic can be healed and welded to form three-dimensional architectures by using water. These unique features of our bioplastic are believed to inspire further exploration and the development of much needed alternatives to conventional plastics.

**SB01.06.10**  
*Towards Biomimetic Programmable Material Systems—Creating Responsive and Intelligent Biomaterial Assemblies to Address an Environment under Stress through Botany, Biology and Charismatic Design* Emelia E. Erland and Raymond Oliver; Northumbria University, United Kingdom

We are experiencing a global environment under stress and if not ‘capped’, will lead to both a biodiversity failure in addition to global warming and adverse greenhouse gas content in the atmosphere. Looking at natural material design we can see a vast range of intertwined materials and biocomposites performing an enormous and impressive range of tasks, utilising often easily obtained and renewable resources. Biological systems are argued to be superior to technological ones in terms of biology’s utilisation of information and structure over energy and materials. There are many opportunities for biogeochemical cycles to inspire a Design:STEM approach that can simultaneously address the opportunities and challenges created by the global resource and waste crises, greenhouse gas emissions, expanding urban populations and environments, and consumer engagement in environmental behaviours.

As part of our work in BioDesign:STEM Integration, we are examining the role that both biology and botany can play in replacing synthetic single use polymers for plastic packaging of foods, consumer products and luxury items. The paper will outline the choice of bio and phyto materials development and the development of multi component composites that are both resilient, have controlled release and targeted delivery behavioural characteristics, and through an LCA methodology can be reused, refunctioned and recomposted after primary use. We are investigating the creation of a biomimetic yarn drawn from examination of the cross sections of plant stems, where each element is analysed and then substituted for a biomaterial with tailored and enhanced properties.

Natural materials are presumed to have enhanced biocompatibility with humans and, from a financial and timing perspective, provide a good material base for enhancement and modification to fit the current manufacturing methods. Their use allows for aims to include desirable and complex materials properties with biodegradable and biocompatible characteristics, as well as providing the opportunity to identify resources that are naturally abundant, renewable and cost effective. Currently major issues for bio-based packaging are the requirements for water and oxygen barriers and so the project aims include identification of structures, processes and biodegradable materials that can achieve water and oxygen barriers for flexible materials, preferably from a renewable source. Another way to ensure cost-effectiveness and resource sustainability is to use the least amount of material possible through
enhancement of material properties and through investigation into structures such as foams. From a design perspective, charismatic effects and aesthetics are being explored through investigations into ideas of elegantly simple, traditionally crafted and overtly natural fabrications concealing a novel, non-intuitive responsive element that adds great functional and experiential value. This interactive behaviour, drawn from our work with thermoresponsive gels, ensures easily repurposable packaging fabrications that engage the consumer. The facile efficiency which the resultant packaging fabrications can achieve serves to inspire the consumer with the potential of natural materials and the natural environment at large.

SB01.06.11
Investigation of Dissolution Temperature of Gold Nanorods Depending on the Size of the Modified Polymer
Tatsuya Fujiwara and Tsuyohiko Fujigaya; Kyushu University, Japan

As a promising candidate for photothermal therapy material, gold nanorods (AuNRs) having high photothermal conversion efficiency, strong absorption and scattering in the near infrared region excellent in biotransparency have been studied. However, one of the problems in practical photothermal therapy application is a burning of organs and/or skin by heating upon light irradiation. Previously, we demonstrated the mechanism which can avoid the overheating even if AuNRs is overirradiated (Autonomous overheat suppression mechanism); namely phase transition of the polymer modified on AuNRs upon heating induced an aggregation of AuNRs and resulted in the shift of AuNRs photoabsorption wavelength [1]. However, in the living body, diffusion of AuNRs is slower compared to that in solution, and rapid aggregation might be difficult. Therefore, in this research, in order to achieve the mechanism of suppressing the overheating of AuNRs itself without involving the change of the aggregation state, we focused on the shortening of AuNRs by the oxidative elution of Au ion from the AuNRs surface [2]. Since the longitudinal absorption wavelength of AuNRs depends on the aspect ratio, the absorption peak will shift to a shorter wavelength by the shortening of AuNRs, and it is considered that the absorption of the irradiation light decreases to suppress the overheating. Therefore, in this study, we studied the shortening temperature of AuNRs depending on the size of modified polymer, in which the density of the polymer coating on AuNRs is expected to change the stability of the Au on AuNRs.

Polymers (RAFT-PEG188, RAFT-PEG500, RAFT-PEG1500) were synthesized by Reversible Addition-Fragmentation Chain Transfer (RAFT) polymerization using polyethylene glycol methyl ether methacrylate (PEGMA) ($\text{M}_n=188, 500, 1500$) having different ethylene glycol length. After the reduction of the polymers to generate -SH group in the polymer terminate, the polymer solution was added to AuNRs aqueous solution. The obtained AuNRs aqueous solution (PEG188-AuNRs, PEG500-AuNRs, PEG2000-AuNRs) was heated from 35 to 115 °C, and the change of the longitudinal absorption peak upon heating was monitored by UV-vis spectroscopy. A blue shift of the longitudinal absorption peak was observed in the PEG-modified AuNRs, while shift of the longitudinal absorption peak was not observed in the excess CTAB-removed AuNRs (CTAB-AuNRs) measured as a comparison. The peak shift onset time was earlier as the side chain length of the polymer was longer. We found that the onset temperature of the AuNRs with RAFT-PEG2000 was lower than that of AuNRs with RAFT-PEG500.

Conclusion
AuNRs was modified by SH terminated polymers having different side chain length synthesized by RAFT polymerization. Heating experiment of AuNRs solution revealed that the onset temperature of the shortening of AuNRs was lowered when the AuNRs was modified by the polymer with longer side chain. We considered that the lowering of the modification density lowered the stability of Au on the surface of AuNRs, resulting the lowering of the shortening temperature.

A Cross-Linking Reagent Derived from 2-Mercaptonicotinic Acid and Its Application to Photoadhesive Materials
Masahiro Furutani, Kentaro Nakayama and Koji Arimitsu; Tokyo University of Science, Japan

Adhesives are one of essential materials for manufacturing industry, especially for that of composite products. Different kinds of parts made from metals, ceramics or polymers are adhered by adhesives, which contributes to
designing, processing, and weight saving. For adhesion of two adherends of dissimilar materials, modification of their surface with laser, plasma or chemicals has been used in general. On the other hand, adhesives having catechol or its analogue moieties have been paid attention, because polymers having catechol moieties show high adhesive strength toward various kinds of adherends. Adhesives of this type are inspired by proteins having DOPA residues in adhesive components of mussels.

2-Mercaptopyridine has a similar chemical structure with catechol, while it is not found in chemical structures of natural proteins. Nevertheless, it has a pyridine ring and a sulfur atom, and these chemical moieties would also interact with kinds of adherends including late transition metals. In this work, a disulfide dimer derived from 2-mercaptobenzonic acid (compound 1) is used as a diacylate cross-linking reagent for radical UV curing of 2-hydroxyethyl acrylate (HEA). The curing system is applied to photoadhesion of dissimilar materials, which enables to adhere two different substrates quickly and selectively under mild temperature conditions. Quantitative consumption of acryloyl groups was confirmed after 4 J/cm² of UV irradiation, by FT-IR spectral measurement (decrease of peak area at 1637 cm⁻¹). The UV-cured products were found to be insoluble to THF. Shear stress of in the range from 0.27 to 1.2 MPa was recorded, and the value for glass was higher than for metals. Triplicate value for the glass-copper sample comparing with glass-aluminum sample would indicate better interaction of sulfur (and nitrogen) atoms from compound 1 with substrate of late transition metals.

Samples preparing with compound 1 showed much higher adhesive property than the control samples. Shear stress was apt to be kept during extension in the cases of glass-glass samples. This is probably due to hydrophilic interaction between glass substrate and hydroxyl groups of the adhesive layer. Furthermore, the UV-cured adhesive layer was stretched before breaking of the sample. This would be due to exchange reactions between disulfide bonds. On the other hand, the difference was much clear in the cases of glass-copper samples. Cross-linking moieties of compound 1 would contribute to both cohesion in bulk of the adhesive layer and interaction in the interface. Intertacial fracture was observed on the glass-copper sample of compound 1, which the UV-cured residue was remained on the both sides.

To investigate chemical states of the nitrogen and sulfur atoms in the UV-cured glass-copper sample of compound 1, XPS spectral measurements were performed. A model compound for compound 1 had simple spectral charts where a peak at 398.8 eV for N1s and a peak pair at 163.4 eV for S2p were observed. The former peak is assigned to nitrogen atom of pyridine. The latter peak pair is assigned to sulfur atom of disulfide. In the N1s spectra of UV-cured adhesive sample of compound 1, new peaks are observed at 400.5 and 402.6 eV on the side of copper substrate. This indicates that a part of nitrogen atoms of the dipyridyl disulfide moiety from compound 1 would interact with the copper surface. In comparison, new peaks are observed in the lower binding energy region, around 162 eV in the S2p spectra of the adhesive sample. This implies the presence of electron-rich sulfur atoms on the both sides. Although the mechanism for generation of such sulfur atoms is still unknown, these sulfur atoms may contribute to the adhesion via hydrophilic interaction (on the glass side) and coordination (on the copper side).

**Smart Materials for the Corrosion Inhibition of Metal Artefacts**

Chiara Giuliani¹, Martina Salzano De Luna², Marino Lavorgna³, Elena Messina¹, Gabriella Di Carlo¹ and Gabriel Maria Ingo¹; ¹Istituto per lo Studio dei Materiali Nanostrutturati - Consiglio Nazionale delle Ricerche, Italy; ²Università di Napoli FedericoII, Italy; ³Istituto per i Polimeri, Compositi e Biomateriali – CNR, Italy

Chitosan-based coatings turned out to be very promising for the development of sustainable and safe multifunctional systems for the corrosion protection of metal artifacts. A promising strategy to achieve long-term efficacy and specific action against corrosion is represented by the encapsulation of corrosion inhibitors inside stimuli responsive nanostructure. With this aim, herein we investigated the effect of the addition of Layered Double Hydroxides (LDHs) smart nanocarriers on the protective performance of chitosan-based coatings. These systems consist of stacks of positively charged layers between which the inhibitor compound can be intercalated. LDHs act as inhibitor reservoir and allow to control its release only in the presence of corrosion related stimuli, i.e. presence of chloride species and acidic pH. Moreover, these systems are able to slow down the photodegradation of the guest molecules, thus prolonging their protective action. Benzotriazole (BTA) and mercaptobenzothiazole (MBT) were used as inhibitor compounds since they possess a recognized anticorrosion efficiency for different metal substrates. In addition, alkaline nanoparticles, deposited at the coating/metal interface, were used to contrast the acidity coming from the environment and/or produced during corrosion pathways. To assess the efficacy of these nanostructured polymer layers accelerated corrosion tests were performed on the coated and uncoated bronze substrates. The coatings with the inhibitors freely dispersed into the polymer matrix were used as reference. The surface properties of bare alloy and of the alloy with the protective coatings were investigated before and after the accelerated
treatments. The obtained results showed that the encapsulation of inhibitors inside LDHs smart nanostructures allow to achieve a specific action against corrosion and also protect the active molecule from photodegradation, thus improving the stability and the protective performance of the coatings. Alkaline nanoparticles with high surface area and reactivity to acids are also able to provide a local buffer action against pH changes at the metal surface, further enhancing the corrosion resistance of the system. It is worth noting that the developed protective materials possess better performance compared to commercial products based on acrylic resins and are also easy to be applied and removed by using not toxic (water-based) solvents.

The multifunctional active coatings containing LDHs smart nanocarriers, corrosion inhibitors and alkaline nanoparticles guarantee a long-term, safe and sustainable protection of metal works of art exposed to indoor environment conditions. These systems combine different functional capabilities: the physical barrier properties of the polymer matrix and the UV/light shielding action of the inorganic fillers, the stimuli responsiveness of the smart nanocarriers and the chemical protective action of corrosion inhibitors.

This research activity has been carried out within the EU H2020 Nanorestart project “NANOmaterials for the REStoration of works of ART” and has also received the “Young Investigator Award 2018” prize in the area of Chemistry for Cultural Heritage from the Department of Chemical Science and Materials Technology (DSCTM) of the Italian National Research Council.

SB01.06.14
Piezoelectric Materials for Autonomous Charge Generation in Biomedical Implants
Julia Glaum1, Kara K. Poon1, Mikalai Zhuk1, Karianne Skaar Fedje1, Karin Karkuszová2, Magnus Rotan1, Matthias Wurm3, Rainer Lutz3 and Mari-Ann Einarsrud1; 1Norwegian University of Science and Technology, Norway; 2Brno University of Technology, Czechia; 3Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The ability to convert an electrical field into a mechanical perturbation and vice versa makes piezoelectric materials versatile components for industrial applications in a range of fields covering vibration control in airplanes, ultrasound applications in marine and medical devices or pickups for musical instruments [1].

In recent years, the value of piezoelectric materials for biomedical applications has been unfolding [2-4]. They can act as self-sustained suppliers of charge for nerve and bone tissue repair or as autonomous in vivo energy harvesting components powering electronic implants. Depending on the specific application, biocompatibility and stable performance in the presence of body fluids determine a materials potential for the task. In some cases, it is necessary that living cells form a close interface with the implanted material and when hard- and/or soft-tissue integration of the implant material is desired, a piezoelectric implant that provides large, open pores allowing the ingrowth of cells and blood vessels, provides a clinical benefit.

The potential areas of application for piezoelectric materials in the biomedical context are manifold, but for their transfer into clinical routines safe and reliable functionality has to be ensured. A fundamental step on this way is to clarify the influence of the rather unusual biochemical boundary conditions of the body as well as the standardized pre-surgery handling routines on chemical and functional stability of the materials.

We have been investigating two promising piezoelectric ceramic systems – BaTiO3 and (K,Na)NbO3 - regarding their potential as functional implants due to their low degree of cytotoxicity. Microstructural features, such as grain size and porosity, influence the dielectric and piezoelectric performance. While a high degree of open porosity is necessary to allow tissue integration and the development of a stable tissue-implant interface, it can be detrimental for the piezoelectric properties. This can be counteracted by grain size adaption allowing optimization of the materials functionality.

The fluidic environment at an implant site triggers chemical interactions that can influence the implants surface chemistry, functionality and reliability. This is especially important for porous materials providing a large surface to volume ratio. The sensitivity of the functional properties on soaking differs significantly for the two systems investigated. This holds promise that both long-term stable as well as bioresorbable compositions can be developed. Apart from reliable functional performance and low cytotoxicity, compliance with pre-surgery routines has to be guaranteed, to transfer a novel material from the lab bench to the surgery room. We investigated the impact of disinfection routines and plasma sterilization on the piezoelectric performance of both material systems. The distinct differences between them are correlated to their Curie temperatures and their electromechanical response.

Protein-Based Piezoelectric Nanogenerators for Wearable and Implantable Electronics

Narendar Gogurla, Biswajit Roy and Sunghwan Kim; Ajou University, Korea (the Republic of)

Harvesting electronic energy from biomechanical motions of a living body is important for health monitoring and biomedical applications. Most tissue surfaces are inherently soft and constantly in motion. Piezoelectric devices enable new electromechanical interfaces with human tissue for monitoring motion signals. However, the electronic devices should be ideally soft and conformal to the tissue surface. Silk protein is one of the finest biopolymer with intriguing properties such as softness, biocompatibility, flexibility in thin film form, and potential to fabricate wearable and implantable electronic devices.

Herein, we present a stretchable, bendable, and biocompatible piezoelectric nanogenerator using silk protein and ZnO nanorods (NR) to monitor and harvest electrical energy from biomechanical motions. Silk protein without ZnO NR produced an open-circuit voltage of ~1.5 V and a short-circuit current of ~5 nA. With the incorporation of ZnO nanorods into silk protein matrix, the output electrical performance is enhanced 8-fold (open-circuit voltage of ~12 V and a short-circuit current of ~0.04 μA). Due to the noncentrosymmetric structure in the wurtzite form and large electromechanical coupling of ZnO, it can produce large piezo-potential in the crystal under strain condition thus lead to higher output performance for ZnO-silk devices. With this high output electrical performance, it can activate small power consumed commercial electronic device (stop-watch). Owing to the softness and stretchability of the devices, they can be contacted conformally to the biological tissue to generate an output voltage of ~7 V from the tissue motions. The study indicates the potential use of biocompatible ZnO-silk devices in harvesting the power from the human body and tissue motion that may be provide an alternative power source for implantable biomedical devices.

Instability-Induced Pattern Formations in Soft Magnetoactive Composites

Artemii V. Goshkoderia1, Vincent Chen2, Jian Li1, Abigail Juhl2, Phil Buskohl2 and Stephan Rudykh3; 1Technion Israeli Institute of Technology, Israel; 2UES, Inc/AFRL, United States; 3University of Wisconsin–Madison, United States

We study magnetomechanical instabilities in magnetoactive elastomer (MAE) composites undergoing finite strains in the presence of a magnetic field. In particular, we consider MAE composites with chain-like microstructure. We analyze the influence of the applied magnetic field along the chains on the stability of the MAE composites at both microscopic and macroscopic length scales [2]. To this end, we develop a numerical scheme to detect the onset of instabilities at the long wave and finite length-scales. By applying the developed numerical technique, we analyze the influence of the materials microstructure geometrical parameters and applied magnetic field on the onset of instabilities in soft MAEs. We found that identical MAE composites with periodically distributed particles can switch to a variety of new patterns with different periodicity under particular levels of the applied magnetic field. The post buckling analysis is performed to numerically realize the newly formed patterns dictated by the magnitude of the applied magnetic field.

References
carry the required drug payload and can serve as a flexible implant particularly when the fibers are made from FDA approved biodegradable materials. However, the proper formulation of the drug-polymer composite and the ability to control their release require a better understanding of the polymer-drug interaction which would determine the kinetics of release.

Mechanism of drug release can also be influenced by the intrinsic properties of the encapsulated drug, such as its molecular weight, hydrophobicity and the drug-polymer formulations. In these cases, the choice of the polymeric matrix and method of electrospinning, play a crucial role in the final release pattern. In the same vein, combining electrospinning with other fabrication techniques, can provide a multifunctional property as well as various means of control over the release mechanism of the enclosed drug.

As a first step we focused on electrospinning process parameters namely flow rate, applied voltage and capillary to collector distance. The voltage field and combination of the polymer/drug and solvent concentration that determines the viscosity, surface tension and electric conductivity were evaluated to obtain the proper fiber morphology with the drug blended in it. We have demonstrated that by applying proper means of control, various stages of drug release can be manipulated, such as initial burst release, final plateau stage and on demand release. Control over the initial burst release of the drug, was applied by controlling the diameter and morphology of the obtained fibers, as well as the level of dispersity of the loaded drug. Meanwhile, the sustained release of the drugs were manipulated by choosing the proper polymeric matrix with appropriate disintegration time. Finally, on demand release of the loaded drugs were investigated by utilizing combinatory techniques with electrospinning.

In this study, we have evaluated the influence of polymer choice with different molecular weights ranging from 40,000 to 240,000 (PLGA 50:50, PCL, PLGA 85:15), morphology of the electrospun polymers, and the combination of various technique with electrospinning, for obtaining desired release mechanisms of three hydrophobic drugs, namely biphenol containing small molecule cancer drug, Honokiol, and peptide based, nitroxide radical containing antioxidants JP-4-039 and XJB-5-131, with different molecular weights, from 200 to more than 900. Drug release is characterized through first order burst release followed by controlled release over time using various techniques. Our choice of drug was driven by their applications. XJB and JP are mitochondrial targeting antioxidants being explored for the treatment of cardiac recovery post myocardial infarction. Honokiol is a natural drug being tested for kidney cancer. Sustained and controlled release locally from patches would be beneficial for these drugs. The effectiveness of each polymer used and combinatorial technique, in providing various spatiotemporal control over the release of the aforementioned drugs have been demonstrated.

**Efficient Molecular Design as Regioregular-block-Regiorandom Poly(3-hexylthiophene) Copolymer for Highly Electrical and Mechanically Robust Semiconductors** Junghun Han, Hyeonjung Park, Boo Soo Ma, Jin-Seong Kim, Youngkwan Kim, Hyeong Jun Kim, Donguk Kim, Taek-Soo Kim and Bumjoon Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In this work, we demonstrate poly(3-hexylthiophene) regio-block copolymers (block-P3HTs) that show both great electrical performance and mechanical robustness. block-P3HTs are composed with crystalline regioregular block (rrre block) for providing efficient charge transport and the amorphous regiorandom block (rra block) for flexibility. To clarify the architecture effects of block-P3HTs, a series of block-P3HTs was prepared to have similar number-average molecular weight (\(M_n\)) of rre block with different \(M_n\) of rra block, while the regioregularity (RR) of each block are the same. The hole mobility (\(\mu_h\)) of all the block-P3HTs are comparable high because the rre blocks confined with the rra blocks provide efficient crystalline domains resulted in fast charge transportations. Especially, the highest \(\mu_h\) (1.5 \times 10^{-1} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}) is obtained in block-P3HT, rather than rre P3HT. The mechanical robustness of block-P3HTs are highly improved with the higher \(M_n\) of rra block. The elongation at break of block-P3HT finally reach at 100 times higher values than that of brittle rre P3HT. The study of block-P3HTs serves an efficient strategy of organic active materials for the coexistence of electrical performance and mechanical robustness.

SB01.06.19
**Implantable Solar Cells Using Upconversion Nanoparticles for On-Demand Controlled Drug Delivery Devices** Seulgi Han, Woong Sung, Taeyeon Kim, Kilwon Cho and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)

On-demand drug delivery devices (DDDs) have been widely investigated for spatiotemporally controlled therapy with greatly improved patient compliance. However, the power system to operate the DDDs is still a serious
limitation, constraining their clinical applications. Here, we developed implantable solar cells using upconversion nanoparticles (UCNPs) for on-demand controlled DDDs. Although skin-penetrating near infrared (NIR) light cannot be used for flexible organic solar cells, UCNPs can convert NIR light to visible light for their operations after implantation to the body. We designed the UCNPs of NaYF\(_4\):Yb/Er@NaYF\(_4\):Yb, which were doped on flexible organic solar cells [PEN/ITO/ZnO(ETL)/Pbdbt:itic(active layer)/MoO\(_3\)(HTL)/Au]. They could generate current flow upon NIR irradiation and used for on-demand DDDs based on the gold (Au) dissolution to AuCl\(_4^-\) by the applied electrical current. The on-demand DDD was fabricated with a SU-8 photoresist on the flexible polyethylene terephthalate (PET) substrate. After that, the on-demand DDD was interconnected with the UCNP coated flexible organic solar cell and passivated with a flexible PET substrate. The successful fabrication of NIR-triggered implantable DDDs was confirmed by TEM, SEM, photoluminescence and absorbance spectrum, current density-voltage (J-V) characteristics, and drug release tests. This new paradigm on-demand DDD might greatly contribute to the progress of light-triggered medical devices and the relevant phototherapy.

SB01.06.20
Nanomeshed Si Nanomembranes Xun Han, Kyung Jin Seo, Yi Qiang and Hui Fang; Northeastern University, United States

One of the biggest challenges in stretchable electronics is to achieve high-performance stretchable semiconductors. Here, we introduce an innovative concept of nanomeshed semiconductor nanomembrane which can be regarded almost as intrinsically stretchable to conventional microelectronic layouts. The nanomembrane is a dense network of fully connected, high quality, inorganic semiconductor traces of nanoscale line width. By making a silicon film into homogeneous nanomeshes with spring-like nano traces from a lift-off and transfer process using a Si-on-insulator (SOI) wafer, we demonstrated a high electron mobility of 50cm\(^2\)/Vs, and moderate stretchability with a one-time strain of 25% and cyclic strain of 14% after stretching for 1000 cycles, further improvable with optimized nanomesh designs. A simple analytic model covering both fractional material and trace sidewall surfaces well predicted the transport properties of the silicon nanomesh transistors, enabling future design and optimizations. Besides potential applications in stretchable electronics, this semiconductor nanomesh concept provides a new platform for materials engineering and is expected to yield a new family of stretchable inorganic materials having tunable electronic and optoelectronic properties with customized nanostructures.

SB01.06.21
Thin, Flexible P(VDF-TrFE) Nanosheet Based Pressure Sensor Artificial Dragon Fly Wings Haruka Harazaki, Ganesh Kumar Mani and Kazuyishi Tsuchiya; Tokai University, Japan

Unmanned aerial vehicles have received tremendous attention for potential use in various real time intelligent systems. Also, many people use these kinds of systems for their hobbies and business using autopilot technology. Due to the increase in number of unmanned aerial vehicles, several accidents happened in recent years due to loss of control. To solve this problem, researchers mimicking the dragonfly wings. Dragonfly gets attraction due to its rapid acceleration, rapid turning, hovering. Therefore, development of a microminiature flying object that imitates the shape and flight method of the dragonfly is being promoted. However, there is a problem with the miniaturized dragonfly type vehicle currently under development. It is said that, the attitude of the projectile becomes unstable and falls when taking off. Thus, continued flight is difficult. Therefore, to maintain the attitude of the flight, wings pressure needs to be precisely monitored without adding much weight to the wings. Hence, this research work is focused on developing lightweight, thin and ultra-flexible P(VDF-TrFE) nanosheet based pressure sensor. Spin coating and thermal evaporation techniques were used to prepare nanosheet and contact electrodes. Finally, bulge tester was used to apply pressure to the nanosheet and evaluated the electro motive force (emf). Also experiments were performed with various thickness of P(VDF-TrFE) to identify the desired pressure sensor with high capability.

SB01.06.22
Functionalized Boron Nitride Nanomaterials as Reinforcement for Polymer Aerogels Haley B. Harrison\(^1\)\(^2\) and Jeffrey R. Alston\(^1\)\(^3\); \(^1\)The Joint School of Nanoscience and Nanoengineering, United States; \(^2\)University of North Carolina at Greensboro, United States; \(^3\)North Carolina Agricultural and Technical University, United States

Boron nitride nanomaterials (BNNTs) and hexagonal boron nitride platelets (h-BNs) have received considerable...
attention for aerospace insulation applications due to their exceptional chemical and thermal stability. Aerogels have
great potential for use as insulation materials but their practical use is limited. Presently, matrix compatibilization of
BN nanomaterials is tricky and BNNTs are difficult to covalently functionalize. In this work, we present novel
sonochemical techniques to covalently attach fluoroalkoxy substituents to the surface of BN nanomaterials.
Attachment is confirmed via FT-IR, solvent compatibility and the use of x-ray photoelectron spectroscopy (XPS).
Presently, BN nanomaterials have limited uses in composite development. Covalent functionalization can enable
BNNTs to crosslink with polymer and composite matrices, improving their mechanical and thermal properties. We
also utilize sol-gel synthesis to incorporate BN nanomaterials into multifunctional polymers composites. Here, we
develop a light weight and flexible BNNT reinforced and crosslinked aerogel that can be effectively integrated into
insulation materials for structural reinforcement.

SB01.06.23
Novel 3D Cell Culture Method Using Thermally Reversible Liquid Culture Medium Composition Daisuke
Hatanaka; Nissan Chemical Corporation, Japan

Regenerative medicine, which has been extensively studied in recent years, requires a large amount of cells.
Therefore, development of a method for efficiently culturing cells is actively promoted, and a three-dimensional
culture method is attracting attention. In the efficient culture method of cells, it is not only just culture of a large
amount of cells, but also efficiently collecting cells cultured in a large amount without damaging the cells is also an
important issue.
A cell culture substratum for controlling the culture and recovery of cells by changing temperature has been studied
as one of the efficient culture methods, but many conventional cell culture substratum having temperature
responsiveness are limited to use in two-dimensional cell culture (e.g. flat culture), and there are few reports that can
be applied to three-dimensional (3D) cell culture (e.g. suspension culture). Therefore, in this study, we performed
the preparation of a thermally reversible liquid culture medium composition that is possible to culture cells three-
dimensionally in a floated state at 37°C and further to be easily recovered cells without damaging the cells in a room
temperature, and then we developed novel 3D cell culture method using the medium composition. The preparation
of the medium composition was performed by blending xyloglucan from which galactose residues was partially
degraded by β-galactosidase into a basal liquid medium at a specific concentration. By using the medium
composition, (1) cells can be preferably cultured in a 3D state maintaining liquidity at temperature over the sol-gel
transition point, and (2) it has been found that the cells and the medium composition can be efficiently separated at
temperature below the sol-gel transition point.

SB01.06.24
Development of a Compliant Bipolar Electrostatic Chuck Having 3D-Printed Elastically-Deformable Beams
for Handling Large Film Terumichi Hayashi, Yuki Taoka, Pasomphone Hemthavy, Kunio Takahashi and Shigeki
Saito; Tokyo Institute of Technology, Japan

In this study, we propose a new system concept of 3D-printed modular compliant bipolar electrostatic chuck for
handling large film. The prototype of the system consists of 3D-printed modules of bipolar electrostatic chuck with
surface flexibility by collective elastically-deformable beam structure. The proposed system is expected to
effectively grip thin film-like objects because the compliance avoids any excessive stress which results in damage of
target objects. The module performance was experimentally evaluated to investigate influence of beam compliance
on attractive force to a target object.
New handling techniques of large thin film/textile materials such as polymer films and papers have been required to
manufacture devices using Organic Electro-Luminescence and many other applications. However, conventional
electrostatic chucks cannot handle those objects because they typically aim to handle flat and hard wafer in semi-
conductor fabrications. Recently, our research group has been developing compliant bipolar electrostatic chucks.
Previous researches validated a concept of module of bipolar electrostatic chucks with surface flexibility by
collective elastically-deformable beam structure, which has been prototyped by 3D-printer. In addition, other studies
shows that the attractive force is greatly increased by smoothing the beam tips. As a next step toward handling large
film, it is necessary to increase effective area of attractive surface of grippers. Therefore, this research proposes
stacking the modules by layers for that purpose and investigate influence of stacking the modules on attractive force.
For proof of the concept, the authors developed two types of bipolar electrostatic chuck modules which have either
high or low compliant beams. By stacking five each of those modules by layer, we synthesized a compliant bipolar
electrostatic chuck having 3D-printed elastically-deformable beams for handling large film. We determined the
maximum attractive force per unit area of each of the single modules and the stacked modules by obtaining force curves for glass surface. Both modules have 3D-printed beam structure and consist of four-sublayer (conductor-insulator-conductor-insulator) structure. The outer insulation layer prevents the beams from contacting each other and energizing when modules are stacked. Carbon-mixed and PLA (poly lactic acid) resin are used for conductor and insulator, respectively. Each module consists of 11 beam-assembly and a support board connected with beams. The 80mm-long bipolar beams are arranged at 45-degrees to effective surface which corresponds array of beam tips. In low-compliance module, both a cross section of a beam and a tip of the beam are rectangle of 1.2 mm × 2.0 mm. In high-compliance module, a cross section of the beam is a rectangle of 0.6 mm × 2.0 mm and each tip of the beams is a rectangle of 1.8 mm × 2.0 mm. By this difference of beam width, high-compliance module has greater compliance than low-compliance.

The results validated that the concept increases the effective area and absolute values of attractive force. In addition, we confirmed that the slide glass (4.2 g) was lifted by the high-compliance system which has the smoothed beam tips. However, the results show stacking modules decreased the attractive force per unit area of a system from a single module regardless the compliance because the beam tips of each module are not perfectly aligned to a flat surface. Especially, the reduction ratio of low-compliance was 30% while that of high-compliance was 10%. This indicates that increasing the beam compliance is a valid design strategy in enlarging the effective area by stacking the modules.

In conclusion, our concept, layer-by-layer bipolar electrostatic modules, was verified to increase the effective area of attractive force. The results suggest that it is necessary to increase beam compliance for the concept to maximize performance of compliant bipolar electrostatic chuck.

SB01.06.25
Soft Robotic Materials Integrating Strain-Sensing and Photo-Actuation Chiao-Yueh Lo¹, Cheolgyu Kim¹, Yusen Zhao¹ and Ximin He¹,²; ¹University of California, Los Angeles, United States; ²Arizona State University, United States

To realize self-regulation for robot automation, robots are usually equipped with sensors, actuators and data-processing component to operate synchronically. Particularly, the signal (i.e. position, image and temperature) is gathered by sensor and processed, finally sent to actuators for a specific action. In spite of many new soft sensors and soft actuators, self-sensing materials that can monitor their own motions are highly desirable but proven challenging to realize. In this work, we present a photothermally-responsive electrically conductive soft material that can serve as a strain sensing and a photo-actuation, simultaneously owning two key functions essential to artificial muscle materials. The nanostructured hydrogel is synthesized into interpenetrating double network, leading to great enhancement of stretchability and responding speed. Photo absorbers are integrated into the hydrogel, enabling to be controlled by remote illumination and achieve various complex photo-driven anisotropic locomotion. At the meantime, the strain produced from the controlled motion can be sensed by the actuator itself in real time. With this unprecedented capability of sensing the magnitude of the strain that the actuator produces, the robust, stretchable, and ultra-sensitive conductive hydrogels will lead to the next-generation soft robots with self-diagnostic feedback-controlled, higher level of autonomy.

SB01.06.26
Inkjet-Printed Electrochromic and Electrofluorochromic Biodegradable Displays Gerardo Hernandez-Sosa¹,²; ¹Karlsruhe Institute of Technology, Germany; ²InnovationLab, Germany

Electro(fluoro)chromic devices (EFCD) have received increased research attention in investigation in the past years because of their potential applications in multifunctional optical devices. Particularly, their simple device architecture, low power consumption, and processability by industrial relevant printing techniques provide great opportunities for the fabrication of low-cost displays and smart window devices. Furthermore, these exceptional properties can be extended with the use of biocompatible and biodegradable materials for the fabrication of transient devices aimed to the reduction of electronic-waste or potential medical applications.

In this work, we report on the fabrication of inkjet-printed EFCDs consisting of biocompatible and biodegradable components on cellulose/gelatin flexible substrates. The electro(fluoro)chromic layers were comprise of two different polymer materials, either a polyindenofluorene-8-triarylamine (PIF8-TAA) or poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS). Additionally, we compared the performance of two
different solid polymer electrolytes, on the basis of gelatin or Poly(D,L-lactide-co-glycolide) (PLGA) in
combination with the non-fluorinated biodegradable salt tetrabutylammonium bis-oxalato borate (TBABOB). The
devices were fabricated in a planar architecture utilizing inkjet printed Au electrodes. The fabricated devices were
characterized in terms of contrast, efficiency and lifetime.

Finally, by subjecting the devices to a standardized composability test, we demonstrate their potential application in
short-lifecycle biodegradable electronics.

SB01.06.27
A Hydrogel-Based Smart Garment for Electrooculography S. Zohreh Homayounfar, Soha Rostaminia, Ali
Kiaghadi, Deepak Ganesan and Trisha L. Andrew; University of Massachusetts Amherst, United States

Eye tracking through novel eye-based assistive wearable devices is considered as a valuable input modality to be
used in different sorts of applications; e.g. medical applications such as visual fatigue, sleep studies and diagnosing a
variety of disease states; as well as human-computer interface applications. However, the most popular method to
detect eye movement is video-based eye trackers in which, generally, a video camera is mounted on a headset to
record the images of the eye, and then, the images are processed to calculate the gaze position. Due to the
considerable computational power cost, this technique cannot be applied for portable on-batteries long term
applications. As an alternative, electrooculography (EOG), through a more convenient wearable device, was
considered as a lightweight, accurate eye-tracking method with low-power consumption. This technique is based on
measuring the corneoretinal biopotential of the eyes, which can be modeled as a constant electrical dipole. The
eyeball rotation leads to the change in the dipole orientation which subsequently gives rise to the change in the EOG
signal amplitude. This signal is generally measured through two pairs of electrodes located in periorbital positions
close to the eyes with respect to a ground electrode.

Different variety of wearable EOG devices have been attempted recently, however, due to ergonomic issues and
limitations exposed by the current bioelectrodes to be mounted close to the eyes, there still exists a tradeoff between
comfortability and the detection of the signal with a high signal to noise ratio. Although the presence of gel is
necessary to improve the signal acquisition, wearing the conventional Ag/AgCl electrodes is not aesthetically
pleasing. In addition, since the signal decades, once the gel is dried out, these electrodes are disposable and cannot
be applied for long-term applications. Considering all the wearable devices recently developed for detecting eye
motion using EOG, none of them allows for an accurately long-term monitoring along with comfortability and low
motion artifact caused by daily activity. Herein, the role of the electrodes, i.e. the interface between the body as the
signal source and the computers as the processing units, is profoundly important. This is the electrode who receives
the charges in the ionic form from the body and injects them as electrons through the wires. Since in EOG, the
electrodes must be attached close to the eyes, designing a pleasing electrode, both aesthetically and comfortably,
which is capable of damping artifacts for efficient data acquisition is still a dire need to be fulfilled.

In the current study, we introduce a novel methodology to fabricate a smart eye mask embedded with a first-in-its-
kind fabric-based hydrogel electrode which can be feasibly adopted to daily life. We synthesized a mechanically
stable, biocompatible, and fully recoverable hydrogel, through initiative chemical vapor deposition of
poly(hydroxyethyl acrylate) on the silver gel. In the retro-design of this electrode, we got inspiration from the
conventional Ag/AgCl electrodes, which, despite all the drawbacks, is still second to none in the market. We have
successfully addressed all those drawbacks in our hydrogel electrode along with reaching to high signal to noise
ratio in long-term data acquisition, wash-stability, breathability, no skin irritation, and is capable for further
miniaturization to be embedded in other wearable platforms rather than the sleep eye mask. The success of the
proposed wearable hydrogel-based EOG device is illustrated through several controlled experiments revealed by a
comparative study between the designed bioelectrode, the standard electrodes, and the dry silver plated fabric ones
based on their biopotential strength and the corresponding signal to noise ratio.

SB01.06.28
Membrane Distillation with Controllable Membrane Pore Size Using Stretchable Superhydrophobic
Membrane Seong Kyung Hong1, Hyonguk Kim2, Seong Jin Cho2 and Geunbae Lim1; 1Pohang University of
Science and Technology, Korea (the Republic of); 2Chungnam National University, Korea (the Republic of)

Membrane distillation (MD) has attracted significant attention as a rapidly emerging water treatment technology
owing to its utilization of low-grade energy. Extensive studies have been carried out in both theoretical and
experimental aspect of this technology. These previous studies, however, focus only on either theoretical or
experimental aspect rather than incorporating both sides for a deeper understanding. It is impossible to perform a comparison study between theoretical and experimental results without being able to reliably control crucial MD membrane parameters, namely the pore size. This remains a critical limitation of most superhydrophobic membranes that the membrane parameters are not versatile once the fabrication process is set. Here, we suggest a stretchable superhydrophobic membrane of which the pore size can be readily controlled through the application of mechanical strain. The membrane was fabricated through simple electrospinning/electrospraying process and was tested of various membrane parameters including pore size, contact angle, and liquid entry pressure. The MD performance of the membrane according to the applied mechanical strain was studied both theoretically and experimentally by comparing the experimental separation flux to that of the predicted value from the computing simulation of MD. As expected, the separation flux was enhanced with increasing the pore size of the membrane. However, the lifespan of usage was shortened with larger pore sizes as it was wetted easily compared to its counterpart with smaller pore sizes. By varying the applied mechanical strain, the optimal pore size in terms of both separation flux and lifespan was found for the MD process.

SB01.06.29
Vertical MEMS Micro-Actuators with Vanadium Dioxide Chengzi Huang, Zhen Zhang, Shriram Ramanathan and Dana Weinstein; Purdue University, United States

Vanadium dioxide (VO$_2$) under goes insulator-metal phase transition (IMT) at 68 °C, accompanied with giant electrical, optical and lattice changes. Combining high Young's modulus (around 140 GPa), large IMT strain shrinkage and moderate IMT temperature, the distinct performance before and after phase transition makes VO$_2$ a competitive candidate for multi-functional MEMS actuators. For VO$_2$ actuators reported to date, lateral structures were used where two electrodes are placed above the phase change material, and current flows via in-plane direction. In this work, a vertical multilayer VO$_2$ MEMS micro-actuator device is reported. Though such configuration is being actively studied for memory devices, there is currently no literature discussing VO$_2$ vertical stack actuators. Here we will report on experimental and simulation studies of the vertical stack on the performance of the VO$_2$ actuator, toward the goal of IC integration for applications benefiting from reduced size, weight, power, and cost.

The VO$_2$ actuator is composed of 3 vertically stacked layers, where a 150 nm thick VO$_2$ layer is sandwiched between top Pt and bottom ITO electrodes. An equivalent thermal circuit is developed with a thermal response time of 0.39 ms. With the IMT of VO$_2$ generating volume change, a 35 μm long VO$_2$ actuator experiences 2 μm deflection across the phase transition driven by heating, and 0.22 μm deflection when electrothermally actuated. COMSOL finite element analysis is performed to determine spatial distribution of current flow and temperature profile, and to verify experimental measurements of strain induced bending in this multilayer vertical structure. The obtained experimental result shows a good fit with simulation analysis, which can in the future be utilized to develop a generic understanding of such vertical MEMS devices incorporating phase changing systems.

SB01.06.30
Self-Directed Self-Assembly of Block Copolymers Hejin Huang and Alfredo Alexander-Katz; Massachusetts Institute of Technology, United States

Self-assembly of block copolymer (BCP) serves as a powerful tool to fabricate complex 2D nanopatterns. Block copolymer are comprised of two or more chemically distinct subchains, which are linked together by covalent bonds. Upon annealing, these different blocks are phase separated into regimes, which forms nanostuctures of different morphologies such as spheres, cylinders and lamellae. By introducing graphoepitaxy such as trenches, post arrays, researchers can ‘direct’ the self-assembly process to form uniform and device-oriented 2D nanostructures. Over the past two decades, researchers have achieved all different thin film patterns through directed self-assembly of BCP. Despite the various 2D structures obtained from BCP, the variety of 3D nanostructures that have been so far achieved is limited. In this work, we present a novel way to fabricate uniform 3D nanostructures using a layer-by-layer approach. We test this new method using dissipative particle dynamics (DPD) to show its promise. Various multilayer structures consisting of spheres, cylinders and lamellae aligned and stacked on each other were achieved. Furthermore, different experimental parameters, which affect the uniformity of the structures, have been studied in the model.

SB01.06.31
Hierarchical Assemblies of Dendrimers Embedded in Networks of Lanthanide-Based Supramolecular
**Polymers**  
*Jianan Huang;* East China University of Science and Technology, China

Supramolecular assemblies of dendrimers, with defined structures and tunable functionalities, are promising functional materials. Here we report a ternary system (lanthanide ion/bis-ligand/PAMAM dendrimer) capable of assembling in a cooperative way by forming a complex between anionic (metal−ligand) coordination polymers and the cationic PAMAM dendrimers. In off-stoichiometric mixtures, charge-stabilized spherical nanoparticles of ~100 nm appear; they have either negative or positive surface charges depending on what the excess component is. Introducing different trivalent lanthanide ions, Ln(III), in the coordination allows tuning both the luminescence emission spectrum and the magnetic relaxivity without affecting the assembly process or the final structure of the particles; this makes them interesting in the context of application. Moreover, the incorporated dendrimer allows us to add functional nanocargo, for example, Au nanoparticles in the cavities of these molecules, again without disturbing the assembly. In this novel way, we obtain versatile, multilevel hierarchical supramolecular dendrimer-containing assemblies with good control over their structures and functionalities. This is very difficult to achieve with conventional covalent compounds but becomes possible because of the supramolecular nature of the coordination polymers and the strong cooperative assembly.

**SB01.06.32**  
**Development of a ReaxFF Force Field for Acrylated Photopolymer Resins in Volumetric Additive Manufacturing**  
*Yihan Huang and Roland Faller;* University of California, Davis, United States

Light-driven and photo-curable polymer based additive manufacturing (AM) has a huge potential due to its high resolution and precision. Unlike point- and layer-wise photopolymer AM technologies, volumetric AM forms the entire part all at once, which produces parts much more rapidly and overcomes such as stair step surface artifacts and inhomogeneous mechanical properties. Acrylated radical chain-growth polymerized resins are widely used in photopolymer AM due to their fast kinetics, and volumetric AM technology readily leverages this set of materials. However, for successful control of the reaction in 3D, the molecular basis of polymer network formation must be understood in detail. We present an optimized ReaxFF force field for acrylates polymer resin to account for the radical polymerization thermodynamics and kinetics, and the polymer network structure and composition. The force field is trained against our extensive training set including density functional theory (DFT) calculations of reaction pathways along the radical polymerization from methyl acrylate to methyl butyrate, C-C and C=C bond dissociation energies of methyl acrylate and methyl butyrate, and structures and partial charges of all molecules and radicals. The parametrization process utilizes a parallelized search algorithm, and the resulting model is able to study polymer resin formation, crosslinking density, chain length and distribution, and residual monomers of the more complex poly(ethylene glycol), diacrylate (PEGDA)/bisphenol a glycerolate (1 glycerol/phenol) diacrylate (BPAGDA) mixture.

**SB01.06.33**  
**Design of Microparticle-Based Soft Electronic Devices for Tactile Sensing**  
*Hyejin Hwang and Unyong Jeong;* Pohang University of Science and Technology, Korea (the Republic of)

While microparticle (MP) assemblies have long attracted academic interest, few practical applications of assembled MPs have been achieved because of technological difficulties related to MP synthesis, MP position registration, and absence of device concepts. The precise positioning of functional MPs in a proper stencil can produce flexible/stretchable electronic devices, even when the MPs themselves are rigid. In recent years, remarkable progress has been made in the programmable position registration of MPs, production of functional MPs, and concepts for MP-based, pixel-type electronic devices. For example, flexible tactile sensors have been intensively studied for healthcare and electronic skin devices.

Non-close-packed MP assemblies on a flexible electrode act as a pressure sensing material like a cartridge film. The cartridge film is made by filling the holes of a stencil film (one MP in each hole) with conductive microparticles (MPs). Using the cartridge film, the sensing material can be cut-and-pasted on electrodes and transferred to other electrodes for reuse. This study analyzes the electrical responses of the sensors made of the cartridge film on the basis of the Hertzian contact theory, and also correlates the sensing performance of the sensors with the conductivity of the MPs and the degree of protrusion of the MPs from the stencil surface.

On the other hand, stretchable strain sensors are manufactured with close-packed MP assemblies. We proposes a dry process of fabricating single crystal-like monolayer which consists of conductive MPs in large area of rubber substrate. Due to their complete two-dimensional assembly, the current map measured by a conductive atomic force...
microscope (C-AFM) provides information to understand the rapid resistance change in small elongation
deformations. Within 15% of elongation strain, the stretchable sensor distinguishes 0.3% fine strain due to high
gauge factor (average value ~ 124.5) and detects sensitively the pulse on a wrist.

Optical Design and Electrohydrodynamic Jet Printing of Polymer Photonic Crystals Brian Iezzi1, Zahra
Afkhami2, David Hoelzle1, Kira Barton2 and Max Shtein1; 1University of Michigan--Ann Arbor, United States;
2University of Michigan–Ann Arbor, United States; 3The Ohio State University, United States

A challenge faced in the creation of increasingly complex and miniaturized sensing platforms is the need for
multiple lithographic masking steps to achieve a particular pattern. In this work, we design and manufacture
microscale arrays of one-dimensional photonic crystals without masking via electrohydrodynamic jet printing.
Transfer matrix simulations are first used to design interference-based, polymer optical filters with reflectance
exceeding 60% in imaging-relevant bands of the visible wavelength range. We describe the material selection rules
and process conditions allowing for multilayered micro-filters with individual layer thickness control from 0.1 to 1
μm, filter edge length less than 50 μm, and compositions using commercially-available polymers with varying
refractive index. A microspectrophotometry tool and process are developed to aid the characterization ex and in situ,
allowing for rapid iterative processing to negotiate optical, interfacial, and rheological constraints of the system.

SB01.06.35
Evaluation of Antifouling Property of Surface Microstructures by Dynamic Wettability in Liquid Media
Maria Inukai and Daisuke Ishii; Graduate School of Engineering, Nagoya Institute of Technology, Japan

Fish skin is covered with a lot of scales which have microstructures on surfaces. It is considered that surface
microstructures are functioned as antifouling property, self-cleaning ability and reduction of fluid resistance. In the
conventional study, antifouling property and self-cleaning ability were evaluated by static wettability analysis.
However, it is not sufficient for the practical evaluation because actual liquid movements cannot be determined by
the static method. Therefore, we suggested a novel experimental method, called “dynamic wettability analysis in
liquid media”, to observe behaviors of air bubbles and micro-droplets in liquid media. The values of dynamic
wettability improved evaluations of antifouling property and self-cleaning ability. We fabricated a series of micro-
structured water channels on silicon wafers by photolithography. The surfaces of water channels were modified
hydrophilic by an excimer lamp. It is thought that antifouling property and self-cleaning ability are changed not only
by surface microstructures but also by surface wettability changes. The surface wettability was measured by static
water/hexadecane contact angles. The abilities of antifouling and self-cleaning of the micro-structured surfaces were
evaluated by the behaviors of the air bubble and the hexadecane droplet in water media. In addition, we investigated
how long hexadecane droplet was easy to invade within micro-structured surface in water media. The surface
microstructures enhanced the water/hexadecane wettability and the movements of the air bubble in liquid media.
The air bubble behaviors in liquid media on micro-structured and flat surfaces were differing unexpectedly. It is
generally thought that liquid droplets or bubbles move easily on surfaces having larger static contact angles, but
these results were not agreed so. We tried to control the movements of the air bubble and the droplet in liquid media
by gradually hydrophilic treatment. The movements of the air bubble and the hexadecane droplet in water media
were improved by hydrophilic treatment. These results indicate that the movements of the air bubble and the droplet
in liquid media become able to evaluate the antifouling property and the self-cleaning ability.

SB01.06.36
Fine-Tunable and Injectable 3D Hydrogel for On-Demand Stem Cell Niche Ki Hyun Hong1,2, Young-Min Kim1
and Soo-Chang Song1,2; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Korea University of
Science and Technology, Korea (the Republic of)

Stem cell based tissue engineering requires increased stem cell retention, viability, and control of differentiation.
The use of biocompatible scaffolds encapsulating stem cells typically addresses the first two problems. To achieve
control of stem cell fate, fine-tuned biocompatible scaffolds with bioactive molecules are necessary. However, given
that the fine-tuning of stem cell scaffolds is associated with UV irradiation and in situ scaffold gelation, this process
is in conflict with injectability. Herein, we develop a fine-tunable and injectable 3D hydrogel system with the use of
thermosensitive poly(organophosphazene) bearing β-cyclodextrin (β-CD PPZ) and two types of adamantane-
peptides (Ad-peptides) that are associated with mesenchymal stem cell (MSC) differentiation that serve as
stoichiometrically controlled pendants for fine-tuning. Given that complexation of hosts and guests subject to strict stoichiometric control is achieved with simple mixing, these fabricated hydrogels exhibit well-aligned, fine-tuning responses, even in living animals. Injection of MSCs in fine-tuned hydrogels also results in various chondrogenic differentiation levels at three weeks post-injection. This is attributed to the differential controls of Ad-peptides, if MSC preconditioning is excluded. Eventually, our fine-tunable and injectable 3D hydrogel could be applied as platform technology by simply switching the types of peptides bearing adamantane and their stoichiometry.

SB01.06.37
Negative Mechanical Materials and Metamaterials James N. Grima-Cornish, Joseph N. Grima and Daphne Attard; University of Malta, Malta

‘Negative mechanical materials / metamaterials’ refer to materials and/or engineered systems that exhibit anomalous macroscopic thermo-mechanical properties that emerge due to the structure of their subunits, rather than the specific chemical composition. As a result of their design/construction, they may exhibit anomalous macroscopic properties such as zero or negative Poisson's ratios (auxetic), moduli and/or indices. Such zero/negative properties are not normally manifested by their conventional counterparts and may thus potentially be used in applications where typical materials cannot. This work will look into some of the more recent developments made in this field, focusing on how existing materials (e.g. crystals) are providing the blueprint for the design and manufacture of novel 'negative materials'.

SESSION SB01.07: Soft Actuators
Session Chairs: Ximin He and Mingming Ma

8:00 AM SB01.07.01
Low Voltage, High Power-Density, Molecularly Ordered Drivers for Untethered Microrobotics Junfeng Gao, Angel Martinez, Arul Clement and M. Ravi Shankar; University of Pittsburgh, United States

Liquid crystal elastomer (LCE) films can be programmed by an array of stimuli, such as light, heat, interaction with alignment layers and mechanical deformation. Well aligned, monodomain films can produce large mechanical strains via order-disorder transitions caused by heating and, thus, high power – density actuations can be realized with low-cross-linked LCEs. Here, we focus on developing the material composition, alignment via mechanical deformation and Joule heating for achieving a low-voltage (<5V), high power-density (~kW/m³) response using LCE actuators. The material design process involved modulating the cross-linker and spacer monomer structure, as well as varying the molar concentrations among mesogenic matrices to simultaneously achieve optimal actuation and stability of the mesophase. To elicit ultrafast actuation by Joule heating, we developed the elements of the microfabrication protocols to integrate electrodes (2nm Ti + 30nm Ag), patterned onto a curved PET shell in mechanical designs. By utilizing non-linear mechanical instabilities (snap-through) in curved shells, an experimental platform was developed for creating millisecond scale actuation. In our experiments, 50um thick LCE films were synthesized and attached to a curved, electrode-patterned 23um PET shell by silicone glue. An Arduino system was used to provide current pulses for periodic heating and a current sensor was integrated to track the actinic current as a function of time. To characterize the actuation, USB digital cameras were used to record the deformation from front and side views and a FLIR infrared camera was positioned to monitor the actuator temperature variation from above. The dynamics of snap-through time (ms) was characterized using high speed imaging. Repetitive actuation over tens of cycles was demonstrated.

Untethered Soft Robotic Matter with Passive Control of Shape Morphing and Propulsion Arda Kotikian¹, Connor G. McMahan², Emily Davidson¹, Jallilah Muhammad¹, Robert Weeks¹, Chiara Daraio² and Jennifer A. Lewis¹; ¹Harvard University, United States; ²California Institute of Technology, United States

There is a growing interest in creating untethered soft robotic matter that can repeatedly shape-morph and self-
propel in response to external stimuli for use in exploratory robots and adaptive structures. Towards this goal, we use multimaterial 3D printing to fabricate active hinges composed of liquid crystal elastomer (LCE) bilayers with orthogonal director alignment that interconnect polymeric tiles. When heated above their respective actuation temperatures, printed LCE hinges exhibit a large, energy-dense, and reversible bending response. Their actuation temperature and bending angle are controlled by employing LCE inks with disparate nematic-to-isotropic transition temperatures ($T_{NI}$) and hinge geometry, respectively. Through an integrated design and additive manufacturing approach, we demonstrate passively controlled, untethered soft robotic matter that adopts task-specific configurations on demand, including a self-twisting origami polyhedron that exhibits three stable configurations and a “rollbot” that assembles into a prism and self-rolls in programmed response to thermal stimuli.

8:30 AM *SB01.07.03
Liquid Crystalline Vitrimer Actuators Mohand O. Saed and Eugene M. Terentjev; Cambridge University, United Kingdom

Covalent crosslinking of a polymer network forms a distinct reference state, with respect to which the changes in liquid crystalline order in elastomers (LCE) could produce significant and reversible actuation. However, it was difficult to process the LCE materials into useful actuating shapes. Vitrimer networks offer a way to make processable plastics with shape-memory properties: with the plastic regime above vitrification temperature, re-shaping and re-alignment of LCE is now possible. Also possible is the joining-together and assembling of complex actuator structures via the bond-exchange reaction across the contact interface. In this talk we present a range of new (exchangeable) xLCE materials, including different bond-exchange chemistry, and also the dual vitrimers where a certain fraction of the polymer network remains permanent – and demonstrate their remarkable physical properties in large reversible actuation, and switchable dynamic adhesion. This new generation of the LCE and xLCE materials, showing both nematic and smectic phases of main-chain LC polymers, is very robust: with strain to break exceeding 150-200% and stress to break exceeding 0.8-1 MPa. The Young modulus of 0.7-1 MPa is found both in the non-aligned polydomain state, and in the aligned monodomain. With the reversible (equilibrium) thermal actuation strain amplitude of over 100%, the density of mechanical work delivered on the full thermal cycle reaches MPa levels, with the speed of response is only limited by the rate of heat diffusion into the elastomer body. We present and discuss practical thermo-mechanical devices using the heat-moulded xLCE as reversible actuators.

9:00 AM SB01.07.04
Light-Induced Athermal Shape Memory Effect in Liquid Crystal Elastomers Chongyu Zhu, Xiao Zhang, Jia Wei and Yanlei Yu; Department of Material Science, Fudan University, China

Shape memory polymers (SMPs) are promising candidates in the emerging fields of biomedicine, aerospace, flexible electronics and nanofabrication thanks to their programmable deformation.1 To date, the shape adaptations in most SMPs are triggered by external heat, which is not favored or feasible in bio-applications. Light-induced SMP has shown potentials owing to its temporal, localized, remote and isothermal triggering and actuation.2,3 However, the current light-induced SMP requires long activation time and the shape fixity rate remains low. Herein, we develop a new strategy to activate shape memory effect (SME) by light. Unlike triggering the thermal SMP by changing the external temperature, we switch the transition temperature of the photoresponsive polymer by light under ambient temperature to realize SME. To demonstrate this strategy, an azobenzene-based liquid crystal elastomer (azo-LCE) with dynamic covalent bonds is designed and synthesized via ring-opening metathesis polymerization. Upon sequential UV and visible light illumination, azo-containing mesogens undergo trans-cis-trans photoisomerization,4 varying the glass transition temperature of azo-LCE,5 thus to allow for the athermal processing of temporary shape. By exploring the SME of LCE, we realize various light-induced actuations with high shape fixity and recovery rate in 2 minutes without generating significant heat. In particular, we demonstrate the programmable shape recovery of artificial *mimosa* from the temporary shape to the original shape upon UV irradiation, mimicking the stimulus-response performance of natural mimosa. Moreover, the employment of dynamic covalent bonds is capable of altering the topology of the network, endowing this cross-linked LCE with excellent processability.6 Therefore, we manage to obtain and reshape different 2D and 3D structures from the same azo-LCE, solving the manufacture issue of conventional SMPs. We expect this light-programmable SMP provides potential applications for the future soft robotics and automation equipment.

References
Stimulus-responsive polymers are attractive for microactuators because they can be easily miniaturized and remotely actuated, which enables untethered operation. Inspired by biology, artificial cilia have been investigated for applications in sensing, microfluidics, and controlled wettability. Functional artificial cilia usually respond to applied stimuli but require maintaining the applied stimulus or are programmed to perform one-way processes that cannot be reset. Reconfigurable artificial cilia are desirable, whose shape can be set, locked, unlocked, and reconfigured. In this work, magnetic iron microparticles were dispersed in a thermoplastic polyurethane shape memory polymer matrix and formed into artificial, magnetic cilia by solvent casting within the vertical magnetic field in the gap between two permanent magnets. In this template-free method, interactions of the magnetic moments of the microparticles, aligned by the applied magnetic field, drive self-assembly of magnetic cilia parallel to the field direction. The resulting magnetic cilia respond simultaneously to magnetic fields and light. Temporary shapes obtained through combined magnetic actuation and photothermal heating can be locked by switching off the light and magnetic field. Subsequently turning on the light without the magnetic field drives recovery of the permanent shape of the magnetic cilia. These cilia are therefore reconfigurable rather than merely responsive. The permanent shape of the cilia can also be programmed after fabrication by applying mechanical constraints and annealing at high temperature. Spatially controlled actuation of cilia is demonstrated by applying a mask for pattern transfer into the array of magnetic cilia. Developing a theoretical model to predict the response of shape memory magnetic cilia elucidates physical mechanisms behind observed phenomena, enabling the design and optimization of ciliary systems for specific applications. Remote reconfiguration enabled by combining applied magnetic fields and light enhances the capabilities and broadens the applications of magnetic cilia.

Switchable Friction Coefficient on Shape Memory Photonic Crystals Yifan Zhang and Curtis Taylor; University of Florida, United States

Friction force on soft material usually is not linearly dependent on normal load because of the nonnegligible adhesion force or surface energy. As the adhesion force is proportional to the real contact area, friction force can be switchable by changing the surface roughness of the material. Here, we introduce a shape memory photonic crystal (SMPC) which is polymeric inverse opal structure and made of polyethylene glycol diacrylate (PEGDA) and ethoxylated trimethylolpropane triacrylate (ETPTA) co-polymer. The original ordered structure of SMPC providing a smooth surface can be programmed into a temporary disordered structure providing a rough surface by water swelling. The disordered structure can be recovered by ethanol swelling. Both programming and recovery are under room temperature. The previous studies demonstrate that this unusual athermal shape memory effect is caused by the competing between the elastic modulus (E) of material and the surface tension (µ) of the chemical solution. During the swelling, the porous structure is order because the polymer chains are lubricated by chemical solution and have high mobility. In this case, polymer chains tend to recover to their original conformation which is ordered porous structure. During the evaporation of the chemical solution, the capillary force from the surface tension (µ) of the solution will deform the porous structure into disordered status if µ is large (such as water) enough to compete with E. On the other hand, the structure will stay order if µ is not large (such as ethanol) enough. In this work, we first characterize the optical property of both ordered and disordered SMPCs by reflection spectra. The SMPCs show an obvious photonic band gap with ~530 nm wavelength in ordered (recovered) status and no
photonic band gap in disordered (deformed) status. Then, atomic force microscopy (AFM) and micro-indentation are used to characterize surface roughness and adhesion, respectively. The adhesion force on recovered SMPCs with a smooth surface is about three times larger than that on deformed SMPCs with a rough surface. Finally, a reciprocating sliding test is conducted on SMPCs by a spherical stainless steel tip under different normal load (0.5mN ~ 7mN). The friction coefficient on the recovered SMPCs can be 14 times higher than that on the deformed one. The mechanism behind this friction coefficient change will be discussed in this presentation.

9:45 AM SB01.07.07
Homogeneous Freestanding Luminescent Perovskite Organogel with Superior Water Stability
Yusen Zhao, Yucheng Zhang and Ximin He; University of California, Los Angeles, United States

Metal-halide perovskites have become appealing materials for optoelectronic devices. While the fast advancing stretchable/wearable devices require stability, flexibility and scalability, current perovskite still suffers from ambient-environmental instability and incompatible mechanical properties. To break the hindrance, recently perovskite–polymer composites have shown improved in-air stability with the assistance of polymers as the embedding media. However, their stability remains unsatisfactory in high-humidity environment or when immersed in water. These methods also suffer from limited processability with low yield (2D film or beads) and high fabrication cost (high temperature, air/moisture-free conditions), thereby limiting their device integration with complex structures and broader applications. Herein, a one-step scalable method is developed to produce freestanding highly-stable luminescent organogels, within which perovskite nanoparticles (NPs) are homogeneously distributed. The perovskite-organogels present a record-high stability, maintaining their high quantum yields for >110 days immersing in water at different pH and temperatures. This paradigm is universally applicable to broad choices of polymers, hence casting these emerging luminescent materials to a wide range of mechanical properties tunable from rigid to elastic. With intrinsically ultra-stretchable photoluminescent organogels, flexible phosphorous layers were demonstrated with >950% elongation. Rigid perovskite gels, on the other hand, permitted the deployment of 3D-printing technology to fabricate arbitrary 2D/3D luminescent architectures.

Photodeformable Liquid Crystal Polymers and Soft Actuators
Yanlei Yu; Fudan University, China

Photodeformable liquid crystal polymers (LCPs) that adapt their shapes in response to light have aroused a dramatic growth of interest in the past decades, since light as a stimulus enables the remote control and diverse deformations of materials.1-3 LCPs, especially the ordered ones, have demonstrated their potentials to dramatically increase the photodeformation extent and construct light-driven soft actuators because they possess fascinating features combining the entropic elasticity of polymeric elastomers and the ability to undergo a reversible and alignment dependent shape-change behavior of liquid crystals (LCs). Much effort was made to develop new photodeformable LCPs, including their basic actuation mechanisms, the various deformation modes, the newly designed molecular structures, and the improvement of processing techniques.4-6 In this report, special attention is devoted to the novel molecular structures of LCPs, which allow for easy processing and ordering. The soft actuators with various deformation modes in response to light are also covered with the emphasis on their photo-induced bionic functions and potential applications in optofluidics and optoelectronic devices.

11:00 AM SB01.07.09
A Multifunctional Shape Morphing Elastomer with Liquid Metal Inclusions
Michael Ford¹, Cedric Ambulo², Taylor Ware² and Carmel Majidi⁴; ¹Carnegie Mellon University, United States; ²The University of Texas at Dallas, United States
Wearable computers, stretchable electronics, soft robotics, healthcare, and other areas of research that require physical human-machine interactions demand materials that are inherently multifunctional. Human-made materials typically lack diverse multifunctionality that is more widely observed in nature, where a material can be soft and stretchable as well as responsive and adaptable to its environment. One promising class of materials is liquid crystal elastomers (LCEs), which are compliant, deformable, and undergo a thermally-activated liquid crystal phase transition resulting in macroscopic shape change. However, LCEs are electrically insulating with low thermal conductivity. Rigid fillers can improve relevant materials properties of LCEs and introduce additional functionalities, but at high loading (greater than a few weight percent), rigid fillers reduce shape-morphing capabilities of the LCE. In the multifunctional composite described in this work, functionality is retained at 50 vol. % (83 wt. %) loading of liquid metal microparticles (LM). Mechanical properties were characterized by mechanical testing and dynamic mechanical analysis. The LM inclusions do not degrades the compliance nor deformability of the LCE matrix, while rigid inclusions increased stiffness and prevented actuation. Thermal conductivity measurements showed improved heat dissipation capabilities of the LM-LCE composite relative to the unfilled material, critical for thermally-activated shape-morphing. Electrical conductivity of the LM inclusions enabled the possibility of Joule-heated actuation. Joule-heated actuation is uniform, robust, and resilient; the composite could actuate even after significant physical damage and could actuate for $>15,000$ cycles at 50 % strain and $>100,000$ cycles at 2.5 % strain. Shape change can be programmed for zero-stress actuation of irregular form factors. A soft crawling entity and architectures that demonstrates sensing, actuation, and traditional electronics interfacing highlight the potential use for this multifunctional composite in active areas of research.

Independent Multi-States of Photo-Responsive Polymer/Quantum Dot Nanocomposite Induced via Different Wavelengths of Light Jiyeon Lee, Wonsik Lee, Dongjun Kim, Myungjun Kim and Jiwon Kim; Yonsei University, Korea (the Republic of)

Stimuli-responsive systems are attractive since their properties can be controlled by external stimuli and/or surrounding environment. Recently, more than one stimulus is utilized in order to enhance the performance of systems, or to bypass undesired effects. However, most of previous research on multi-stimuli has been focused on enhancing or inducing changes in one type of response. Herein, we developed a nanocomposite material with independent multi-states composed of photo-responsive polymer and quantum dots (QDs), in which its properties can independently be controlled by different wavelengths of light. More specifically, azobenzene-incorporated poly(dimethylsiloxane) (AzoPDMS) triggers photobending (PB) by 365 nm light and uniformly dispersed methylammonium lead bromide perovskite (MAPbBr3) QDs show photoluminescence (PL) by light below 500 nm. The PB and PL could be simultaneously and independently controlled by the wavelength of applied light creating multi-states. Our approach is novel in that it creates multiple independent states which can further be used to transfer information such as logic gates ($00(2)$, $01(2)$, $10(2)$, $11(2)$) and possibly widen its application to flexible and transparent opto-electric devices.

11:30 AM SB01.07.11
Design Optimization of Liquid Crystal Elastomers with Programmable Stiffness David Yoo¹, Seung-Yeol Jeon², Andrew S. Gillman³, Sung H. Kang² and Phil Buskohl³; ¹UES, Inc, United States; ²Johns Hopkins University, United States; ³Air Force Research Laboratory, United States

Elastomeric lattices are widely applicable for energy absorption, impact protection, and signal propagation, due to their capability to undergo large, reversible strains and energy-dissipating buckling instabilities. In particular, architected liquid crystal elastomers (LCEs) combine the structural properties of lattice-based design with programmability of the material stiffness, offering tailored energy absorption properties. The stiffness of the LCE is locally programmed by the applied strain field, which orients the director (mesogen) of the LCE. However, the set of physically accessible strain profiles is regulated by the shape and spacing of the LCE beams within the lattice, creating a large design space to navigate. To address this challenge, a Bayesian optimization framework is utilized to design the shape of the LCE beams to achieve specific spatial strain distributions under applied loading. The beams are parametrized with a Fourier-series expansion, which controls the thickness as a function of beam length in terms of the magnitude, periodicity, and phase of the top and bottom layers. The Bayesian optimizer utilizes the posterior
distribution of the response surface that is obtained by a Gaussian process, creating a less expensive surrogate model for optimization and visualization. Representative 2D lattices for both bending and stretching dominated behavior under uni-axial loading were prescribed. The strain field within the designed LCE beams was calculated using a nonlinear finite element simulation to capture the geometric and material nonlinearities of the model. After calculating the strain field, statistics of the spatial distribution were compiled to predict the average stiffness increase of the lattice due to LCE director programming. The mean, variance and number of modes of the strain distribution were evaluated as objective functions for optimization. Preliminary results suggest uniform thickness beams with a range of lower periodicity (< 4) increases the variance of the strain distribution in the LCE. In contrast, beam designs with regions of narrow thickness result in lower variance of the strain distribution, but have larger differences in the maximum to the minimum strain difference, as the strain fields become more localized. Collectively, this design tool provides an initial framework to explore the coupling between geometry, strain and material programmability in the LCE system and has potential to inform the design of other material systems with strain-based patterning mechanisms.

11:45 AM SB01.07.12
Precise Network Polymerized Ionic Liquids for Low-Voltage, Dopant-Free Soft Actuators
Christopher Evans, Chengtian Shen and Qiujie Zhao; University of Illinois, Urbana-Champaign, United States

There has been substantial research interest in ionic liquids and polymerized ionic liquids (PILs) over the past decade due to their potential applications in energy storage, ion exchange membranes, gas/liquid separation membranes, and stimuli-responsive devices. Typically, a trade-off is observed between ionic conductivity and mechanical properties. Polymers provide a route to improve flexibility and mechanical properties of electrolytes but generally at the expense of conductivity. Here we report a new class of electroactive polymer that was designed and synthesized based on covalently crosslinked network PILs (n-PILs) to decouple conductivity and mechanical strength. Through molecular engineering, we are able to precisely control the spacing between ions, crosslinking density and linker polarity (hydrocarbon or oligoether). The resultant n-PILs exhibit low $T_g$ (~ -40°C), tunable ionic conductivity (> $10^{-5}$ S/cm under ambient conditions), and are self-standing (Young’s modulus 0.2-2.2 MPa) at room temperature. These n-PILs were investigated as dopant-free, single ion conducting actuators and showed bending strains as large as 0.9% under DC testing conditions which is comparable to the best performing ionic liquid swollen block copolymers. A large electrochemical window (±3 V) and absence of water or solvent allows our n-PIL actuators to retain >85% of the original bending strain after 1000 cycles under 3V, 0.1 Hz AC current. Modulus controls the response under DC conditions while the AC measurements are dependent on the ionic conductivity as well.

SESSION SB01.08: Multifunctional Hydrogels
Session Chairs: Michael Dickey and Richard Trask
Wednesday Afternoon, December 4, 2019
Hynes, Level 3, Ballroom A

1:45 PM SB01.08.01
A Multifunctional Anti-Icing Hydrogel for Controlling Ice Nucleation, Propagation and Adhesion
Zhiyuan He¹, Ximin He², Jianjun Wang¹ and Mutian Hua; ¹Chinese Academy of Sciences, China; ²University of California Los Angeles, United States

The ice formation processes on solid surfaces are complex and diverse, which makes it a daunting challenge to design an iceophobic material functional under different icing conditions in complex varying real-life environment. Developing an effective iceophobic material surface with multiple anti-icing functions through simple design and large-scale production is highly desirable. Biological antifreeze proteins (AFPs) offer a great example of multifunction integrated anti-icing materials that excel in all the three key aspects of anti-icing process, i.e., they can depress the freezing temperature, prevent the ice growth, and inhibit the ice recrystallization simultaneously by tuning the structures and dynamics of interfacial water. Inspired by antifreeze proteins (AFPs), a multifunctional anti-icing platform based on polydimethylsiloxane (PDMS)-grafted polyelectrolyte hydrogel is reported. The properties of interfacial water can be controlled via tuning the synergy of hydrophobicity and ion-specificity, which provides us a
promising route to integrate various icephobic advantages into one material. The controllability of interfacial water
grants the polyelectrolyte hydrogel coating high performance in inhibiting ice nucleation (ice nucleation temperature
lower than -30 °C), preventing ice propagation (ice propagation time higher than 500 s/cm²), and decreasing ice
adhesion (ice adhesion strength lower than 20 kPa). These low-cost hydrogels can be large-scale coated onto
different inorganic and organic materials, such as metals, plastics, oxides and ceramics. The simplicity, mechanical
durability, and versatility of these smooth hydrogel surfaces make it a promising option for a wide range of anti-
iccing applications.

Stretchable Distributed Waveguide Sensor with Deformation Differentiation Capability Hedan Bai, Shuo Li,
Yaqi Tu, Jose Barreiros, Clifford Pollock and Rob Shepherd; Cornell University, United States

Soft materials deform in a distributed fashion and in various modes. Although stretchable sensors have been
developed to sense the deformations of soft-bodied robots or human organs, each sensor can only sense one
deformation, and offers limited knowledge about the deformation’s mode and location. Advanced mechanical
sensing with richer information is usually achieved through sensor networks, or machine learning techniques, which
are complex on a systematic or computational level. In a step toward reducing complexity associated with advanced
mechanical sensing, we present a compact and low-cost design of a stretchable optical waveguide sensor, which
achieves the goal through sensing the rich information carried by light. The waveguide, composed of multi-core
structure and patterned with absorbing dyes, differentiates the deformations’ modes among stretching, bending and
pressing, and senses deformations’ location and magnitude. Furthermore, the sensor is capable of decoupling
deformations happening at multiple locations at the same time, and decoupling different modes of deformations.
These features are demonstrated in a 3D printed glove, which can use one waveguide sensor to sense in real time the
bending angles of the three joints on a finger, and simultaneously detect location and magnitude of an external press.

2:15 PM SB01.08.03
Light-Degradable Hydrogels as Dynamic Triggers in Implantable Devices Ritu Raman, Tiffany Hua, Declan
Gwynne, Joy Collins, Siddartha Tamang, Vance Soares, Tina Esfandiary, Jianlin Zhou, Simo Pajovic, Alison
Hayward, Robert Langer and Giovanni Traverso; Massachusetts Institute of Technology, United States

Introduction: There is a critical need for a safe, non-contact, and dynamically activated trigger for actuating
implantable devices. Inducing on-demand degradation of these devices enables tuning treatments to the needs of
individual patients, diseases, and recovery schedules. Triggers based on other stimuli, such as heat, pH, or enzymatic
chemicals, have been employed in some in vivo applications, but come with many restrictions that limit their use for
several disease use cases. Light-triggerable materials offer non-contact on-demand degradation with high spatial and
temporal resolution. We have developed a tough light-triggerable hydrogel with tunable mechanical properties and
modular design that can be degraded in a safe and non-contact manner in vivo. We apply these materials to two
applications in the gastrointestinal tract: a bariatric balloon and an esophageal stent. We demonstrate
biocompatibility and on-demand triggering of the material in vitro and in vivo. We characterize performance of the
system in a large animal model with an accompanying ingestible LED. This is, to our knowledge, the first
demonstration of light-degradable hydrogels in vivo.

Methods: We custom-manufactured an acrylated ortho-nitrobenzyl (oNB)-based compound and used it as a linker
to polymerize hydrogels from a range of materials, including polyacrylamide (PAAM) and poly (2-acrylamido-2-
methylpropane sulfonic acid) (PAMPS) single network gels and tough PAMPS/PAAM double network gels.
Cytotoxicity of the materials and degradation byproducts was evaluated on two cell lines. Mechanical properties
were measured using rheological testing and compression testing. Materials were degraded in vitro and in vivo
(porcine model) using custom-made LED arrays and ingestible light-emitting pills.

Results & Discussion: The mechanical properties of our material far exceeded previously reported properties for
light-degradable gels (>100 times stronger) and enabled, for the first time, their in vivo use. The mechanical
properties and degradation timelines of these materials could be tuned using a variety of parameters, such as gel composition and light wavelength, intensity, and distance from the material. The material could be dissolved within minutes of irradiation and its degradation byproducts, as well as degradation light wavelengths (365-405 nm) were proven biocompatible. We showcased the advantageous properties of our material in two use cases: a gastric resident bariatric balloon and an esophageal stent. In the gastric resident device, we triggered light-activated reduction in the size of an ingestible space-filling balloon in vivo using an ingestible LED pill. If employed in a patient, this functionality could enable on-demand passage of the space-filling device when residence is no longer required. This would provide a significant advantage over the current clinical standard, which requires an invasive endoscopic procedure to retrieve the balloon. Similarly, we have developed a triggerable gel-linked esophageal stent in which light irradiation provides a non-contact method for safely dissolving and removing the stent from the esophagus without risking off-target detrimental effects to the tissue lining that arise from mechanical-, heat-, or chemical-based triggers. This could be used to treat benign and malignant stenoses or strictures. Our material enables dynamic, biocompatible, spatially controllable, and non-contact degradation in vivo.

Conclusions: Triggerable materials stand to transform our capacity to precisely control biomedical device activity and performance while reducing the need for invasive interventions. Our light-triggerable hydrogels have the potential to be applied broadly throughout the GI tract and other anatomic areas. By demonstrating the first use of light-degradable hydrogels in vivo, we provide engineers and clinicians with a novel, safe, dynamically deliverable, and precise tool to design dynamically actuated implantable devices.

Efficient Fabrication of Stimuli-Responsive PNIPAM Hydrogels and Programmable Soft Actuator Jingwei Liu, Xuhao Fan, Yufeng Tao, Chunsan Deng, Wenguang Zhang and Wei Xiong; Huazhong University of Science and Technology, China

Stimuli-responsive hydrogels have been widely used in many fields, including soft robots, bioengineering, and smart sensors, due to their excellent flexibility, stimuli responsiveness, and shape change performance, which have attracted extensive attention. However, the tedious and time-consuming preparation process, low response speed, and requirement of toxic additives/solvents severely limit their practical application. Here, we reported a cost-efficient two-step synthetic method for stimuli-responsive Poly(N-isopropylacrylamide) (PNIPAM) hydrogel with additive-free, fast response, large swelling ratio, and high fatigue resistance. Results show that the overall performance of the as-synthesized PNIPAM hydrogels is among the top level compared with other reported work despite the significantly shortened preparation time. Moreover, we have also achieved large photo-thermal response and remote control capabilities by introducing multi-wall carbon nanotubes (MWNTs) into the PNIPAM hydrogel, demonstrating precise tuning of the bending angle and deformation geometry of the nanocomposite hydrogel under infrared laser irradiation. Lastly, we designed and integrated the stimuli-responsive hydrogels with stretchable circuits to make an electric-driven soft actuator, which is capable of multi-mode programmable electric-driven actuation. It is expected that the electric-driven soft actuator could have great potential for the application of artificial muscles and aquatic soft robots.

3:45 PM SB01.08.05
How Smart and Actuatoric Hydrogel Systems Can be Developed by High-Energy Electron Treatment Stefanie Riedel1,2 and Stefan G. Mayr1,2; 1Leibniz Institute for Surface Modification, Germany; 2Universität Leipzig, Germany

The development of smart biomaterials is a challenging task. Via the promising high-energy electron treatment, biological relevant hydrogels such as gelatin can be engineered to become smart materials. Due to their original biocompatibility and cytocompatibility, they show a high potential for applications in biomedicine and related fields. Therefore, reagent-free methods to develop smart hydrogels are required. A highly favorable technique is high-energy electron treatment, which can be used to develop smart and stimuli-responsive hydrogels. Within this contribution, we will present two different preparation processes utilizing high-energy electron treatment to develop effective thermo- and hydration-responsive gelatin hydrogels. Since high-energy electron treatment is highly advantageous for reagent-free modification of biological hydrogels, the resulting smart hydrogel materials have a great potential for applications in biomedicine and related fields.
4:00 PM SB01.08.06
AFM Assessment of the Mechanical Properties of Stem Cells During Differentiation
Jie Zou¹,², Weiwei Wang¹, Xianlei Sun¹,³, Wingtai Tung¹,³, Nan Ma¹,² and Andreas Lendlein¹,³; ¹Helmholtz-Zentrum Geesthacht, Germany; ²Free University of Berlin, Germany; ³University of Potsdam, Germany

During tissue formation and regeneration, the dynamic mechanical force transmitted through microenvironments continuously impacts on the mechanics of cells. Cellular mechanical properties are closely related to genes and proteins expressions [1, 2]. The mechanical properties would alter during the procedure of stem cells differentiating into different lineages. At different stages of stem cell differentiation, the cells display varying levels of mechanical properties in response to surrounding microenvironments, which depends on the composition and organization of subcellular structures, especially the cytoskeleton and nucleus. The mechanical properties of cell nucleus affects the proteins folding and transport as well as the condensation of chromatin [3], which further regulates cell fate. However, few studies have assessed stems cells mechanical property during differentiation. In this study, the mechanical properties change of human bone marrow mesenchymal stem cells (hBMSs) during the procedure of adipogenic and osteogenic differentiation were determined by atomic force microscopy (AFM) at different time points. Simultaneously, the change of histone modification level and cytoskeleton were characterized by laser confocal microscopy and flow cytometry. Through comparing the mechanical properties of the nuclei at different stages of cell differentiation found that the stiffness of nuclei increased with the induction time prolongation. Immunofluorescence results show that the intensity of H3K27me3 significantly increased over the differentiation. Our results indicate that AFM is a facile and effective method to monitor stem cells differentiation.

Key words : stem cell, cell mechanics, AFM

Wood-Inspired Aligned Hydrogels with Structural Control for All-Solid-State Supercapacitors
Yusen Zhao and Ximin He; University of California, Los Angeles, United States

Wood in nature has well-defined vertical structure with low tortuosity to facilitate the mass transport. Inspired from the wood structure, we designed anisotropic hydrogels with alignment to increase the ionic conductivity of materials. The pore size can be rationalized and reduced even smaller than natural wood to increase the specific area, while maintaining the alignment. Conducting polymer, owing to its mesoporous structure and high electrical conductivity has been widely used for supercapacitors. By incorporating the conducting polymer in hydrogel-based matrix, the all-solid-state supercapacitor with high electrochemical performance can be fabricated. Such conducting polymer-hydrogel composites exhibit unprecedented ionic conductivity, areal supercapacitance, power density, energy density, capacitance retention and cyclic stability. Besides, the hydrogel matrix also provides excellent flexibility under cyclic bending, making it possible for flexible electronics.

Multifunctional Hydrogels as an Emerging Platform for Sustainable Energy and Environmental Technologies
Guihua Yu and Xingyi Zhou; The University of Texas at Austin, United States

Given their intrinsic hierarchical micro-/nano-structures, unique chemical/physical properties and tailorable
functionality, hydrogels and their derivatives have emerged as an important class of materials for many exciting applications beyond their traditional biomedical applications. Bottom-up synthetic strategies to rationally design and modify their molecular architectures enable functional hydrogels to address critical challenges in renewable energy and environmental technologies.

In this talk, I will present our recent advances made in nanostructured functional hydrogels, particularly those based on conjugated polymers, as an emerging material platform for sustainable energy and environmental technologies, including high-energy-power batteries and supercapacitors, and solar water desalination and atmospheric water harvesting. I will further illustrate ‘structure-derived multifunctionality’ of this special class of materials.

Evaluation of Anisotropic Dynamic Wettability and Liquid Movement on Cuticle Structure
Nozomi Ito, Daisuke Ishii and Shingo Ito; Nagoya Institute of Technology, Japan

Introduction
Many animals including humans have a lot of hairs on their body surface in order to protect their body surface. The outermost surfaces of the hair have cuticle structures in a scaly overlapping manner from the root to the tip of hair. The cuticle plays an important role as protection of the interior of the hair against external irritation. Furthermore, it is said that it plays a role of transporting the sebum secreted near the root to the tip of hair. Anisotropic surface structure such as cuticle greatly contributes to wettability. However, we have a question about the direction of sebum transport phenomena due to the fine cuticle structure.
In this research, we tried to investigate dynamic wettability of the cuticle structure, to clarify regularity in this fine structure, and to consider correlation with the liquid transport phenomenon. To elucidate the wettability of anisotropic surface structures can be expected to apply to microfluidic devices, hair cosmetic products, and antifouling coatings.

Experimental Method
Dynamic wettability toward water droplet of 3 to 40 pL such as a receding angle and a droplet evaporating behavior was measured by using Microscopic Contact Angle Meter (MCA-3 type I). Distilled water, which is a volatile liquid, evaporates in less than 30 sec. The receding angle can be measured during the evaporation process. The amount of the droplet during the measurement is kept much smaller than the capillary length at which the liquid begins to be affected by gravity, it is possible to measure dynamic wettability of the cuticle structure excluding the influence of gravity.

Results and Discussion
The dynamic wettability of the cuticle structure toward to picolitter-scaled water droplets indicated that, an anisotropic pinning effect was observed at the cuticle structures in the case of the longer diameter of water microdroplet than the interval of cuticle. The receding angle from the tip side to the root side of the hair was measured during evaporation of the water microdroplet. This result also indicated that the anisotropic water spreading from the tip to the root of hair was depended on commonly consideration of sedum transporting on the cuticle from a root to a tip of hair surfaces. The water manipulation learning from this mechanism will help to produce biomimetic fluidic devices.

Facile Method to Synthesize Ultra-Stretchable Light Managing Soft Materials for Performance Enhancement of Optoelectronic Devices
Hanmin Jang, Kang Won Lee, Sungwon Jo and Dong Rip Kim; Hanyang University, Korea (the Republic of)
We report the synthesis method of ultra-stretchable soft materials for effective light modulation of optoelectronic devices such as solar cells and light emitting diodes. We controllably generate multi-scale pores within soft materials (e.g., silicone rubber) to effectively control their light reflection properties by using the water-streaming method, which can be extended to ultra-stretchable soft materials. Specifically, formation of the pores on the surfaces of soft materials enables to fabricate the anti-reflective soft materials with light reflection of less than 4% in the visible wavelengths. In addition, multi-scale pore generation within the soft materials leads to achieve light reflection of more than 95% in the visible wavelengths without incorporation of metallic or ceramic components. The fabricated soft materials exhibit ultra-stretchable properties of up to ~300% engineering strain. Those layers are assembled to commercial organic solar cells as anti-reflective and back-reflective layers as such they significantly increase the light absorption and the light energy conversion efficiency of the solar cells due to the enhanced light trapping effects. Our all-polymer platform with effective light managing properties can be readily applied to commercial optoelectronic devices for their enhanced performance with diverse applications.

Patterning Magneto-Actuation of Polymer Composites Microarrays Jisoo Jeon1, Jeong Eun Park1, Sei Jin Park2, Sukyoung Won3, Hangbo Zhao3, Sanha Kim1, Bong Sup Shim1, Augustine M. Urban4, Anastasios J. Hart3, Zahyun Ku2 and Jeong Jae Wie1; 1Inha University, Korea (the Republic of); 2Lawrence Livermore National Laboratory, United States; 3Massachusetts Institute of Technology, United States; 4Wright-Patterson Air Force Base, United States

Magneto-responsive materials are emerging sources for packaged shape reconfigurable devices owing to its rapid contactless actuation by the external magnetic field. While programmability of magneto-responsive materials enables multi-modal actuation such as bending, twisting, and their hybridized actuation mode, most reports are limited to demonstrate of single actuation mode in a single sample. Herein, we report patternable actuation modes within a single sample by utilizing the patterned magnetic field to align the magnetic component. Furthermore, we also demonstrate programmability of actuation modes in a single sample by adapting a masking technique for arbitrary patterned actuation of the microarray. Remarkably, reversible magnetic actuation of patterned microarrays is achieved 100 actuation cycles. The programmable magneto-responsive microarrays could be served as a general platform for shape reconfigurable tunable microdevices.

SB01.09.05
Biomimetic and Bioinspired Structures for Energy Harvesting and Sensors in Piezoelectricity Chang Kyu Jeong; Chonbuk National University, Korea (the Republic of)

Elastic composite-based piezoelectric energy harvesting technology is highly desired to enable a wide range of device applications, including self-powered wearable electronics, robotic skins, and biomedical devices. Recently developed piezoelectric composites are based on inorganic piezoelectric fillers and polymeric soft matrix to take the advantages of both components. However, there are still limitations such as the weak stress transfer to piezoelectric elements and the poor dispersion of fillers in matrix. In this talk, a highly-enhanced piezocomposite energy harvesters (PCEH) is representatively developed using a three-dimensional (3D) interconnected electroceramic skeleton by mimicking and reproducing the sea porifera architecture (although the speaker will introduce other research examples and achievements). This new mechanically reinforced PCEH is demonstrated to resolve the problems of previous reported conventional piezocomposites, and in turn induces stronger piezoelectric energy harvesting responses. The generated voltage, current density and instantaneous power density of the biomimetic PCEH device reach up to ~16 times higher power output than that of conventional randomly-dispersed particle-based PCEH. This work broadens the further developments of high-output elastic piezocomposite energy harvesting and sensor application with biomimetic architecture.
An Optimized Spring Roll Dielectric Elastomer Actuator Design for Various Situational Applications

Seung Mo Jeong and Ki-Uk Kyung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Dielectric elastomers are a type of electro-active polymers that have been investigated for its use in artificial muscle-like stretchable actuators. Dielectric elastomers are characterized by their high energy density, large strain rate, fast response, softness, lightweight, and low cost [1]. There have been many attempts at harnessing and utilizing these characteristics. To apply elastomers in various conditions and structures, numerous actuator configurations were designed, such as spherical, cylindrical/tubular, and zipping actuators [2][3]. Also, to produce a larger linear motion or to maintain stability, soft actuators combined with other actuation mechanisms, such as hydraulics and magnetism, have been fabricated [4][5]. A spring roll actuator is composed of a thin dielectric elastomeric sheet wrapped around a spring core. This configuration converts the dielectric membrane’s expansion into linear motion. As a result, upon activation, a muscle-like movement is produced. Designing of spring roll actuators based on models has been attempted, to obtain an optimal design and to increase the performance [1][6-8]. Although the model-based approach was effective, experimental results did not completely match with model predictions, due to nonlinear properties. We propose a model-based spring roll actuator design, which considers both static and dynamic conditions. Using strain energy functions, a viscoelastic material model of the actuator is established. Then, overall governing equations are derived from the Helmholtz free energy equation and the viscoelastic model. With fabricated spring roll actuators, the proposed actuator model is experimentally verified in static and dynamic conditions. In conclusion, we present a general model of spring roll dielectric elastomer actuators and its optimized fabrication parameters for specific operating conditions.

Reconfigurable Microswarm Mimics the Structure and Function of Ant Bridges for Electronic Applications

Dongdong Jin, Jiangfan Yu and Li Zhang; The Chinese University of Hong Kong, Hong Kong

Ant colonies in nature are able to cooperatively accomplish complex tasks that are beyond the capabilities of individuals through self-organizing into sophisticated and functional structures. For example, to traverse difficult terrain, ants grip firmly the bodies of each other, and constitute a living, flexible and robust chain-like ant bridge to march across the gaps beyond the reach of individuals.

Emulating natural collective behaviors promises benefits in various engineering fields, and has been partially realized through elaborate algorithm and physical designs in traditional large-scale robotic swarms. Further downsizing the swarms to micro-/nanoscale is envisioned to expand their applications in the hard-to-reach regions for humans, such as targeted delivery, microelectronics, and so on[1, 2]. However, to date, developing microswarms with group-level functionality still remains a challenge.

Previously, our group has developed various magnetic actuation strategies for microrobotic systems[3-5]. Herein, we present a magnetic microswarm that emulates the collective behaviors of ant bridges for electronic applications[6]. The building blocks of microswarm are fabricated by functionalizing Fe₃O₄ nanoparticles with a continuous gold surface layer, so that they are both paramagnetic and electrically conductive. Under a programmed oscillating magnetic field, the building blocks are reconfigured into a ribbon-like microswarm, which can perform reversible elongation with a high aspect ratio. Through elaborately tuning the magnetic field parameters, we apply the microswarm to self-assemble a chain-like conductive pathway for electrons between two disconnected electrodes with the bodies of building blocks, thus mimicking both the structure and function of ant bridges. We demonstrate that the microswarm is capable of serving as a microswitch, repairing broken microcircuits and constituting flexible circuits with the advantages of customizable controllability, high precision and long-term stability. This work
provides an example of how science and technology can be inspired by nature. Further adjusting the surface functionalization process may endow the microswarm with new collective behaviors and functions, thus paving the way for better understanding the complex collective behaviors of living systems.

ACKNOWLEDGMENT
This work is financially supported by the General Research Fund (Nos. 14203715 and 14218516) from the Research Grants Council of Hong Kong, and the ITF project (No. MRP/036/18X) from the HKSAR Innovation and Technology Commission.

Tantalum Oxide Nanoparticles as a Contrast Agent for Articular Cartilage Imaging Anisha Joenathan1, Taylor Lawson1, Janne Mäkelä2, Brian Snyder1,4 and Mark Grinstaff1; 1Boston University, United States; 2University of Eastern Finland, Finland; 3Boston Children's Hospital, United States; 4Beth Israel Deaconess Medical Center, United States

Cartilage consists of a collagen network coupled with a hydrated matrix of negatively charged sugars known as glycosaminoglycans (GAGs). GAGs are responsible for attracting and immobilizing water within the tissue as well as providing high resistance to compression due to charge repulsion. A decline in GAG content is an early indication of osteoarthritis (OA), a disease that deteriorates the mechanical integrity of cartilage. To date, early diagnosis of OA remains nearly impossible. Using contrast enhanced computed tomography (CECT), tissues such as cartilage can be visualized to ascertain properties such as thickness, morphology, and biochemical states of various tissues. Nanoparticles (NPs) are of particular interest as a CECT contrast agent due to their modifiable properties such as composition, diameter, high surface area, and confined electronic structure. NPs containing gold, bismuth, and tantalum have been used as X-ray contrast media for CECT. Tantalum is biocompatible, can be functionalized with a variety of silane ligands, and absorbs a greater fraction of X-rays compared to conventional iodinated contrast agents, making it an attractive contrast agent material for CECT. We have synthesized a new positively charged tantalum-oxide nanoparticle (Ta2O5 NP) as a contrast agent for CECT assessment of cartilage health and integrity. The NPs were synthesized with positively charged tetra-ammonium ligands to bind to anionic GAGs and a short polyethylene glycol layer to improve biocompatibility. We have successfully imaged naturally occurring osteoarthritic defects in ex vivo human metacarpal phalangeal joints using CECT with NPs with different surface charges. Additionally, we measured NP diffusion into tissue and subsequently characterized the biochemical and biomechanical state of the entire cartilage.

Self-Assembly of Polysaccharide LC Domains over Millimeter Scale During Evaporation and Their Anisotropically Swelling Hydrogels Gargi Joshi, Kosuke Okeyoshi, Maiko K. Okajima and Tatsuo Kaneko; Japan Advanced Institute of Science and Technology, Japan

Self-assembly of biopolymers like proteins and polysaccharides, through their liquid crystalline (LC) state, provides reconfigurable structures in nature. These are effectively mimicked by researchers to develop highly ordered architectures through various self-assembly processes. We reported the self-assembly of polysaccharides, sacran and xanthan gum upon drying their aqueous LC solution from a limiting interface as an example of instability-driven pattern formation. By controlling the cell width, the polysaccharide deposited to form multiple vertical membranes, bridging the millimeter-scale gap between the substrates, partitioning the available space. The interesting aspect is the size of the LC structural unit (mesogen) of sacran. It has been reported to be 1 µm in diameter and < 20 µm in length, the aspect ratio being more than 20, when compared to other popular biopolymers like CNF, DNA. The size and interactions between these mesogenic units have not been considered. The basic
theory is that as the receding air-water evaporative interface reaches their location, the domains are formed like a crust/ skin-layer. In order to create a new surface, energy is needed which comes from the supplied temperature as thermal energy. They experience capillary forces towards the substrate-wall as well as strong interparticle capillary interactions. In this competition of forces, the interparticle interaction is long-ranged and also stronger, resulting in bridging depositions. In this study, we have explored the effect of the size of the LC domains of the polysaccharide solution in the space partitioning phenomenon.

G. J. is grateful for the JSPS Fellowship and the KAKEHNI Grant #JP18J11881.
Then, we have fabricated LCE lattice structures based on the design guidelines and characterized their mechanical behaviors. We synthesized main-chain LCEs in a replica mold of the desired shape through a two-stage thiol–acrylate reaction. Before the second stage reaction, the LCE structures were detached from the mold and different amount of strain was applied to the structures. In accordance with generated strain distribution, mesogens were differently aligned inside the structures. As a result, different modulus distribution was achieved. After that, the alignment was fixed with UV light and the structures were restored to their original shape by heating. Then, we investigated mechanical behaviors of differently “programmed” structures using universal testing system and found that the structures show different mechanical behaviors depending on the changed modulus distribution as a result of “programming”. For example, a structure with the same shape changed its behavior from positive stiffness to almost zero stiffness, i.e. stresses maintained nearly constant within broad strain range, after programming. In addition, we will present our characterization results of strain distribution in the LCE lattices and resulting modulus change to compare with the prediction from Bayesian optimization as well as our studies of combining different types of programmed structures to achieve various mechanical behaviors.

We envision that our findings can contribute to enabling the next generation meta-materials by providing the capability to manipulate the mechanical behaviors of lattices through a simple programming procedure with applications including load bearing (positive stiffness), energy absorbing (negative stiffness), and large actuation with minimum input energy (near zero stiffness). It can also contribute to improving an engineering system efficiency by enabling multi-functionalities from one component.

SB01.09.12
Facile Fabrication of Micro/Nano-Structured Wrinkles by Controlling Viscoelasticity of Soft Elastic Substrates Eun Seon Kim1,2, Sung Hyun Kim1, Sang-Jin Lee1, Dong Hack Suh2 and Woo Jin Choi1; 1KRICT, Korea (the Republic of); 2Hanyang University, Korea (the Republic of)

Wrinkling rendered by the buckling of a strained stiff layer attached to a soft elastomer substrate has been widely used in various applications such as smart adhesion, optical grating, precision metrology, surface engineering, stretchable electronics, and antifouling coating. This is because it is an efficient and low-cost strategy to control surface morphology. There were many researches on the formation of wrinkle surface in film/substrate bilayers through compressive stresses by various factors such as mechanical compression, thermal expansion mismatch, lattice mismatch, solvent-induced swelling, capillarity force, environmental stimulus, and bubble inflation, etc. Especially, the method of strain mismatch leads to thermal stress from a difference in the coefficient of thermal expansion between thin films and soft substrates for producing a wrinkled structure which has been extensively investigated throughout theoretical and experimental approaches. Bowden et al. first reported that complex surface patterns are formed by depositing a metal thin film onto a polydimethylsiloxane (PDMS) due to thermal contraction of the soft substrate by electron beam evaporation1. Stafford et al. observed that the formation of complex surface patterns can be controlled by elastic modulus depending on the difference in thermal expansion when the ultrathin amorphous polymer on a soft elastic substrate2. Im et al. have theoretically studied that the viscoelastic properties of thin polymer films play an important role in fabricating ordered structures by modeling3. However, rheological properties of viscoelastic substrates for developing wrinkle structures by the sputtering system are still insufficient up to now.

In this research, we report the controlled surface morphologies of fluorocarbon thin films deposited on soft elastic substrates by a mid-frequency sputtering using the sputtering target of carbon nanotube/polytetrafluoroethylene composite polymer. The fluorocarbon thin films deposition and particle bombardment can produce heat the PDMS substrates greatly during the sputtering process. We demonstrate a one-step method to obtain the micro/nanostructured wrinkles by changing the viscoelastic properties of PDMS substrates. The viscoelasticity of substrates was controlled with various amount of curing agent and different curing conditions such as temperature and time. The surface morphology for these samples strongly depended on the viscoelastic properties of PDMS substrates. The rheological properties and surface morphologies were systematically studied and discussed. This study provides a facile and effective method for fabricating different wrinkle structures by controlling the viscoelasticity of PDMS substrates.

The nanocomposite coating system was constructed by a composite film composed of inorganic polymer and graphene for metal protection. The anti-corrosive technology for metal protection is essential in contemporary industry. Although the metal species such as copper (Cu), aluminum (Al), stainless steel, etc., have a very important role in wide commercial application fields including building, automobiles, electronics, etc., they are susceptible to corrosion; spontaneous degradation reaction showing similar mechanism to electrochemical reaction at the interface between electrode and electrolyte [1]. This kind of reaction leads to undesirable deterioration of own functional properties by structure deformation of materials and a lot of financial losses. So far, most researches have been focused on the fabrication of insulating coating barrier as one of the candidates to break through this problem [2,3]. However, the necessity which requires multifunctional roles not only defending main materials but also having additional functionality such as electrical conductivity and thermal conductivity came to the fore. Furthermore, selectivity properties against various environmental factors for protective barrier layer are issues in recent semiconductor electronics, many devices including anti-icing, electromagnetic shielding (EMI) and energy storage systems [4-6].

With this consideration, we studied about dual function behaviors of electrically conductive anti-corrosion coating layer which is composed of inorganic polymers such as polysiloxane (PSX) or polysilazane (PSZ) and graphene. Inorganic polymer, PSX or PSZ, was used as a main barrier matrix with excellent chemical stability and defect covering agent for graphene and graphene, a 2-dimensional carbon allotrope, was applied as a conductive filler and a stress relaxation agent of composite matrix. The Inorganic polymer-graphene nanocomposite shield layer was fabricated on metal substrate such as Cu or Al by a simple coating process using a metering rod or a doctor blade. After curing process, the inorganic polymer-graphene nanocomposite barrier film showed enhanced corrosion inhibition properties when they were exposed to seawater (3.5 wt% NaCl) or sulfuric acid (H2SO4) comparing to both of bare Cu or Al substrates. To be specific, the corrosion rate of inorganic polymer-graphene nanocomposite film was prominently decreased (minimum 1/40th compared to bare Cu in 3.5 wt% NaCl solution and 1/2000th compared to bare Al in 0.5M H2SO4 solution) and charge transfer resistance was noticeably improved (minimum 2×10^4 times higher than bare Cu in 3.5 wt% NaCl solution and 2.77×10^6 times higher than bare Al in 0.5M H2SO4 solution). Furthermore, this coating film exhibits the electrical conductivity enhancement as increase of conductive carbon filler to maximum 1.70×10^3 S m^-1 on Cu and to 35 S m^-1 on Al. With the result of this study, the inorganic polymer-graphene nanocomposite coating layer exhibits superior multifunction properties including anti-corrosion and electrical conductivity with the synergetic effect between inorganic polymer and graphene.

We believe that further understanding and modifying inorganic polymer-graphene nanocomposite coating system has the potential to broaden the area of application which needs multifunctionality in the field of thermal interface materials, EMI, anti-icing and etc.

cross-linkers to make solid-state chemical ion gels. We fabricated stretchable ion gels that can be applicable to various electronic/optoelectronic devices by controlling the crosslinking density of the network polymer. By modifying the interface of the target substrate, stretchable devices could be stick to various substrates including SiO₂, metal, plastic, and rubber surfaces, which clearly demonstrates versatility of the adhesive ion gels for E-skin devices. We introduced adhesive ion gels to fabricate flexible strain sensors. Electrical properties of the flexible sensors including sensitivity, linearity, transmittance, and durability were systematically investigated. The resulting sensors using adhesive ion gels performed better than normal ion gel sensors without adhesive functionality. Furthermore, we controlled the structure and morphology of the adhesive ion gels to enhance the sensing performance.

Compositional and Morphological Study on a Polyaniline (PANI) Hydrogel for a 3D Porous Electrode Ji Hye Kim¹, Ju-Hee So², Sungkon Kim³ and Hyung-Jun Koo¹; ¹Seoul National University of Science and Technology, Korea (the Republic of); ²Korea Institute of Industrial Technology, Korea (the Republic of); ³Chonbuk National University, Korea (the Republic of)

Since any electrochemical reactions occur at surface of electrodes, an electrode with well-defined porous structure, and therefore high surface area, would be preferred. Upon crosslinking with phytic acid, polyaniline (PANI) forms a conducting hydrogel with a hierarchical 3-D porous structure. Such a PANI-based hydrogel could be a promising electrode for various electrochemical applications. Here, we present the effect of compositions in preparation of PANI on its pore morphology and electrical property. It turns out that the composition of monomer, initiator, and crosslinker in preparation has a significant influence on the morphology of the PANI hydrogel. As initiator/crosslinker increase or monomer decreases, the PANI conducting hydrogel has denser morphology with decreased pore size, resulting in higher electrical conductivity. The PANI conducting hydrogel with 3-D porous morphology could serve as an efficient electrode of an electrochemical capacitors. In the 3-electrode configuration, the PANI hydrogel electrode prepared at the optimized compositions exhibited 294 mF/cm² of capacitance with ~50% retention rate after 5000 cycles. Finally, we fabricated a practical capacitor with two symmetric PANI hydrogel electrodes, which shows 195 mF/cm² of capacitance with improved cycle stability of 80% retention rate.

SB01.09.16
Type 2 Nanotheranostics—MRI Guided Hyperthermia Using Magnetic Softness Tuned γ-Iron Oxide (MSTIO) Nanoprobes Jiwook Kim and Seongtae Bae; University of South Carolina, United States

Theranostics is a combination of the terms diagnosis and therapeutic. This concept was further developed to Nano-Theranostics with advancements in nanotechnology over the last decade. In the Nano-Theranostics, nanoscale imaging module, targeting module, or therapeutic module were incorporated into a single system by chemical conjugation or encapsulation methods. However, the multiple compositions and complex structure of these Nano-Theranostics agents (we call this “Type 1 Nano-Theranostics agent”) have several hurdles (i.e., low reaction yield, high synthetic cost, and difficulty in verifying their toxicity) for biomedical applications. Here, we introduce next-generation of Nano-Theranostics agent, called “Type 2 Nano-Theranostics” which is MRI guided hyperthermia using magnetic softness tuned g-iron oxide (γ-Fe₂O₃, MSTIO) Nanoprobes. While the conventional magnetic nanoparticle-based agents are optimized for the individual function of MR effect or heat induction power, MSTIO possesses both exceptionally high intrinsic loss power (ILP, ~ 7.0 nHm²kg⁻¹) at a biologically safe range of AC magnetic field (H_{appl} f_{appl} = 5.0×10⁶ Am⁻¹s⁻¹) and a significantly enhanced r2-relaxivity of MRI (r₂ = 647.94 mM⁻¹s⁻¹). The enhanced hyperthermic antitumoral effects and T₂-MR contrast imaging of MSTIO tested in rat models are primarily due to the dramatically increased saturation magnetization (M_s), resulted from the precisely controlled occupation of Ni²⁺/Zn²⁺ cations in T₂ and O₃ sites. We also found that 20-30 nm of the γ-Fe₂O₃, nanoparticles with ultra-thin surface layer shows best heat induction performance under the bio-safe range of AC magnetic field (f=100 kHz, H=120 Oe) from the numerical simulations and experimental results. Due to their excellent dual functionalities implemented in a simple system, we believe that MSTIO nanoprobe will be one of the best candidates of Type 2 Nano-Theranostics for future nanomedicine.

SB01.09.17
Reconfigurable Photonic Surfaces Assembled by Amphiphilic Photonic Tiles at the Air-Water Interface Jong Bin Kim, Gun Ho Lee and Shin-Hyun Kim; KAIST, Korea (the Republic of)
Many organisms in nature have a photonic epidermis composed of an assembly of iridophores, iridocytes, or iridoplasts rather than a monolithic photonic layer. The cell assembly enables the organisms to reorganize the photonic surfaces during dynamic transformation and growth. Inspired by the organisms, we propose the two-dimensional (2D) assembly of amphiphilic photonic tiles at the air-water interface to provide unprecedented reconfigurability that has never been achieved with a conventional film format of the colloidal lattice. The photonic tiles are prepared using a photocurable dispersion of silica particles in a carefully-selected resin as a photonic ink. In the ink, the silica particles spontaneously form nonclose-packed face-centered cubic (fcc) lattice due to the interparticle repulsion caused by the solvation layer. The nonclose-packed lattice is instantly captured in a polymeric matrix upon photopolymerization of the resin, where the shape of the colloid-polymer composite is featured to a hexagonal disc by photolithography. The silica particles are selectively etched out from the hexagonal disc, which results in a porous internal structure with strong iridescence. To render the photonic discs amphiphilic, the top side surfaces of the tile are subjected to reactive ion etching with sulfur hexafluoride gas, which makes the surfaces highly porous and hydrophobic according to Cassie-Baxter model. As a result, the photonic tiles sit on the air-water interface while exposing the body of the tile to the air. This configuration significantly deforms the interface by the action of gravity, which leads to the strong capillary attraction between the tiles. Therefore, the tiles assemble to form a dense photonic layer without large voids under gentle agitation. The assembly of photonic tiles rapidly adapts to the dynamic undulation of the interface and shape transformation of the container as the individual tiles can rearrange while the capillary force holds the tiles assembled. The assembly can be applied to a shape-shifting reflective display. The assembly can be also transferred onto a solid substrate by either using the Langmuir-Blodgett method or forming an elastomer on the top of the assembly. The two methods construct a highly reflective photonic coating on a wide range of substrates, which can also make a flexible photonic device. In addition, the tiles can be assembled on the surface of the water drop, forming a photonic liquid marble. It potentially serves as a reservoir for cells and algae and helps the organisms to be photo-protected and photosynthetically efficient, which is modeled after nature mentioned in the introduction. We believe that the interfacial assembly of amphiphilic photonic tiles will provide new means to create high-quality photonic coatings on wide solid supports as well as highly reconfigurable photonic surfaces at free interfaces.

Colloidal, Nanoelectronic State Machines Based on 2D Materials as Smart Aerosolized Probes and Recorders
Volodymyr Koman, Pingwei Liu, Daichi Kozawa, Albert T. Liu and Michael Strano; Massachusetts Institute of Technology, United States

A here-to-fore unexplored property of two-dimensional (2D) electronic materials is their ability to graft modular electronic functionality onto colloidal particles so as to access local hydrodynamics in fluids to impart mobility and enter spaces inaccessible to larger electronic systems. Herein, we demonstrate the design and fabrication of fully autonomous state machines (only 100x100x1 µm³ in size) built onto a SU-8 particles powered by a 2D material-based photodiode. The on-board circuit connects a chemiresistor element and a memristor element, enabling the detection and storage of information after aerosolization, hydrodynamic propulsion to targets over 0.6 m away, and large area surface sensing of triethylamine, ammonia and aerosolized soot in inaccessible locations. An incorporated retro-reflector design allows for a facile position location using laser-scanning optical detection. Such state machines may find widespread application as probes in confined environments, such as the human digestive tract, oil and gas conduits, chemical and biosynthetic reactors, and autonomous environmental sensors.

Control of Liquid Transport Velocity of Open-Type Micro-Blade Arrays Inspired by Wharf Roach
Rikima Kuwada, Koji Muto and Daisuke Ishii; Nagoya Institute of Technology, Japan

Recently, microfluidic devices are much paid attention, because these are used in many ways such as bio analysis, chemical synthesis and heat pipe devices. However, current microfluidic devices have some problems, that these need high pressure to transport liquid, since these are composed of some closed tubes. And more, these are susceptible to bubble entrapment, inpurities, and consequently variation in the metered volume. In order to solve these problems, we focused on a coastal animal wharf roach that has open-type flow micro-passages on the legs which can transport water to their gills spontaneously by the surface free energy. It was found out that the flow passages were composed of micro-blades oriented in several parallel lines. We fabricated a series of flow passages
composed of micro-scaled epoxy blades on silicon wafer by photolithography inspired by those on legs of Wharf Roach. Fabricated samples can also transport liquid spontaneously against gravity. The purpose of this research was to clarify the factors controlling the velocity of liquid transport by changing several parameters defined the size, gap and arrangement of the micro-scaled blades. The velocity through these flow passages was experimentally determined by measuring the vertical rise of liquid column across a series of vertical microstructure surfaces with varying characteristic dimensions. The plot of transport distance to elapsed time is accurately approximated by the equation of motion for the capillary rise of liquid in a porous medium using Darcy law.

From these results, it was found out that the velocity of liquid transport through these flow passages was determined by the balance of the capillary pressure, the weight of the liquid column, and the pressure loss defined by the kinematic viscosity, the porosity and the permeability. Furthermore, it is suggested that the capillary pressure, the porosity and the permeability can be controlled by several parameters of the sample, and the liquid transport velocity can also be adjusted.

Transparent Wearable 3D Touch—Self-Generated Multiscale Structure Engineered by Laser-Induced Thermal Gradient Kim Kyun Kyu and Seunghwan Ko; Seoul National University, Korea (the Republic of)

Pressure-sensitive touch panels provide an intuitive and natural method to sketch and write with new levels of control and interactivity. However, they require a combination of sensors or a stylus-based interface to identify 3D signals, which prevents their implementation in a wide spectrum of applications. Here, we report a transparent and flexible 3D touch which operates in a single device with the assistance of multiscale structures and a nanowire percolation network. The device could assign functionalities to objects without reference to any varying surfaces. Rigorous theoretical analysis allowed us to achieve the target pressure sensitivity, and successful 3D data acquisition was carried out through the 6-wire measuring technique

SB01.09.21
A Degradation-Induced Shape Memory Elastomer Melodie Lawton1,1, Caitlin D'Ambrosio1, Meaghan Yant1, Devon A. Shipp2 and Patrick T. Mather1; 1Bucknell University, United States; 2Clarkson University, United States

Tasking polymeric materials with functionalities beyond their primary (often load-bearing) role has gained significant interest in the development of smart materials. We have recently developed a reconfigurable shape memory elastomeric composite (Re-SMEC) featuring a water-degradable, elastomeric polyanhydride (PAH) matrix that, unlike most polymeric shape memory systems, features an original geometry that can be thermomechanically altered at will. In our past work, we reported that this reconfigurability was possible since the constituent bonds of the polyanhydride elastomeric network undergo dynamic covalent exchange between neighboring anhydride groups. This exchange enables one to customize the geometry of the “target” shape during shape memory activation. Taking advantage of these new properties, we present a new shape memory elastomeric composite featuring elastic fibers as the permanent, memory retaining phase, and a polyanhydride-based elastomer matrix as the fixing phase. Unlike other fiber-reinforced shape memory systems, where the fibrous phase typically serves to temporarily fix geometry, this design utilizes a reconfigurable matrix as the shape-fixing phase. Moreover, this new design enables recovery of the original shape in response to degradation of the matrix. We report on the degradation profile of this composite, with quantification of mechanical properties and the effect of fiber orientation on this new shape memory phenomenon.

Nanofiller Particles Migration to Polymer Composite Melt Boundaries—Experimental and Numerical Studies Oleg V. Lebedev1,2, Leonty A. Mukhortov1,2 and Alexander N. Ozerin2; 1Moscow Institute of Physics and Technology, Russian Federation; 2Enikolopov Institute of Synthetic Polymer Materials, Russian Federation

In this work a study of an effect of nanofiller particles migration to the polymer composite melt surface was conducted. The effect’s nature was investigated and methods of its control and diagnosis were developed. The results of the work allowed to controllably obtain materials with properties of surface layer drastically different from the properties of the bulk. Such composites are considered as functionally graded materials that attract a lot of attention in recent years from research society and industry.

To experimentally investigate the process of nanosized particle migration, series of composite mixtures were prepared, based on polymer matrix of different types (polypropylene, polyethylene, polystyrene, etc.) and carbon
nanofillers of different aspect ratio, such as single- and multi-walled carbon nanotubes, graphite nanoplatelets, and electroconductive carbon black. Mixing of the components was performed using melt mixing method for a wide range of the filler concentrations values below percolation threshold, which was determined beforehand for each matrix/filler pair. The resulting compounds were processed further into samples of cylindrical shape in a heated press-form with minimal heating and cooling times.

To constantly monitor the filler particle migration to the surface the electrical conductivity measurements were conducted for the melted in a closed heated press-form samples. This allowed to observe steady increase of the material electrical conductivity over time, possible due to the inherited high electrical conductivity of the nanoparticles chosen. The effect of conductivity increase was present for each matrix/filler combinations. Analysis of the filler geometry influence on the characteristic times of the electrical conductivity changes respectively to the percolation threshold values was conducted. Dependencies of the process dynamics on the melt temperature, number of cycles of melting and cooling, etc. were additionally investigated.

Removal of a thin surface layer (< 10μm) of the pre-annealed and instantly cooled solid composite samples demonstrated that the high conductivity is provided by the composite boundary layers enriched with nanoparticles in the course of the annealing, which was also confirmed by the analysis of electron microscopy data of the samples’ fracture surfaces.

To help developing an analytical model describing the process of nanofiller migration to the composite material surface, a numerical model was proposed based on the experimental results for the electrical conductance measurements. The simulations were performed for nanotubes using molecular dynamics methods for ranges of modelling parameters, such as inter-nanoparticle interaction force values, force between the particle and surface, and the temperature of a medium. Different conductivity calculation methods for simulation boxes allowed to plot the dependencies of conductivity of the material on time, which was successfully correlated with experimentally obtained results.

The reported study was funded by RFBR according to the research project 18-29-19112

Ultraflexible and Transparent Pressure-Imaging Skin Using Cellulose/Nanowire Nanohybrid Networks for High-Information-Density Human-Machine Interfaces

Byeongmoon Lee1, Ji-Young Oh2, Hyeon Cho1, Hyungsoo Yoon1, Sujin Jeong1, Nae-Man Park2, Chi-Sun Hwang2, Seong-Deok Ahn2, Jeong-Ik Lee2 and Yongtaek Hong1; 1Seoul National University, Korea (the Republic of); 2Electronics and Telecommunications Research Institute, Korea (the Republic of)

Electronic skin realizes seamless interfaces between human and computers, enabling mechanical and chemical sensing on human skin with applications for healthcare/monitoring devices and user interfaces for augmented reality. Multifunctional devices that can map high-resolution pressure distribution over arbitrary surfaces would enable novel applications such as skin prosthesis, artificial nerve systems for soft robotics, and advanced human-machine interfaces. For this reason, many studies on conformable force sensors have tried to map spatial pressure by employing matrix design and sensor pixels. However, they show poor spatial fidelity mainly due to their low pixel density, crosstalk among pixels, and bulky electrical wires for data acquisition. Furthermore, pressure distribution could be severely distorted by device structures such as uneven or thick sensing layers, structural inhomogeneity, and limited conformability. Therefore, the new homogeneous and conformable design should be developed to bridge the fidelity gap. However, existing methods for flexible or soft pressure sensors show limited design freedom to satisfy the demand due to their impractical fabrication process. Although pressure sensors exploiting contact resistance between engineered micro-/nano-structures and conductive films are promising due to their high stability and fast response time, reported works cannot offer viability because they need bulky micro-fabricated or pre-established structures such as a sponge and tissue paper.

In this work, we propose a homogeneous and ultrathin device structure to autonomously capture and image pressure distribution over 3D surfaces with high spatial fidelity, and appropriate materials and a manufacturing method for highly sensitive and transparent pressure sensors that can be readily integrated into the proposed device.

Specifically, we develop a solution-processable nanohybrid network of nanocellulose and conductive nanowires for ultrathin and transparent piezoresistive pressure sensors. As compared to previously reported cellulose-based piezoresistive pressure sensors where microfibers are coated with conductive nanowires, our nanohybrid network features a nanostructured surface morphology where dense nanocellulose encircles each conductive nanowire. This unique nanostructured surface results in unprecedentedly high sensor sensitivity (> 1000 kPa⁻¹), a fast response time (< 1 ms), and high transparency (~80%). We combine the transparent piezoresistive network coated on an ultrathin
(~1 μm) colorless polyimide (PI) film with a quantum dot-based electroluminescent film. The two functional films conform to each contact object and effectively form conductivity distribution in a continuous domain with minimal distortion of contact pressure. This patterned conductivity brings out high-resolution (> 1000 dpi) electroluminescent imaging of the pressure distribution without the need for pixel structures. The spatial resolution depends only on the thickness of the films, whose effect on output images is systematically investigated by a finite element analysis and measuring images of spatial pressure applied with micropillar arrays. We further demonstrate the feasibility of our approach by constructing high-information-density human-machine interfaces such as a transparent touch interface that can identify the user in addition to touch information. This study provides a new pathway to high-fidelity stimulus imaging with potential applications for bio-imaging, wearable human-machine interfaces, and force-sensing deformable displays. The detailed methods and results will be discussed later.

This work was supported by Institute for Information & Communications Technology Promotion (IITP) grant funded by the Korean government (MSIP) (No.2017-0-00048, Development of Core Technologies for Tactile Input/Output Panels in Skintronics (Skin Electronics)).

**Octopus-Inspired Light-Responsive Smart Adhesive Pads for Macroscopic/Microscopic Applications**

Hochan Lee, Ayoung Choe, Seungyoung Park and Hyunhyub Ko; UNIST, Korea (the Republic of)

Smart adhesive system which easily adhere to and release from a target surface on demand by external signals can be employed in broad applications in medical industry, robotics, industrial transporting system, and smart printing. By employing light-responsive actuation of hydrogel composites and octopus-sucker-like microstructure of elastomer, here, we demonstrate a high-performance light-responsive smart adhesive pad, in which the adhesive properties can be actively and remotely controlled by external light stimulus. The light-responsive hydrogel composite, which consists of a thermo-responsive hydrogel (poly(N-isopropylacrylamide) (pNIPAM)) and photothermal carbon materials, acts with a switchable motion of shrinking/swelling by turning on/off a near IR light. This hydrogel composite on the octopus-sucker-like microcavity-patterned elastomer (polydimethylsiloxane (PDMS)) can generate/remove a differential pressure between the inside and outside of microcavity, which can induce/withdraw an adhesive force to grab/release a foreign target surface. Finally, the light-responsive smart adhesive pad shows a switchable adhesive performance through the control of irradiation of near-IR (NIR) light, enabling the switchable adhesive strength from 0.15 kPa (NIR light ‘off’) to 26.32 kPa (NIR light ‘on’) with an on/off switching ratio of adhesion of 175 in fast response to the remote NIR light without any preload. Thanks to these superior adhesive properties, the smart adhesive pad can be applied to broad macroscopic/microscopic applications such as an adhesive patch which can endure a weight or a micromanipulation to easily pick and release micro/nano-membranes of semiconductors by the remote control of NIR light.

**Control of Lateral Buckling in High Aspect Ratio Structures by Bilayer Formation**

Hyemin Lee¹, Jung Gun Bae², Yerin Ryu¹, Won Bo Lee² and Hyunsik Yoon¹; ¹Seoul National Univ of S&T, Korea (the Republic of); ²Seoul National University, Korea (the Republic of)

Buckled structures originated from the compressive stress on a film have been exploited to generate randomly or regularly grating patterns, or as a method to fabrication of foldable or stretchable devices. Laterally buckled structures, which is resulted from the compression of high aspect ratio line patterns have been reported for an academic interest or an application about the anti-counterfeit patterns generated by a mechanical response. In the presentation, we show the control of the features of laterally buckled patterns by the manipulation of the compressed area in the bilayer system. In addition, we demonstrate a potential application to absorb the mechanical stress by using the unique spring-like structures of lateral buckling.

**Fluorinated Epoxy Siloxane Hybrid Materials for Bio-Fluidic Barrier on Flexible Electronics**

Injun Lee, Wonryung Lee, Yong Ho Kim and Byeong-soo Bae; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Injun Lee, Wonryung Lee Yong Ho Kim, and Byeong-Soo Bae

Wearable Platform Materials Technology Center (WMC)

Dept. of Mater. Sci. & Eng., KAIST, Daejeon 34141, Republic of Korea
The barrier is a key component of bio-integrated electronics, protecting the device from the bio-fluid environment and enabling high performance without degradation over time. Recently, the bio-fluidic barrier on the ultra-thin device offers reliable measurement of various bio-signals from even on skin or organ due to the defect-free passivation layer[1]. To meet the requirement of low water permeability, inorganic material based bio-fluidic barriers such as thermal grown SiO2 [2] and bilayer of SiO2/SiNx[3] have been exhibited superior barrier performance. However, the inorganic materials for the barrier have process incompatibility, including high processing temperature and harsh etching conditions. Thus, the organic materials based on bio-fluidic barriers, such as polyimide[PI][4] and SU-8[5] have been also investigated due to their process compatibility. But such organic-based barriers are unstable under the water environment, resulting in unreliable ultra-thin devices for the bio-applications. Therefore, hybrid material for the bio-fluidic barrier that has advantages of both organic and inorganic is needed.

Here, we demonstrate the siloxane(inorganic) based fluorinated epoxy(organic) hybrid materials(FEH) for the bio-fluidic barrier and confirm the barrier performance for the flexible system by using the solution-processed oxide thin-film transistor(TFT)s on ultra-thin polyimide film. Our sol-gel derived FEH is inorganic-organic hybrid materials for the bio-fluid barrier, which is capable of simple spin-coating and UV-patterning by cationic polymerization without additional etching process. Furthermore, FEH exhibits superior water repellency and hydrophobicity compared to other conventional organic films due to the fluorine functional group, which can be confirmed by magnesium soaking test and water contact angle. To evaluate the electrical stability of the barrier in the bio-fluidic environment, we confirm no leakage through defects of films using electrical impedance spectroscopy analysis. To verify the barrier performance in real-time, we demonstrate the solution-processed indium oxide TFTs with the FEH barrier and measure the transfer characteristics in the phosphate-buffered saline (PBS). The oxide TFT, which is vulnerable to water, passivated by FEH barrier films exhibits transfer characteristics with no dramatically change during 16 hours in the PBS. Furthermore, to realize the FEH barrier for flexible systems, we demonstrate the solution-processed oxide TFTs on 1μm-thick polyimide film with the FEH barrier and successfully measure the transfer characteristic, which is consistent with the result of TFTs on rigid glass wafer. In conclusion, we envisage the potential of our FEH as a bio-fluidic barrier for future bio-integrated devices and advanced electronics.

Promotion of Crystallinity and Actuation of Polyvinylidene Fluoride/Single Walled Carbon Nanotubes Composite for Soft Robotics Applications
Ji Eun Lee¹, Ryan Nam¹, Behnam Ashrafi², Michael Jakubinek², Wajid Chishty², Hani E. Naguib² and Tianhao Chen¹; ¹University of Toronto, Canada; ²National Research Council, Canada

Piezoelectric materials are extensively used as actuators in various sectors such as biomedical, manufacturing and robotics. This is due to its piezoelectric property that allows the material to actuate when an electrical field is applied. Compared to traditional electric motors, piezoelectric polymer actuator, Polyvinylidene Fluoride (PVDF), offer advantages such as conformability, ease of processing, better biomimicking ability, lower cost, higher power-to-weight ratio, increased control, and response time. PVDF is a semi-crystalline polymer where its zigzag all-trans (TTT) b crystal phase is responsible for the actuation ability. To promote this unique crystal phase, there has been research on processing methods, such as the addition of fillers to align and stabilized the TTT conformation on the surfaces of the nanofillers. The current study investigates the use of single-walled carbon nanotubes (SWCNT) in a PVDF matrix to increase: (i) its piezoelectric property for enhanced actuation and (ii) its mechanical property to withstand the environmental conditions of various actuation applications. The weight percentage (wt.%) of SWCNT within the PVDF matrix and its dispersion, enhanced actuation displacement, and response time due to higher conductivity were explored with parametric studies. This study also reports on the effects of popular processing
methods (i.e., mechanical stretching) in promoting the alignment of the fillers, resulting in an alignment of the crystal structures. Initial results found an optimal weight percentage of SWCNT to be 0.5 and 3%, where both mechanical, electrical, and actuation properties excelled. At 1 wt.% CNT, the composite increased its conductivity by 4 magnitudes, and its density and ultimate yield strength increased by a factor of 70%. While its b content at 1 wt.% had no significant change, at 2 wt.% CNT, the b phase increase to 40%, 10% higher than that of the pure PVDF sample. With an increase in conductivity and piezoelectric property, the material’s actuation can be performed with greater displacement and lower power. This study provides insight to future research utilizing piezoelectric materials for actuation application that can advance into soft robotics.

SB01.09.28
Antibacterial Surface with Novel Biocompatible Metal-Ceramic Composite Material via Sputtering Method for Wearable Devices Joon-Min Lee1,2 and Chan-Hwa Hong2; 1University of Science and Technology, Korea (the Republic of); 2Electronics and Telecommunications Research Institute, Korea (the Republic of)

Antibacterial surface coatings have become a primary solution for preventing device-associated infections (DAIs). Even though extensive progress reducing DAIs has currently been made, recent antibacterial surface coating methods are complicated and do not effectively kill infectious bacteria.

In this research, we propose novel biocompatible metal-ceramic composite material that exhibits selective bacteria-killing properties. Because the metal-ceramic composite surface was coated by a sputtering method known as physical vapor deposition (PVD) at room temperature, this method can be applied to flexible and stretchable substrates of wearable devices.

We confirmed the metal-ceramic composite surface exhibits a damaging effect to both Gram-positive bacteria (S. aureus) and Gram-negative bacteria (E. coli). Thus, the biocompatible metal-ceramic composite material surface which induced in this research can be a good candidate for the antibacterial solution of biomedical and wearable devices.

Continuous Gradation of Multi-Material Biopolymer Hydrogels Nicolas A. Lee1, Ramon Weber1, Joseph Kennedy1, Jorge Duro-Royo1 and Neri Oxman1,2; 1Massachusetts Institute of Technology, United States; 2Massachusetts Institute of Technology, Media Lab, United States

We present advancements to a water-based digital fabrication and design platform that allow for the continuous gradation of mechanical properties, biocompatibility, and biodegradability in pectin-based biopolymer hydrogels. Continuous gradation of these properties across scales ranging from centimeters to meters are achieved using the same fabrication methods and computational workflow. Fabrication parameters including extrusion pressure and feedrate are assigned and varied without discretization, allowing material proportions to be precisely tuned by graded computational inputs. Localized diffusion of extruded materials further increases the continuity of multi-material transitions beyond the limits of mechanical resolution.

Both functionally graded and homogeneous combinations of silk, pectin, and chitosan hydrogels are presented and characterized with a focus on the ability to tune stiffness, dissociation rate, and the proliferation rate of biological agents as independent variables The implemented digital-fabrication system further enables the real-time modification of extrusion parameters through feedback-driven control logics, thereby allowing the further customization of hydrogel properties in response to environmental parameters. These capabilities constitute a set of methods by which a diverse array of material properties can be precisely tuned and spatially templated from a relatively limited material palette for the creation of functionally-graded multiscale hydrogels.

Colorimetric Recording of Thermal Conditions Using Thermal Creep Behavior of Polymeric Inverse Opals Seung Yeol Lee, Joon-Seok Lee and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

It is important to record thermal history in our daily lives. Although conventional digital-based thermometers have a high accuracy of temperature measurement and its recording, they usually consist of electronic circuit board, battery,
and display as well as temperature sensor, which are expensive and not disposable. Moreover, the electronic thermometers have difficulties on applying to an infant skin for monitoring long-time fever or applying to packages of edible products and cosmetics for checking staleness, causing intense demand for disposable, patch-type thermal recorders. The non-electronic, disposable thermal recorders can be prepared by using materials that have colorimetric response for temperature. Metallic nanoparticles, thermochromic dyes, fluorescent dyes, or liquid crystals have been used as constituent materials for the temperature recording. However, it is elusive to decouple temperature and time from color change of the materials.

Here, we design photonic films that record thermal condition through irreversible structural deformation and intuitively display the thermal condition as color patterns. The photonic films are polymeric inverse opals whose frameworks are made of negative photoresist. When the polymeric inverse opals are heated up, they experience creep deformation due to the large surface energy at the pores, causing shrinkage. Polymeric inverse opals attached on a solid substrate show the shrinkage along the direction normal to the substrate while maintaining regularity of their cavity array. This anisotropic shrinkage leads to a blue-shift of the structural color. The rate of the blue-shift or equivalently rate of deformation strongly depends on the temperature. The relation between the rate and temperature can be described by time-temperature superposition principle or Williams-Landel-Ferry (WLF) model. That is, time and temperature are equivalent so that it is difficult to separately estimate time and temperature from the single magnitude of the blue-shift. To decouple and separately estimate temperature and time for isothermal heating, crosslinking density of the negative photoresist is regioselectively adjusted by controlling ultraviolet (UV) dose, which determines thermal and mechanical properties of the photoresist. As the different crosslinking density provides different time-temperature relation, several independent relations can be obtained from a set of distinct UV doses. For isothermal heating, an invisible pattern with regioselective UV doses turns into a multicolor pattern. Using the multiple structural colors of the single inverse opal film, multiple superposition equations are deduced, from which temperature and time are separately estimated. To the best of our knowledge, there has been no thermal recorder that is able to decouple temperature and time. Our patch-type inverse opal is potentially useful as the disposable thermal recorders for various applications.

SB01.09.31
A Facile Fabrication Method for Bio-Inspired Compound Eyes with Printing and Dry-Phase Rubbing Process Seunghwan Lee, Byeongmoon Lee and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Bio-inspired compound (BIC) eyes have been emerging as a main component of optical systems, and many researchers have been interested in their unique optical characteristics such as wide field-of-view, low-aberration, and high sensitivity to light [1,2]. To fabricate BIC eyes structures, several methods are generally used such as precision machining, thermal reflow, and femtosecond laser writing [3-5]. However, these methods are time-consuming and involve high-cost associated with photolithography and etching. Self-assembly of microparticles in liquid can be an alternative method [6] because it does not require vacuum system. But it is not appropriate for large-area fabrication and has a disadvantage in that the process control is difficult.

In this work, we report a facile fabrication method for BIC eyes with printing and dry-rubbing assembly process. Firstly, a hemispherical lens is fabricated by dispenser printing method, which is suitable for rapid-processing of optical components [7]. After that, we adopt dry-rubbing process, which is one of the methods for arranging microparticles in dry-phase [8], to form microparticle monolayer onto the surface of hemispherical lens. This hierarchical microstructure is used as a template of BIE eyes, and replicated in soft materials including polydimethylsiloxane and ultraviolet-curable epoxy resin. Because the BIC eyes structure is fabricated from soft materials, it has stretchability, thus it is expected that the optical properties can be easily tuned by applying mechanical strain. We believe that our method can be applied to the various imaging systems such as cameras, endoscopies, and light-emitting devices. Detail fabrication process and experimental results will be discussed at the conference.

Facile Synthesis of Thermo-Plasticized Cellulose via Graft of ε-decalactone in Ionic Liquid
Woojin Lee, Yongjun Ahn, Dae-Yeon Won and Seung-Yeop Kwak; Seoul National University, Korea (the Republic of)

Natural polymer is one of the most promising material to reduce dependence on petroleum-based polymer. Cellulose is the most abundant natural polymer on the planet. In particular, the use of cellulose is not only a fundamental solution to the focused microplastic problem, but also is high utilization value as industrial material due to high strength, biodegradability and thermal stability. However, it is well known that cellulose does not have $T_g$ and melting temperature because of their strong hydrogen bonding network and chain rigidity. These limitation makes difficult to be thermally formed as certain shape and control mechanical properties to apply industrial fields. Therefore, it is necessary to develop technology capable of controlling strength, flexibility, and stretchability by inducing thermoplastic properties. Many researchers have studied methods of microstructural change to develop thermo-plasticized cellulose by introducing macromolecules on cellulose backbone. However, those methods have critical limitation because of low efficiency of plasticization and complex process that precedes the synthesis of cellulose derivatives.

In this study, we developed method to efficiently plasticize cellulose via change of grafting architecture which composed of ester molecules. To control chain flexibility and free volume, three different types of grafting molecules were employed; ε-caprolactone (ε-CL) / Cell-g-PCL, ε-decalactone (ε-DL) / Cell-g-PDL, and L-lactide / Cell-g-PLLA. The grafting molecules were synthesized at hydroxyl groups on cellulose backbone via ring-opening polymerization in 1-buthyl-3-methyl-imidazolium chloride, which was observed by $^1$H NMR and FTIR. Furthermore, degree of polymerization (DP) of grafted molecules was controlled to confirm effect of side chain size on plasticization performance. The microstructure of cellulose was significantly disrupted by grafting molecules. This deconstruction behavior became more clear when the size of grafting molecules was larger. Despite of similar molecular weight of grafted molecules, the branched architecture easily dissociated the cellulose crystalline. This results led to decrease of glass transition temperature ($T_g$) of cellulose. ε-DL-grafted cellulose exhibited $T_g$ at 30°C, while $T_g$ in ε-CL and L-lactide-grafted cellulose was not observed in similar DP. This results suggested that the grafting molecules with branched structure was more effective to hinder intra- and inter-chain network of cellulose, compared to linear structure.

Femtosecond Laser-Assisted Etching for Anti-Biofouling and Anti-Fogging Endoscope Lenses with Physical and Chemical Durability
Yeontaek Lee1, Jaeho Park2, Hojeong Jeon2 and Jungmok Seo1; 1Yonsei University, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of)

Clear endoscopic vision is essential for laparoscopic surgery. However, body fluids such as blood and peritoneal fluid cause sight loss, which make the surgical operation difficult. Conventional methods such as irrigation, rubbing lenses, and particle-based porous coating infused with lubricant have been conducted to prevent sight loss, but functional stability issues are not solved[1]. Here, we present directly engraved nano-microstructure lubricating (DENL) method, which demonstrates anti-biofouling and anti-fogging ability without any additional device and strong physical and chemical durability due to engraved nano-microstructure. DENL method involves the formation of robust nano-microstructure on the endoscopy lenses via etching with a femtosecond laser. After the process, Fluorine-based self-assembly monolayer (SAM) was applied on the substrate to enhance the chemical affinity of the substrate to perfluorocarbon-based lubricant. We further demonstrated that the developed lens maintained a transmittance of 80% in the visible light region and confirmed its anti-biofouling and anti-fogging ability via dipping (>5 cycles) and fogging (>30 mins, >RH 90%) test using various body fluids. Also, the clear vision was
secured even in extreme condition where various attempts were made to damage the developed lenses via exposing it to various chemical solutions and mechanical stresses. We believe that the endoscopic lenses produced by DENL method bring excellent benefits in endoscopic surgery compared to a conventional method by securing clear sight for stable operation and miniaturizing the endoscopic instrument for minimally invasive surgery.

Optimizing Optical and Thermal Properties of Polyethylene Aerogels for Radiative Cooling Arny Leroy, Bikram Bhatia, Lin Zhao and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Radiative cooling enables passive cooling of terrestrial objects to sub-ambient temperatures by rejecting thermally emitted infrared radiation to the cold outer space through the infrared (IR) transparent window of the earth’s atmosphere (8-13 µm). However, achieving low sub-ambient emitter temperatures and high cooling power during the day under direct sunlight remains a challenge due to significant absorption of solar irradiation and high parasitic heat gains from the ambient environment. In this work, we address these challenges by developing polyethylene aerogels (PEAs) covers that are optimized to achieve high solar reflection, near-perfect infrared transmittance and ultra-low thermal conductivity which can minimize solar absorption and parasitic heat gains at the emitter. The PEA samples were fabricated using thermally induced phase separation of polyethylene in a solvent followed by supercritical CO₂ solvent extraction. The optical and thermal properties were optimized by altering the nanoporous structure of the PEA using different solvents (decalin, paraffin oil or paraffin wax) and varying the density (between 10 and 80 kg/m³) of the aerogel. The optical characterization of the fabricated samples revealed a solar-weighted reflectance as high as 92% and a mid-infrared (8-13 µm) transmittance as high as 80% for a 6 mm thick sample. We also performed a detailed thermal characterization of PEA samples using a custom-made guarded hot plate thermal conductivity setup and measured thermal conductivity as low as 28 mW/mK. By performing measurements under different gas pressures and boundary conditions (optically black or reflective boundaries), we were further able to experimentally decompose the total thermal conductivity \( k \) of PEA into its three subcomponents – solid \( k_s \), gaseous \( k_g \), and radiative \( k_r \). Finally, we performed outdoor experiments to demonstrate the benefits (ultra-low thermal conductivity and high solar reflectivity) of our optimized PEA for daytime radiative cooling. Under direct sunlight at solar noon, we measured a sub-ambient cooling of up to 13 °C for an emitter covered with 12 mm thick PEA – greatly surpassing the performance (1.7 °C sub-ambient cooling) of a similar emitter without PEA.

Macroscopic Actuators Based on Super-Aligned VO₂ Nanowire @ CNT Bimorph Yuxing Liang, Pengcheng Chen and Chun Cheng; SUSTech, China

Vanadium dioxide (VO₂) is an ideal inorganic driving material for actuators with outstanding performance due to its giant power density (7 J/cm³) and ultrafast response (~ picosecond). Single-crystalline VO₂ nanowires (NWs) have demonstrated supreme actuation capabilities while the VO₂-based flexible devices up to centimeter-size toward macroscale robotics are rarely explored. Here, we develop a kind of macroscopic, flexible and all-inorganic bimorph actuators composed of super-aligned VO₂ NWs and carbon nanotube (CNT) films for the first time. Super-aligned VO₂ NW films in large scale (several square centimeters) were achieved by assembling and post-annealing ultra-long \( \text{H}_2\text{V}_2\text{O}_5 \) NWs. The as-grown highly-anisotropic VO₂@CNT films showed tailoring direction-dependent bending morphologies and actuation performance, in which giant displacement/length of 0.83; high power density of 3.2 J/cm²; two orders of magnitude higher than mammalian muscle, fast response up to ~15 Hz, and long lifetime more than 1 million actuation cycles were demonstrated. The excellent thermal/electrical conductivity and light absorption of CNT thin films enable the actuators highly responsive to multiple stimuli including heat, light, and electricity. Notably, the whole-inorganic structure as well as remarkable anisotropy allow the remarkable actuation of VO₂ NWs in a macroscopic scale mechanical device with fantastic performance for versatile applications, including biomimetic geometry, mini jack, inspect wing, mini elephant trunk, torsional artificial muscle, etc.

Gapless Total Transfer for Skin Electronic Devices Jong Tae Lim, Bock Soon Na, Himchan Oh, Yun-Jeong Kim, Hye-Jin Kim, Sung Haeng Cho, Chi-Sun Hwang, Kang-Ho Park, Seong Hyun Kim, Seong-Deok Ahn and Jeong-Ik Lee; Electronics and Telecommunications Research Institute, Korea (the Republic of)

Our bodies and smartphones will be connected to the bodyNET in the near future [1]. Electronic devices that can stretch, from circuits and batteries to sensors and screens, will realize with the demand of such bodyNET and will extend our senses and abilities. To fabricate devices within our clothes and accessories, attached to our skin and implanted in our bodies, a new platform transfer technology is required. In particular, the technique of forming conformal contacts, which remove air at the interface, is of paramount importance. Air trapping at the interface cause air to bulge due to small thermal changes during the device driving and even during post-processing such as vacuum, ultraviolet curing, heating and plasma processes, etc. The interfacial air-bulging problem could lead to not only delamination but also the breaking of films and metal interconnections in the devices. As a result, the interfacial expansion of air damages the electrical characteristics of the device. Meanwhile, the degree of air-bulging at the interface could be increased as Young’s modulus of a stretchable materials is low.

In this talk, we introduce how to remove air in the interfaces for the fabrication of skin electronic devices (skintronics). It is possible by using a gapless vacuum laminator with a stretchable jig. Skintronics were designed to the wrinkled structure, to impart stretchiness in one axis direction without destroying the function of the device while stretching or compressing the device. The gapless laminating process consists of a first step of removing air from the interface and a second step of applying pressure. Skintronics are fabricated by four essential fabrication steps. First, polyimide (PI) is spin-coated on a carrier glass. Second, the functional layers constituting the device are individually fabricated on a sample of glass/PI. Third, a sacrificial film (SF) is fabricated on a sample of glass/PI/device, followed by a laser lift-off process to detach a glass from a sample of glass/PI/device/SF. Finally, a sample of PI/device/SF is totally transferred on pre-stretched elastic substrate by a gapless vacuum lamination [2]. Spontaneous wrinkles are formed on skintronics, which has the structure of elastic substrate/PI/device, after both removing a SF and relaxing a stress. Here, we prove that the devices fabricated by a new total transfer method are stable and reproducible in the electrical property during a device driving. Also, we demonstrate that this excellent electrical property of the device is due to the reduction of a long-range-order deformation as well as a formation of conformal contact at the interfaces.

This work was supported by Institute for Information & Communications Technology Promotion (IITP) grant funded by the Korea government (MSIP)(No.2017-0-00048: Development of Core Technologies for Tactile Input/Output Panels in Skintronics(Skin Electronics)).

Photothermal Effect of Fe3O4 and Fe3O4@Cu2-xS Nanoparticles Coating for Energy-Efficient Applications Jou Lin, Yuan Zhao and Donglu Shi; University of Cincinnati, United States

Energy saving in buildings is a critical problem due to the poor thermal insulations, especially for windows in cold climates. The conventional approach mainly relies on a double-pane design. We have previously reported a concept that by applying photothermal coating on single-pane windows, the thermal insulation property (U-factor) can be dramatically lowered. Both Fe3O4 and Fe3O4@Cu2-xS nanoparticles coatings have shown promising photothermal effect, maintaining good transparency. By comparison of the same average visible transmittances (380-760 nm) of Fe3O4 and Fe3O4@Cu2-xS coatings, Fe3O4@Cu2-xS shows better photothermal effect under simulated solar irradiation (0.1 W/cm²). This is due to the better NIR absorbance of Fe3O4@Cu2-xS nanoparticles compared to Fe3O4 nanoparticles. Similar results were also found through monochromatic irradiations (785 nm laser, 0.1 W/cm²).

Therefore, under the same requirement of visible transmittance, a photothermal coating with better NIR absorbance will perform the better photothermal effect, as well as better thermal insulation improvement for the coated single-pane window.

Forming Diverse Pollen-Like Particles from Liquid Crystalline Oligomers via a Biological Pathway Jiaqi Liu, Asja Radja, Yuchong Gao, Rui Yin, Alison Sweeney and Shu Yang; University of Pennsylvania, United States

Synthetic microparticles have been widely used in drug delivery, imaging, light scattering, pigmentation, cell
mimicking, and understanding of cell phagocytosis. Surface patterns could play important roles in their functions, yet it remains challenging to reproduce spherical microparticles of diverse surface patterns with submicron resolutions. In contrast, nature uses a bottom-up mechanism, via phase separation of extracellular material mechanically coupled to an elastic cell membrane, to create infinitely replicable but diverse surface patterns on spherical cells, such as fungal spores, insect cuticles, and pollen grains. Here, taking the biological pathway that nature has perfected over evolutionary history, we design and fabricate liquid crystal elastomer (LCE) microparticles (diameter, 1 ~ 10 um) with various surface patterns including holes, stripes and spikes, recapitulating the key features in pollen pattern formation that involves phase separation and kinetic arrest of polysaccharides of different chemistry and elasticity at the extracellular membrane. Our approach takes advantage of the anisotropy of liquid crystal oligomers (LCOs) and mixture of different chain lengths in a single droplet. While the chain length of LCOs determines the surface energy and elasticity, thus surface anchoring behaviors at the interface; the heterogeneity of LCOs leads to chain segregation within droplets, thus, facilitating kinetic arrest of LCOs at the interface. Diverse surface patterns are formed after UV curing of the LCO droplets, which are not seen from non-LCOs. Our study also confirms that heterogeneity can be a feature but not a bug in self-assembly. The ability to form diverse and complex surface patterns on microparticles could not only improve our understanding of the general rules about self-assembly in micro- and nano-environments, but also open doors to mass production of functional nano-/micromaterials.

**Optical Engineering of Polymer Composites for Simultaneous Color and Thermal Management** Luis M. Lozano¹,², Yoichiro Tsurimaki³, Yi Huang¹, Gang Chen¹ and Svetlana V. Boriskina¹; ¹Massachusetts Institute of Technology, United States; ²Tecnológico de Monterrey, Mexico

For centuries, optics and photonics have been key enabling technologies in art, design, and architecture in a manner that architects and designers, in their struggle to enrich visible light with color, have experimented with adding pigments, textures, and nanoparticles to construction materials. However, the sunlight not only brings bright visual illumination and color to the building exteriors and interiors, but also radiative heat, which can either be used to warm the buildings or needs to be reflected to avoid overheating. Ideally, the two functions can be combined in one material or a single structural design concept. Recent development of spectrally-selective nano-structured materials and meta-surfaces has opened opportunities to manage both visible light and radiative heat year-round with conventional window and rooftop designs. In this regard, lightweight, flexible, and durable polymer materials, as well as organic-inorganic composites are increasingly replacing conventional natural materials across different sectors of economy, including new construction, historical buildings retrofitting, and design of new multi-functional wearables. Here, we report on the design, fabrication, and characterization of polymer-based organic-inorganic composites with tailored broadband spectral properties, and controllable thermal conductivity. We show that by varying the degree of crystallinity of ultrahigh molecular weight polyethylene (UHMWPE) and the composition of nanoparticle fillers, we can achieve simultaneous control over optical and thermal properties of the resulting composite material. The development of new optical functionalities that go beyond normal light diffusion in disordered polymer-based materials are also explored by introducing pseudo-random order to the material internal meso-structure.

**Multi-Material 3D Fabrication—CNT-Polymer Hybrids with Controlled CNT Alignment and Multifunctionality** Mostakima M. Lubna, Philip Bradford and Jakub Sciora; North Carolina State University, United States

The development of today’s smart devices not only focused on the miniaturization of complex material systems also the design flexibility, adaptability, and sustainability of a product are major concerning areas for researchers. The great opportunities offered by the nanomaterial-polymer systems from nano-micro to mesoscale have engendered scientists to design innovative structures with multifunctionality. Recently, carbon nanotubes (CNTs) are extensively used to fabricate multifunctional structures for wearable electronics, robotics, as well as in a wide range of other textiles and biomedical applications. CNTs hold substantial promise for fabricating the ideal multifunctional system; owing to their inherent properties of high aspect ratio, conducting network formability, thermal stability, compatibility with different polymers, ultralow-density and design flexibility. Though significant researches have been done previously regarding CNT-polymer hybrid structures, the superior nano-properties offered by CNTs are not fully being harness yet due to the randomness variability and complexity of multi-step processing. Typically, in fabricating CNT-polymer hybrids, solution-based dispersion or/inorganic acid assisted chemical surface
modification of CNTs were done prior to the addition of a specific polymer. These approaches of CNT processing routes are fully selective regarding the hydrophobic/hydrophilicity of a polymer and specifically customized focusing the system thus no design flexibility. Considering the percolation threshold and electrical property prediction uncertainty of the final CNT-polymer structure due to CNTs randomness, and allowance of a broader range of polymer incorporation possibility we have innovated a simple strategy with the inverse design approach. At first, we fabricated a stable ultra-low-density 3D anisotropic CNT foam structure with dry spinnable CNTs followed by pyrolytic carbon coating (PyC), where we can control the interconnected CNT network alignment directions within the structure which eliminate the CNT dispersion randomness limitation. And then, infiltrate polymer within the CNT structure, where the density of the final product can be tuned in a wide range by varying the polymer solution concentration. Very short-duration (few second) corona treatment was done on the dry CNT foams if hydrophilic polymers were to be infiltrated. The polymer infiltration technique is the same regardless of the polymer types (hydrophobic or hydrophilic). We have fabricated low density, stable and multifunctional 3D CNT-polymer hybrid structures using several different polymers, e.g., polydimethylsiloxane, polycarbonate, and polyvinyl alcohol. The results showed better structural stability in several hundred successive dynamic cyclic compression loading, tuneable low-density ranging from ~8.8 mg/cm³ to ~107 mg/cm³, ultra-porosity up to ~99.89%. The multifunctionality of CNT-polymer hybrids was successfully demonstrated in piezoresistive sensing for human motion detection, in electromagnetic interference shielding performance with thickness only 1 mm S21 is 63.4 dB for X-band and oil absorption applications. This 3D design provides the benefit of easier multi-material incorporation with controllable interconnected CNT alignment which can be used as a platform for the development of multi-nanomaterials systems.

Biomimetic Fibronectin Fibrillogenesis at Air/Water Interface Thanga Bhuvanesh Vijaya Bhaskar1,2, Rainhard Machatschek1, Burkhard Schulz1,2, Nan Ma1,2 and Andreas Lendlein1,2; 1Institute of Biomaterial Science, Teltow, Germany; 2Institute of Chemistry, Germany

Fibronectin (FN) fibrillogenesis plays crucial roles in vivo by orchestrating embryogenesis, tissue organization by promoting the assembly of other extra-cellular proteins such as collagens, fibrillins, and tenasin-C and cell adhesion and growth [1]. This process is initiated by binding of FN to the cell surface through integrins and subsequent association with polyanionic proteoglycans (PGs) such as chondroitin sulphate resulting in FN unfolding from compact form to an extended form [2]. FN-self association through N-terminal domains and additional binding sites after FN unfolding result in fibril growth stabilized through non-covalent FN-FN interactions. To realize FN fibrillization artificially in vitro, the assembly of FN at the air-water (A-W) is an attractive solution [3]. The 2D confinement and high local concentration at the A-W interface enhances the FN-FN association essential for fibril growth and the acidic pH of the subphase can mimic the negatively charged PGs to promote FN unfolding. It is hypothesized that FN assembly at the A-W can simulate the FN assembly on cell membranes and result in fibril formation. FN was spread as droplets from concentrated solution (1 mg/mL) on subphase pH 2 in a circular trough (diameter 9 cm) and the assembly process was followed using in situ characterization tools. Surface pressure increases with time plateauing at 11 mN/m after 350 min and this indicates that surface adsorption is favorable on the subphase with pH 2, which is a pre-requisite for self-assembly. In parallel, the assembly process was investigated by polarization-modulation infrared reflection absorption spectroscopy (PM-IRRAS) to get information about the conformation of the FN layer. Amide I peak shifted from 1627 cm⁻¹ to 1621 cm⁻¹ after 30 min indicating unfolding of the FN from the compact native form. Finally, FN self-crosslinking was proven using interfacial rheology by the increase in interfacial elastic modulus and interfacial loss modulus with time (upto 16 h). The elasticity of FN fibrils was confirmed from the much higher elastic modulus (6 mN/m) than loss modulus (1 mN/m). Therefore, FN fibrillation can be realized in a cell-free environment using the A-W interface as a platform for assembly and such fibrils can be produced artificially in a facile manner on large-areas (12 cm²). We envision that such FN fibril networks can be transferred onto substrates for stem cell differentiation or as biomimetic scaffolds for tissue engineering and regenerative medicine.

**Mosquito Bite Inspired Miniaturized Sensor Technology for Healthcare Applications** Ganesh Kumar Mani and Kazuyishi Tsuchiya; Tokai University, Japan

Always there is great demand for *in vivo* testing to understand more about body metabolism to provide effective diagnosis and therapy. Currently no industrial technology available for single cell especially for pH, temperature or other cell metabolites. Compared to conventional sensors, research on single cell microneedle sensor is still in its infancy due to their difficulty in fabrication, poor flexibility, toxicity, scarcity of nanomaterials, instrumentation difficulty and poor stability. Meanwhile painless micro/nano needles have been widely used for extraction skin interstitial fluid, vaccine and drug delivery over the past two decades, but their potential as sensor remains largely unexplored. Therefore we aim to develop single microneedle based sensor for detection of pH and other cell metabolites in single cell. A ~4.8 µm pH sensor was fabricated and tested it *in-vivo/in-vitrosensing* capability was demonstrated. High stability and sensitivity make this novel pH sensing microneedle is a cost effective and easy fabrication tool for biological sensing especially at the single cell level. The developed sensor exhibited the Nernstian response of ~46 mV/pH. The fabricated microneedle sensor ability is proven by in vivo testing in mice cerebrospinal fluid (CSF) and bladder. The pH sensor reported here is totally reversible and results were reproducible after several routine testing. This type of sensor development definitely will bring new innovative ideas that have the huge potential for drug development while continuous metamorphosis observation.

**Active Microfluidic Substrates Based on Electroactive Electrospun PLLA Membranes** Ricardo Pereira¹, Eduardo Pimentel¹, Estela Carvalho¹, Pedro Martins¹, Senentxu Lancers-Mendez² and Vanessa Cardoso¹; ¹Universidade Do Minho, Portugal; ²Basque Centre for Materials, Applications and Nanostructures, Spain

Microfluidic paper-based analytical devices (µPADs) represent a promising platform for fast, portable, low-cost and easy-to-use analytical tools for point-of-care (POC) devices. Cellulose’s hydrophilicity, combined with patterned hydrophobic microfluidic channels generate sample flow from the inlet to a defined location for subsequent analysis. Nevertheless, the entry of µPADs into a real-life application is still minimal, mainly due to the inherent limitations of the materials used for the manufacture of µPADs, including their passive role as support element with no control on the fluid flow.

The present work develops microfluidic substrates based on piezoelectric electrospun poly(L-lactic acid) – PLLA membranes, optimised and properly characterised in terms of morphology, physicochemical properties and capillary flow rates. Oriented PLLA electrospun membranes were first produced to mimic the structure of commercially available *Whatman®* papers, commonly used in the fabrication of µPADs. Further, oriented PLLA membranes were also produced to study the effect of fibres orientation. As proof of concept, a disposable PLLA microfluidic system was designed and fabricated for the detection and quantification of glucose.

**Mechanically Induced Hydrophobic Recovery of PDMS for Patterning Surface Wettability** Ali J. Mazaltarim, Jay M. Taylor, Abhiteja Konda, Michael Stoller and Stephen Morin; University of Nebraska-Lincoln, United States

Silicone elastomers are widely used in “stretchable” technologies (e.g., wearable electronics) that require the elastomeric components to accommodate varying magnitudes of mechanical stress. Understanding how mechanical
stress influences the surface chemistry of these elastomeric components is therefore critical to the performance of these materials. We treated silicone films (polydimethylsiloxane; PDMS) with oxygen plasma and systematically exposed these films to various magnitudes of tensile stress while studying the associated surface chemical changes using contact angle measurements, X-ray photoelectron spectroscopy, and gas chromatography-mass spectrometry. We discovered that mechanical stressing oxidized PDMS films resulted in the on-demand restoration of the film’s hydrophobicity due to: i) cracking of the brittle surface oxide layer, ii) migration of uncured monomers from the bulk towards the surface, and iii) surface rearrangement. We utilized these understandings to develop a facile method for the rapid, on-demand switching of surface wettability and the generation of surface wettability patterns and gradients. These findings are broadly applicable to the fields of microfluidics, soft robotics, printing, and to the design of adaptable materials and sensors.

**Controlled Release from Core-Shell Electrospun Gelatinous Scaffolds** Adnan Memic, Tuerdimaimaiti Abudula, Kalamegam Gauthaman, Ahmed AlShahrie, Numan Salah, Angelo Chianese, Pierfrancesco Morganti and Ali Tamayol; ¹King AbdulAziz University, Saudi Arabia; ²Sapienza University of Roma, Italy; ³University of Naples, Italy; ⁴University of Nebraska–Lincoln, United States

Non-healing, chronic wounds have placed an enormous stress on both patients and the healthcare systems that served them. Severe complications induced by these wounds can lead to limb amputation or even death. Treatment of the hostile wound environment requires effective drug delivery systems able to overcome current limitations. Electrospun biomaterial scaffolds have showed a great potential for in both wound healing (i.e. as wound dressing materials) as well as controlled drug delivery applications. More specifically, electrospun gels due to their high moisture adsorption capacity and ability to interact with wide ranges hold a lot of promise. Previously, we developed bio-waste derived chitin-lignin gels, and demonstrated that they can be integrated as a native tissue-like fibrous membrane. However, their clinical application was limited by solubility and undesired burst release. Here, we developed a coaxial electrospinning approach to first encapsulate the gels with polycaprolactone (PCL). Presence of a PCL shell layer provided longer shelf life for the chitin-lignin gels in moisture environments and provided a sustainable release of drug molecules. Model drug and antibiotics were loaded into core-shell fibrous platform, which effectively inhibited both gram -positive and -negative bacteria without inducting observable cytotoxicity. Therefore, these PCL coated chitin-lignin fibrous gel platforms may be a good candidate for controlled drug release based wound dressing applications.

**Dynamic Wetting of Dandelion Pappus and Its Bioinspired Applications** Qingan Q. Meng, Huan Liu, Masao Doi and Lei Jiang; Beihang University, China

Learning from nature is the important fountain for the materials development. In recent years, the biomimic functional materials and structure have been paid more attention. Taraxacum officinale, often simply called dandelion, is a common composite perennial Asteraceae species with the capitulum containing a white ball of fluff composed of many pappi in an arrangement of horizontal radial geometry when the dandelion seeds are ripe. The most attractive feature of the dandelion is that the seeds are easily to be detached from the mother plant by wind after maturity and then start the new generation somewhere the seeds were parachuted. Interestingly, we observed another intriguing but less studied feature that the geometry of the pappus changed from open state (paratrute) to closed state, even a big water droplet could be encapsulated by the pappi of the dandelion seed after raining. However, the mechanism of the pappus undergoing hydro-actuated configuration alteration and water encapsulation in high efficiency have been unknown. Starting from the dynamic phenomenon of dandelion pappus in response to wet environment, we reveal the mechanism of dynamic wetting behavior of the pappus. Then drawing inspirons from above, we design and develop the intellgent materials and devices for realizing highly efficient liquid capture, transport and realizing stimuli-responsive spatial movement to the environment humidity, offering novel strateries for the development of highly efficient and controllable liquid transfer and intellgent aircrafts.

**SB01.09.49**

**A Comparative Analysis of Mechanical Properties and Release Characteristics of Drug Eluting Bone Cements** Lydia M. Mensah and Brian Love; University of Michigan-Ann Arbor, United States

We have been producing and testing aqueous amphiphilic copolymer polyether solutions, formulated with varying
amounts of a third constituent added with the notion of forming higher-throughput, drug-loaded gels. These gels have also shown potential in localized drug delivery and displace drug-eluting bone cements and spacers. So long as there are no structural requirements for the spacers, the cement matrix can be loaded with more than a few percent of the mass of the spacer with an antibiotic. To establish baselines of drug release in drug eluting cements, their transport attributes have been assessed either in terms of directly qualitatively observing an infection response clinically, or by measuring drug release into a tissue, or a receiving solution to mimic the tissue. Direct assessments of reduced infection by imaging or indirect protocols using a spacer interacting on a bacterial culture plate and resolving a zone of death emanating from the spacer are both indications of transfer of some antibiotic from the spacer and into the surrounding medium allowing some sort of assessment of a minimum inhibitory concentration (MIC). To assess the elution features of gentamicin and vancomycin incorporated into bone cements, we probed the spacer and into the surrounding medium allowing some sort of assessment of a minimum inhibitory concentration.

Hemocompatible Hybrid Magnetic Block-Copolymer Nanocapsules—UV Light Triggered Morphological Conversion from 3D Nanocapsule to 2D Nanowire-Network

Saijad H. Mir, Brian Jennings and Parvaneh Mokarian-Tabari; Advanced Materials and BioEngineering Research Center (AMBER) & CRANN Institute, Trinity College Dublin, The University of Dublin, Dublin 2, Ireland

Chemical versatility of polymers provides a wide range of functionalization inputs onto the shell of the nanocapsules that play an essential role in the interactions with their surroundings. Moreover, the polymeric shell enhances the lifetime of the encapsulated drugs by protection from harsh environment factors such as pH value, enzyme activity, and avoids side effects of the cargo molecules to the living environment by decreasing rapid leakage. For this purpose, the development and engineering of smart polymeric nanocapsules have gained a high interest. Various materials have been adopted for encapsulation, and a variety of chemical and physicochemical methods have been developed in order to prepare hollow spheres with controlled size and shape. Although each method has its own merits and demerits, they all need either a preorganized structure or template to shape a hollow shell structure, and furthermore require time-consuming and laborious multi-step processes including removal of core or templates. Moreover, in polymers, dye/drug release can be achieved by introducing a photo-sensitive segment, whose activation leads to either rupture or modification of the diffusive properties of the capsule shell, allowing the delivery of the encapsulated material. Considerable efforts have been thus devoted to prepare stimuli-responsive hollow capsules which undergo a structural transition in response to small changes in the environmental conditions such as pH, temperature, redox-state, medium, and ionic strength. However, polymer nanocapsules which change the morphology from 3D nanocapsule to 2D nanowire-network on UV light exposure are not reported. Herein, we have developed a new, direct synthetic method for polymer nanocapsules without need of any template, pre-organized structure, or core removal. Wherein, introduction of the ferrocene-based moiety into the copolymer induced the formation of the nanocapsules. We demonstrate the switchable encapsulation and release of a fluorescent dye, when exposed to UV light. This process which is fully reversible and is due to transformation of spherical morphology into nanowire network.

Polymer nanocapsules were obtained by self-assembly of poly(styrene-b-vinylpyridine) (PS-b-P2VP) block copolymer and poly(chlorostyrene-co-vinylferrocene) (CIPS-co-PVF) in a mix solvent of THF/methanol without addition of any surfactant. The nanocapsules are paramagnetic in nature; this helps easy separation of polymer nanocapsules from solution by application of external magnetic field. Encapsulation of the fluorescent dye occurs during self-assembly step. Upon triggered with UV light for 2 h, the capsules gradually shrink and fuse into each other to transform into a nanowire-network and release the fluorescent dye gradually. The polymer nanocapsules were treated with human blood, which showed good hemocompatibility and did not cause any platelet aggregation.
This has good implications for the development of the drug carriers. In conclusion, we have synthesised a new hemocompatible, hybrid magnetic light responsive polymer nanocapsules with a controlled dye releasing capacity by a facile and robust preparative protocol in one pot. It is anticipated that this material will find applications in target specific drug delivery systems responsive to light and other external stimuli.

Highly Fluorescent Dynamic Hydrogels Via 2:2 Cucurbit[8]uril Host Guest Complexation Stefan Mommer and Oren A. Scherman; University of Cambridge, United Kingdom

Hydrogels are an important class of materials and have until now spread over a variety of fields in modern sciences. Other than covalent networks, non-covalent hydrogels consist of transient physical cross-links and have the inherent advantages that they are flexible and show self-healing as well as shear-thinning behaviour. Specific binding motifs have to be chosen to render a hydrogel non-covalent. Beside hydrogen bonding, electrostatic interactions or metal complexations, the self-assembly between a host and a guest molecule can be a powerful tool to mediate gelation in a given material. Cucurbit[8]uril represents such a host molecule and can complexate a variety of guest molecules. Recent reports have shown, that depending on the aromatic guest structure, complexes of 1:1:1, 2:1, 2:2 and even 2:3 (guest:host) stoichiometry can be formed. In this work we harvest the capacity of Cucurbit[8]uril to form 2:2 complexes, where now 2 modified viologen derivatives are stacked and handcuffed by 2 Cucurbit[8]uril macrocycles. The used guest molecules are fluorophores of aromatic nature and show unique optical and electrical properties. Once brought together, charge transfer complexes are formed that are glued together by the Cucurbit[8]uril macrocycles and therefore the optical and electrical properties dramatically change. By copolymerizing acrylamide with only little amounts of these fluorophores, polymers are obtained that readily form hydrogels upon addition of Cucurbit[8]uril to the system. The resulting highly fluorescent hydrogels show unique mechanical properties that are supported by rheological data. Due to their high elasticity and fluorescent properties, hydrogel materials based on these 2:2 Cucurbit[8]uril host-guest complexes hold promising potential for imaging applications in biomedical systems or as self-reporting materials.

Metal Deposition-Made Intrinsically Stretchable Conductors on Strain Absorbable Surface Structures and Their Use in Analog Position Sensors Sungmin Moon, Hyejin Hwang, Wonjeong Suh and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

Intrinsically stretchable conductors are essential components for soft electronics, a new field of electronics, which includes deformable displays, stretchable transistors, energy storages, and health care devices. Most of the cases, they were usually made in the form of the conductive composite using percolation networks; conductive filler and intrinsically stretchable polymer matrix. Although they show great performance with high conductivity and large deformability, in terms of the fabrication process, their process is far from the conventional electronic fields where sputtering deposition is widely used. If the sputtering process can be applied to the manufacturing process of soft electronics, the potential for industrialization and commercialization will be greatly enhanced.

In this presentation, therefore, a bridge between the industry field and the new electronics will be suggested; stretchable conductors are made by metal deposition method on strain releasable structured substrates [1-3]. The intrinsically stretchable substrates (Styrenic block copolymers (SBC)) dissipates strain during the elongation through their surface network structures (microfibrils network, nanofiber network).

With these substrates, the deposited brittle conductive metal lines can maintain their network and conductivity
during harsh deformation condition (up to biaxial stretched ~ 100 %, ~ 20 Ω/sq). To demonstrate the advantages of the deposition method, tunable conductivity (i.e. strain sensitivity), patternability with various pattern width, areal uniformity and practical application are proposed. In addition, in order to clarify the fundamental mechanisms for maintaining the conductivity during the deformation, various experimental results and finite element method (FEM) focusing on mechanical deformation were investigated. Finally, a novel but simply designed tactile sensor fabricated only through metal deposition method on a single substrate will be presented that reacts to pressure and detects 2-D position information.

**Dynamic Transport of Liquid Droplets Using Mechano-Adaptive Chemical Gradients** Stephen A. Morin and Ali J. Mazaltarim; University of Nebraska-Lincoln, United States

Spatial variations in the wettability of surface-chemical gradients has been used to transport liquid droplets along predefined paths at predictable velocities. In these demonstrations the chemical gradients were synthesized, almost exclusively, on rigid, planar substrates which limit their adaptability. We have pioneered a set of techniques which enable the facile synthesis of large-area surface-chemical gradients on soft elastomers (e.g., PDMS) with mechanically switchable surface microtopography. These advances enabled the fabrication of, for the first time, mechano-adaptive soft surfaces capable of controlling the transport of liquid droplets dynamically. We provide an analytical model which predicts droplet velocity based on critical parameters such as strain state, droplet radius and viscosity, surface microroughness, and steepness of the wettability gradients. Further, we demonstrate the use of these mechano-adaptive gradients in the performance of functions directly relevant to surface-fluidic applications. We believe these findings are generally applicable to the generation of mechano-adaptive surfaces with dynamic, programmable surface-liquid interactions and chemical reactivity and directly useful to, for example, the design and fabrication of surface fluidic systems, adaptive surface coatings, and smart textiles.

**Hybrid Additive Manufacturing of Poly(caprolactone)-Modified Bone-Ligament Composite Scaffolds for Interface Tissue Engineering** Lorraine Mottishaw, Christopher Buksa, Marissa Perez, Nafisa Elghazali, Ruben Trujillo, Serafina Lopez, Fermin Prieto, Matthew N. Rush and Christina Salas; The University of New Mexico, United States

In a ligament rupture reconstruction, a tendon autograft is used to restabilize the bones around it. This procedure requires: surgically removing a portion of a tendon adjacent to the site of injury, drilling holes in the bones at the ligament insertion sites, funneling the tendon through the bones, pulling them taut, and restraining them with bone anchors. In addition to being fraught with limitations, this procedure and reconstructed joint cannot recapitulate the functionally-graded biochemical and biomechanical bone-ligament interface. Precise control of material properties and architecture could be the solution to reproducing native tissue properties at the bone-ligament interface.

3D bioprinting (3DBP) has shown promise for creating tissue engineered scaffolds with excellent resolution and controlled architecture. Commonly made from bioinks of biocompatible polymer-based solutions, these 3DBP scaffolds can be optimized to match the structural competency needed for bone tissue regeneration. Additionally, near-field electrospinning (NFE), an additive manufacturing technique, can produce smaller feature sizes than 3DBP. By applying a voltage between the build surface and the needle of the bioink syringe, the solution can be drawn from the syringe using electrostatic potential and thinning of the bioink filament. This system produces highly controlled, high-tensile resistant fibers very similar to ligament tissue fibers. Using a custom platform that merges the two manufacturing systems, we can fabricate complex composite scaffolds with fully integrated bone (3DBP) and ligament (NFE) phases. The current study focuses on optimization of the biochemical and biomechanical properties of each distinct phase of the composite scaffolds and characterization of the mechanical capability of the composite.

Poly(caprolactone) (PCL) in chloroform with decellularized bone particles was used as a bioink for the fabrication of the 3DBP bone phase scaffold. PCL in chloroform was mixed with Hexafluoro-2-propanol (HFIP) as a bioink for
the NFE ligament phase. 3DBP and NFE scaffold deposition parameters (extrusion rate and print speed) were characterized as a function of viscosity and solvent evaporation using an Anton-Paar rheometer. Bone phase 3DBP scaffolds of PCL only, PCL w/10% bone, and PCL w/40% bone were mechanically tested for compressive strength using an MTS servohydraulic actuator. Ligament phase NFE fibers were evaluated for tensile strength in 0° uniaxial, 90° biaxial, and 45° biaxial configurations using dynamic mechanical analysis. Cell viability of 3DBP and NFE scaffolds using NIH/3T3 fibroblasts was conducted along with cytoskeletal structural analysis through immunocytoskeletal staining and confocal imaging. Furthermore, the mechanical response of the 3DBP/NFE composite scaffolds were mechanically characterized and the microscopic structure examined using scanning electron microscopy.

By combining the 3DBP and NFE additive manufacturing techniques, we’ve created a structurally integrated composite scaffold for bone and ligament phase tissues. The hybrid system can create functionally graded architectural features that mimic bone and ligament tissue by altering scaffold geometry. Adapted bioink composition can tune the mechanical properties of the scaffold for fabrication of biologically relevant bone-ligament tissues.

Modelling of Carbon Nanotubes Based Multilayered Dielectric Elastomer Actuators
Seshadri Reddy Nagireddy and Aftab M. Hussain; International Institute of Information Technology (IIIT) - Hyderabad, India

Dielectric Elastomer Actuators (DEAs) are emerging as pseudo-muscular actuators for applications in the field of soft robotics. DEAs work on the principle of actuation due to electrostatic pressure. Because DEAs are electromechanical transducers based on capacitive architecture, all the components in the actuator (namely the dielectric elastomer and electrode) must contract and stretch. In order to achieve the requisite stretchability, carbon nanotube (CNT) based electrodes are used, which retain conductivity even at large strains. The CNT thin film consists of a large number of individual CNTs interwoven into a mesh. When these films undergo strain, the CNTs merely slide on each other increasing the lateral dimensions of the film without loss of conductivity. However, this interwoven structure causes the thin film to resemble a perforated film instead of a continuous conductive film, which causes the electrostatics to be complex. Apart from the need for compliant electrodes, another key disadvantage of DEAs is their high driving voltage of 0.3-4 kV. To reduce the actuation voltage without reducing the thickness, or increasing the relative permittivity of the dielectric material, multilayered structures can be used. These structures increase the actuation force without the need to increase driving voltage. This can create complex electric field patterns especially with perforated CNT-based thin films. In this work, we study the electrostatics of such multi-layered structures focusing on screening or lack of screening of electric fields created by ad-joint capacitors made of perforated CNT thin films and the effect it has on the observed capacitance of the system. Under theoretical treatment, it has been found that for an n-layered interdigitated structure with uniaxial perforation the capacitance of the system can be estimated by the equation: $C_n = C_0[n - 2(n-1)\beta + 2(n-2)\beta^2 - ... + 2(-\beta)^{n-1}]$, where $n$ is the number of layers, $\beta$ is the constant dependent on perforation ratio, $C_0$ is the capacitance of single layer with all solid electrodes. Further, the above theoretical model is verified using finite element analysis (FEA) in both 2D and 3D space. The perforated electrode is modelled as a charged metallic electrode with gaps in 2-dimensional case, and a metallic sheet with circular holes in 3-dimensional case. The analysis is carried out on an interdigitated structure to obtain capacitance of multilayered structure (up to 10 stacked layers). The electric field is seen to briefly fringe very close to the perforations as there is discontinuity in charge at these points. At large distances from the perforations, the electric field is approximately constant as predicted by Grosser and Schulz [1]. From these results it has been found that $\beta$ is independent of number of layers and is dependent only on electrode perforation. The obtained data closely matches the theoretical analysis results for normalized capacitance, which is calculated to show the percentage change with that of a capacitor with solid electrodes. The drop in normalized capacitance increases as the perforation ratio increases, while the normalized capacitance decreases with increase in number of layers but saturates afterwards. The change in capacitance due to perforations in the electrode system is limited (<0.5%) for an electrode area coverage of more than 90%. We believe this modelling and analysis is important to develop robust, reliable CNT based DEA structures.

Preparation of α-synuclein-Mediated Multi-Component Nanofilm Comprised of CNTs, AuNPs and MNPs and Its Use as Stimuli-Sensing Element for Shape Deformation

Funjeong Nam1, Yeji Kwon1, Jong Tak Lee1, Jung Hee Lee1,2 and Seung R. Paik1; 1Seoul National University, Korea (the Republic of); 2AweXome Ray Inc., Korea (the Republic of)

Integration of various nanomaterials into one multi-component system is prerequisite to produce multifunctional materials. In this study, a self-assembly protein of α-synuclein (αS), an amyloidogenic protein responsible for Lewy body formation found in Parkinson’s disease, has been employed to fabricate the multi-component nanofilms containing carbon nanotubes (CNTs), gold nanoparticles (AuNPs), and magnetic nanoparticles (MNPs). Ultra-thin 2D film of CNTs was prepared with the αS-CNT conjugates in which the N-terminal region was demonstrated to form α-helix on the hydrophobic CNT surface while the acidic C-terminus was exposed outward as determined by CD and NMR spectroscopy. Following a slow vacuum filtration of αS-CNTs through a polycarbonate membrane filter, chloroform was then used to unleash the CNT film by dissolving the underlying filter membrane, which also facilitated the αS-αS interactions by forming enhanced anti-parallel β-sheet and α-helix as evaluated with FT-IR. The light-responsive CNT film ornamented with or without αS-AuNPs in the presence or absence of αS-MNPs was transferred to the surface of a thermo-responsive double network hydrogel sheet composed of poly-N-isopropylacrylamide (PNIPAAm) and alginate, and sandwiched with a passive polymer layer of Ecoflex. Upon a near infra-red laser irradiation to trigger the photothermal effect of CNT, the entire triply structure exhibited a distinct shape deformation via a heat-induced shrinkage of the CNT immobilized area. In addition, the MNP co-localized films were shown to cause unique locomotions in the triply form under a rotating magnetic field. These multi-component nanomaterial films are therefore suggested to be utilized as a stimuli-responsive element to cause the shape deformation of hydrogels, which could serve as a critical part for the development of various areas including soft robotics, theranostics, and human-machine interfaces.

A Fully Integrated 3D Deformable Heterogeneous Sensors Based Biomedical Device for Clinical Emergency

Muhammad Naqi1, Srinivas Gandla1, Sanghoo Lee2, Ulihyun Jung1, Mingo Lee2, Hyunk-jun Kwon1 and Sunkook Kim1; 1Sungkyunkwan University, Korea (the Republic of); 2Korea Electronics Technology Institute, Korea (the Republic of); 3Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of)

Wearable wireless sensor technologies are of greater concern for delivering the real-time healthcare information through personalized smart mobiles. Despite significant developments in active components, device geometry, sensors and efforts have been made to introduce new forms of natural inspired mechanical architectures that can accommodate large strains and geometrical deformations that are subjected to complex stress environments. Herein, we introduce, a fully integrated wearable wireless sensory patch system with strain-free mechanically robust structures inspired from both natural kirigami and serpentine patterns that are sticky, conformable, and mechanically robust to achieve high-levels of sensing performances. The present work addresses the challenge of all-day continuous monitoring of human body biological signals by introducing the well-equipped breathable (water permeability ~ 80 gm-H/1h), excellent adhesion to the skin (peel strength < 200 gf/12mm), bio-compatible, and conformable smart patch that can absorb the moisture (sweat) generated from the skin without any harshness and allowing the users’ to continuously monitor the early detection of diagnosis. Moreover, the hologenous stretchable temperature and humidity sensors have been introduced with high electrical properties and sensitivity under various temperature and relative humidity (%RH) scales. Theoretical and experimental results highlight the importance of sensor structural designs under various mechanical loading and deformations. The integrated sensory systems are equipped with breathable, bio-compatible patch, and protective layers, so that the user can conformably wear through the day for continuous analysis of early diagnosis, thereby allowing the patients to improve healthcare problems at different stages through mobile monitoring. Furthermore, the proposed integrated sensor enables the wireless sensing capabilities in response to a rapid variation equipped with customized circuit design, low power Bluetooth (BLE) module and signal processing integrated circuit (IC), thus, establishing a unique platform for multifunctional sensors to interface with hard electronics and emerging opportunities in the biomedical field and internet of thing (IoT) applications as well.

SB01.09.58
Polydopamine-Mediated Surface Modification Promotes the Adhesion and Proliferation of Human Induced Pluripotent Stem Cell

Yan Nie1,2, Zijun Deng1,2,3, Weiwei Wang1,2, Thanga Bhuvanesh1,2,4, Nan Ma1,2,3 and Andreas Lendlein1,2,4; 1Institute of Biomaterial Research and Berlin-Brandenburg Center for Regenerative
Therapies, Helmholtz-Zentrum Geesthacht, Germany; ²Helmholtz Virtual Institute – Multifunctional Biomaterials for Medicine, Germany; ³Freie Universität Berlin, Germany; ⁴University of Potsdam, Germany

With their abilities of self-renewal and pluripotency to differentiate into all three germ layers, human induced pluripotent stem cells (hiPSCs) are promising cell sources for cell-based drug and implant testing [1, 2]. However, the large-scale expansion and maintenance of hiPSCs require adhering to strict conditions [3, 4]. Sample systems for the cultivation of high-quality hiPSCs are highly demanded to meet the application requirements. In this study, we probe the possibility of modifying the polymeric substrates for maintaining the self-renewal and pluripotency of hiPSCs. Here, polydopamine (PDA), typically used to join two materials including a wide range of inorganic and organic materials [5, 6], was employed to immobilize the Laminin 521 (LN521) onto the surface of polyethylene terephthalate (PET). An aqueous solution of dopamine with concentrations ranging from 0 to 2.0 mg/mL was applied on PET surfaces. These PDA-modified surfaces were further functionalized with LN521. Surface wettability was evaluated by measuring the water contact angle (WCA) and surface properties of the modified substrate were analyzed using an atomic force microscope (AFM). Initial hiPSC attachment (1h after seeding) and cell proliferation were evaluated by counting the total cell number. The maintenance of pluripotency was evaluated at different time points. WCA of the PDA-LN521 surfaces gradually decreased from 62.1°±6.3° to 8.1°±2.9°. The maximum peak-to-valley height roughness (Rt) of PDA-LN521 modified surfaces determined by AFM increased in a dopamine-concentration-dependent manner, ranging from 43.9±1.6 nm to 126.7±7.6 nm. Young's modulus of PDA modified surfaces was substantially increased from 0.980±0.36 GPa to 4.810±2.41 GPa. There was a significant enhancement (13.0±7.2% and 24.2±8.1%) of hiPSC adhesion on PDA-LN521 (dopamine concentration at 0.125 and 0.25 mg/mL). When increasing the dopamine concentration to 0.5 and 1.0 mg/mL, there was no further increase in hiPSC adhesion on PDA-LN521 surfaces. Moreover, hiPSCs proliferation was remarkably enhanced on PDA-LN521 surface (dopamine solution at concentration from 0.125 to 1.0 mg/mL). Pluripotent gene expression of hiPSC, including Oct-4, Sox2, and SSEA4, was not affected by PDA treatment. PDA modification did not impair the pluripotency of hiPSCs. In conclusion, polydopamine-mediated surface modification is an effective approach for the robust expansion and maintenance of hiPSCs on polymer substrates.

An All-Polymer Biofuel Cell for Bioelectronic Applications Georgios Nikiforidis, David Ohayon, Achilleas Savva, Shofarul Wustoni and Sahika Inal; KAUST, Saudi Arabia

All electronic devices require a power source to operate. The need to have portable power sources becomes more crucial for miniaturized bioelectronic devices that detect biological signals such as the heartbeat, muscle movements, as well as critical biomarkers. We herein present an all-polymer enzymatic biofuel cell to power such bioelectronic devices. The anode is an NDI-T2 copolymer (P-90) consisting of alternating naphthalene dicarboximide (NDI) acceptor and bithiophene (T2) donor subunits with randomly distributed alkyl and ethylene glycol side chains, while the cathode is a p-type thiophene-based copolymer P(EDOT-OH-EDOT). The enzyme (glucose oxidase) has efficient electrical communication with the n-type polymer film, rendering P-90 suitable as an anode for the enzymatic biofuel cell. The p-type cathode material demonstrated stable catalytic activity towards oxygen reduction reaction (ORR). Upon introduction of glucose into PBS, the former is oxidized to gluconolactone by GOx, producing electrons that are transferred to the P-90 anode. These electrons then travel through the external
circuit to the cathode which reduces dioxygen to water generating power from glucose and oxygen in aqueous media. The biofuel cell exhibited a cell open circuit potential of 0.3 V when operated at physiologically relevant glucose concentrations, enough to power organic electrochemical transistors (OECTs), state-of-the-art sensor configuration of organic bioelectronics. The powering device is stable for 35 days in a membrane-free configuration and yields a power density of 20.7 mW.cm⁻² at 100 µM of glucose. Implementing an OECT sensor that can be indefinitely powered by glucose through the biofuel cell can lead to self-reliant devices.

**SB01.09.60**
**Temperature-Responsive 4D Printing with Fast, Controllable and Reversible Self-Deformation** Je Hoon Oh¹, Jongbeom Kim¹, Je Jun Jeong¹, Kyu Hwan Oh¹ and Myoung-Moon Moon²;¹ Seoul National University, Korea (the Republic of);² Korea Institute of Science and Technology, Korea (the Republic of)

4D printing is a technology that makes the 3D printed structures deformed by responding to external stimuli such as temperature, pH, UV, and magnetic field. Recently, 4D printing has been actively explored for the application in several field such as soft robotics or biomedical devices such as a stent or a sensor that detects and reacts under the biofluidic environment. However, there are still many challenges. One is that it is difficult to control the deformation speed and the other is irreversible deformation which changes only in one direction.

In this study, we present a temperature-responsive 4D printed structure deformed by controlling the two distinct memory effect of ‘strain memory’ and ‘stress memory’. Shape memory has two concepts: one is 'strain memory' and the other is 'stress memory'. 'Strain memory' means to remember the shape of the structure and to be restored to that shape by the stimuli condition. 'Stress memory' means that the structure accumulates and memorizes the stress, not just the shape. Even if the same structure deforms to the same strain, the stress that acts on the structure can also be programmed differently by the material of the structure, 3D printing conditions, and additional processes.

When a 3D printed structure is deformed, the external strain applies to each of the printed thermoplastic fibers composing the structure. The strain applied to a 3D printed SMP (shape memory polymer) with a rubbery state at Tg or higher would be stored in a glassy state when cooled. Stress memory inside the printed structure can be residually controlled by stacking output layers with different recovery stresses. By programming the stress acting on each layer in the process of returning to the memorized shape, it is possible to make the stress more than necessary in the shape recovery process differently for each layer. We shows that by alternatingly programmed with the layer with stress memory effect on top of the upper layer with strain memory effect, it is possible to make a reversible structure in deformation. By relieving the stress memory, the structure in the high temperature is transitionally deformed into programmed shape with a faster speed, then by the strain memory effect, the programmed shape returns to the original shape that was initially memorized at the 3D printing process. Through this study, we demonstrate this concept for a structure similar to the stimuli responsive plants behavior like Mimosa, which rapidly self-deforms to instantaneous external stimuli, and gradually restores to its original structure even when the external conditions are intact.

**SB01.09.61**
**Reversible Nanoscale Switch with Short Responsive Time** Seoyeah Oh, Myungsoo Han, Jihyeon Park and Jiwon Kim; Yonsei University, Korea (the Republic of)

Nanomaterials with high specific surface area and nanoscale detection capability via reversible process is promising for real-time monitoring. In nanoscale detection, the system needs to show long-term stability, rapid response, precise detection, and high ON/OFF ratio. Herein, we present a nanoscale switch which is reversible with short response time and stable for many cycles. Switch is composed of gold nanoparticles(NPs) functionalized with carboxylic functional group (11-mercaptoundecanoic acid; MUA) and tert-ammonium functional group ((11-mercaptoundecyl)-N,N,N-trimethylammonium bromide; TMA) with 5:1 ratio. These NPs were stable in both acidic (pH 3) and basic (pH 11) conditions, and surface charges rapidly changed by changes in the environmental pH. We propose two models to monitor changes in surface charges upon changes in environmental pH via zeta potential: ‘dilution model’ and ‘conservation model’. In dilution model, the pH control solution was directly injected into the NP system, which showed rapid response (< 30 s) with ~30 cycles. In conservation model, NPs were isolated in a semipermeable membrane in order to avoid accumulation of counterions. Conservation model showed relatively slower response time (< 5 min) compared to the dilution model, but the stability improved to 45 cycles. NP-based nanoscale system showed high ON/OFF ratio of 1.3 due to the high surface area, and reversibly switched with fast response time (< 30 s) with ~30 cycles. We believe this system will provide significant advances in the field of real-time nanoscale monitoring (e.g. in vivo monitoring where the environment changes in real time due to homeostasis)
and receptors for molecular communications which quickly respond to continuously delivered messenger molecules.

**Zeolite-Templated Carbon Network—A Beta Zeolite Case Study**  
Eliezer F. Oliveira¹, Leonardo D. Machado² and Douglas S. Galvão¹; ¹State University of Campinas, Brazil; ²Federal University of Rio Grande do Norte, Brazil

3D structures formed from carbon nanotubes could present interesting mechanical and electronic properties [1]. Some studies have shown that these structures are dominated by the topology of the carbon nanotubes networks, which makes their properties tunable [1]. However, up to now the synthesis of such structures has been very limited [2,3]. It has been previously shown that it is possible to grow carbon nanostructures inside the channels of the zeolites [2,3]. Among the large number of possible zeolites [4], good candidate structures to allow the synthesis of 3D carbon nanotubes network are the beta zeolites [3], as they have interconnected channels. In this work we report a preliminary study, based on molecular dynamics simulations about 3D carbon nanotube networks that could be formed inside beta zeolites. We investigated their structural stability and mechanical properties. Our results show that from all possible carbon nanotubes that can be embedded inside the channels of the beta zeolite, the one with chirality (6,0) is the most stable. Using the carbon nanotube (6,0), it is possible to built 3D structures with both all (higher density) and only partially (lower density) filled zeolite channels. The 3D low-density carbon nanotube networks are anisotropic and can be stretched along the direction in which all nanotubes are perpendicular up to 130% of strain without fracture. Also, the porosity and network stiffness can be tuned depending on the amount of carbon nanotubes filling the zeolites channels.

**Development of “Fullerene Nanowhisker-Composite Paper”**  
Taku Onishi and Takahide Oya; Grad. Sch. of Eng. Sci., Yokohama National University, Japan

We propose a new functional paper containing fullerene nanowhiskers (FNWs), i.e., an “FNW-composite paper.” It is known that FNWs have an n-type semiconducting property and are used in a diverse range of applications, including field-effect transistors, solar cells, chemical sensors, and photocatalysts. Therefore, many studies have been conducted until now by lots of researchers. However, because the FNW is a nano-scaled material, so that it is difficult to handle, generally. In this study, we develop an “FNW-composite paper” by mixing FNWs with pulp fibers (raw materials of papers) and solve the problem. Since a paper is lightweight, easy to process, inexpensive, and familiar material for us, the “FNW-composite paper” can be expected to be applied to various things. It is well known that the FNW is prepared using the method of liquid-liquid interface precipitation (LLIP). In this method, it is necessary to put a poor solvent of fullerenes above a good solvent saturated solution of them and form an interface between them. After a while, thin cylindrical shape substances are grown at the layer and FNWs are reduced.

In this study, we use the LLIP. As a first step of fabricating our “FNW-composite papers,” pulps (150 mg) are stirred in pure water (10 ml) for 60 minutes to prepare a pulp dispersion. Then, C₆₀ (fullerene, 40 mg) is dispersed in m-Xylene (10 ml), which is a good solvent of fullerenes, to prepare a fullerene dispersion. After that, the pulp dispersion and the fullerene dispersion are poured in a square case. Since water has a greater specific gravity than m-Xylene, the layer of the fullerene dispersion is above it of the pulp dispersion. Then, isopropyl alcohol (IPA, 10 ml), which is a poor solvent of fullerenes, is poured from above the dispersions carefully to form an interface between the fullerene dispersion and IPA. After that, the prepared liquid is left for 112 hours at 4 °C. Next, the liquid is heated to evaporate moisture. Finally, the material in the case is pressed to finalize the making process. As results, we could gain a sample in this way and confirm that FNWs existed on the pulps by SEM. FNWs have a lot of great features as we showed above. We expect to prepare the paper which has an n-type semiconducting property and use it as a field-effect transistors, chemical sensors, and so on.

Bioactive Glass Nanoparticles as Antibacterial Tool against Antibiotic-Resistant Infections Natalia Pajares Chamorro1, Yadav Wagley2, Neal Hammer1, Kurt Hankenson2 and Xanthippi Chatzistavrou1; 1Michigan State University, United States; 2University of Michigan–Ann Arbor, United States

Infections are a major concern in orthopedics. Bacteria colonization is often the reason for prosthetics failure that causes biofilm formation and induces bone degenerative diseases. The emergence of resistant bacteria has hindered the ability of common antibiotics to fight these infections. For example, Staphylococcus aureus (S. aureus) is able to encode methicillin (i.e. MRSA strains) and it is responsible for 60% of sepsis implant failure. The elevated morbidity and mortality associated with resistant infections support the need for innovative approaches that not only improve treatment outcomes but also reduce the risk of developing further antibiotic resistance. Antibacterial agents such as silver ions are of great interest as broad-spectrum biocides to overcome and prevent the development of resistance in many pathogenic strains. We have developed Ag containing bioactive glass-ceramics with advanced antibacterial and bioactive properties. The synthesis of bioactive nanoparticles (BGN) with complicated composition remains a big challenge. In this work, this challenge is addressed, as we deliver nanoparticles in the desired composition. These nanoparticles are expected to show enhanced antibacterial and bioactive behavior compared to their microsize counterparts due to the increase in their surface area. Here, a modified Stöber method is presented for the successful incorporation of ions that play a key role in the bone regenerative properties of the BGNs. Synthesis parameters were systematically modified in terms of solvent, reagent addition order and stirring time to accomplish particles of the nominal composition being below 100 nm in size and with moderate dispersity. A final protocol was optimized for the synthesis of silver-doped BGN (Ag-BGN) containing SiO2-CaO-P2O5-Al2O3-Ag2O. Characterization techniques such as SEM-EDS, TEM, FTIR, XRD, and solid-state MAS-NMR were used to demonstrate the composition, morphology and structure of the BGN and Ag-BGN synthesized. The antibacterial properties were also evaluated against MRSA by colony forming unit quantification after direct exposure. The cell-material interaction was studied using human marrow-derived mesenchymal progenitor cells. In conclusion, this work addresses the challenges in the development of nanoparticles with multiple ions in nominal concentrations and presents the advancements in antibacterial and bioactive characteristics.

SB01.09.65 Preparation and Degradation Analysis of Multifunctional 3D-Architectured Gelatin-Based Hydrogels Jun Hon Pang1, Christian Wischke1 and Andreas Lendlein1,2; 1Helmholz-Zentrum Geesthacht, Germany; 2Potsdam University, Germany

Mimicking the native extracellular matrix (ECM) using multifunctional materials is a promising approach to direct tissue regeneration in vivo. In particular, pure biomaterial-based strategies without further incorporation of growth factors or surface functionalization are desirable, owing to lower production cost and complexity.

Targeted towards clinical translation of an implant capable of modulating regenerative processes in vivo, a one-pot synthesis of 3D-architected gelatin-based hydrogels was designed, in which the biomolecule is chemically functionalized [1]. These structured hydrogels exhibit essential properties and functions including presentation of cell adhesive sequences, interconnected porous architecture, degradability, dimensional stability upon swelling, as well as tailorable elastic properties. The gelatin-based hydrogels were manufactured in a cleanroom facility. While it is known that such scaffolds are degradable in vivo, there is limited understanding on the contribution of different degradation mechanisms, particularly in relation to the role of crosslinks.

In this study, samples of 1.5 x 1.5 cm2 with thickness of ~3.5 mm were incubated at 37 °C with mild agitation in solutions simulating pure hydrolytic degradation (phosphate buffered saline, PBS), oxidative degradation (3 % v/v H2O2) and enzymatic degradation (0.2 U/mL Collagenase I), which are supplemented with 0.01 % w/w sodium azide to exclude microbial contamination. The hydrolytic and oxidative buffer conditions simulate real-time degradation [2]. Collagenase I was selected to elucidate enzymatic degradation due to its presence in damaged tissue and reports of degrading other gelatin-based materials [3]. The influences of the three degradation conditions on mass loss, morphological and chemical properties of the scaffolds were investigated.

The scaffolds degraded rapidly under oxidative and enzymatic conditions, with endpoint of >95 % mass loss achieved in 2.5 weeks. In contrast, the scaffolds were relatively resistant to hydrolytic degradation, with merely mass loss of 20 % after 20 weeks. SEM analysis indicated varied degradation behavior among the different sample groups based on changes in porous structure alongside crack formation.
We discuss degradation mechanisms and products in relation to the chemistry of the scaffold, specifically on the role of the involved crosslinks. Oxidative and enzymatic degradations were shown to be the key mechanisms for in vivo degradation of our gelatin-based hydrogels. Such analysis is vital for biodegradable implants to elucidate degradation behavior and products, both of which are essential for translation of novel biomaterial-based implants.

**Effects of Geometry on Magnetic Actuation of Micropillar Arrays**

Jeong Eun Park1, Jisoo Jeon1, Sukyoung Won1, Jehwan Hwang2, Sang Jun Lee2, Augustine M. Urbas2, Zahyun Ku3 and Jeong Jae Wie1; 1Inha University, Korea (the Republic of); 2KRISS, Korea (the Republic of); 3Wright-Patterson Air Force Base, United States

Reversible shape-reconfiguration of magnetic composites has been demonstrated by pre-programming the alignment of magnetic particles within micropillar arrays. The alignments of magnetic particles determine the magnitude and directionality of magnetic-actuation dependent to the offset angle from the external magnetic field axis. Previous reports on magnetic microstructures have mostly been employed symmetric cylindrical or rectangular geometry, resulting in balanced stress distribution for actuation by the external magnetic field. Herein, we demonstrate the effects of asymmetric geometry on magnetic actuation with the rectangular and triangular form factor. Upon the external magnetic field, the magnetic torque generates concentrated magnetic momentum in anisotropic micropillars, resulting in enhanced magneto-mechanical actuation. To elucidate the relationships between geometry factors of pillars and magnetic-actuation, we will discuss structure-property relationships of triangular and rectangular micropillars for both bending and twisting actuation.

**SB01.09.67**

**Time-Controlled Nanoscale Delivery System**

Jihyeon Park, Seoyeah Oh, Dongjun Kim and Jiwon Kim; Yonsei University, Korea (the Republic of)

Delivering cargoes at desired time points and positions in nanoscale is necessary in order to precisely control the time-dependent reactions. For example, each drug needs to be delivered at desired time point in order to increase the efficacy of multi-drugs. The delivery time and position also need to be finely controlled if cargoes should be combined before they degrade for activation. However, it is difficult to develop a spatio-temporally controlled delivery system (especially for multi-cargos, delivery time difference with a short period time (< a few minutes)) due to random walk motion of cargoes, difficulty of applying two different driving forces on the same type of nanoscale delivery system, and an interference between cargoes. Herein, we designed two (or more) types of nanomotor which can travel at different speeds upon a single magnetic stimulus. Nanomotors were composed of nickel head – silver flexible filament – gold tail encapsulated with N-isopropylacrylamide (NIPAm) based hydrogel. The difference in speed was quantitatively controlled by adjusting the length of each compartment whereas the cargo releasing time was regulated by optimizing the thickness of encapsulating hydrogel. Our nanomotor based nanoscale delivery system demonstrated sequential cargo delivery with time-difference of a few minutes. This delivery system can possibly increase the gene editing efficiency (e.g. CRISPR/Cas9 system) and efficacy of multi-drugs by allowing drugs or genetic materials to be activated at different time points. Furthermore, our time-controlled delivery system in nanoscale can also be applied in molecular communication via applying sequential (bio)material transmission as a signal.

**SB01.09.68**

**Controlling Microstructure of Bombyx mori Silk for Water-Responsive Actuation**

Yaewon Park1, Yeojin Jung1,2, Raymond Tu1,2 and Xi Chen1,2; 1Advanced Science Research Center at City University of New York, United States; 2The City College of New York, United States

Water-responsive (WR) materials that swell and shrink in response to changes in relative humidity could serve as high-energy actuators, providing new engineering opportunities for soft robotics, sensors, and energy harvesting devices. Spider silk has been shown to be a WR material and has a higher energy density than conventional
actuators. However, natural silk’s relatively low production efficiency and variations in water-responsiveness limit their practical applications. Bombyx (B.) mori silk is also reported to have a WR property, but B. mori silk has a lower energy density than that of spider silk. Here, we demonstrate that the processing of the B. mori silk can dramatically increase regenerated B. mori silk’s WR energy density. To control the grain size and volume ratio of Silk II structures, we treated regenerated B. mori silk films with water vapor and methanol under various conditions which yield higher volume ratios. FTIR and AFM experiments subsequently confirmed the variation of Silk II structures resulted from these post-treatment methods. We found that Silk II structures’ crystallinities, sizes, and distributions define the silk’s WR behaviors. For example, as the volume of Silk II increases, regenerated silk’s WR energy density increases and reach ~500 kJ m⁻³, which is comparable to that of spider silk. This work is a proof-of-concept that a powerful WR actuator can be fabricated with cost effective and naturally abundant B. mori feedstocks.

Humidity Sensing Microfibers Containing Conducting Nanofillers in an Agarose Matrix and Impedance Analysis on Their Opposite Humidity Response Ye-Jin Park¹, Yangwoo Lee¹, Ju-Hee So², Sungkon Kim³, Bongjun Yeom⁴ and Hyung-Jun Koo⁵; ¹Seoul National University of Science and Technology, Korea (the Republic of); ²Korea Institute of Industrial Technology, Korea (the Republic of); ³Chonbuk National University, Korea (the Republic of); ⁴Chonbuk University, Korea (the Republic of); ⁵Hanyang University, Korea (the Republic of)

Inspired by a human or animal hair as a natural humidity sensor, two types of humidity sensing microfibers based on an agarose polymer as a hydrophilic matrix and conducting fillers are reported. The microfibers are fabricated with simple extrusion of the agarose composites containing two different conductive nanofillers: (1) graphene oxide (GO, chemically reduced after extrusion)/silver nanowires (AgNWs) and (2) carbon nanotubes (CNTs). Both microfibers at optimum filler content exhibit the enhanced electrical conductivity and mechanical properties, due to intrinsic property of CNT or synergistic contribution of AgNWs and reduced GO (rGO) as 1D and 2D nanofillers, respectively. As a result, the microfibers have 3~4 times higher values of Young’s modulus than commercial nylon-6 and polyamide and are flexible enough to be knotted. The composite microfibers have an ability to be humidity sensors owing to their humidity-dependent conductivity. The microfiber containing rGO/AgNWs shows positive dependence of its conductivity on environmental humidity, upon ionization of water molecules by rGO. On the other hand, the microfiber with CNT shows negative dependence of its conductivity on humidity, due to decreased junction density of CNT resulting from swelling of the hydrophilic agarose matrix at high humidity. In order to delve into the opposite humidity response of two composite fibers, we performed impedance analysis of the fibers at various humidity conditions, which will be discussed. The composite microfibers show reliability, reversibility and feasibility of humidity sensing demonstrated by repetitive changes in humidity and practical usages such as human breathing. The humidity sensing microfibers could have applications to smart textile and wearable devices.

SB01.09.70
Artificial Synapses and Resistive Switching Memory Based on Biomaterials Youngjun Park, Min-Kyu Kim, Dongshin Kim and Jang-Sik Lee; Pohang University of Science and Technology, Korea (the Republic of)

Biocompatible and implantable electronics have gained increasing attention due to growing interest in health care. The advances in the electronics require the development of biocompatible and implantable memory that performs the data processing and storage. However, conventional memory devices are not suitable for this purpose because they are not biocompatible and sometimes even toxic. We present the memory devices and artificial synapses based on natural, biocompatible, and biodegradable materials on flexible polyethylene terephthalate substrates [1]. Multi-bit data storage capability is achieved by controlling maximum reset voltages and compliance current. The switching behavior is thought to be related to the carbon atoms in the active layer, which could form the carbon filament. Synaptic functions including analog switching behavior and potentiation/depression are realized by controlling the formation and rupture of filament [2]. By properly modulating the stimulation pulses, both short-term plasticity and long-term plasticity of biological synapses can be achieved. Moreover, the devices can be stably operated under mechanical bending stress. These researches will offer a new possibility for biomaterials to be used in next-generation memory devices and neuromorphic systems. In this presentation, characteristics of biomaterials for application to memory devices and artificial synapses will be presented in detail.

**Multifunctional and Biodegradable Self-Propelled Protein Motors**  
Abdon Pena-Francesch, Joshua Giltinan, Metin Sitti and Ugur Bozuyuk; Max Planck Institute for Intelligent Systems, Germany

A diversity of self-propelled chemical motors, based on Marangoni propulsive forces, has been developed in recent years. However, most motors are non-functional due to poor performance, a lack of control, and the use of toxic materials. To overcome these limitations, we have developed multifunctional and biodegradable self-propelled motors from squid-derived proteins and an anesthetic metabolite. The protein motors surpass previous reports in performance output and efficiency by several orders of magnitude, and they offer control of their propulsion modes, speed, mobility lifetime, and directionality by regulating the protein nanostructure via local and external stimuli, resulting in programmable and complex locomotion. We demonstrate diverse functionalities of these motors in environmental remediation, microrobot powering, and cargo delivery applications. These versatile and degradable protein motors enable new design, control, and actuation strategies in microrobotics as modular propulsion sources for autonomous minimally invasive medical operations in biological environments with air-liquid interfaces.

SB01.09.73  
**Programming Tri-Peptides Water-Responsive Materials**  
Roxana Piotrowska1,2, Travis Hesketh3, Alan Martin4, Deborah Bowering4, Chunhua Hu5, Haozhen Wang1, Xi Chen7 and Rein Ulijn1; 1Advanced Science Research Center, United States; 2The City University of New York, United States; 3University of Strathclyde, United Kingdom; 4University of Strathclyd, United Kingdom; 5New York University, United States

Water-responsive (WR) materials that exert significant forces in response to changing hydration levels are receiving growing interest due to their potential applications, including use as actuators for energy harvesting devices, artificial muscles, and soft robotics. Reported examples include biological and synthetic materials with abilities to efficiently convert chemical potential of water into mechanical actuations. However, these systems are typically complex, and consequently, their WR mechanisms are not well-understood thus preventing rational design and optimization. Here, we demonstrate that tri-peptides, which are modular organic building blocks with precisely tunable non-covalent interactions, spontaneously associate to form hierarchical ordered crystalline structures, which exhibit WR behavior that is strongly dictated by their building blocks’ chemical nature and consequent organization. Our tripeptide crystals, with intrinsic water channels in nanoscale, has the ability to swell and shrink in response to changes in relative humidity (RH). The crystals also exhibit outstanding mechanical properties including a stiffness of 0.5 - 2GPa depending on RH, leading to a high WR energy density of more than 80kJ/m³. Due to its biodegradability and relative simplicity, this system could not only serve as an excellent platform to enhance understanding of such material’s WR mechanisms, but also holds much promise for programing better WR materials for future applications.

**Effect of Mechanical Mismatch on Failure Mechanism of Substrate-Electrode Systems in Stretchable Electronics**  
Reihaneh Jamshidi; University of Hartford, United States

All-organic electronics have gained increasing attention due to their biocompatibility, intrinsic flexibility, as well as lower cost compared to inorganic materials. It is hypothesized that the similarity of mechanical properties between the electrode and substrate in all-organic electronics, facilitates improved mechanical performance in these structures. Here, we report the comparison between failure mechanism of an all-organic bilayer and a metal-polymer bilayer to demonstrate the effect of inherent properties of layered structures on the overall mechanical performance of the system.
High-Performance Actuators for Untethered Applications Seyed M. Mirvakili, Robert Langer and Ian W. Hunter; Massachusetts Institute of Technology, United States

In this work, we are presenting a simple approach for the fabrication of high-performance muscle-like actuators (artificial muscles) for untethered applications. Artificial muscles are exploited in various applications, including soft robotics, bio-medical devices, and even energy harvesting systems, to name a few. One of the limitations of such actuators is the need for wiring, pressurized gas tanks, electrolytes, etc. Here we are demonstrating how we can make wireless actuators that can perform as good as the tethered counterparts.

Emerging Materials Robotics S.K. Smoukov1,2; 1Queen Mary University of London, United Kingdom; 2University of Cambridge, United Kingdom

Molecular robots are all around and inside us – from viruses injecting their RNA and highjacking cellular machinery for replication, to myosin contracting our muscles, to the ribosome translating our DNA. Such invisible machinery is key to us being alive. Can we start growing functional nanomachines artificially? In this talk I will outline progress we have made towards this goal. From creating programmable materials that can move, sense and respond to their environment in complex ways, to artificial morphogenesis – we have the ability to shape particles and our future. & much of this story is based on liquid droplets.

Our work on topological inter-penetration of functional materials[1] replaced unpredictability in multifunctional synthesis with combinatorics - choosing 3 phases of 20 already optimized functions would lead to over 8000 trifunctional materials. We demonstrated new supercapacitor architectures,[2] as well as emerging self-sensing artificial muscles.[3] We also discovered artificial morphogenesis – transformation of liquid droplets into a large variety of complex regular micro- and nanostructures. Our methods of growing from single molecules many shapes, including octahedra, hexagons, rhomboids, triangles and fibers[4] have yielded a polymerization process[5] that could potentially replace the expensive infrastructure and waste of lithography. We have classified dozens of pure[6] and mixed component systems (including triglyceride oils) capable of shape-change[7] which could let us synthesize novel shaped lipids or polymer drug carriers. We use thermodynamic understanding and mathematical modelling to predict and control the observed shapes[8]. Transforming almost 100% of a liquid droplet into a final shape is ideal for sustainability and for space manufacturing.

Current projects aim to move beyond manufacturing static shapes. By combining bottom-up growth with multifunctional polymer synthesis, we aim to produce functional micro- and nanoparticles with autonomous behaviour, e.g. movement, sense and response to environmental stimuli, as well as on-board energy storage. Surprisingly, some of our artificial systems already mimic life by repeatedly harnessing thermal fluctuations in the environment, and storing energy by breaking up into smaller and smaller emulsion droplets.[9] I will outline implications for further fundamental discoveries and for potential applied explorations.

9:00 AM SB01.10.03
Printed Wearable Multi Sensors on Soft Robotic Gripper for Detection of Tactile Signals Tomohito Sekine1, Yi-Fei Wang1, Yasunori Takeda1, Daisuke Kumaki1, Santos Fabrice Domingues Dos2, Atsushi Miyabo3 and Shizuo Tokito1; 1Yamagata University, Japan; 2Piezotech, France; 3Arkema K. K., Japan

Tactile sensing is required for a dexterous feedback system of an object in robotic-skin applications. Moreover, an ability to monitor various physical forces such pressure and shear in real time is a key technology for a slip detection with fragile objects. As a way of solving the above, a flexible printed sensor will be invaluable. Because these possess great potential advantages for the robotics-skin applications due to high sensitivity. Previously, fabrication of soft sensors and their application for robotic skins was reported by many groups; however, realization of a multi-sensing devices by printing methods remain a challenging task. Recently, we reported flexible and soft sensors that were fabricated using a ferroelectric polymer, P(VDF-TrFE) and Carbon nanotube (CNT) by printing methods for shear and pressure detection. Furthermore, we developed a printed temperature sensor using PEDOT:PSS. Integration of these sensors on a one-tip-substrate will enable realization a physical multi-sensor for tactile signals. Here, we report a wearable and printed soft robotic multi sensor composed of shear, pressure and temperature sensors for detection of tactile signals.

The various shear, pressure and temperature sensors were fabricated on a flexible film by printing methods. First, we fabricated the shear sensor using P(VDF-TrFE) by Screen printing method. A cross-linked poly(4-vinylphenol) (PVP) solution mixed with the PVP and 1-methoxy-2-propyl acetate as the solvent was formed by spin-coating onto the substrate as the planarization layer. Lower and upper electrodes of the sensor were formed using conductive polymeric materials and annealing at 140 °C for 30 min. The P(VDF-TrFE) layer was formed as the detecting layer of shear force by screen printing and annealed at 135 °C for 1 h. The polarization and the coercive electric point of the sensor were 7.0 µC cm⁻² and 50 MV m⁻¹. These performances are reasonable as printed ferroelectric devices. Next, we fabricated the pressure sensor using the CNT solution mixed with a 4-dodecylbenzenesulfonic acid by Dispense equipment. The electrodes of this sensor were formed by the Ag nanoparticle ink and annealing at 150 °C for 30 min. The CNT layer was formed as the detector of pressure force by Dispensing and annealed at 100 °C for 12 h. The initial resistance value of this sensor was 10 kΩ. Finally, the temperature sensor using PEDOT:PSS was fabricated by Screen printing. After formation the PEDOT:PSS layer, the substrate was annealed as 100 °C for 12 h. The output voltage of the shear sensor linearly displayed a clear correlation with the applied shear force and the output voltage. It showed approximately 50 mV in the shear speed of 200 mm s⁻¹. Similarly, the relationship between applied pressure and output voltage in the pressure sensor was measured. The pressure was applied by using a pressure tester to the sensor. This resistivity was changed from the initial value to 1 kΩ when pressure of 2.0 N applied. These results indicate that the fabricated various devices will be candidate for tactile sensors of a robotic-skin due to high sensitivity.

Robotic controlling experiments were performed demonstration the use of our sensors to monitor tactile signals in real time. The gripper can grip various objects by a pneumatic driving system. Moreover, our multi sensor were attached on a soft robotic gripper. An oscilloscope recorded the signals of output voltage from the sensors. We can estimate tactile signals of shear, pressure and temperature at the same time when the gripper handled objects. From these outcomes, the information obtained from the fabrication of the multi sensor used in this study further illustrates the potential in an elaborate robotics controlling system with a closed loop feedback.

9:15 AM SB01.10.04
Stimuli Responsive Microscale Architectures—Two Photon Lithography with Shape Memory Polymers Luizetta V. Navrazhnykh, Erika Salzman and Julia R. Greer; California Institute of Technology, United States

Shape memory polymers (SMPs) can respond to heat by generating programmable movement, which can enable multiple technological advances in deployable structures, biomedical device placement, and sensing applications. Many of these technologies could benefit from miniaturization: deployable micro-sized drug delivery vehicles, neural probes and stents could enable minimally invasive access to targets that are currently surgically inaccessible. The shape change requirements of drug delivery have motivated the development of isolated three-dimensional (3D)
SMP structures through molding and emulsion techniques, resulting in relatively simple geometries: spheres, cubes and boomerangs with whose critical dimensions are 1-35 µm\(^1\text{-}^3\). Many other applications require shape transformations to occur in structures with substantially more complex geometries, i.e. a stent or neural probe, which drives the need to synthesize complex architected shape memory structures with sub-micron resolution.

We developed a benzyl methacrylate-based photosensitive resin that polymerizes into programmable 3D shapes with minimal dimensions of 650nm using two photon lithography direct laser wiring (TPL-DLW). We synthesized this resin for shape memory actuation via a glass transition, i.e. the produced structures transform from glassy to rubbery state in response to increased temperature to enable shape programming and recovery. Dynamic nanomechanical analysis (DnMA) was performed through the 22°C to 87°C temperature range on individual TPL-sculpted SMP cylindrical pillars with diameters of 10µm and revealed the initiation of a glass transition at 60°C. We performed shape memory programming by first applying a 400µN load to individual pillars at 77°C and then cooling them to the glassy state at 42°C while maintaining the mechanical load. After load removal, the structures retained their shapes over 7 days at room temperature and recovered to their original dimensions when heated to 87°C within 5 minutes. This shape memory occurred in all 3D micro-architectures that we programmed, including pillars, cubic lattices, and flowers, with a characteristic shape recovery ratio of 86% +/- 4%.

This technique provides a promising pathway to miniaturize shape memory devices and to develop stimuli responsive microscale mechanical metamaterials. Utilizing shape memory polymers as constituent materials could enable miniaturization of existing macroscale shape memory devices, as well as the development of stimuli responsive materials that display amplified and unusual mechanical properties that stem from emergent nano-size effect in materials.

**Biodegradable Soft Robotics and Electronics** Florian Hartmann, Melanie Baumgartner, Michael Drack, David Preninger, Daniela Wirzl, Lukas Lehner, Stepan Demchysyn, Robert Gerstmayr and Martin Kaltenbrunner; Johannes Kepler University, Austria

Cephalopods, caterpillars and other soft creatures inspired a broad spectrum of bio-nimetic actuators capable of sensing and adapting to their complex erratic environments. Yet, they are missing a feature of nature’s designs: biodegradability. Soft robots that degrade at the end of their life cycle reduce electronic waste and are paramount for a sustainable future. At the same time, medical (robotic) technologies benefit from biodegradable materials since they are often single-use devices and have to address hygiene requirements. We therefore develop biodegradable hydrogels (biogels) for single-use wearable electronics and transient soft robots that are reversibly stretchable, are able to heal, and are resistant to dehydration. Soft machines and robots – built from biogels with tuned mechanical properties – are designed to be operated in ambient conditions and degrade after use. An equally compostable electronic skin provides our soft actuators tactile feedback and temperature sensing, directly processed with a recyclable on-board computation unit. Besides progressing stand-alone soft machines, our advances in the synthesis of biodegradable hydrogels bring bionic soft robots a step closer to nature.

9:45 AM SB01.10.06
**Origami-Designed Artificial Muscles (O-DAM) Electroactive Soft Robotic Actuators** Madison B. Emmett, Shardul Panwar, Jillian Jakubiec and Michael Rowe; Toyota, United States

Electroactive artificial muscles actuators are unique and lightweight devices that will revolutionize automotive applications by their large strain (120%) and high specific power (160 W/kg), but still require improvement in energy density to be commercially viable. Through design aided by finite element analysis (FEA) and material research, these in-house fabricated artificial muscles were improved by recursive optimization. This led to a new origami-inspired design for a compact, foldable electrode stack that consists of an inner zig-zag structure suspended in dielectric fluid, surrounded by an outer double helix of electrode leads. We refined the electrical insulative material to increase the breakdown voltage per micron of film thickness by more than 30%. This improvement enables actuators to operate at higher voltages, thus increasing the maximum actuator force. Our origami-designed artificial muscles (O-DAM) increase the active electrode surface area which enhances the performance of the device. These soft robotics actuators promise to revolutionize the future of human-machine interactions.

**Cell-Sized Robots** Marc Miskin¹², Alejandro Cortese², Kyle Dorsey², Paul McEuen² and Itai Cohen²; ¹University of Pennsylvania, United States; ²Cornell University, United States

This talk presents an approach for fabricating cell-sized robots massively in parallel. By building upon existing microelectronics technology, we show how to overcome the key challenges for miniaturizing robotic systems. We use this approach to build and deploy microrobots that walk, are fully untethered, are individually addressable, and wirelessly receive power and instructions through light. They use a new class of voltage controllable, electrochemical actuators made from nanometer thick membranes of platinum. Our fabrication process is completely compatible with silicon microelectronics processing and results in millions of microrobots per four-inch wafer. Combined, these results present a broad platform that can unite mechanical systems, information processing and control to make autonomous robots the size of cells.

**Graphene – Carbon Nanofibers Hybrids for Stretchable and Healable Electronics with Application in Soft Robotics** Pietro Cataldi, Dimitrios Papageorgiou, Robert Young, Mark A. Bissett and Ian Kinloch; University of Manchester, United Kingdom

The advancement of stretchable electronics is instrumental for new-generation compliant and wearable devices. High-performing strain sensing technologies have already been realised by exploiting the high gauge factor of graphene-related materials coupled with elastomers [1,2]. Nevertheless, the manufacture of graphene-based electrodes that display outstanding electrical features which remain constant during mechanical deformation, is still challenging [3,4]. On this basis, we fabricated a deformable electrode by simply spray-coating nitrile rubber with graphene-based elastomeric conductive inks. Painting stretchable polymer dispersions carrying graphene nanoplatelets (GnPs) or hybrids of GnPs and carbon nanofibers led to the production of novel electrodes with low sheet resistances (~10 Ω sq⁻¹). The hybrid electrodes that were prepared in this work, exhibited enhanced electrical conductivity at low nanofiller loadings and upgraded performance after repeated bending and folding cycles, compared to the GnP-based electrodes. Both conductors sustained repeated washing cycles and preserved 50% of their initial electrical conductivity at 12% elongation. The strain stability of their electrical properties was enhanced by pre-stretching the rubber substrate before spraying the conductive ink. With this approach, both GnP- and hybrid-based electrodes preserve more than 70% of their initial electrical conductivity at 12% stretch. In this case, at 80% elongation the hybrid material displays electrical conductivity 4 times higher than the GnPs conductor. This is because the GnP-based coating forms cracks already at 30% elongation while the hybrid shows a crack-free morphology even at 100% strain. Repeated stretch-release cycles produced an electro-mechanical deterioration that can be restored simply through a heating treatment. The healing procedure also restored the electromagnetic interference shielding efficiency that was normally reduced after repeated stretch-release cycles. The developed technology finds application as stretchable parallel-plate capacitive touch sensor [4]. Tactile forces as low as 0.03 N and as high as 5 N can be detected by the device bended over curvilinear surfaces or under elongation.

**Magnetically-Triggered Ultrafast Soft Robots with Embedded Magnetic Cognition and Feedback Control** Xu Wang, Gilbert Santiago Canon Bermudez, Jürgen Fassbender and Denys Makarov; Helmholtz-Zentrum Dresden-Rossendorf, Germany

In the last years, soft robots have been designed and developed to fulfil demands of better malleability and adaptability to changing environment [1-2]. They can be made of various stimuli responsive materials, which respond to magnetic field [3], light [4], temperature [5], electric fields [6], chemicals [7], pressure [8], etc. In
contrast to other actuation mechanisms, magnetic fields are appealing for numerous application scenarios (e.g. environmental, biological, medical), where their long-range penetration, easy accessibility, and controllability [2, 9, 10] offer exciting advantages. Despite the significant advances in soft magnetic actuators, real-time monitoring and precise feedback control [11-13] remain a challenge for magnetic soft robots.

Here, we present a soft robotic system capable of precisely controlling its deformation degree by means of embedded highly compliant, high-performance magnetic sensors. Our ultrathin (7-100 μm) and ultrafast soft robots that can be actuated by in external magnetic fields pulsating at rates of up to 200 Hz. The high-performance magnetic field sensor is based on the giant magnetoresistive effect and is prepared on ultrathin polymeric foils [14-17] to assure its high mechanical stability combined with mechanical imperceptibility. The latter is crucial to avoid any disturbance of the soft actuator due to the presence of magnetic sensing device. The self-sensing function is realized by monitoring the change of the sensor signal upon approaching it to a magnetic patch applied to the soft robot. This concept of an entirely soft and integrated sensor-actuator system enables contactless self-tracking of motion for magnetic soft robots and can be readily extended to other stimuli-driven soft actuators. These developments will pave the way towards intelligent soft robots, autonomous and reactive soft devices, and new types of human-robot interaction.

**SB01.10.10 Soft Dielectric Materials for Sensing and Energy Harvesting Applications** Philippe Poulin; CNRS University of Bordeaux, France

High permittivity and efficient electromechanical coupling are critical to perform energy storage or conversion between mechanical and electrical energy for various applications of electrostrictive polymers. We report a giant electrostriction effect in liquid crystalline graphene doped elastomers. The materials are formulated by an original phase transfer method which allows the solubilization of graphene oxide monolayers in non-polar solvents. It is shown in particular that liquid crystal transition leads to an increased percolation threshold. Because of their unique liquid crystal structure, the resultant composites show a giant electrostriction coefficient ($M\sim \times 10^{-14}$ m$^2$/V$^2$ at 0.1 Hz) coupled with good reproducibility during cycles at high deformation rates. This work offers a promising pathway to design novel high performance soft dielectric materials for sensing or energy harvesting applications. We will also discuss recent developments concerning dielectric foams and multilayers systems that allow ultra-low pressure sensing via piezo-capacitive effects.
1:30 PM *SB01.11.01
Programmable Composites for Stiffness-Changing and Shape-Shifting Soft Robots
Rebecca Kramer-Bottiglio; Yale University, United States

Soft robots have the potential to adapt their morphology, properties, and behavior to different tasks or changing environments. This adaptive capability is often inspired by biological systems. For instance, humans can transition between forceful and gentle tasks by controlling the stiffness of skeletal joints through co-contraction of antagonistic sets of muscles. In another example, the remarkably dexterous motion achieved by skeleton-free animal parts such as elephant trunks, octopus arms, and human tongues is attributed to selective contraction of layers of uni-directional muscle fibers. During this talk, I will present recent work towards programmable composites that address variable stiffness properties and variable trajectory motions inspired by these capabilities in animals. First, I will present a particulate additive designed to undergo a repeatable solid-liquid phase change within a polymeric matrix and demonstrate its use to achieve unprecedented changes in bulk material stiffness and elasticity. The solid-liquid phase change of Field’s metal inclusions allows a composite to dramatically adjust its mechanical response, as demonstrated in two matrix materials: a thermoset epoxy and a silicone elastomer. Second, I will describe a soft composite lamina comprised of an elastic matrix with uni-directionally embedded inextensible fibers and an adhesive backing, which was inspired by soft body control strategies using fiber-architectures. In contrast to existing soft actuators with fixed deformation trajectories, this composite is simply placed on the surface of an inflatable body to govern its deformation trajectory, can be re-arranged in-situ to change this trajectory, and is created using a high throughput, automated manufacturing process. Finally, I will speculate on how these two composites could be combined to achieve new capabilities in next-generation soft robots.

2:00 PM SB01.11.02
Freeform Fabrication of Dielectric Elastomer Actuators for Soft Robotics Applications
Theo Calais, Elgar Kanhere, Siddharth Kumar, Thileepan Stalin and Pablo Valdivia y Alvarado; Singapore University of Technology and Design, Singapore

The emergence of soft robotics has given rise to new challenges in both the development of functional materials and the design of innovative versatile manufacturing techniques. Additive manufacturing is generally cited when discussing promising versatile fabrication processes. Indeed, a wide range of materials, such as thermoplastic polymers, metals, elastomers, biomaterials, and yarns, can be used for freeform fabrication and integration into complex structures using different additive manufacturing techniques. Among these techniques, the extrusion of materials is the most commonly adopted due to its relative simplicity. However, the choice of materials has been limited to materials exhibiting a phase transition at appropriate temperatures (e.g. thermoplastics) or to thixotropic materials that flow under stress. Hinton et al. reported the use of a support bath, made of a microparticulate hydrogel (Carbopol), allowing the freeform embedding of PDMS in the liquid state before reticulation of the elastomer. After curing, the hydrogel is dissolved by changing the pH, and the 3D-printed object is released. However, Carbopol is highly sensitive to the ionic composition and pH, thus excluding various materials with incompatible chemical compositions. In this contribution, we present the use of a new aqueous-based support bath made of nanoclay suspension for the printing of functional devices. This new support enables the printing of a wider range of materials, including thermosensitive and UV-curable materials, that can be combined into functional devices. We illustrate the advantages of this economical and reusable support by fabricating dielectric elastomer actuators (DEAs) inspired by the Peano-HASEL actuator published by Keplinger’s group. In a facile and fully integrated process, we used the aqueous-based support bath to print advanced muscle-like actuators. First, the dielectric liquid is encapsulated by printing an elastomeric envelope. Electrodes, made of a UV-curable polyacrylamide hydrogel, are successively integrated into the elastomer before curing. Finally, materials are left for curing at room temperature for about 24 h and the support bath is washed away. This facile method allows the assembly of multiple actuators with various complex forms. We present the rheological properties of the support bath, its compatibility with a wide range of materials, and the fabrication and characterization of a DEA device.

Polymeric actuator materials are able to shift their shape reversibly and repetitively in response to an environmental stimulus. Shape-memory polymer actuators function by utilizing the crystallization-induced elongation and melting-induced contraction of an actuation domain, the orientation of which is maintained by a rigid skeleton domain. The interconnection between the domain-forming segment chains is provided by a network of cross-links, which are usually of a covalent nature and therefore preventing the reprocessing of the material after fabrication. The implementation of physical cross-links, based on e.g. hydrogen bonding, thermally stable crystals or ionomers, aims to provide a solution to this problem. In this work, we introduce shape-memory polymer blend actuators, where the cross-links are formed by the physical interaction between a multiblock copolyester and an oligoester. By utilizing this supramolecular interaction, we create a rigid structure, stable up to 200 °C, formed in a one-step process without any post-treatment. The blending approach allows us to tune the actuation performance of the materials simply by adjusting the composition.

Plant-Like Robots are Growing Up

Barbara Mazzolai; Istituto Italiano di Tecnologia, Italy

A rich literature exists in bioinspired robotics and recently the use of soft materials and variable stiffness technologies represents an emerging way to build new classes of robotic systems that are expected to interact more safely with natural unstructured environments and with humans, and that better deal with un-certain and dynamic tasks. Despite the big achievements in this field, robotic technologies are still inadequate to mimic the biological system capabilities in changing their morphology and adapting their body and functionality during their lifetime. Growth is a very interesting feature of living beings that can inspire a generation of robots with new and unpredictable abilities of movement. Noteworthy, plants represent an alternative model of movement in robotics based on growing.

We propose a new generation of self-creating plant-like robots that are able to move adding new material to their bodies while adapting to external conditions. We also focus our research on designing and developing innovative actuation solutions taking inspiration from unexplored biological phenomena, such as osmosis. In this field, we propose the first soft robot mimicking plant tendrils. The robot is able to curl and climb, using the same physical principle determining water transport in plants (osmosis).

The potential impact on society of plant-like self-creating robots could be huge and wide, e.g., in rescue, medical applications, space, or environmental monitoring. Since the design of these robotic solutions is deeply based on a few selected plant features, a new view of robots for biology can be envisaged, with the goal to give insights on the organisms themselves and open new exciting opportunities both in science and engineering.

Bio-Inspired Multifunctional Materials Systems—Plants as Concept Generators for Soft Robotics and Architecture

Thomas Speck; University of Freiburg, Germany

Plant organs and tissues represent from a materials science point of view hierarchically structured multifunctional adaptive materials systems which in addition typically are equipped with various self-x-functions including for example self-repair. This makes them to interesting role models for many potential applications in high-end
technologies including soft robotics, aviation and space flight, automotive, and future-bound green architecture, but also for sports equipment and for prostheses or orthoses. An often overlooked potential of bio-inspiration from plants are complex motions found in the not at all static and immobile plants. These motions can either be actively actuated (by turgor or growth processes) or can be passively actuated (by changes in humidity). In the latter case, motion patterns are imprinted in the structure of fiber-reinforced plant materials systems allowing for one, two and three-phase motions.

Novel methods for quantitative analysis and simulation of the form-structure-function relationship at different hierarchical levels provide fascinating insights into multiscale mechanics and other functions of plant material systems. New production methods such as 3D & 4D-printing, laser sintering and melting, and 3D braiding pultrusion make it possible - similar to biology - to produce from small to large and to functionalize different hierarchical levels. This allows cost-effectively to convert many outstanding properties of biological models into innovative biomimetic products. The examples presented include the development of material systems for a novel type of soft robots that climb like plants and adapt to their environment. The “GrowBot” research groups aim to transfer the skills of climbing plants who can find suitable support structures with their stems in complex, unknown 3D environments. Their different anchoring strategies allow the plants to attach themselves to different surfaces. In a first phase the transfer of stems structure and of the various attachment system (e.g. roots or tendrils) into bio-inspired (self-)adaptive materials systems for soft-robots is intended. A second example are anti-adhesive materials systems and surfaces inspired by plant surfaces on which insects cannot find grip and slip off. These bio-inspired micro-structured surfaces can be embossed on adhesive tapes that can help protect food or medicines from pest insects. Further examples are based on plant movements and aimed for the development of novel bio-inspired motile materials systems, e.g. for architecture. They include one and two phase motion patterns found in pinecone scales (Pinus spp.) and three phase motions occurring in the involucral bracts of the silver thistle (Carlina acaulis). These organs combine sensor, actuator, reactive movable element, and support structure in one materials system, do not consume energy (i.e. move entirely passive), show high level of functional integration and display extraordinary high functional resilience and robustness. Active motion processes served as role model for the biomimetic façade shading system flectofold which was inspired by the trap movement of the waterwheel plant (Aldrovanda vesiculosa), and by the wing folding patterns of the Italian striped bug (Graphosoma italicum). The waterwheel plant together with the Venus flytrap (Dionaea muscipula) served additionally as concept generator for adaptive biomimetic actuator systems reacting to various stimuli and combining two biological snap-trap mechanics. The bio-inspired demonstrators not only incorporate the actuation principles and movement behaviours of the two carnivorous plant species but also show adaptive responses to different environmental triggers. In the presented actuator systems we succeeded to implement several plant movement, actuation and deformation systems into one versatile adaptive technical compliant mechanism.

4:00 PM SB01.11.06

**Light Responsive Magnetic Cilia for Local Actuation**  Meng Li, Taehoon Kim, Giulia Guidetti, Yu Wang and Fiorenzo Omenetto; Tufts University, United States

Cilia are thin hair-like structures that cover living surfaces for motion and swimming. Numerous studies have been focused on replicating the properties of these morphologies by exploring artificial biomimetic cilia for applications in microfluidic propulsion/mixing[1], surface property modification [2], catalytic reactions [3], microrobots/swimmer [4] among many others.

Among multiple possibilities for actuation, magnetic fields present an opportunity given their advantageous properties for quick response and wireless operation. However, localizing the actuation of only a small area of the cilia structure or even individual pillars, presents a challenge since the magnetic field is not localized and does not present defined confining boundaries. In this work, we use light as a wireless and localized stimulus to modulate the magnetic force and control the movement of a small fraction of cilia within a large magnetic cilia array. Chromium dioxide (CrO₂) is a black ferromagnetic material with lower Curie temperature than other commonly used magnetic fillers. By taking advantage of the high absorbance and temperature-sensitive magnetic susceptibility of CrO₂, we have demonstrated a novel mechanism by combining light and magnetic field to actuate soft actuators [5]. In this work, the technique is applied in the microscale to high aspect-ratio arrays of pillars that form magnetically responsive cilia. The cilia are fabricated with CrO₂ and PDMS mixture using silicon molding techniques and present a 9:1 aspect ratio (i.e. 5 μm in diameter and 45 μm in height) over a 1 cm 1 cm patch.

The cilia move in accordance with the external magnetic field and exhibit a deformation-dependent transparency. Because of the periodic pattern of the cilia, the structure also exhibits far-field diffraction patterns from whose
diffraction efficiency can be wirelessly tuned with the magnetic field. With the measurement of the change of
diffraction efficiency, a theoretical estimation of the cilia movement can be made. Furthermore, by taking advantage
of the high light absorption and good photo-thermal properties of CrO$_2$, the cilia array can be locally heated through
light irradiation. Along with its thermal-demagnetization effect, embedding CrO$_2$ in the structure grants the uniform
magnetic cilia array unique properties: cilia can be actuated locally and at the same time globally with untethered
stimuli – light and magnetic fields yielding three distinct modes of controls that can be used to actuate the cilia
array- (a) only with light, (b) only with magnetic field, and (c) with both in combination. By using light only,
accurate actuations can be made even with individual cilia while the rest remains unperturbed; with the sole use of
the magnetic field, all the cilia are synchronized and move together. When using light in concert with the magnetic
field, one can modify the cilia movement locally on top of a global cilia movement. This is hard to achieve with
either only light or magnetic field on a uniform sample without imposing material constraints to generate a material
gradient during synthesis and material fabrication. Among potential applications, this concept cilia composite can
add utility in soft-robotic approaches, or biomimetic microrobots with higher control degree-of-freedom when
combined with other non-reciprocal cilia designs.

*Magnetically Addressable Shape-Memory and Stiffening in a Composite Elastomer* Paolo Testa$^{1,2,1}$, Robert
Style$^1$, Jizhai Cui$^{1,2}$, Claire Donnelly$^{1,2}$, Elena Borisova$^2$, Peter Derlet$^2$, Eric Dufresne$^1$ and Laura Heyderman$^{1,2}$;
$^1$ETH Zürich, Switzerland; $^2$Paul Scherrer Institute, Switzerland

With a specific stimulus, shape-memory materials can assume a temporary shape and subsequently recover their
original shape, a capability that renders them relevant for applications in fields such as biomedicine, aerospace and
wearable electronics. Shape-memory in polymers and composites is usually achieved by exploiting a thermal
transition to program a temporary shape and successively recover the original shape. This may be problematic for
heat sensitive environments and when rapid and uniform heating is required. In this work, a soft magnetic shape-
memory composite is produced by encasing liquid droplets of magneto-rheological fluid into a polydimethylsiloxane
matrix. [1] Under the influence of a magnetic field, this material undergoes an exceptional stiffening transition, with
an almost 30-fold increase in shear modulus. Exploiting this transition, fast and fully reversible magnetic shape
memory is demonstrated in three ways, by embossing, by simple shear and by unconstrained three-dimensional
deformation. Using advanced synchrotron X-ray tomography techniques, the internal structure of the material is
revealed, which can be correlated with the composite stiffening and shape-memory mechanism. Based on this
simple emulsion process, this material concept can be extended to different fluids and elastomers, and can be
manufactured with a wide range of methods.

4:30 PM *SB01.11.08
*Programmable Multi-Responsive Soft Actuators Based on Conductive Polymer Composites* Mingming Ma;
University of Science and Technology of China, China

Conductive polymers such as polythiophenes, polyanilines and polypyrroles, have been widely studied for many
potential applications, such as organic photovoltaic cells, organic electronics, supercapacitors and actuators. One
major barrier that restricts their application is their poor mechanical properties. The poor mechanical properties of
conductive polymers are mainly due to their conjugated molecular structure, which makes the main chain very rigid.
Inspired by the structure of bones, where rigid hydroxyapatite crystals and soft collagen fibers cooperate to form
strong and tough materials, we proposed to incorporate ‘soft’ polymers into rigid conductive polymers to improve the
mechanical properties. The soft polymer ingredients are designed to interact with rigid conductive polymers through
supramolecular interactions, such as hydrogen bonds, charge-charge interactions, dynamic covalent bonds and so on.
Upon a large stress, the weak supramolecular interactions between soft polymers and rigid conjugated polymers
would break to help dissipate destructive energy, which would greatly improve the toughness of the materials. Beyond that, the dynamic nature of supramolecular interactions could also enable the conductive polymers stimuli-responsive properties. Herein, we report two examples of utilizing conductive polymers composite to make programmable soft actuators that are responsive to multiple stimuli.

In the first case, PEDOT, PAA-AMPS and PVA are crosslinked by hydrogen bond, electrostatic interaction and coordination to form a supramolecular network. In response to environmental moisture, the resulted composite PPA can not only generate powerful actuation with a contractile stress up to 13 MPa, but also perform programmable helical motions. PPA films with internal stress along the radial directions were prepared by a simple solution casting method. Driven by moisture, rectangular stripes cut from the same PPA film but with different cutting angles can perform direct bending, left-handed or right-handed helical motions, demonstrating the generation of chirality from asymmetric internal stress. By modulating the distribution of internal stress in PPA stripes, their moving direction and speed are readily prescribed. The powerful and programmable PPA stripes can be used to make soft devices, such as moisture-responsive switches and transporters.

In the second example, we report a multi-responsive polymer composite (PHP) based on poly(N-isopropylacrylamide) (PNIPAm), polyaniline (PANI) and polydimethylsiloxane (PDMS). PNIPAm shows reversible volume change in response to the change of temperature, humidity and ionic strength. PANi can efficiently absorb visible light and convert the light energy to heat. PDMS is a transparent and robust elastomer, with a high positive coefficient of thermal expansion. PNIPAm and PANi are incorporated together to give the PNIPAm-PANI hydrogel, which is coated with a PDMS layer to give the PHP bilayer film. Owing to the synergistic effect of these three functional polymers, the PHP bilayer film can perform rapid and reversible transformation between multiple complex shapes (upon global stimuli) and patterns (upon localized stimuli), driven by four types of stimuli: light, heat, humidity and ionic strength. The transformation of PHP is well programmable by using different orders of sequential stimuli. With its powerful actuation and excellent repeatability, the programmable PHP bilayer actuator can be utilized as environment-sensitive devices, such as switches and smart curtains.

By these examples, we wish to demonstrate that the supramolecular approach could be a general method not only improve the mechanical properties of rigid conductive polymers, but also enable good stimuli-responsive properties to conductive polymer composites. These programmable multi-responsive actuators are promising for fabricating smart soft robotics.

SB01.12.01
Efficient Shockwave Energy Dissipation in Self-Healing Dynamic PDMS Rubber Jaejun Lee, Brian Jing, Laura Porath, Nancy R. Sottos and Christopher Evans; University of Illinois, Urbana-Champaign, United States

Polymer networks containing dynamic bonds have received increasing attention over the past decade. Depending on the specific bond, a certain amount of energy is required for the bonds to undergo an exchange process. We hypothesize and demonstrate that dynamic bonds in polydimethylsiloxane (PDMS) networks can be used as an effective mechanism for dissipating energy, in particular from a shockwave. The density of dynamic bonds can be controlled which controls the modulus while the network Tg is unchanged. Using a classical laser induced shockwave technique, superior energy dissipation is observed in a PDMS dynamic rubber compared to the benchmark polyurea. The dynamic PDMS also outperforms covalently crosslinked PDMS and shows a monotonic improvement in dissipation performance with increasing density of dynamic boronic ester bonds. In all cases, the Tg is invariant in the different networks (-125 °C) implying a minimal role of segmental dynamics on dissipation in these specific networks. The dynamic networks can be shocked multiple times with invariant performance due to their self-healing ability, suggesting the mechanism is non-destructive and related to bond exchange rather than
Porous Carbon Fibers from Blends of Polyacrylonitrile and Sacrificial Polymers by Gel Spinning

Jyotsna Ramachandran, Mingxuan Lu, Pedro J. Arias-Monje, Mohammad Hamza Kirmani and Satish Kumar; Georgia Institute of Technology, United States

High strength and high modulus carbon fibers are produced by carbonization of polyacrylonitrile (PAN) precursor fibers processed through continuous gel spinning [1]. The density of solid carbon fibers made from PAN precursors is in the range of 1.73-1.93 g/cm³. Further reduction in the density of the carbon fibers and increase in specific surface area are possible by introducing porosity. Controlling the pore size and distribution in the porous carbon fiber are ways to tailor the mechanical and structural properties. This study explores the conditions to introduce porosity in carbon fibers produced by continuous gel spinning of blends of PAN and sacrificial polymer, with good mechanical properties. Sacrificial polymers including poly(acrylic acid) (PAA), poly(methyl methacrylate) (PMMA), poly(styrene-co-acrylonitrile)(SAN), are chosen based on their incompatibility for blending with the carbon source, PAN. Pore size, distribution and morphology in the carbon fibers are found to be dependent on factors including the choice of sacrificial polymer, blend ratio, solvent and coagulation conditions used for spinning. The influence of the above mentioned processing factors on the mechanical and structural properties of the precursor and resulting carbon fibers are evaluated in this study. This comparative study paves the way for identifying the optimal PAN-sacrificial blend system for production of gel spun porous carbon fibers that are strong, light and possess uniform network of porosity. Porous carbon fibers from gel spun precursor, possessing high mechanical strength could create a spectrum of applications of lightweight, self-sustaining structural reinforcements with energy storage or filtering capabilities. One could envision the body of an aircraft or car made with porous carbon fiber that could store energy and lead to energy efficient smart vehicles.

Scalable and Low-Cost Preparation of Smart Textiles with CuO and ZnO In Situ Synthesis Using Cyclodextrin Functionalized Cotton Fabrics

Wellington M. Rangel, Rozineide A. Boca Santa and Humberto G. Riella; UFSC, Brazil

Smart textiles are a topic of growing interest combining traditional uses of clothes with functional properties. The increasing number of antibiotic-resistant microorganisms and consequently its infection diseases frequency, and the rising of skin cancer incidence are two examples of smart textiles applications. Antimicrobial properties and UV blocking could be developed in fabrics by using metallic oxides. The broad range of metallic oxides properties and their stability are of great interest, and the methods for its grafting in textile substrates are divided into two groups: ex-situ and in-situ.

In this work, cotton weave fabric samples were prior treated with enzymatic desizing, and a scouring/bleaching simultaneous process to develop a high absorbing material. A factorial experiment suggested a treatment procedure with 0.2% NaOH and 2% otw of H₂O₂ for best results of weight loss, whiteness index and water absorption rate (warp and weft directions).

Then, a new two-step method is proposed to prepare in-situ copper oxide (CuO) and zinc oxide (ZnO) inside the cotton fibers in the pre-treated textile fabric, and after grafting with a reactive monochlorotriazine (MCT) beta-cyclodextrin. The grafting of MCT-beta-cyclodextrin in cotton fibers was made by the pad-dry method. Copper and zinc sulfates were used as precursors, to achieve concentrations of copper and zinc ions from 1% to 5% inside the fibers (until copper sulfate solubility limit). These methods are low-cost and scalable into the textile industry finishing process.

The main purpose of this work is to prepare a smart textile with a never reported method. Using water-soluble precursors applied by a pad-dry process. Followed by a reduction wet process to prepare nanostructured metallic oxides inside cotton fibers. The change of solubility from the precursors to the prepared oxides is proposed as a mechanism to improve the washing fastness and durability of the treatment.

The new materials were characterized using FTIR, SEM, EDX, TEM, DRX and thermogravimetric analysis to understand the structural properties and nanostructured particle morphology.
A Water Activated Switch Using a Kirigami-Inspired Robotic Finger

Jihyun Ryu, Mehdi Tahernia, Maedeh Mohammadifar and Seokheun Choi; State University of New York at Binghamton, United States

We created a kirigami-inspired self-folding robotic finger with a microfluidic capillary force in paper. When water was sprayed on hydrophilic regions patterned on paper, the 2-D sheet of the kirigami-based finger was controllably self-folded and popped up to touch/connect two electrodes and switch on LEDs. When the water in the paper evaporated, the popped-up structure was unfolded into its original planar sheet. The fold-to-pop-up structure can be readily fabricated via a double-sided wax printing method, forming a bilayer structure of the hydrophilic regions and the hydrophobic wax, in which these two layers have different swelling and shrinking properties. This novel activation technique enabled a flat paper finger to self-fold with desired angles by controlling hydrophilic/hydrophobic patterns and their lengths. The patterned paper performed folding actuation with water and unfolding behavior with evaporation without being mechanically manipulated by external forces or moments. This proposed technique will be advantageous for many applications (e.g. humidity sensors) inexpensively and autonomously in remote and resource-limited environments. Soft robotics is recently considered as one of the most exciting research topics because of their deformability, flexibility, and adaptability to environmental changes. Soft actuators have been one of the most significant core technologies to enable autonomous capabilities for various soft robotic applications like rehabilitation and training robots, surgical robots, and diagnostic robots. Several promising soft actuators have been proposed including shape memory alloys, electro active polymers, fluidic elastomer actuators, and electro-magnetic actuators, achieving multiple degrees of freedom and delicate object manipulation. However, these techniques are very complicated, expensive, and inefficient in terms of energy use [6]. This work demonstrated an innovative self-actuating method with a microfluidic capillary force in paper through rapid and low-cost prototyping. Through the prescribed planar design of patterned folds and cuts, we demonstrated a kirigami-inspired programmable self-folding of the robotic finger with defined curvatures. The operating principle of the fluidic actuation in paper, which consists of a swelling process with sprayed water and a drying process with evaporation. This actuation used a two-layer configuration with one passive wax layer and one active water layer. The passive layer developed a negligible mechanical move compared to the active layer with the water-based swelling process. This difference in expansion or contraction between the two layers generates localized bending of the paper finger and touches/connects two pre-patterned electrical wires (conductive PEDOT:PSS polymers) for LEDs lighting. The bilayer of the hydrophobic and the hydrophilic regions had drastically different swelling behavior in response to water spraying, spontaneously folding-up and actuating from the 2-D pattern on the paper, turning on the LEDs. The folded structure can also unfold itself with evaporation, turning off the LEDs. Electronics components (i.e. resistors, LEDs and SN75468 IC) were mounted on the paper printed circuit boards. Under repeated swelling and drying processes, the designed paper successfully folded and unfolded without any mechanical degradation. The length of the hydrophobic wax was controllably increased, reducing the ratio of the wax to the hydrophilic part of the paper and controlling the switching duration with water sprayed. The stability and conductivity of the electrical wires were significantly enhanced by the addition of graphene even under repeated folding and unfolding deformations.

Sub-Nanoscale Self-Assembly of Block Copolymers by Local Heating Using Magnetite Nanoparticles

Smriti Sahu, Natalia da Silva Moura, Tochukwu Ofoegbuna and James A. Dorman; Louisiana State University, United States

The growth rate of next generation advanced electronic devices revolves around the formation of high-resolution patterns on semiconductor substrates. Lithography is the most widely used patterning technique that has enabled progressive miniaturization of semiconductor industry and development of the incredibly small technology node of ~7nm till date. However, this top-down scaling comes at a compromise with the cost and tedious processing steps. Hence, the propensity of block copolymers (BCPs) to self-assemble at nanoscales have attracted significant interest of researchers from diverse fields. BCPs assemble into various morphologies viz. spherical, lamellar, cylindrical etc. when treated with heat. Self-assembled periods as small as ~50nm have been reported, that can be used for templating nano-features over macroscopic areas. In addition, BCPs are extremely flexible in terms of their morphology, block size and phase formations, that can be controlled by tuning molecular weights, Flory-Huggins interaction parameter and the degree of polymerization. Although having an interesting property portfolio, the integration of BCP self-assemblies in practical nanoelectronic device designing is still a challenge. The controlled
placement of the nanodomains require conjunction with nano-imprint lithography, that itself is a complex process. Hence, our work focuses on further reducing the period sizes and providing an independent nanoscale control on BCP domains by generating localized heat using RF-actuated magnetic nanoparticles. We have used magnetite (Fe₃O₄) nanoparticles of diameter ranging from ~20-100 nm, that are known to generate heat when placed in an RF magnetic field. The experiment is performed with combinations of various BCPs and different shapes and sizes of nanoparticles to thoroughly study the localized heating effect and its efficiency in transferring this heat to self-assemble the BCP films coated on top. This local heating strategy of the BCPs would prove to be a step towards further scaling down of the device features and meet the needs of current technology node, with using traditional cumbersome lithographic techniques.

SB01.12.08
Silicone-Based Membrane-Interface-Elastomer (MINE) Structures for Ultrasoft Wearable Electronics Kory Schlingman and Tricia B. Carmichael; University of Windsor, Canada

Soft and stretchable electronics present opportunities to change how humans interact with technology, promising improvements to healthcare monitoring, communications, and accessibility. Stretchable devices, particularly those designed to be worn on the human body, require soft, deformable elastomeric substrates that can withstand torsional, shearing, and multiaxial strains in addition to normal wear and tear. The elastomer polydimethylsiloxane (PDMS) has been widely used: It is soft, stretchable, biocompatible, transparent, and easy to mold. Most importantly, PDMS possesses surface properties that make it easy to integrate with functional electronic materials for stretchable device fabrication. Plasma oxidation increases the wettability of the PDMS surface by generating a hydrophilic surface silicate layer, enabling the deposition of functional materials from solution and chemical surface modifications via the chemisorption of organosilanes. Still, bulk PDMS suffers from mediocre tear strength, a relatively high Young’s modulus of 1.5-2.0 MPa and an elongation at break of ~140%. Replacing PDMS with other elastomers that offer useful properties such as high dielectric strength, edge-tear resistance, extreme stretchability, and ultra-low modulus is a challenge due since they often lack the ideal surface chemistry of PDMS necessary for device integration.

Our approach to solving this fundamental problem fuses two different elastomers together to form a layered structure, transforming the elastomeric substrate into a multifunctional element that combines different properties, providing functionality that a single elastomer cannot deliver. We previously demonstrated the idea using an organosilane-based “molecular glue” to adhere a thin membrane of PDMS onto the surface of a transparent butyl rubber substrate. The resulting membrane-interface-elastomer (MINE) structures uniquely combine the surface chemistry of PDMS with the intrinsically low gas permeability of butyl rubber for the fabrication of robust stretchable device. This structure enables functionalization of the PDMS surface with conductive metal films while retaining the gas impermeability of the butyl rubber below. Interestingly, metal films deposited on this structure remain conductive to 85% elongation by generation of microcracks in the surface in a way that is not observed in native PDMS. In this presentation, we describe new MINE structures fabricated by adhering a PDMS membrane to the elastomer Ecoflex. The low Young’s modulus (68 KPa) of Ecoflex is similar to human skin, making this elastomer ideal for skin-mounted electronics. However, we show that the silicone oils and low molecular weight petroleum plasticizers that make Ecoflex so stretchable also cause poor surface chemical properties: Plasma oxidation of Ecoflex results in migration of these low molecular weight additives to the surface, disrupting the formation of a hydrophilic silicate layer. The fabrication of PDMS-Ecoflex MINE structures uses the platinum-catalyzed crosslinking chemistry common to both elastomers, producing a covalently-crosslinked interface between the two elastomers.

We show that together, the layered MINE structure exhibits the best properties of PDMS and Ecoflex: The PDMS membrane surface can be plasma oxidized to increase the wettability and support subsequent chemical modification, whereas the mechanical properties of the Ecoflex elastomer dominate mechanical behaviour of the composite. PDMS-Ecoflex MINE structures demonstrate stretchability to 400% elongation before delamination of the PDMS layer, as well as a Young’s modulus at the surface of 100 KPa, comparable to Ecoflex alone. We also demonstrate the use of pre-strained PDMS-Ecoflex MINE structures to fabricate gold films that retain conductivity to 300% elongation.

Active Membranes for Ionotronic Systems Thomas B. Schroeder and Joanna Aizenberg; Harvard University, United States

Final Program 1/13/2020 2404
Ionotronic systems consist of hybrid electrical circuits that use both ions and electrons as charge carriers. The constituent materials of synthetic ionotronic systems, such as hydrogels and dielectric elastomers, often exhibit properties such as softness, transparency, stretchability, and biocompatibility that are desirable in a range of contemporary applications such as soft robotics and biological interfaces. Recent years have seen the development of ionotronic sensors, actuators, and power sources that leverage these characteristics. Such engineered systems often share their function, morphology, or mechanism with excitable biological tissues, which also use ions as charge carriers in aqueous media.

Membranes are a key component of both biological and synthetic ionotronic systems, owing to their utility as selective barriers and capacitors with variable properties. Electrolyte gradients across selectively permeable membranes provide the driving force for the generation of electrical potentials such as the resting potential of a cell membrane, and capacitive membranes between electrolyte-bearing reservoirs can laterally transport electrical signals quickly in the manner of a transmission cable or an axonal segment between nodes of Ranvier in a neuron. In this work, we trigger selective permeabilization events within an insulating membrane in response to various stimuli in order to generate and transmit electrical signals within soft materials in the manner of a dendrite. We compare the voltage decrement along such membranes with that of an electrotonus in excitable tissues. This bioinspired transduction scheme leverages the toolkit of stimuli-responsive chemistry to enable the development of systems that produce fast electrical responses to a range of environmental changes. The ionotronic systems described here may be useful as sensors when interfaced with existing electronics or, when coupled with actuators, may serve as functional elements of autonomous systems exhibiting homeostatic or oscillatory behavior.

The DAGS-Chemistry—Droplet Assisted Growth and Shaping of Polymeric Nano- and Microstructures for Design of Multifunctional Materials

Stefan Seeger, Naeem-ul-Hasan Saddiqi, Sandro Olveira, Xiaotian Zhang and Georg Artus; University of Zurich, Switzerland

The synthesis of nano and microstructures are an emerging field in chemistry and materials science. They can be made from a large variety of materials, for example metals, semi-metals, or polymeric substances. Usually, these particles exhibit a comparable simple shape, for some are high temperature is required and for many (except polymers) of them no covalent bonds are formed during formation /1/.

Some years ago, we have presented the synthesis of silicone nano filaments in particular for coatings delivering superhydrophobic, superoleophobic, or superamphiphobic surface properties (fig. 1) /2, 3/. Also, nano- and microstructures different from filaments have been synthesized in a reproducible manner /4/.

Recently, we have shown a reaction mechanism, the Droplet-Assisted Growth and Shaping, explaining how this one-dimensional growth is initiated by a delicate interplay between surface properties, phase equilibrium, and reactivity /5/. Based on this new scheme we are able to synthesize nano- and microparticles of different shapes depending on the reaction conditions.

The DAGS approach is not only applicable to silicon containing polymers. Recently, we could show that DAGS also leads to ermaniumoxide structures and Alumina containing nanostructures.

In this presentation, we will give an overview about this novel synthesis scheme. Applying appropriate reaction conditions allows for the directed growth of nano- and microstructures of complex shape. We believe that this reaction scheme is very promising in chemical synthesis and material science, since it enables us to form complex nano and microstructures from polymeric materials at room temperature in aqueous medium. Beyond this, we also draw the attention on multifunctional materials obtained by strategies implementing DAGS chemistry, e.g. wetting
and electric conductivity features.

One-Touch Embeddable Microneedles for Hair Loss Treatment
Keum-Yong Seong1, Min Jae Kim1, Hye Seon Lee1, Seung Soo Lee2, Hoon-Soo Kim1, Beum-Soo An1 and Seung Yun Yang1; 1Pusan National University, Korea (the Republic of); 2SNvia, Korea (the Republic of)

With increasing clinical needs for painless and easy administration of therapeutic drugs through a transdermal route, microneedles (MNs) have been extensively exploited as a new technique for facilitating percutaneous drug delivery in a minimally invasive manner. However, a precise control of dose and the risk of secondary infection through punctured holes by MNs have remained unsolved. Here we present a bullet-shaped, swellable MNs prepared by crosslinked biopolymers, enabling shear-induced implantation inside skin following distal swelling of MN tips by absorbing body fluids. The embeddable MN patch was prepared by a solvent-casting with a mold and the swellable tip height of MNs to be embedded was controlled by the concentration of polymer solutions. After insertion into skin, swollen MN tips of more than 90% were separated from the patch following simple shear actuation and the embedded swollen MNs in skin offered a superior barrier function by tight sealing of punctured holes. For potential applications, the biodegradable embeddable MN platform were investigated for promoting hair growth by effective intracutaneous delivery of minoxidil (MXD), commonly used for the treatment of androgenetic alopecia. The MXD-loaded MN tips embedded in animal skin tissue achieved a prolonged release of MXD more than 48 h. In pilot animal studies, the MXD-loaded MN group (1 MN patch application/3day) showed better hair growth efficacy compared to topical MXD treatment group (2 topical application/1day).

SB01.12.12
Efficacy of Thin-Film MgO and SiO2 Layers in the Prevention of Mo Diffusion at Elevated Temperature
Kevin Shah and Harry Efthathiadis; SUNY Polytechnic Institute CNSE, United States

Thin-film layers deposited on flexible metal foils can offer functionality for many applications, including semiconductors, detectors, refractory shielding, insulators, catalysts, and optical layers. With favorable manufacturability and low cost of thin-film deposition, various stacks of thin-films can be layered to produce multifunctional properties. For processes that require high temperatures, in this case up to 1450°C, it is imperative to limit the diffusion from the underlying metal foil substrate into the functional top layer thin-film, to reduce impurity contamination that may otherwise degrade the performance of the functional layer(s). Here, thin-films of MgO and SiO2 were deposited onto molybdenum metal foil and heated to 1410°C in a controlled vacuum environment with argon gas. Mo impurity concentration was characterized by dynamic secondary ion mass spectrometry (SIMS) depth profiles, both before and after high temperature annealing, and compared for MgO and SiO2 diffusion barriers. The films were also examined in secondary electron spectroscopy (SEM) to assess the impacts of high temperature annealing on film adhesion and cracking, XRD to measure effects of annealing on film crystal structure, and AFM to determine topography.

SB01.12.13
Identical Material-Based Self-Powered Triboelectric Sensors via Ferroelectric Polarization
Young-Eun Shin, So-Dam Sohn, Huijun Han, Hyung-Joon Shin and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)
In a triboelectric system, two different materials with large difference of polarity in triboelectric series are generally required for the enhanced triboelectric output performance. This requirement of contact pairs restricts the selection of triboelectric materials and the use of identical materials for contact electrification. In addition, it impedes the facile fabrication of triboelectric devices with enhanced performances. Here, we demonstrate a facile approach for the development of triboelectric devices based on an identical material for the contact pair by switching the triboelectric polarity of ferroelectric copolymer, poly (vinylidenefluoride-co-trifluoroethylene) (P(VDF-TrFE)). The aligned dipoles in P(VDF-TrFE) have a great effect on the triboelectric polarity, which relies on the applied bias direction during electrical polarization. This approach does not need any additional chemical functionalization or mechanical modification to fabricate identical material-based triboelectric devices with remarkably enhanced output performances. The inversely-polarized P(VDF-TrFE) device exhibits ~106 times higher output currents and ~126 times higher output voltages than those of non-polarized P(VDF-TrFE) devices. Moreover, the high sensitivity of our triboelectric device in the subtle pressure range enables the simultaneous monitoring of weak pulse pressure of the carotid artery. This work demonstrates a facile fabrication to realize identical material-based triboelectric device with outstanding output performances via dipole-alignment of ferroelectric polymers. Our proposed strategy provides the capability to tune the triboelectric polarity of identical material without additional complicated process, paving the way for the development of high-performance triboelectric devices.

**SB01.12.14**
Dynamic Wavelength Tunable Functions of Near Infrared Photoluminescent Single-Walled Carbon Nanotubes by Local Molecular Functionalization

**Tomohiro Shiraki, Yasuto Nakagawa, Naotoshi Nakashima and Tsuyohiko Fujigaya; Kyushu University, Japan**

Single-walled carbon nanotubes (SWNTs) with semiconducting features show near infrared (NIR) photoluminescence (PL). Recently, locally functionalized SWNTs (lf-SWNTs) that are synthesized by local chemical functionalization of the tube structures have been developed as new types of NIR PL nanomaterials.[1-8] Therein, by the chemical reactions, new emissive sites that have different electronic structures from non-modified SWNTs are created on the tubes. As a result, the lf-SWNTs emit red-shifted PL with high efficiency (E$_{11}$*) compared to original PL (E$_{11}$) of the non-modified SWNTs. Furthermore, the E$_{11}$* PL of lf-SWNTs is found to show different PL wavelengths depending on the modified molecule structures.[1-5] Thus, this feature would be promising to create multifunctional NIR PL nanomaterials based on molecular functionalities of the modified molecules.

Here we report dynamic E$_{11}$* PL wavelength tuning techniques by covalent modification of functional molecules on the local functionalized moieties of lf-SWNTs. In this technique, driving forces for the wavelength shifts are designed based on molecular functions including molecular recognition[6,7] and dynamic covalent bond formation[8]. It allows us to control lf-SWNTs that response to various external stimuli with NIR PL shifting features.

Firstly, phenylboronic acid (PB), which binds sugar molecules selectively, so-called “sugar recognition”, was functionalized to SWNTs through diazonium chemistry to synthesize phenylboronic acid-modified lf-SWNTs (lf-SWNTs-PB).[6] The E$_{11}$* PL of lf-SWNTs-PB appeared at 1138 nm. When D-fructose was added to the aqueous solution of lf-SWNTs-PB, the E$_{11}$* peak was blue-shifted to 1124 nm according to the increase in the D-fructose concentration. This shifting was induced by electronic property changes of the functionalized PB moiety through boronate ester formation with D-fructose. As another molecular recognition motif, azacrown ether groups were functionalized to lf-SWNTs (lf-SWNTs-CR).[7] The lf-SWNTs-CR showed spectral red-shifts of E$_{11}$* PL by silver ion inclusion and protonation of amine part (pH variation), and, interestingly, the shifted wavelengths were different between these two systems. In the dynamic covalent bonding system, arylaldehyde groups were introduced in lf-SWNTs (lf-SWNTs-CHO).[8] When aniline derivatives having different substituents were mixed with the lf-SWNTs-CHO, wavelength shifts of the E$_{11}$* PL occurred, which provided different wavelengths depending on the chemical structures of the bound aniline derivatives. This wavelength shifts were induced by the imine bond formation (condensation reactions between amine and aldehyde groups). Moreover, additional chemical reactions including dissociation and exchange reactions of the bound aniline derivatives, and the Kabachnik-Fields reaction realized further wavelength changes in the E$_{11}$* PL. Thus, the present approach using imine chemistry at the functionalized sites achieves multistep PL modulation.

Therefore, molecular design of the local functionalized sites produces multifunctionalities in lf-SWNTs that response to various stimuli and environmental changes, which would be applicable to biological sensing and environmental monitoring by using their NIR PL features.

SB01.12.16
Fully Printed Metal-Free and Complex-Shaped Sensors via Direct Functional Microparticle Writing Leonard Siebert1, Maik-Ivo Terasa1, Mattia Mirabelli2, Maik Tienken1, Philip Schäfer1, Sören Kaps1, Oleg Lupan1,2 and Rainer Adelung1; 1Institute for Materials Science – Functional Nanomaterials, Germany; 2Department of Microelectronics and Biomedical Engineering, Moldova (the Republic of)

3D-printing has become one of the most fascinating subjects of research during the last decades because of the sheer amount of different design strategies and the implied manufacturing philosophies it has enabled.[1] Crucial to the impact of additive manufacturing is the possibility to freely design devices and structures without the necessity for highly complex technologies by combining standard materials science with standard mechanical engineering on varying levels of technological profoundness. Especially the fields of biomedical engineering and printed electronics profit from the simplicity of 3D-printing, allowing for sophisticated material design and advanced circuitry.[2] Additionally, microparticles with complex shapes and integrated functionalities have been used in a broad range of applications since their geometry cannot be easily reproduced with clean room technology to implement structural benefits in a microscopic range.[3] Here, combining both of these aspect, we demonstrate multiple, microparticle based architectures for both biomedical and electronic applications. The benefit of using microparticles is the multitude of well grounded, standard techniques for their usage and the possibility to elevate their functionalities by integrating them into 3D structures. Custom geometries of metal-free sensors for different signals have been fabricated, just using metal oxide microparticles from materials science in a common Direct Ink Writing (DIW) approach. As an example, a heterojunction net of CuO/Cu2O/Cu has been grown by simple step integration of copper microparticles on glass substrates and additional rapid thermal annealing, exhibiting high sensitivity for acetone, enabling its use as a sensor for breath analysis. Another example is the usage of complex-shaped single crystalline ZnO tetrapodal microparticles, which are highly sensitive towards UV light and are used as UV-sensors without the necessity for clean room technology. For the field of biomedical engineering, ZnO-biopolymer composite printed constructs show antibacterial properties for potential applications as functional wound dressing. These findings only hint at the much larger potential of the DIW of microparticles into functional devices which will enable more simple fabrication techniques for future challenges.

Self-Limiting Electrospray Deposition for Postprocessing of 4D Printing Lin Lei, Dylan Kovacevich, Christianna Kuznetsova, Daehoon Han, Howon Lee and Jonathan P. Singer; Rutgers University, United States

Electrospray deposition is a spray coating process that utilizes a high voltage to atomize a flowing solution into charged microdroplets. These self-repulsive droplets evaporate as they travel to a target grounded substrate, depositing the solution solids. We have classified a regime of self-limiting electrospray deposition (SLED) that enables the coating of surfaces hidden from the spray needle’s line-of-sight. In this regime, the deposited solids are insulative and have minimum mobility at the substrate, causing charge to gradually accumulate. Future generations of droplets are redirected to uncoated areas, yielding more uniform coverage of the entire substrate. In this study, we used stimuli-responsive hydrogel 3D structures fabricated through projection micro-stereolithography as our substrates to demonstrate the effectiveness of SLED for the coating of 4D-printed structures. We first examined model metallic geometries to classify the limits of the SLED phenomenon, including gaps and rapid bends. These revealed that SLED could readily enter gaps of less than 100 µm and undergo bends at a rate of an estimated 500 rad/s. We then coated 3D printed octet-truss lattices. The lattices had edge lengths of ~1 cm and struts of ~250 µm.
diameters and were coated with hierarchically-structured styrene-butadiene-styrene block copolymer-toughened polystyrene. By monitoring coated and uncoated lattices were enclosed in a camera-monitored humidity chamber, the swelling-driven dimensional changes in lattice over time were recorded. The polymeric coating acted as both a moisture barrier and mechanical coating, both reducing the extent and regulating the rate of hydrogel swelling. This represents a means of decoupling the surface and bulk properties of 4D-printed materials to provide for surface-gated control of the final structures.

SB01.12.18
Morphological and Mechanical Properties of Polymer Composites Created by Self-Limiting Electrospray Deposition Lin Lei, Luc Bontoux, Christiana Kuznetsova, Dylan Kovacevich, Max Tenorio, Assimina Pelegri and Jonathan P. Singer; Rutgers University, United States

The electrospray process utilizes the balance of electrostatic forces and surface tension within a charged spray to produce charged microdroplets with a narrow dispersion in size. By adding dilute solids to the spray, electrospray deposition can be employed for the manufacturing of nano- to micro-scale coatings. We have identified a regime of the spray of insulating materials onto conductive substrates where a limiting thickness emerges where the accumulation of charge that repels further spray. Self-limiting electrospray deposition (SLED) can uniformly cover complex multiscale structures with a variety of morphologies, including nanoshells and nanowires. Here, we investigate the application of polymer blends to modify the morphology and, through nanoindentation, the mechanical properties of the spray films for different applications. On the morphological side, blending immiscible non-self-limiting materials can alter the fill and porosity of the shell structures or the length and alignment of wire structures by tuning the droplet phase evolution. In mechanical properties, we demonstrated that the addition of a miscible curing agent to an epoxy resin can maintain the hierarchical spray structure to result in a tougher and stiffer coating for protective barriers. Further, the porosity of these films can be tuned spatially or programmed into the spray composition. In contrast, to make films that are more flexible for compliant surfaces, blends of plastic homopolymers and elastomeric block copolymers were sprayed. The net result of elastomeric blending was a coating that could enhance adhesion and sustain ~17% strain in the underlying structure.

SB01.12.19
Manufacturing Biohybrid Textiles through a Robust Fiber Based Cell-Free Expression System Rachel S. Smith, Miana Smith, Susan Williams and Neri Oxman; MIT, United States

The emergent field of biohybrid fiber systems has derived several techniques to entrap, encapsulate, or adsorb living or bioactive agents within woven and non-woven constructs, to simultaneously benefit the survivability of the biological agent and augment the functionality of the fiber. However, these techniques remain largely incompatible with existing textile manufacturing technology and lack the robustness of commercial woven fabrics. The incorporation of bacteria-derived [SS1] biosynthesis systems into fibers that can survive industrial spinning, weaving, or knitting processes is a method of producing biocomposite textiles across scales, and further, for using textile patterning methodologies for fiber templating and distribution.

To achieve the necessary preservation of biological activity within industrially-workable threads, we experiment with techniques such as lyophilization and the use of cell-free expression systems. The efficacy of a PURExpress cell-free system soaked into commonly used natural and artificial fibers is first demonstrated using the expression of Green and Red Fluorescent Protein (GFP, RFP). The cell-free system is then preserved on the fibers via lyophilization and the output is compared to that of the fresh system using the difference in the expression of GFP/RFP as determined by the intensity of fluorescence. The expression of more functional genes, such as the one which produces serratiopeptidase, a proteolytic enzyme that dissolves silk and other proteins, is then tested using the cell-free fiber system.

To assess their industrial usability biohybrid threads are used in established textile manufacturing techniques, and monitored for robustness and for the controlled spatial distribution or patterning of biofunctional properties into woven or knit textile structures. We hypothesize that when preserved onto silk fibers, the expression of serratiopeptidase would create a subtractive process by which the biosynthesized outputs of a silk textile would actively alter the geometry of the textile. We envision future textiles with a controlled patterning of biosynthetic compounds via biohybrid threads could have applications ranging from autonomous modifications in fabric structure, to wound care and the promotion of the migration of other pharmaceutical agents to areas of interest.
SB01.12.20
Interfacial and Mechanical Properties of Different Organosilane-Treated Ceramic/Photopolymer Resins for SLA 3D Printing Se Yeon Song1,2, Jung Woo Lee2 and Ji Sun Yun1; 1Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); 2Pusan National University, Korea (the Republic of)

Silane coupling agents (SCAs) with different organic functional groups were used to investigate the interface and mechanical properties of highly dispersed ceramic resins for stereolithography (SLA) 3D printing. The different organic functional groups of the SCAs used in this study were vinyl group, acryloxy, methacryloxy, and acrylamide groups. The Al2O3 ceramic particles were uniformly coated by various SCAs through a hydrolysis and condensation reaction, and then highly dispersed in commercial photopolymers based on interpenetrating networks. The uniformly coated surface and coating thickness were observed by FE-TEM, and similar coating properties were observed in all SCAs. The dispersion stability and interface properties of Al2O3/photopolymer composite resins with different SCAs were investigated by Turbiscan, relaxation NMR, and Rheolaser Master, and the resins with Al2O3 coated by the acrylamide group showed the best dispersion stability and viscoelastic behavior. The best dispersion stability and strong viscoelastic behavior of the resins contributed to improve the mechanical properties of the 3D-printed objects.

SB01.12.21
Versatile Soft Robotic Web Inspired by Spiderweb Won Jun Song, Younghoon Lee and Jeong-Yun Sun; Seoul National University, Korea (the Republic of)

Nature is the best pioneer of science based on their optimized functions for thousands of years. Spiders and spider webs, among them, have been tremendously attracted for prey capturability optimized by sensing of prey approaching, vibration cleaning the surface from droplets. Although spider web have provided various inspiration, simultaneous mimicry of the functions in a simple structure meets challenges due to needs of complex mechanism and proper materials. Here, we explored a multi-functional ionic spider web, which is electrostatically capturable, cleanable and self-powered sensible dielectric elastomer actuators optimized by behavioral inspiration of spider web. To combine the multi-functions resulting in increase of capturability, ionic spider web was driven by a stretchable and translucent electroactive structure made of dielectric elastomer and ionically conductive organogel. The electric field generated by the potential difference between a pair of ionic spider tube induces polarization in an adjacent target to realize electrostatic adhesion. Self-powered sensing by electrostatic induction from a naturally electrificated target to ion in the tube realized switchability to ionic spider web to avoid from undesirable contamination on the surface, resulting in increase of capturability. Furthermore, electrostatic vibration of ionic spider web driven by alternating electrical attraction and repulsion forces readily cleaned droplet on ionic web, leads increasing capturability. Plasma and (heptadecafluoro-1,1,2,2-tetrahydrodecyl)trichlorosilane treatment on dielectric elastomer readily increased (sensibility) and cleanability and it prevented the evaporation of organogel, which leads increase of durability of ionic spider web. We demonstrated the integrated approaches with autonomous ionic spider web sensing approaching targets and robustly capturing various materials after cleaning the surface. Ionic spider web lays the foundation for multi-functional robots inspired by nature.

SB01.12.22
Adaptive Self-Strengthening and Actuation via Multiphasic Composite Materials Nicholas Vishnosky and Rachel Steinhardt; Syracuse University, United States

Materials that respond to stimuli by moving and/or changing modulus are needed for emerging applications in fields ranging from soft robotics to medicine. To fill this need, we create composite materials consisting of regions of heterogeneous physical phases: liquid or gas vesicles encapsulated in a solid or complex fluid matrix. Through incorporation of energy transferring nanoparticles and coatings at the interphase of these phases, we are able to actuate microscale phase transitions that result in a macroscale change in morphology/modulus of the material. This property may lead to tetherlessly actuated robotics, and new medical devices.

SB01.12.23
Mechanics of a Three-Dimensional Spider Web Isabelle Su1, Zhao Qin1, Tomás Saraceno2, Roland Mühlethaler2, Ally Bishop2, Evan Ziporyn1 and Markus J. Buehler1; 1Massachusetts Institute of Technology, United States; 2Studio Tomás Saraceno, Germany
Spiders are abundant in most ecosystems in nature, making up more than 47,000 species. This ecological success is due to the web architectures and the exceptional mechanical properties of spider silk. Silk’s combination of strength, elasticity, toughness, and robustness originates from its hierarchical structure and has been a template for high-performance material design. In particular, spiders have optimized and adapted their web architecture to survive in their environment.

The most studied and familiar spider web is the 2D orb web which is composed of radial and spiral threads. However, 3D webs, such as sheet, funnel, or cob webs, are more common in nature. In contrast to 2D webs, where the spider is vulnerable to attacks, 3D webs surround the spider and offer a defensive advantage by warning the spider of intruders, blocking its predators and entangling prey.

Here, we investigate the mechanical properties of a Cyrtophora citricola 3D web, the architecture of which has been digitally modeled with micron-scale details from images of full-scale laboratory experiments (Su, Qin, Saraceno, Krell, Mühlethaler, Bisshop, Buehler, Royal Society Interface, 2018). Extending this work, we use a coarse-grained bead-spring model based on the 3D spider web network model and silk fiber properties to study the response of a realistic web structure to mechanical loads and the interplay between material and performance.

Understanding the roles of structure, material, and web spinning process, in the functionality and evolutionary fitness of spider webs could lead to innovative 3D spider web-inspired structures such as high performance lightweight long-span structures or fiber reinforced composite materials.

SB01.12.24
Miniaturized Flexible Capacitive Shear Force Sensor Using Ion Gel Wonjeong Suh and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

A soft shear force tactile sensor is essential for sensitive stretchable e-skin as well as pressure sensor. Especially, small size shear sensor has large potential of development in surgical robots which need delicate movement and grasping. However, capacitive type shear sensor has limit to miniaturization because the signal is weak in pF when it gets smaller. Here, we enable miniaturization of capacitive shear sensor using ion gel. Ion gel constructs electrical double layer (EDL) so that the sensor can make big signal at a small size. It provides nF scale capacitance which is about 10^4 ~ 10^5 times bigger than general polymer dielectrics. Also, our sensor has simple structure composed of well-shaped wall and pillar in the center. The ion gel located between wall and pillar make it possible to detect 4 different directions with high accuracy according to movement of pillar. Moreover, the sensor itself is made of conductive Ag ink and polydimethylsiloxane (PDMS) so it has high mechanical flexibility and stability. The single sensor has 5 x 5 mm^2 area and 2 mm height pillar and produces up to 100 nF. Finally, we demonstrate practical application of shear force sensing with 3 x 3 array in 27 x 27 mm^2. This flexible tactile sensor shows great promise for delicate robot finger which needs careful touch and sensitivity.

SB01.12.25
Sinking-Floating Control on a Hydrophilic-Hydrophobic Pattern Inspired by a Surface of Dixidae Larvae Naoya Tagata and Daisuke Ishii; Nagoya Institute of Technology, Japan

Dixa Longistyla is a family of flies and the larvae can float for a long time on water. A hydrophobic-hydrophilic pattern presents on the surface of larvae’s abdomen. The hydrophobic region is ring-shaped and the inside is hydrophilic. When the larvae float on water, a water droplet is held inside of the hydrophobic ring. Due to the drop, it is considered that the larvae sink down to water easily and need lower energy than the completely hydrophobic surface. Moreover, a bubble ring is formed on the hydrophobic region in water and the maggots can float up more easily than completely hydrophilic objects. Therefore, they have a both hydrophobic and hydrophilic region in terms of floating and sinking to water. Applying the pattern, we can control sinking and floating properties. The purpose of this study was to mimic the hydrophilic-hydrophobic pattern and to examine the effect of the pattern on water sinkability.

Sample were fabricated by oxygen plasma treatment of hydrophobic sheets through ring-shaped masks. The sheet surface under the mask was not oxidized, so that a hydrophobic region was remained after the plasma treatment. The sinking position, which was related with interaction on the hydrophilic-hydrophobic pattern, was measured using by surface tension balance. If the sinking position is shallow, it seems that the sample easily sinks into water. Two
different shapes of mask, annular and disk, were prepared and the samples were fabricated by using of each mask. Moreover, in the case of measurements of the annular sample, volume of water held inside the hydrophobic ring was changed systematically. There was almost no difference in sinkability between ring pattern without any water droplet inside the ring and disc pattern. On the other hand, the sinkability of the sample improved as volume of water inside the ring increased. The experimental results indicated that volume of water inside the ring affects the sinkability. The reason why the ring-shaped pattern and the disk-shaped pattern did not have a difference in the sinkability is considered that water was not sufficiently held inside the ring-shaped pattern.

**Formulation of Filled Direct Ink Write Resins for Shockwave Applications** Samantha J. Talley¹, Brittany Branch², Cynthia F. Welch¹ and Kwan-Soo Lee¹; ¹Los Alamos National Laboratory, United States; ²Sandia National Laboratories, United States

Polymer foams are widely utilized in the aerospace and defense industries for applications including structural support, vibrational dampening, and shockwave mitigation. Through a materials-by-design approach, the Direct Ink Write (DIW) additive manufacturing (AM) method is an attractive approach for the design and fabrication of porous structures capable of achieving controlled mechanical response of the underlying deformation mechanisms. Two geometries of porous, periodic AM pads were printed using new DIW resin formulations containing up to 25 wt.% of functional filler (TiO₂, Al₂O₃, or graphite). All AM pads were characterized using chemical (FTIR, MS, NMR), thermal (TGA, DSC), and mechanical techniques (DMA, compression). Dynamic compression experiments coupled with time-resolved X-ray imaging were performed to obtain insights into the role of filler interactions in the *in situ* evolution of shockwave coupling in these functional, periodic porous polymers.

**SB01.12.27**

**Noise Control and Vibration Energy Harvesting with Soft Acoustic Blackhole Based on Hyperuniform Disorder Scatters** Hanchuan Tang, Zhuoqun Hao and Jianfeng Zang; Huazhong University of Science and Technology, China

Living creatures and artificial objects like engines that possess dynamically varying and highly unconventional geometries are full of elastic waves. Such elastic energy with different frequencies could be power source of devices while few work demonstrates the elastic energy utilization on curved surfaces. The difficulties include that elastic waves in human beings and artificial objects are dispersed and relatively weak at local parts. Meanwhile, unconventional geometries and multiple frequencies of elastic waves require soft materials and more complicated structures of devices.

The acoustic blackhole (ABH), generally made of wedge structures, could damp the induced elastic wave velocity into zero, due to its power-law profile change in the thickness. ABHs have great potential for mitigating vibrations and noise. However, the fabrication limitation of the wedge may greatly affect the ABH performance. Besides, the rigid irregular structure of traditional ABHs reduces the strength of the whole device and limit their application in complex scenarios.

Here, we demonstrated an ABH mode with soft hyperuniform disordered structure that dramatically concentrate elastic wave energy and eliminate reflections on uneven surface. Hyperuniform disordered structures exhibit acoustic bandgap, and its randomness showing potentials to design novel devices. While this topic draw increasing attentions, application based on which is few. We arranged hyperuniform pattern with a smooth power-law profile edge in the soft matrix to realize the hyperuniform disorder acoustic blackhole (HABH). The numerical simulation shows good suppression of reflection and concentration of energy at the tip. The design method of HABH and double layer HABH is discussed. The HABH doesn’t require delicate process build while shows convincing ABH effect. The soft matrix of HABH makes it possible to attach on uneven surface. Our work provides a prominent solution to realize energy harvesting on human beings and noise reduction in automotive or architecture with lightweight, strong compatibility and low cost. Besides, the combination of hyperuniform structure and traditional configurations like ABH bring the unprecedented characteristic of devices, which can be translated to photonic crystals or other wave controlling systems.

Real-time Characterization of the Degradation and Chemi-Crystallization Phenomenon in Natural-Based
Polymers at the Air-Water Interface—The Story of Bacterial Polyesters

Natalia Tarazona1, Rainhard
Machatschek1, Burkhard Schulz1,2 and Andreas Lendlein1,2; 1Helmholtz-Zentrum Geesthacht, Germany; 2University
of Potsdam, Germany

Interest in natural-based degradable polymers has placed bacterial polyhydroxyalkanoates (PHAs) under the
spotlight. PHAs are linear and isotactic polyesters composed of (R)-hydroxyalkanoic acid monomers. The
knowledge of degradation and crystallization mechanisms of PHAs, which leads to shifts in their mechanical
properties, is of critical importance for application development.

Naturally, biodegradation of a material starts at its surface. Using the Langmuir monolayer degradation technique,
combined with in situ Brewster Angle Microscopy (BAM), several aspects of the degradation of polymer materials
were directly observable. Since degradable polymer films at the air-water interface form water-soluble degradation
products, the concentration of chain segments at the surface decreases during degradation leading to a decline of the
surface pressure1.

Thin polymer films of poly(3-(R)-hydroxybutyrate) (PHB) and poly[(3-(R)-hydroxyoctanoate)-co-(3-(R-
hydroxyhexanoate)] (PHOHHx) were exposed to a degrading medium consisting of i) phosphate-buffered saline
(PBS, pH 7.4), ii) KOH (pH 10-13) and iii) KOH plus a PHA depolymerase enzyme (pH 10). In Langmuir layers,
both polymers were highly stable in PBS and up to pH 12, demonstrating that the hydrolysis of PHAs ester bonds is
only catalyzed at very highly alkaline conditions. At low packing densities of the films, the molecular degradation
curves at pH >12 suggested a chain-end scission mechanism with an almost linear decrease of the surface pressure.
This process did not induce a drastic shift in the crystallization state and therefore in the mechanical properties of the
polymers, as observed by BAM and interfacial rheology measurements.

PHB with high initial degree of crystallinity (Xc = 55–65%), showed slightly faster degradation curves when
compared to PHOHHx. Most likely, the amorphous polymer chains entrapped by the PHB spherulites (interlamellae
amorphous regions) degraded faster than free amorphous polymer chains, as established in semi-crystalline poly(L-
lactide)2.

The degradation of PHAs by a specific PHA depolymerase showed a typical and fast random scission mechanism
for both polymers. However, the PHA-degrading enzyme was more efficient on PHOHHx with longer side chain
and lower degree of crystallinity. Interestingly, the degradation of PHB followed a two-steps mechanism that could
be observable at the air-water interface. In the first stage, a decrease in the mechanical strength was observed, which
was followed by a second step that agrees with a secondary crystallization process or chemi-crystallization.

We present the Langmuir degradation technique as a potential standard to characterize and compare several
functionalities of polymers of different origin, structure and composition.

Understanding the Effect of Solution Spinning Processing Parameters on the Structure and Properties of
Carbon Nanotube Fiber

Lauren W. Taylor, Oliver S. Dewey and Matteo Pasquali; Rice University, United States

Since their discovery in 1991, carbon nanotubes (CNTs) have been of great interest for multifunctional materials due
to their outstanding electrical, thermal, and mechanical properties. Unfortunately, it has been challenging to translate
the excellent properties of single CNT molecules into macroscale materials. A promising technique for obtaining
high performance fiber materials is wet-spinning solutions of CNTs in chlorosulfonic acid (CSA). CSA and other superacids overcome the strong van der Waals forces between the CNTs by protonating the sidewalls of the CNTs to individualize the molecules to form a true solution. The CNTs in solution follow classical soft matter physics behavior; the solutions are isotropic at low concentration and liquid crystalline at sufficiently high concentration. The transition between these phases depends on the aspect ratio (the ratio of the length of the CNT to the diameter). Here, we study how the rheology and phase behavior of the solutions affect the spinning process and the electrical and mechanical properties of the resulting fibers. We have examined this experimentally by varying key processing parameters such as solution extrusion rate, CNT solution concentration, fiber draw ratio, and choice of coagulant. We find that spinning at lower concentrations yields significant improvement in tensile strength but no change in conductivity. Preliminary tensile testing data demonstrates that fibers spun from lower concentration solutions have a higher elongation at break. This suggests that the improvement in tensile strength can be attributed to the formation of larger bundles of CNTs within the fiber. Continued research of the fluid behavior will enable us to create the next generation materials for sensors, electrodes and wiring.

SB01.12.30
A Soft Ultra-Flexible Tactile Sensor for Robotic and Prosthetic Applications Andrei Nakagawa Silva1,2, Deepesh Kumar2, Tomoyuki Yokota3, Takao Someya3, Nitish Thakor2,4 and Alcimar Soares1; 1Universidade Federal de Uberlândia, Brazil; 2National University of Singapore, Singapore; 3The University of Tokyo, Japan; 4Johns Hopkins University, United States

SOP: In this paper, we present the development of a novel ultra-flexible tactile sensor that makes use of such organic photo diodes (OPDs) embedded into a soft skin construct, measuring force based on its deformation. Our goal is to integrate this sensor with robotic and prosthetic fingers for improved sensing and control. Developing an electronic skin (e-skin) that is highly flexible, durable and scalable is a highly desired goal. We model the e-skin sensor design and application after human hand and skin. Our skin provides a sophisticated sense of touch, contact-based information, as well as perception of texture, shape, etc. Beneath the skin, mechanoreceptors act as transducers, generating precisely timed spikes that are informative of contact forces and surface properties such as textures, edges and curvatures. A wide variety of sensors based on piezoresistive, capacitive and optical principles have been proposed with varying degrees of resolution, sensitivity and sizes. However, the development of flexible sensors that can be attached to robotic fingers and e-skins is still an unresolved issue. OPDs, especially designed on flexible substrates, constitute a new technology for applications to robotic and prosthetic hands.

Methods: The sensor is composed of 3 layers: The top one is formed by a matrix of 3x2 light-emitting diodes (LEDs), the middle layer is made of a soft elastomeric material (Ecoflex) that serves as the transduction layer and the bottom layer is formed by an ultra-flexible, ultrathin OPD 3x2 array. The transduction layer was painted with black pigment and has six cavities through which each LED target one OPD directly. Deformation of the soft layer induces changes in the light received by the OPDs and is informative of the applied forces over the skin. We performed a compression test to characterize the output voltage of the OPDs. From this relationship, we built a neuron model that mimics the activity of Merkel Cells (SA-I) akin to physiological data.

Results: The compression test demonstrated that it was possible to detect deformations of at least 0.5 mm. The relationship between compression and voltage was mostly linear and the sensitivity can be improved by making use of a programmable amplifier. The firing rate of SA-I afferents is associated with indentation depth according to a sigmoidal function. We applied such function to map indentation to a proper input to the SA-I neuron model. Our results demonstrated that it was possible to obtain firing rates that were similar to the physiological behavior of SA-I, where larger indentation amplitudes led to higher firing rate.

Conclusion: The proposed ultra-flexible tactile sensor paves way for improved e-skin design in robotics and prosthetics, especially for soft robotics where flexibility is a must. This sensor can also be used for improving the tactile perception of textures and shapes, besides dexterity in manipulation. The conversion of the signals into spiking activity of SA-I afferents that are more faithful their biological counterpart is also promising for delivering more naturalistic touch feedback from prosthetic hands to amputees via nerve stimulation.

SB01.12.31
Soft Robotic Steerable Microcatheter for the Treatment of Cerebral Aneurysms Gopesh C. Tilvawala1, Jessica Wen1, David Santiago-Dieppa1, Bernard Yan2, Alexander Norbash1, Alexander Khalesi3 and James Friend1; 1University of California San Diego, United States; 2Royal Melbourne Hospital, Australia

Nearly one-fourth of neuro interventions fail to treat cerebral aneurysms, imposing a significant sociological and
economic burden. Treatment is beneficial but was limited to surgical clipping until the advent and broad clinical adoption of endovascular coiling [1, 2], now a preferred, relatively inexpensive, and statistically more successful option [3]. It involves deploying platinum detachable coils into the aneurysm through a microcatheter; the coils aid formation of blood clots within the aneurysm, excluding it from circulation. However, the current microcatheters lack the much-needed steerability for precise tip positioning. Magnetic [4], piezoelectric ultrasonic [5], and wire-pulley [6] devices have been proposed in the past, but have not found broad acceptance. The existing panoply of passive guidewires and catheters, cannot be steered in vivo resulting in treatment failure, principally due to the difficulty in navigating tortuous vasculature, accessing, and optimally placing the microcatheter tip in the aneurysm dome for coil deployment.

Balloon catheters, which represent a crude form of soft-robotics, are broadly accepted in clinical use. However, fabrication of soft-robotic devices at length scales between 50 micrometers and 1 mm – the critical length scale which endovascular neurosurgical catheters demand – remains a challenge because both photolithography and 3D printing are inadequate. We combine innovative micro-fabrication techniques with intuitively engineering hyperelastic polymers, and direct hydraulic microactuation to provide steerable catheters for endovascular neurosurgery to overcome the high failure rate of current devices. Our novel fabrication methods enable delivery soft-robotic devices at the small length scales (<100 μm) with aspect ratios over 400. This delivers complete 3D hemispherical and direct handheld control of the microcatheter tip orientation to the neurointerventionist. We further test and validate the performance of the soft robotic steerable catheter in CT-Angiograms based silicone models to provide a representative test bed. The representative ex vivo silicone phantoms of vasculature start from the femoral artery, through the aortic arch to the internal carotid artery and the aneurysm, and include non-Newtonian blood flow analog with pulsatile pumping to mimic the heart. The testing in silicone models is used to iteratively improve performance paving the way for in vivo tests in porcine. The resulting data shows that the technology demonstrates promise through quicker treatment with fewer mistakes in comparison to the existing gold standard devices.

SB01.12.32
Multifunctional Magneto-Fluorescent Core-Shell SPIONs for Single Particle Fluorescence Imaging, Magnetic Resonance Imaging and Targeted Drug Delivery Ashish Tiwari and Jaspreet Randhawa; Indian Institute of Technology, India

Developing multimodal imaging probe without compromising their properties for different imaging modalities is essential but very challenging. Superparamagnetic iron oxide nanoparticles (SPIONs) have shown great potential as magnetic resonance (MR) contrast agent. However, lack of fluorescence in SPIONs restricts their applications as multimodal imaging probe. Here, we demonstrate a single step synthesis of carbon coated core–shell multifunctional fluorescent SPIONs with excellent magnetic susceptibility, inherent fluorescence, multicolor emission and high photostability. MR imaging shows significant potential of SPIONs as a contrast agent in cancer diagnosis. Single particle fluorescence imaging revealed that SPIONs show high photon counts and a single step photobleaching than the commonly used Cyanine dye. After evaluating the multimodality, these SPIONs were formulated as drug carrier for targeted cancer therapy. In vitro cytotoxicity and MR imaging studies on cancer cells showed the active targeting ability of SPIONs nanocarriers. Biocompatibility of SPIONs nanocarriers was ascertained ex-vivo by hemolysis and serum stability studies. Thus, the synthesized SPIONs nanocarriers, a multimodal imaging probe, illustrate great potential in targeted drug delivery to improve the existing cancer theranostics.
SB01.12.33
Drug Delivery Microneedles Coated with Electrosprayed Micro/Nanoparticles for Cosmetic and Medical Skin Treatments Serdar Tort, Daewoo Han and Andrew J. Steckl; University of Cincinnati, United States

Microneedles (µNeddles) are an attractive option for painless drug delivery vs. hypodermic needles. µNeddles have gained popularity for cosmetic and medical applications because they create micro-punctures without damaging the skin epidermis and deliver drugs or nutrients deeper into the skin layer. Coating the microneedles is an interesting approach for delivering specific drugs and/or nutrients. Electrospraying is a versatile method to produce micro/nanoparticles and can control the particle size by changing process parameters or solution properties. Electrospraying process was used for producing micro/nano particles of insulin, folic acid, titanium dioxide, antimicrobial agent before. However, limited studies are available on coating of microneedles. In this study, we have demonstrated microneedles can be controllably coated with an electrospraying method. The effect of electrospraying process parameters (electric field, electrospraying time) and solution parameters (molecular weight, solvent properties) were evaluated using two dermarollers with µneedle arrays 0.25 and 2.00 mm in height. To determine the solution parameters of the electrospraying process, two different molecular weight of poly(ethylene oxide) (Mn 100 kDa and 1000 kDa) and two different solvents (water and ethanol) were used. Water soluble Keyacid Red (KAR) dye was used as a model molecule. For successful electrospraying, a solvent with high surface tension and low vapor pressure, high electric field between nozzle and collector, low polymer molecular weight are required. Because a limited amount of particles can be coated on microneedles, optimizing polymer to drug ratio is critical to incorporate the required amount of drug into microneedles. The loaded dye was released completely within 5 min. As expected, dye loading was increased with electrospraying time up to 60 min, after which loading on the µneedles no longer increases as the particles begin to accumulate and branch on top of each other.

Further research is being carried out to determine the performance of the nanoparticle coated microneedle delivery system in ex vivo and in vivo studies.

SB01.12.34
Mo⁶⁺ Doped Ag/Ag₃PO₄ System—Influence of Femtosecond Laser Irradiation on Its Structural, Photocatalytic and Antimicrobial Properties Aline B. Trench, Thales Machado, Mayara M. Teixeira and Elson O. Longo; Federal University of Sao Carlos, Brazil

The development of functional materials has been widely investigated due to its large range of applications. In the heterogeneous photocatalysis field, one of the most interesting material is the silver phosphate (Ag₃PO₄), which presents a remarkable photocatalytic activity using visible light irradiation. Herewith, several methods of modification aiming to improve the Ag₃PO₄ properties have been performed. The doping modification has been proved as an effective method for improvement and modulation of properties of semiconductor materials. In addition, another powerful method for improvement of properties is the irradiation with a femtosecond pulsed laser, which tends to generate structural changes and semiconductor/metal interface. Therefore, the main proposal of this work was to investigate the influence of concomitant Mo doping and femtosecond pulsed laser irradiation in Ag₃PO₄ in its structural, photocatalytic, bacterial and photoluminescent properties. The material was characterized by X-ray diffractometry (XRD), ultraviolet-visible absorption spectroscopy (UV-Vis), Raman spectroscopy, scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray spectroscopy (EDX). The photocatalytic activity was evaluated for the degradation of rhodamine B under visible light irradiation. The results showed that the photocatalytic activity of the samples modified by doping and nanoparticle growth showed a promising result, degrading 100% of the pollutant in 2 minutes while the pure sample degrades about 53% in the same time interval. The bactericidal activity was tested for Escherichia coli bacteria, and the results showed that the modified samples have a superior antimicrobial activity than the pure ones. Thus, both the improvement in the photocatalytic and antimicrobial activity can be explained by the synergic effect between the silver nanoparticles obtained by irradiation in femtoseconds with the different cluster of the material.

SB01.12.35
Cellulose-Based Materials for Magnetic Paper Ana C. Trindade¹, João Canejo², Sergio H. Toma², Susete Fernandes², Maria Helena Godinho², Koiti Araki³ and Jon O. Fossum¹; ¹Norwegian University of Science and Technology, Norway; ²Universidade NOVA de Lisboa, Portugal; ³University of São Paulo, Brazil

It is known that iridescent solid films can be produced from cellulose nano crystals (CNCs) solutions in the presence
of the earth Magnetic field, [1] after solvent evaporation. The CNCs have a negative magnetic susceptibility, which allows the production of aligned solid films, with the cellulose nano rods main axis aligned parallel to the air interface, after the evaporation of the solvent.

Cellulose derivatives, for example cellulose acetate (AC), can form homogenous solutions with CNCs, from which films and fibers can also be prepared [2], the CNCs align their main axis along the main axis of the fibers, which translates into the enhancement of the mechanical properties of the electrospun micro/nano fibers [3]. To investigate the broken symmetry of the system CNCs rods were mixed with symmetric particles, spheres of iron oxide metallic nanoparticles (IONs).

The IONs were chosen due to their shape and because they are magnetic [MG2] nanoparticles, with diameters of the order of 10 nm, and can be conjugated with different other agent nanoparticles [4]. We prepared micro/nano fibers from AC with different quantities of IONs conjugated with CNCs and determined the critical concentration of IONs needed to induce magnetic properties to the fibers.

The precursor suspensions and the micro/nano electrospln fibers were investigated by using different techniques as scanning electron microscopy (SEM), atomic force microscopy (AFM), polarizing optical microscopy (POM), X-ray, small angle X-ray scattering (SAXS), and nuclear magnetic resonance spectroscopy (NMR). The mechanical properties as well as water contact angle measurements, of the electrospun membranes, were also investigated, with and without the nanoparticles.

This work demonstrates that it is possible to produce magnetic paper by adding a low amount of magnetic cellulose-based nanoparticles, which opens new horizons to the design and control of mechanical and magnetic properties of cellulotic materials.

Alvarez1,1,8 and Grissel Trujillo-deSantiago1,1,8; 1Tecnologico de Monterrey, Mexico; 2Harvard Medical School, United States; 3Isfahan University of Medical Sciences, Iran (the Islamic Republic of); 4University of California, Irvine, United States; 5Delee Corp., Mexico; 6Laboratorio Nacional de Manufactura Aditiva y Digital, Mexico; 7Harvard-MIT Division of Health Sciences and Technology, United States; 8MIT, United States

The fabrication of complex microstructure at high resolution and speed continues to be a technological challenge. We introduce continuouschaotic printing—the use of chaotic flows to continuously print hydrogel fibers with a high amount of internal (lamellar) microstructure at high resolution (a few microns) and speed (~1.0 meters of fiber/minute). We coextrude two inks (i.e., a suspension of microparticles, dispersed in a hydrogel) through a printing head that contains a miniaturized Kenics mixer (a simple on-line mixer) that contains multiple helicoidal mixing elements.

The diameter of the printing head and the number of mixing elements determines the number of internal lamellae produced according to a process of successive bifurcations that yields an exponential generation of inter-material area. By using 7 internal elements, 256 lamellae of average widths of 4 µm can be generated in a 1 mm cross-section fiber, and an inter-material area of ~ 0.067 m² cm⁻³ can be achieved. These values for microstructure resolution, internal surface area density, and fabrication speed all exceed the capabilities of any of the currently available commercial microfabrication techniques (i.e., commercial 3D printers) for the creation of microstructure.

In the present work, we include several application examples. We demonstrate the feasibility of reinforcing alginate fibers by precise engineering of lamellar arrays of graphite microparticles. We calculate the distribution of the
relevant length scales (i.e., the distance between lamellae) and demonstrate that the process of creation of microstructure is robust, reproducible, and self-similar. In addition, we demonstrate the possibility of designing living societies of bacteria, finely ordered in well-defined lamellae within the same construct, so that different cell types share a substantial contact interface. This enables, for example, the facile fabrication of complex bacterial community models for biomicrogeography studies. In proof-of-principle experiments, we demonstrate the bioprinting of mammalian cell-laden fibers in gelatin-methacryloyl (GelMA), a commonly used hydrogel for cell culture applications.

In an exciting further development, we demonstrated that the output of a continuous 3D chaotic printing head can be fed into an electrospinning head. We have shown that the microstructure created by 3D chaotic printing can be further scaled down by three orders of magnitude. A comparison of our experimental and computational results demonstrates that the output of the chaotic printing process is robust, predictable, and amenable to mathematical modeling.

The simplicity and high resolution offered by chaotic printing could enable novel biomedical and electronic applications, including the fabrication of tissue-like structures and reinforced or super-catalytic materials.

**Analysis of Nanofiber Formation for High-Throughput and High-Quality Electrospinning Process**

Kenya Uchida¹, Ikuo Uematsu¹, Yasutada Nakagawa¹, Tomomichi Naka¹ and Hidetoshi Matsumoto²; ¹Toshiba Corporation, Japan; ²Tokyo Institute of Technology, Japan

A nanofabrication including nanofiber formation gives novel functions to materials. Due to the large surface area, interconnected framework, and pore structures, nanofibers and nanofiber membranes show superior properties in the applications such as sensors, catalysts, filters, protective clothes, and biomaterial scaffolds(1). An electrospinning is a straightforward and versatile fabrication method for the nanofiber membrane from polymer solutions and melts. One major advantage of this method is applicable for a wide range of materials, such as inorganic materials, synthetic polymers and biological materials. Recently, the development of high-throughput and high-quality electrospinning system is strongly required. The process of nanofiber fabrication during electrospinning is too complicate to clarify the mechanism.

Some researchers reported the direct observation of fiber formation during electrospinning by using a high-speed camera. Few reports, however, deal with the analysis of the electrified-jet behavior in bending instability region(2). We performed quantitative analysis of nanofiber fabrication process during electrospinning. The electrified-jet phenomenon from the nozzle to the substrate was observed by a high-speed camera(3). To analyze electromagnetic and kinetic parameters, the flying velocities of the electrified-jet were measured and the electric potentials were obtained from a finite element method analysis of an electric field. The charge density and a size of the electrified-jet in the bending instability were determined by solving the equation of motion for the electrified–jet. By using this analytical approach, the effects of the applied voltage and the addition of an electrolyte to the spinning solution on nanofiber formation were demonstrated. The insights obtained here enable precise design of the high-throughput and high-quality electrospinning process.

In addition, we carried out theoretical analysis of liquid impregnation behavior into well-defined nanofiber membranes. The determining factors for controlling liquid impregnation is investigated using numerical analyses based on the Kozeny-Carman equation.

Finally, an application of nanofiber membrane derived from material properties and nanofiber morphology is demonstrated to show the advantages of electrospinning technology.

**SB01.12.38**

**Pattern Formation in the Heterostructured Gel by the Ferrocyanide-Iodate-Sulfite Reaction**

Tomonaga Ueno¹ and Ryo Yoshida²; ¹Nagoya University, Japan; ²The University of Tokyo, Japan

Coupling of reaction and diffusion forms a spontaneous pattern. Turing theoretically predicted that stationary pattern forms in reaction-diffusion systems and stated the formation conditions of stationary patterns. In reaction-diffusion
systems, the medium is an important. The diffusion coefficients of the activator and the inhibitor are important for pattern formation. We have tried to control pattern formation in the Ferrocyanide-Iodate-Sulfite (FIS) reaction, which is pH-oscillating reaction, by controlling solute diffusion via the network density of polymer gel. In this study, we reported the pattern formation in heterostructured gels with different network densities by the FIS reaction. The chemical states of the gel depend on the diffusivity, which in turn depends on the network density of the gel. Consequently, a pH pattern reflecting the heterostructured gel emerged. Furthermore, adjusting the condition produces novel patterns in the heterostructured gel.

A heterostructured gel was prepared by a two-step synthesis method with photo polymerization. Acrylamide (AAm), the cross-linker N,N'-methylenebisacrylamide (MBAAm), and the photopolymerization initiator Irgacure 2959, were used. Two gel precursor solutions with different monomer contents were prepared. The monomer contents of gel precursor (20) and gel precursor (10) were 20 and 10 wt%, respectively. A continuous stirred tank reactor (CSTR) covered with a gel was constructed. The gel was set in the space between reactor. The temperature of the reactor was set at 50 °C with a thermostatic bath. Solution A ([NaIO₃]₀: 75 mM, [H₂SO₄]₀: 3.6 mM, [NaOH]₀: 0.25 mM) and solution B ([Na₂SO₃]₀: 89 mM, [K₄Fe(CN)₆]₀: 25 mM) were fed separately into reactor with HPLC pumps. By controlling the flow rate, the difference in the diffusivities in the heterostructure gel was converted to a difference in the pH states via the FIS reaction. Furthermore, the boundary conditions given by the striped heterostructured gel gave rise to stationary linear patterns, which are formed in the reaction-diffusion system. In this way, pattern formation in the FIS reaction was controlled by the artificially designed heterostructured gel.

SB01.12.39
Isolation of Chloroplasts from Grass to Design Photobioreactors by Using High Internal Phase Emulsions
Andrea E. Vaca, Alicia E. Sommer and Renata A. Montero; Universidad de Investigación y Tecnología Experimental Yachay Tech, Ecuador

The deficient disposition of the pruning waste from grass (Poaceae), has been converted into a considerable environmental problem in Ecuador since it is discarded in common garbage dumps. As a result, gases and lixiviates are generated producing a negative impact on the environment. This project takes advantage of these residues to isolate their chloroplasts, with the aim of subsequently developing bioreactors to make the absorption of CO₂. Several investigations have been carried out in order to encapsulate chloroplasts obtained from other species, in inorganic matrices[2,3], since these molecular machines transform light energy into chemical energy, through the process of photosynthesis[1]. However, it is still a challenge to find an adequate method to encapsulate them and to maintain their vital function. In this work we present, for the first time, the encapsulation of grass chloroplasts into silica monolith with a hierarchical texture, using high internal phase emulsion (HIPE). Based on the results obtained, it was demonstrated that it is possible to extract chloroplasts from the grass with high yield. The chloroplasts extracted were encapsulated into silica monolith. The synthesized samples were analyzed by optical and scanning electron microscopy, as well as by DRS-UV-Vis and Fluorescence spectroscopy to monitor the photosynthetic activity of chloroplasts and it was shown that it was possible to keep it up to more than 90 days.

SB01.12.40
Micro-Structuring of Multilayered Thin Films Enables Stretchable Interconnect Technology
Nicolas Vachicouras, Christina Tringides, Yohann Thenaïs, Florian Fallegger and Stephanie P. Lacour; École Polytechnique Fédérale de Lausanne, Switzerland

We propose a new strategy to engineer elasticity in otherwise rigid materials by structuring them with specific patterns. This happens spontaneously at the microscale on stretchable thin gold films on silicone that display dense distributions of Y-shaped cracks to favor out-of-plane deformation. We drew inspiration from these cracks to pattern Y-shaped cuts and engineer reversible elasticity in a multi-layer of metallic and plastic thin films. First, the geometry and density of the Y-shaped patterns were first optimized using finite element analysis and macroscopic models. Next, we developed the fabrication process enabling the micro-patterning of thin polyimide/platinum/polyimide interconnects with microscopic Y-shaped cuts (branches of dimensions ~15 μm, thickness < 10 μm). Encapsulation in silicone rubber completed the fabrication of stretchable interconnects that can be easily manipulated.
The micro-structured metallic films exhibit a sheet resistance of $\sim 15\text{--}20 \ \Omega/\text{sq}.$ and display surprising deformability and stability compared to non-micro-patterned interconnects of identical thickness. 200 µm wide, 17 mm long, Y-shaped metallic tracks mechanically fail at 80 % tensile strain albeit do not fail electrically while plain tracks of identical geometry fail both mechanically and electrically at only 3 % applied strain. The micro-patterned interconnects sustain repeated cycling at 10% tensile strain for 1 million cycles with remarkable electrical stability. Moreover, this technology allows for the patterning of tracks down to 20 µm in width and complex layouts on a wafer-level scale. Through pattern optimization, mechanical gradient may be engineered across the structure, defining non-deformable to elastic areas, thereby providing an interesting platform for the hybrid integration of stiff and rigid components with stretchable interconnects. Finally, we verified the micro-structured tracks impact only minimally the mechanical properties of the silicone carrier in terms of apparent elastic modulus (apparent elastic modulus increased from 2.3 MPa to 3.2 MPa).

We have implemented this soft technology to prepare stretchable micro-electrode arrays for neural recordings but we anticipate this strategy will be implemented in a range of wearable and implantable bioelectronic interfaces.

SB01.12.41
Characterization and Evaluation of Antibacterial Activity of Hydrothermaly Synthesized Iron Oxide Coatings
Svetlana Vihodceva1, Jurate Siugzdaite2 and Andris Sutka1; 1Riga Technical University, Latvia; 2Lithuanian University of Health Sciences, Latvia

As surface contamination can contribute to transmission of bacteria, the development of surface enhanced coatings that causes sanitization of the surface is an important development in reducing hospital acquired infections. To develop antimicrobial coatings with “sharp” Z-scheme photocatalytic nanoarchitectures. Hematite (Fe2O3) as non-toxic narrow band gap semiconductor with broad absorption in the visible light, will be used as the main element in coating, “sharp” structures offering a long optical path for efficient light harvesting, that will increase photocatalytic efficiency of structures. Similar “sharp” structures proved it effectiveness in bacteria killing by piercing into the bacterial cell wall and as repelling surfaces that resist bacteria attachment. Thereby, in this work an antimicrobial activity of Fe2O3 coatings was studied by Agar diffusion and JIS tests. Hematite coatings were obtained by one step hydrothermal method. Ferric chloride and urea were dissolved in a distilled water, this solution was transferred into autoclave containing an rubber substrate fully immersed into the solution. Then the autoclave was placed in a hot air oven at constant temperature 150 C for 3 hours in air. Finally, substrate with coating was taken out from the autoclave and washed in DI water and dried in air at room temperature. Obtained coating were characterized by SEM, FTIR and XRD.

Escherichia coli ATCC 25922, Staphylococcus aureus ATCC 2593, Staphylococcus epidermidis ATCC 12228, Staphylococcus saprophyticus ATCC 15305, Pseudomonas aeruginosa ATCC 10145, Bacillus cereus ATCC 11778, Enterococcus faecalis ATCC 29212, Listeria monocytogenes ATCC 13932, Salmonella typhimurium ATCC 14028 were used as a test cultures. The microbiological testing results show the efficiency of the hematite coatings against all test microorganisms.

SB01.12.42
GER Driven Artificial Muscles—Nano-Catalyst Laden Filament for 3D Printed Pneumatic Actuators
Marcos Villeda Hernandez, Charl F. Faul and Michael P. Dicker; University of Bristol, United Kingdom

Soft Robotics offers solutions to problems where human or animal-like architectures and materials are needed. Tasks requiring strength yet finesse, currently only achieved through human operators, may in the future be automated by developments in soft robotics. Further than just mimicking biological systems in performance, the aim of soft robotics is to develop robots which are both safe and compliant for human interaction. Pneumatic actuators are widely studied in soft robotics as the compliant actuation of these systems is comparable to that found in Nature. However, conventional pneumatic actuators are powered by externally tethered hard air compressors or accumulators.

Gas Evolution Reactions (GER) are widely found in biochemical processes [1,2]. Hydrogen peroxide is a sub-product of cellular metabolism that protects the cell against anaerobic pathogens. Given its reactivity, it must be quickly transformed into less harmful or reactive compounds. In vivo, the decomposition of hydrogen peroxide to water and oxygen is catalysed enzymatically by catalase [3]. Soft, porous catalytic nanocomposites can perform a similar function to enzymes while also mimicking the desirable compliance of biological systems.

Platinum is a catalyst used in the decomposition of hydrogen peroxide [4]. This work reports the development and
characterisation of a Platinum nano-catalyst laden 3D printing filament, created by loading a commercially available porous filament (POROLAY LAYFOMM 40) with platinum nanoparticles. The nanocomposite filament is used to create a one-step multi-material 3D-printed GER pneumatic soft artificial muscle. The resulting pneumatic actuator with embedded catalysts converts energy-dense liquid chemical fuel (hydrogen peroxide) into actuating gases (oxygen). Actuator geometries for optimising the amount of oxygen harnessed from the hydrogen peroxide decomposition are explored through finite element analysis. The potential for the configuration to create a fully soft untethered device capable of gentle movements for locomotion or handling of delicate objects is discussed. Developing such advanced methods for manufacturing and powering soft robots is critical in order to realise their potential to generate real societal impact.

SB01.12.43
Bacterial Cell Walls Exhibit High Water Responsive (WR) Pressures and Energy Densities Haozhen Wang1,2, Zhi-Lun Liu3 and Xi Chen1,3; 1Advanced Science Research Center (ASRC), The City University of New York, United States; 2PhD Programs in Physics, The Graduate Center of the City University of New York, United States; 3The City College of New York, United States

Nature has developed remarkable WR systems that dramatically deform in response to changes in relative humidity (RH), such as the actuation of pine cones opening and releasing their seeds and wheat awns propelling their seeds into the ground. Such WR actuations can be extremely powerful, and have a great potential to power modern engineering systems. Here, we present our discovery of bacterial cell walls that exhibit extremely high energy density of 72.6 MJ/m3 and power density of 9.1 MW/m3, surpassing that of existing actuator materials and artificial muscles. By using our customized AFM, we characterized WR properties of bacterial cell walls from three species, including Bacillus subtilis, Staphylococcus aureus, and Saccharomyces cerevisiae. We found that cell walls from these three species have significant water-responsiveness, and their WR strains reach 27.2%, 19.1%, and 11.2%, respectively. To measure their WR energy densities, we have created a thermodynamic cycle where applied forces and RHs can be varied to maximize cell walls’ WR work. Using this method, we have measured their energy densities to be 72.6 MJ m-3, 47.9 MJ m-3, and 29.9 MJ m-3. Considering their cycle period (8s), cell walls’ power densities are estimated to be 9.1 MW m-3, 5.9 MW m-3, and 3.7 MW m-3, respectively. We also note that, while these cell wall structures share similar molecular structures, they possess diverse water-responsiveness, motivating further studies of cell walls’ WR fundamental mechanisms.

SB01.12.44
Highly Sorptive and Breathable PIM-1-Based Fabrics with Enhanced Mechanical Strength for Chemical and Biological Protection Siyao Wang1, Natalie Pomerantz2, Erin Anderson3, Todd Miller2, Saad Khan1 and Gregory Parsons1; 1North Carolina State University, United States; 2U.S. Army Combat Capabilities Development Command – Soldier Center, United States; 3Battelle Memorial Institute, United States

Recently, Polymers of Intrinsic Microporosity (PIMs) have attracted attention as a novel class of high free-volume polymers with highly rigid and contorted molecular structure. Most research on PIMs has focused on fundamental material and membrane properties, with only a few studies on materials in fiber form. In this study, PIM-1 polymer fiber mats were fabricated by electrospinning using different solvent systems consisting THF, DMF and toluene. The resulting fiber mats showed excellent breathability and high porosity, indicating potential for applications in protective clothing. The surface area of the PIM-1 fiber mats was typically 650 m2/g, which is close to 750 m2/g measured for the starting neat powder. A problem, however, is that the produced fiber mats have very poor mechanical integrity due to low interchain interactions of PIM-1, hindering their practical use. In our work, we have
developed a unique PIM/PAN hetero-structure synthesis approach by incorporating PAN fibers as a structural reinforcing material into the PIM fiber matrix. The as-prepared PIM/PAN composite fibers exhibit 40 times improvement in tensile strength compared to the PIM fibers, with a net surface area of 360 m²/g, indicating only a moderate loss in porosity. In addition, metal-organic framework (MOF) particles with the capability of degrading toxic chemicals, such as chemical-warfare agent (CWA) simulants, were integrated into the composite fibers. The resultant PIM/PAN/MOF composite fibers show 2-3 times higher removal capacity of dimethyl methylphosphonate (DMMP) than the baseline material and demonstrate the detoxification of 4-nitrophenyl phosphate (DMNP) as monitored by UV–vis spectroscopy, among which DMMP and DMNP are both chemical nerve agent simulants. These findings indicate that functionalized PIM-1-based fabrics are a promising material for applications in chemical protection and detoxification.

SB01.12.45
Application of Janus Graphene Nanofluids for Enhanced Oil Recovery Wei Wang and Sehoon Chang; Aramco Research Center-Boston, United States

Anisotropic nanomaterials composed of two halves with different structure, chemistry, or polarity, known as Janus nanomaterials, have distinct properties when compared to symmetrically functionalized analogues. These materials have recently gained significant attention in many applications such as electronic thin films, drug delivery, sensors, optics, oil/water separation membranes, photoactivated micromotors, photocatalysts, and interfacial modification. Among the many Janus structures, two-dimensional (2D) Janus nanomaterials with high aspect ratio in rod-like or planar (i.e., nanosheets) morphologies, are especially intriguing considering their interfacial properties as well as their ability to assemble into higher order and hybrid structures. In this research, we describe an approach to mass synthesis of Janus graphene nanosheets in highly controllable ways via a novel “Interfacial Nanoreactor” system. We have characterized and proven the asymmetric structures of the synthesized Janus graphene nanosheets by Langmuir-Blodgett (LB) surface pressure-area (π-A) curves, fluorescence spectroscopy, contact angle measurement and scanning electron microscope (SEM) characterizations. The Janus graphene nanosheets with two chemically different compartments show very unique behaviors at liquid interfaces. We observed surfactant-like interfacial phenomena of the Janus graphene layer when its surface density increases, which is similar to the way that micelles or lipids form in a bulk phase above the critical micelle concentration (CMC). The one of applications for the nanofluids of Janus graphenes is to be a chemical agent for enhanced oil recovery (EOR). To demonstrate this applications, we used a microfluidic-based reservoir-on-a-chip model to understand oil-water-rock phase interactions and visualize the fluid transport processes in micropores, and more than 10% improvement in oil recovery was observed using the Janus graphene nanofluids in comparison to just using seawater flooding. The 2D Janus graphenes also present great opportunities to further create tailored and functional hierarchical structures of interest to molecular biology and medicinal chemistry.

SB01.12.46
Transparent and Flexible Pressure Sensor for the Human/Machine Interface Elena E. Watts1, Ning Xu2 and D. Jason Riley1; 1Imperial College London, United Kingdom; 2ROLI, United Kingdom

With the movement towards flexible and transparent electronics[1] for use in displays[2], electronic skins[3] and wearable healthcare monitoring[4], electrical components such as pressure sensors must evolve alongside circuitry and electrodes to ensure a fully flexible and transparent system. In the past, piezoresistive pressure sensors made with flexible electrodes have been fabricated, however, many of these systems are opaque.[5]

For the first time, we present a technology that exploits the natural self-assembly of polystyrene nanospheres to reproducibly create optically transparent pressure sensors with sensing performance comparable to industry standards. We have demonstrated flexible sensors with transparencies as high as 79.3 % transmission, fast relaxation times of <50 ms, and sensing response up to 200 kPa.

The performance of the piezoresistive pressure sensor relies on uniform elastic nano-dome arrays. A thin and homogenous lining of PEDOT:PSS renders the domes conductive and retains the transparent and flexible qualities of the underlying polymer. The highly tunable multi-step fabrication procedure establishes the potential for the mechanical properties of the sensor to be tailored and tuned.

This presentation will include the design, fabrication details and scale-up potential of the sensor. Alongside this, the
performance metrics will be demonstrated, and the pressure sensing mechanism analysed with reference to some preliminary in-situ SEM compression testing.

SB01.12.47
Thin Hydrogel Coatings by Enzyme-Catalyzed Mechanism Christian Wischke1, Marlin Kersting1,2, Alexander Welle2, Ludmila Lysyakova1, Steffen Braune3, Karl Kratz1, Matthias Franzreb2 and Andreas Lendlein1,3; 1Institute of Biomaterial Science and Berlin-Brandenburg Center for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; 2Institute of Functional Interfaces, Karlsruhe Institute of Technology, Germany; 1Institute of Chemistry, University of Potsdam, Germany

Technologies for modification of material surfaces to create specifically envisioned interfacial properties are of high technological interest, particularly when it comes to in situ thin layer coatings with very hydrophilic materials, i.e. hydrogels, on hard materials. While spin coating of precursors and crosslinking of reactive moieties via UV irradiation may be applicable to flat materials [1], alternative approaches are of interest that conceptually would be applicable to any surface shape by initiating hydrogel formation from the surface itself [2]. In this context, the capability of enzymes to crosslink polymeric precursors to form hydrogels [3] may be applied to realize a “coating-from” rather than a “coating-to” approach for functional interfaces.

Based on previous experience of relatively slow conversion of substrates by mushroom tyrosinase after surface immobilization [4], here horseradish peroxidase was selected and successfully coupled to amino-functionalized glass or gold surfaces by use of glutaraldehyde. When exposed to solutions of hydrophilic 4-arm star shaped telechelics from poly(ethylene glycol) bearing end groups derived from aromatic amino acids, the envisioned in situ formation of thin layer hydrogel coatings was achieved.

Contact angle and zeta potential analyses were applied to determine physicochemical properties of the surfaces. A qualitative proof of hydrogel deposition was provided by time-of-flight secondary ion mass spectrometry (ToF-SIMS), showing ethylene glycol repeat units as well as the crosslinkable aromatic moieties at higher concentrations for enzyme triggered crosslinking conditions as compared to pure adsorption of the precursor. A quantitative assessment of the coating thickness was performed by atomic force microscopy (AFM) and quartz-crystal microgravimetry, suggesting very thin homogeneous hydrogel layers of 100 - 250 nm being formed. As a key function needed for hemocompatible devices, low thrombogenicity of the hydrogel coating similar to clinical accepted implant materials was demonstrated with human blood from several donors according to the protocol approved by the ethics committee (# EA2-018-16; Charité University Medicine Berlin, Germany).

This “coating-from” approach may in the future be applied to various shapes of surfaces, e.g. for cell culture, protein/biofilm repellency in technical applications, or in flexible electronics.

SB01.12.48
Multimodal Magnetomotility of Multiple Soft Robots Sukyoung Won1, Sanha Kim2, Jeong Eun Park1, Jisoo Jeon1 and Jeong Jae Wie1; 1Inha University, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of)

Magnetic soft robots facilitate battery-free contactless control of sub-mm soft robots. However, simultaneous programming of magnetic field is required in both 3-axial direction and magnitude to navigate through obstacles. Hence, parallel control of multiple soft robots becomes prohibitive. Herein, we demonstrate maneuverability of multiple polymeric microbots capable of on-demand orbital navigation inspired by hierarchical rotation and revolution of our Solar System planets. Here, the hierarchical magnetomotility for soft robots is achieved by planar rotations of permanent magnet. Simple change of rotational speed of magnets allows reversible control of trimodal
rotation including rotating, pivoting, and tumbling. Remarkably, different orbital radius and/or velocity for each soft robot can be achieved in multi-body system due to aspect ratio dependent magnetic motility of soft robots. The hierarchical magnetomotility promotes adaptable self-correcting locomotion since blocked rotations shift revolution pathway, providing multi-terrain navigation functionality including stairs and uphill climbing as well as underwater and above water swimming. We will also discuss collective behaviors of the magnetic soft robots to accomplish a certain mutual goal.

SB01.12.49
Dual-Porous Cellulose Nanofibril Aerogels for Organic Pollutant Removal and Silver Ion Recovery from Wastewater Tingting Wu1,2, Qinghua Zhang1 and Gustav Nyström2,3; 1Donghua University, China; 2Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 3ETH Zürich, Switzerland

The growing world population and the related increase of chemicals used in daily life leads to higher concentrations of chemical substances in our water reservoirs. It is therefore crucial to develop green, stable and efficient absorbents for purification of contaminated water. In this work, an anionic cellulose nanofibril (CNF)-based hierarchical aerogel with high specific surface area (up to 430 m²/g) was prepared via a combined directional freeze-thawing (macro-pores) and supercritical drying (meso-pores) method. By adjusting physical and chemical cross-linking, we can obtain a high Young's modulus (711 kPa) and hydrophobic performance (contact angle ~120°), which help to maintain the stability of aerogels in aqueous conditions. The cationic dye methylene blue (MB) was chosen as a model organic molecule to investigate the absorption properties of the aerogels by changing the pH, absorbent dosage, initial dye concentration, and contacting time during the adsorption process. The aerogels showed a maximum adsorption of MB up to 234 mg/g, and remain intact in the dye solution even after 24 h of shaking during the adsorption test. Inspired by the excellent adsorption performance of cationic MB, we selected Ag⁺, a metal ion that has been rarely studied in the literature for ionic adsorption. The maximum adsorption of Ag⁺ was found to be 116 mg/g. A high specific surface area and a strong electrostatic interaction are the prominent mechanisms behind the good adsorption capacities to both MB and Ag⁺. These results indicate that the prepared macro- and meso- dual porous CNF aerogels are promising candidates for wastewater purification. Considering the economic factor, a reduction reaction was performed on the aerogels after the Ag⁺ adsorption enabling a conversion of ionic to metallic Ag. This allows for a recovery of the extracted silver and a potential reuse of the materials within antibacterial or catalytic applications.

SB01.12.50
Rapid and Facile Fabrication of Self-Similar Hierarchical Broccoli-Like Structures Zhigang Wu, Shuo Zhang and Qin Jiang; Huazhong University of Science and Technology, China

Cross-scale micro-nano hierarchical structure in the living systems often provides unique features on surface and serves as an inspiration source for artificial materials or devices. Among them, artificial made broccoli-like structure demonstrates excellent surface performance such as ultra-high hydrophobicity or hydrophilicity in various situations.

In this work, by introducing a solvent-assisted UV laser treatment, we establish a rapid yet facile approach to fabricate self-similar hierarchical broccoli-like micro-nano structures on silicon with super hydrophilicity and high light absorbance. Specifically, through adjusting the operating parameters of the UV-laser (scanning speed, v and space between adjacent scanning lines, ΔL) and immersing solvents, we can tune the surface morphology of the surface, such as surface roughness and height difference, to obtain uniform, robust surface topography. According to micro-views, we observe regular microgrooves consist of abundant “peaks” and “valleys” that stack vast broccoli-like structures. We also investigate the forming mechanism of such broccoli-like structures. It is found that phase change, micro-/nano-particles sputtering and depositing, disintegration and re-depositing, and solvent evaporating etc are important issues during the forming process of self-similar structure.

Through optical test of UV-treated Si samples, the results reveal that such broccoli-like structures have a consistent high light absorbance (>90%) in an ultra-broad spectrum from ultraviolet to infrared spectrum (in 200-2 500 nm spectral range). It may provide a low-cost way to fabricate black Si for solar energy harvesting in common laboratory environment.

Further, the patterned silicon can be used as a master for capillary assembly of soft electronics on elastomeric substrates with water/liquid alloy-amphiphilic zones, or as a self-cleaning surface and a heat transfer surface. The demonstrated facile way for a broccoli-like structure fabrication may encourage more researchers to investigate unique features of self-similar micro-/nano surfaces, and further exploit their great potential in applications towards
diverse directions.

**SB01.12.51**

**Tactile Sensor for Magnitude and Direction Detection Based on a Liquid Alloy Droplet**

Zhigang Wu¹, Wenci Xin¹ and Bei Wang¹,²; ¹Huazhong University of Science and Technology, China; ²Uppsala University, Sweden

To perceive the tactile signals, such as magnitude, strain and especially direction, researchers have developed various types of sensors. However, these devices are either only could obtain single signal or super complex in structure. This work presents a novel soft tactile sensor with capacitance between liquid alloy based hemisphere and planar electrodes. Due to the nature high surface tension and flowability of liquid alloy droplet, the dynamic re-distribution of charges on electrodes can achieve high sensitivity, wide range and abundant functions, e.g. magnitude or direction of external force.

In demonstration, a flexible tactile sensor based on morphological deformation of liquid alloy was fabricated. The bottom electrode was a hemi-sphere liquid alloy droplet pinned on a circle copper pad, which was surrounded with liquid alloy phobic substrate to avoid the adhesion of liquid alloy during deforming. While the upper electrode was made of planar liquid alloy, which was divided into several isolated equal sections. Hence, the entire device can be viewed as several capacitance sensors with a shared fluidic electrode. In intact situation, most of the charges would concentrate on the top of hemisphere at first. With the approaching of the electrodes, the charges would disperse to a wider contacting area, which was reflected on the change of capacitance in each sector. Thus the information of the tactile signal could be calculated according to the results from all of the capacitances, and the magnitude and direction were acquired at the same time. Without the constraint of wrapped materials, the droplet is only limited by its high surface tension, which leads to a high sensitivity. At the same time, the charges dispersion following the deformation also contributes to the sensitivity. The impact parameters including the amount of liquid alloy, the size of bottom and upper electrodes, and the fabricating technique also were studied. The response time, repeatability, hysteresis etc. demonstrated the performance of this novel tactile sensor.

**SB01.12.52**

**Facile Fabrication of Flexible Discrete Magnetization Soft Robot via Laser-Tuned Selectively Adhesive Transfer Printing of Anisotropic Magnetized Silicone Cells**

Zhigang Wu, Xingxing Ke and Shuo Zhang; Huazhong University of Science and Technology, China

This work presents a facile method to assemble discrete magnetization soft robots via laser-tuned selectively transfer printing different patterned anisotropic magnetized silicone cells. This technique could be simply implemented via anisotropic magnetization, magnetized cells cutting and transfer printing of magnetized cells in three major steps. It is very promising to parallelly flexibly input magnetization information into a three-dimensional structure for diverse applications.

Spatial preset of specific properties in a configurable way is a key to develop active devices running in dynamic scenarios such as that in soft robotics, biomedicine, functional materials and four-dimensional (4D) printing. Despite success in recent development, current fabrication technique still too complicated to implement in a facile and rapid way enabling flexible spatial preset of magnetization in soft materials.

In this work, by introducing a laser-tuned selectively adhesive transfer printing of anisotropic magnetized silicone cells, we present a facile fabrication technique to flexibly preset discrete magnetization in soft materials for making fast-transforming untethered magnetic robots. Such a preset of magnetization pattern can be easily tuned during the transfer process by alignment adjustment or laser parameters tuning. Different magnetized cells can be selectively picking up by tuning the surface morphology and hence adhesiveness of magnetized film with a different laser-treatment parameter setting. Spatial preset of magnetism can be achieved by geometrical alignment and configuration adjustment of different magnetized cells. Moreover, magnetization in each layer can be easily tuned in arbitrary direction on demanded and thus empower the independent addressability to different magnetized cells in a global actuating magnetic field. Further, we can use planar structure to achieve complex 3D structures and the flexibility of the re-assembling based this method enable it ease of geometrical re-configuration, which can totally change its response behavior accordingly.

Finally, two demonstrations are presented: 1) the re-assembling process of sub-robots together with its responding behavior in different geometrical configurations, and 2) a targeted drug delivery of a hollow 3D structure with excellent passibility and flexible steering inspired by tumbleweed.

Fabrication of Seamless Integrated Perception Layer for Fully Soft Robots via a Conformal Masked Printing
Zhigang Wu and Shuo Zhang; Huazhong University of Science and Technology, China

Nowadays, intelligent home robots are meeting a giant demand in people’s daily life, including healthcare detecting, environment monitoring and so on. Among them, fully Soft robots are attracting huge attentions due to its great adaptability in various environments and enhanced safety, particularly when interacting with people. Therefore, it’s important to improve the comfort level of human-robot interaction rather than a rigid or statistic contacting, where diverse soft functional circuits are needed to be integrated on the 3D complex surfaces for environmental perception and to endow soft robotics with more features. However, present approaches for perception layer are almost based on planar techniques in a very limited area, or costly equipment to print 3D circuits but time-consuming, cannot satisfy the demanding from soft robots without seamless integration without hindering the great adaptability and dynamic 3D morphology. Hence, direct conformal print of perceptive circuits on arbitrary robots’ external surfaces is one of the most effective and convenient solution to achieve excellent environmental perception for soft robots. In this work, we present a method of fabricating intuitive perceiving layer integrated on soft robots with a conformal masked printing combined with UV-laser patterning and liquid alloy (Galinstan) circuits spraying. Specifically, an ultra-flexible and sticky elastomer is employed as a mask to be conformably attached on the target surfaces under a gentle pressure after laser patterning. Following with liquid alloy sprayed and mask peeled, the liquid alloy circuits are completely conformal printed on arbitrary surfaces of soft robots, including developable/non-developable surfaces, curvilinear surfaces with sharp edges and other 3D complex surfaces. Finally, through connecting with functional component units and sealing via dip-coating, we can obtain the fully soft robot with soft/conformal functional layer.

Upon this technique, we employ a soft robot hand integrated with functional layer, which consists of liquid alloy connections and component units, such as thermistors, to detect pressure, strain or near-field heat source. Further, combining with a feedback circuit and soft actuator, the soft robot hand could help monitor human healthcare signal when we touch/shake with it. In addition, it can be actively away from heat source because of temperature sensor module. That would be a great potential for endowing soft robotics with more functionalities.

Electrically Modulated Highly Switchable Adhesion of N-Doped Graphene Interfaces for Robust Micromanipulation
Yiyang Wan¹, Yong Gao² and Zhenhai Xia¹; ¹Univ of North Texas, United States; ²Northern Polytechnical University, China

Smart surfaces or interfaces, which can turn their adhesive force on and off spontaneously under natural or provoked stimuli, renders them appealing for many applications. We demonstrated a smart interface, N-doped graphene, with highly switchable adhesion and robust micromanipulation capability triggered by external electric signals. Upon applying a small DC or AC electrical bias, this nano-textured surface can collect environmental moisture to form a large number of water bridges between the graphene and target surface, which lead to a drastic change in adhesive force. Turning on and off the electrical bias can control this graphene interface as a robust micro/nanomanipulator to pick up and drop off various micro/nano-objects for precise assembling. Molecular dynamics simulation reveals that electrically induced electric double layer (EDL) and ordered ice-like structures at graphene-water interface strengthen the water bridges and consequently enhance force switchability. In addition to the micro-/nanomanipulation, this switchable adhesion may have many technical implications such as climbing robots, sensors, microfluidic devices, and advanced drug-delivery.

SB01.12.55
Biocompatible Nanocomposite Fibrous Membranes Fabricated by 2D-Controlled Close-Range Electrospinning
Siyu Xiong and Kwang-leong Choy; University College London, United Kingdom

Electrospun fibrous membranes have been investigated by many biomedical researchers due to their extraordinary biomimetic morphology and superior biocompatible performance, which promote the compatibility between the biomaterials and the host environments. Active materials have been adapted for the electrospun fibrous membranes for various applications, including catalysts, absorbents, cell supports, and drug carriers. In this presentation, silicon oxide (SiO2), titanium oxide (TiO2), chitosan (CS), and graphite were incorporated with polycaprolactone (PCL) to produce highly interactive fibrous membranes by a 2D-controlled close-range electrospinning method. The electrospun membranes were characterized using a combination of scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS) for the surface morphology and chemical composition analysis. The
2D-controlled close-range electrospinning warrants the production of fine fibers with well-controlled microstructure and diameter, and the active materials were well dispersed along the fibrous matrix to facilitate their applications. The relationships among process, structure, and property of the electrospun biocompatible nanocomposite fibrous membranes will be presented.

SB01.12.56
Fine-tuning of Rat Mesenchymal Stem Cell Senescence via Microtopography of Polymeric Substrates Xun Xu1, Weiwei Wang1, Yan Nie1,2, Karl Kratz1, Nan Ma1,3 and Andreas Lendlein1,2,3; 1Institute of Biomaterial Science and Berlin-Brandenburg Center for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; 2Institute of Chemistry, University of Potsdam, Germany; 3Institute of Chemistry and Biochemistry, Freie Universität Berlin, Germany

The therapeutic potential of mesenchymal stem cells (MSCs) has been demonstrated in regenerative therapies. However, their therapeutic efficacy could be attenuated when undergo cellular senescence caused by various environmental stressors. The senescent MSCs could remain viable but presented an irreversible growth arrest and deficient proliferation. Tissue regeneration would be impaired due to their influence on the function of neighboring cells via altered secretome profile [1, 2]. MSCs can be modulated by not only the biochemical signals but also the physical cues such as the substrate topography [3, 4]. However, little is known about the influence of the topographic cues on cellular senescence of MSCs. In this study, the influence of microscale roughness on MSC senescence was investigated on the poly(ether imide) (PEI) substrates as a model system. Three distinct levels of roughness were created in the bottom of PEI inserts via injection molding: smooth surface R0 (root mean squared roughness (Rq): 0.2 ± 0.1 µm); R1 (Rq: 3.9 ± 0.2 µm) and R2 (Rq: 22.7 ± 0.8 µm). The senescence and proliferation of rat MSCs on the substrates were examined using senescence-associated β-gal assay and a cell counting kit. The paracrine effect of MSCs on different substrates was studied using a transwell system. MSCs were cultured in PEI inserts, then the MSC-laden transwells were put into the insert. The proliferation of cells inside the transwells was assessed via CFSE staining followed by flow cytometry analysis. After 5 days of culture, MSCs in different inserts showed high cell viability and similar spindle-shaped morphology. The lowest senescence ratio was observed in MSCs cultured on R1 (35 ± 4% decreased compared to R0). Cells on R1 presented the highest proliferation rate (5.1 ± 0.2 fold increase of cell number), as compared to cells on R0 (4.3 ± 0.5) and R2 (3.9 ± 0.4). The MSCs cultured on different substrates could effectively influence the proliferation of cells inside the transwell via their paracrine effect. The R0 secretome inhibited cell proliferation compared to R1 secretome (1.8 ± 0.2 fold decrease after 20 days of culture). In summary, the PEI substrate with roughness R1 provided a more superior surface environment for MSC culture, which inhibited cellular senescence and promoted cell proliferation. Such a microscale surface roughness can be considered as a key parameter for surface design of stem cell culture device and implants to improve the quality and therapeutic potential of stem cells.

Syringe-Injectable and Self-Expandable Shape Memory Polymer Ultrathin Films Kento Yamagishi1, Akihiro Nojiri2, Eiji Iwase2 and Michinao Hashimoto1; 1Singapore University of Technology and Design, Singapore; 2Waseda University, Japan

We developed ultrathin films of polyurethane-based shape memory polymer (SMP) as a syringe-injectable and self-expandable platform for implantable medical devices. Free-standing polyurethane ultrathin films with the thickness less than 1 µm and the flexural rigidity less than 10^-2 nN m have been demonstrated as a promising material for a minimally-invasive platform for the delivery of molecular and cellular drugs. Despite their potential merits, however, conventional nanosheet technologies based on polymers such as poly(lactic acid) (PLA) and poly(lactic-co-glycolic acid) (PLGA) are yet limited by (1) the size of needle that injects nanosheet from syringe (maximum lateral size of 15 mm could be ejected from a 19G needle (inner diameter (I.D.) = 0.7 mm)), (2) the ability to expand after injection and (3) the ability to control the motion after injection. To address these limitations, we developed free-standing SMP nanosheets embedded with magnetic nanoparticles (MNP), termed MNP-SMP nanosheets. The
temperature-mediated shape memory effect (SME) of the SMP with the glass transition temperature ($T_g$) of 25°C provided following four capabilities to the 710-nm-thick MNP-SMP nanosheet; (1) syringe-injectability through the medical needles (a nanosheet with the lateral size of 15 mm could be ejected from a 20G needle (I.D. = 0.6 mm)), (2) self-expandability after injection to aqueous media, (3) conformability and removability on the biological surfaces, and (4) guidability in an external magnetic field. In addition, the MNP-SMP nanosheets were readily interfaced with an additional layer of PLGA to extend the functionality as a carrier of molecular and cellular drugs without compromising the demonstrated capabilities. The MNP-SMP nanosheets will contribute to the development of advanced syringe-injectable medical devices as a platform to deliver drugs, electronics, biological cells and engineered tissues to the specific site or lesion in the body for minimally invasive diagnosis, therapy and regenerative medicine.

**Cellulose/BaTiO$_3$ Nanocomposite Dielectric Films with High Energy Density**

Quanling Yang, Chenggang Zhang, Yanan Yin and Chuanxi Xiong; Wuhan University of Technology, China

Cellulose/BaTiO$_3$ nanocomposite films were fabricated by incorporation of BaTiO$_3$ nanoparticle (BTNP) or BaTiO$_3$ nanofiber (BTNF) in regenerated cellulose (RC) via simple blending in aqueous NaOH/urea solution. The results showed that a proper addition of BTNP or BTNF could improve the dielectric constant, breakdown strength, energy density of RC and reduce the dielectric loss simultaneously. Meanwhile, RC-BTNF composites exhibited better dielectric and mechanical properties than RC-BTNP. Especially, the RC-2BTNF composite film with 2 vol% BTNF exhibited an ultrahigh discharged energy density of 13.14 J/cm$^3$ at breakdown strength of 370 MV/m. Moreover, the discharged energy density of 9.45 J/cm$^3$ at 300 MV/m of RC-2BTNF is the highest discharged energy density of reported polymer-based dielectric films at 300 MV/m (close to actual electric field strength when film capacitors work). Therefore, these flexible cellulose-based dielectric materials are promising in the field of novel high-performance film dielectric capacitor.

**Temperature-Sensitive Hydrogels for the Local Delivery of Antibiotics**

Rong Yang$^1$, Michelle Calabrese$^2$, Bradley Olsen$^3$ and Daniel Kohane$^4$; $^1$Cornell University, United States; $^2$University of Minnesota, United States; $^3$Massachusetts Institute of Technology, United States; $^4$Harvard Medical School/Boston Children's Hospital, United States

Hydrogel with reverse thermal gelation has been an important tool in drug delivery. Some of them, such as poloxamer 407 (P407), have been approved by the FDA for various biomedical applications. Despite the clinical importance of P407, its assembly in the presence of therapeutics and other bioactive molecules was not well understood, deterring rational design and improvement of hydrogels and limiting their implementation in the clinical practice. We have bridged this gap by elucidating the effects of some molecules, which are commonly delivered using P407 (chemical permeation enhancers, antibiotics, and anesthetics), on the hydrogel gelation mechanism. We also charted a path forward to manipulating these interactions and thus rendering the gelation more robust in biomedical applications, achieved by chemical modifications to the polymer.

As a proof-of-principle, chemically modified P407 was used to treat otitis media (OM), the most common reason for antimicrobial prescription to US children. The current standard of care is a requisite 7-10 day course of oral antibiotics. The treatment is challenging to deliver in children, entails potential systemic toxicity, and encourages selection of antibiotic-resistant bacteria. Building upon the modified P407, we developed a drug delivery system which, when applied once to the tympanic membrane (TM) through the external auditory canal, delivers an entire course of antimicrobial therapy to the middle ear. The pentablock copolymer was designed to flow easily during application then form a hydrogel on the TM. Chemical permeation enhancers within the drug delivery system then assisted flux of the antibiotic ciprofloxacin across the TM. This drug delivery system successfully treated OM from non-typeable *Haemophilus influenzae* (NTHi) and *Streptococcus pneumoniae* in chinchillas. Biocompatibility was excellent, and ciprofloxacin was undetectable in blood, implying no systemic drug exposure in treated patients.

**Harnessing Kirigami Shells for Ultra-Thin Flipper-Like Soft Gripper**

Yi Yang, Katherine Vella, Peter Zink and Douglas Holmes; Boston University, United States
Harnessing soft materials and compliant structures to build robotic grippers has pushed the boundary in advancing robotic systems and materials science. Mimicking the morphology and grasping mechanisms found in biological systems has attracted tremendous attention in the design of soft grippers. Although hand morphology of primates inspired a variety of soft gripper designs, due to the complexity, bio-mimicking the thumb–index hand morphology is limited and challenging. In contrast to the hand morphology of primates, marine tetrapods, such as sea turtles, utilized their flipper-like articulating limbs to capture and manipulate prey. This simple posture for holding and pinching could be effectively achieved by utilizing the underactuated deformation of compliant structures, such as kirigami. In this talk, we present a novel design of an ultra-thin soft gripper that mimics the grasping posture of marine tetrapods using kirigami shells. Through a combination of mechanical modeling and experiments, we demonstrate the morphology and principle of grasping, and characterize the performance of the kirigami shell gripper by picking up a various objects with different shapes and examining the loading capacity. We find that the kirigami shell gripper can perform a variety of grasping tasks which cannot be easily accomplished by current soft gripper designs. The gripper is low-cost, scalable, ultra-thin, and ultra-lightweight with a payload to weight ratio of 270, and provides a novel approach to the design of soft robotic grippers.

3D Printing of Soft Responsive Structures Incorporating Stimuli-Responsive Microcapsules Seon Ju Yeo1, Sangchul Roh2 and Orlin D. Velev1; 1North Carolina State University, United States; 2Cornell University, United States

The design of inks for three-dimensional (3D) printing of actuatble structures is of importance since the principles of ink design have a great influence on the response and the general materials characteristics. Thus, creating new types of ink materials with a programmable response is an ongoing challenge. This study demonstrates a new class of stimuli-responsive inks for 3D printing containing microcapsules, which contain small droplets of an aqueous solution of water and glycerol in the core. Polydimethylsiloxane (PDMS) capsules are generated by using water-in-oil-in-water double emulsions as templates. PDMS microcapsules can swell in deionized (DI) water by the difference in osmotic pressure between the inner and the outer phases of the complex emulsions. The swelling ratio in DI water can be controlled by the ratio of water to glycerol in the inner phases, and it is closely related to the resulting mechanical properties of the composite materials. In addition, they exhibit shape memory behavior due to inhomogeneous swelling behavior of the composites. Subsequently, the generated PDMS microcapsules are connected to each other by capillary bridging with liquid PDMS precursor for use as 3D printing inks. The composition of the outer phases (i.e., with glycerol or without glycerol, the molecular weight and the concentration of the surfactants) is varied to understand the relationship between rheological properties and printing performance. Overall, by taking advantage of controlled swelling and shape memory behavior of composite inks containing osmotically sensitive capsules, complex architectures capable of actuating can be fabricated, which opens up new opportunities in soft robotics and stimuli-responsive materials.

SB01.12.62
Soft Artificial Tongue Detecting Astringency Jeonghee Yeom, Ayoung Choe and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

A tongue is a soft muscular organ which is one of the most sensitive and flexible human body parts transducing vital chemical information for the survival and health. One of the unique functions of the tongue is perceiving astringency, which is resulted from the strong association of the ingested astringent molecules and saliva proteins covering the tongue. Previously, artificial tongues are presented based on the lipid/polymer membranes, human taste receptors, and stripped epithelium cells. However, these works are hardly emulating human tongue due to the low selectivity for the target tastes, bulky and rigid structures. Here, we present a soft artificial tongue mimicking the mechanism of the human astringency perception based on the polyacrylamide hydrogel containing mucin (MUC) as secreted protein and lithium chloride as electrolyte. The thickness of soft hydrogel layer is comparable with that of actual saliva layer (70-100 μm) on the tongue, enabling efficient absorption and diffusion of astringent compounds (tannic acid, TA). Moreover, a flexible artificial tongue is fabricated by the polymerization of soft astringent hydrogel on the polyethylene-naphthalate (PEN) film, exhibiting stable sensing performances even after bending. Our resistive-type astringent sensor exhibits wider sensing range (10 g/L–0.001 g/L) and lower threshold sensing concentration (0.001 g/L) compared with the panel tests and other evaluating methods such as potentiometry, turbidity, and tribology. In addition, the astringent hydrogel shows better selectivity (ΔI/Io) for the TA compared with the same concentrations (5 mM) of other tastants and derivatives of TA. Finally, as a proof-of-concept
demonstration, we fabricate the artificial tongue sensor array which can be utilized as a portable taste sensing pad for the taste mapping and wipe-and-detection performance.

**Realization of Bio-Inspired 3D Structures by Deformation of Soft Structures** Jaekyoung Kim, Hyemin Lee and Hyunsik Yoon; Seoul National University of S&T, Korea (the Republic of)

In decades, there have been many efforts to study the superb functions of unique structures in Nature. Researchers have tried to fabricate the artificial structures inspired from moth eyes, lotus leaves, gecko’s feet, wings of Morpho-butterfly and developed nano-, micro- and hierarchical structures. However, most of the features in Nature have 3D structures and they show more sophisticated functionality such as high adhesion in a wet condition of octopus and robust oleophobic surfaces inspired from springtails. In this talk, I explained a simple method to realize 3D structures by using the structures deformed by the mismatch of volume expansion of two different materials. Furthermore, I demonstrate the functions of oleophobicity, adhesion in dry and wet conditions, etc.

**SB01.12.64**  
**Inkjet Printing of Latex Based High-Energy Microcapacitors** Fernando Torres-Canas, Jinkai Yuan, Isabelle Ly, Wilfrid Neri, Annie Colin and Philippe Poulin; Ctrde Recherch Paul Pascal, France

Micro-energy storage devices are appealing, and highly demanded for diverse miniaturized electronic devices, ranging from microelectromechanical system, robotics, to sensing microsystems and wearable electronics.[1,2] However, making high-energy microcapacitors with currently available printing technologies remains challenging. Herein, we show the possibility to use latex polyvinylidene fluoride (PVDF) as aqueous ink for making dielectric capacitors on the microscale. The dielectric properties of printed microcapacitors can be optimized based on a novel approach, i.e., mixing PVDF latex with polyvinyl alcohol (PVA) to realize dielectric organic nanocomposites. The PVA prevents the coalescence of PVDF nanoparticles and serves as a continuous matrix phase with high dielectric breakdown strength. While the well-dispersed PVDF nanoparticles serve as highly polarizable and isolated domains, providing large electric displacement under high fields. Consequently, a high discharged energy density of 12 Jcm⁻³ is achieved at 550 MVm⁻¹. [3] These printed microcapacitors demonstrate mechanical robustness and dielectric stability over time.

**SB01.12.65**  
**Formulation of Lightweight Cement-Based Materials for 3D-Printing in Warmer Climates** Lyn Zemberekci¹, Wael Ali Saeed Aldulaimi², Can Akaoglu¹, Hay Rotana³, Kemal Celik² and Ozge Akbulut¹; ¹Sabanci University, Turkey; ²NYU Abu Dhabi, United Arab Emirates

Recent developments have allowed for the layer-by-layer deposition or 3D-printing of cement-based materials, which promise i) a decrease in the total duration of a construction process and labor costs, ii) a customizable design, and iii) elimination of the use of formwork. Here we report a lightweight cement composite that contains cenosphere, white cement, and white silica fume to be used in 3D printing. We designed a poly(carboxylate ether)-based additive to enable the rheological control such that the mixture is i) 3D-printable—extrudable through a nozzle and can be layered successfully, ii) lightweight—resulting in a decrease in the total dead weight of the structure, iii) high-strength, and iv) thermally insulating, which is useful for warmer climates. This mixture, which contains a significant amount of recycled materials, was optimized with respect to its rheological and mechanical properties and we have reached high compressive strength up to 80 MPa and an 11.5 % reduction in dry hardened density. According to ACI, this formulation is classified as high performance (>55 MPa) and lightweight (320 – 1920 kg/m³).

**SB01.12.66**  
**Multifunctional Semi-Liquid Surfaces with Durable Liquid Repellency** Lei Zhang, Xianming Dai, Zongqi Guo and Jyotirmoy Sarma; The University of Texas at Dallas, United States

Liquid repellent surfaces have attracted broad interests in both fundamental studies and engineering applications.
The current state-of-the-art liquid repellent surfaces are centered on either superhydrophobic/superoleophobic surfaces (rely on air lubricant) or liquid infused surfaces (rely on liquid lubricant). However, these surfaces suffer from severe durability issues: air/liquid lubricant loss or topography damage. Here, we present a semi-liquid surface(s) (SLS) that shows ultralow contact angle hysteresis ($\leq 1.0^\circ$) to liquids with surface tensions in the range of 10-72.8 mN m$^{-1}$ including perfluorinated liquids like FC72 and Krytox101, as well as complex fluids like urine and crude oil. Such a surface is made by tethering a flexible polymer on a solid substrate with a one-step self-catalyzed grafting method. The mobile molecular chains of the flexible polymer behave as liquid-like lubrication on a solid substrate. The liquid repellency can be maintained after heating at 105 $^\circ$C for more than three months, as well as 1000 cycles of abrasion and adhesion tests. The SLS can be fabricated on various substrates, such as silicon, glass, and metals. We have demonstrated that the SLS, owing to its tethered mobile molecular chains, outperforms superhydrophobic surfaces and liquid infused surfaces in fog harvesting and self-cleaning under durable operations. Such a semi-liquid surface may open up new opportunities for scientific studies and engineering applications related to polymer, surface chemistry, wetting, adhesion, fluid dynamics, anti-biofouling, anti-icing and heat transfer owing to the exceptional liquid repellency and durability. It is anticipated that such a surface can be developed to meet emerging needs in energy efficiency, water harvesting, bio-adhesion, advanced heat exchangers, drag reduction, and other areas that are beyond the reach of existing liquid repellent surfaces. Therefore, it will be of great interest to interdisciplinary areas.

Reconfigurable Architectured Materials through Hybrid Design and Manufacturing

Pu Zhang, Fanghang Deng and Quang Nguyen; SUNY Binghamton, United States

Reconfigurable architectured materials exhibit tunable shapes and functionalities that are of great interest to modern engineering like aerospace, robotics, wave control, sensing, etc. Most of the reconfigurable architectured materials are composed of only single phases of materials with their shapes manipulated by external mechanical, thermal, pneumatic, electrical, and magnetic stimuli. In this presentation, we report a new type of reconfigurable architectured materials composed of two materials organized in a co-axial way. This hybrid design enables the architectured materials with thermal-tunable shapes and properties. The developed architectured materials are fabricated by combining 3D printing, molding, and coating. The mechanical properties and reconfigurability of these architectured materials are studied via experimental testing. We expect that this new type of dual-phase architectured materials will greatly expand the current realm of architectured materials and bring about novel functional applications.

Artificial Synaptic Behavior of Aloe Polysaccharides-Based Device with Au as Top Electrode

Zhe Xi Lim1, I. A. Tayeb1, Zuratul Ain Abdul Hamid1, M. F. Ain1, A. M. Hashim1, J. M. Abdullah1, Feng Zhao4 and K. Y. Cheong1; 1Universiti Sains Malaysia, Malaysia; 2Universiti Teknologi Malaysia, Malaysia; 3Universiti Sains Malaysia Health Campus, Malaysia; 4Washington State University, United States

Formulated, processed, and dried Aloe polysaccharides thin film sandwiched between ITO as bottom electrode and Au as top electrode has been adopted as an artificial synapse to emulate behavior of neuromorphic computing. The synaptic plasticity or weight has been modulated with this simple metal-insulator-metal structure by applying voltage sweep and voltage pulse, with excitatory postsynaptic current being monitored. Synaptic potentiation and depression has been demonstrated by applying 6 consecutive sweeps of voltage in positive and negative polarity, respectively. By varying number (10 – 50) of voltage pulses, variable synaptic weight has been measured with paired pulse facilitation and post-tetanic potentiation indexes of 4.38x10$^{-9}$ and 1.30x10$^{-6}$, respectively. The short-term plasticity and long-term potentiation can be clearly revealed when applying 40 pulses and beyond, with extracted time constants of approximately 28 s at 40 pulses and 90 s at 50 pulses.

Effective Reduction of Building Heat Loss without Insulation Materials via the Photothermal Effect of a Chlorophyll Thin-Film Coated “Green Window”

Yuan Zhao1,2, Andrew W. Dunn1,3, Jou Lin1, Enhe Zhang2, Julian Wang2 and Donglu Shi1; 1University of Cincinnati, United States; 2The Pennsylvania State University, United States; 3Cincinnati Children's Hospital Medical Center, United States

One of the critical components of energy savings in buildings is thermal insulation, especially for windows in cold
climates. The conventional approach mainly relies on a double-pane design. In this study, a new concept of “Green Window” has been designed for single-pane applications that lower the U-factor. The “Green Window” is structurally and simply composed of a thin film window coating of chlorophyll that exhibits pronounced photothermal effect, while remaining highly transparent. We demonstrate a new concept in “thermal insulation” via optical means instead of solely through thermal insulators or spectral selectivity. This concept lifts the dependence on insulating materials making single-pane window highly possible.

SB01.12.70
Photo-Regulated Motion for Solar Harvesting and Autonomous Locomotion Xiaoshi Qian, Yusen Zhao, Yousif Alsaid and Ximin He; 1University of California, Los Angeles, United States; 2California Nanosystems Institute, United States

Stimuli-responsive materials are a class of materials that can be implemented for robotics using power supplies. Particularly, photo energy has widely been used for generating motion due to the versatility, ubiquity and properties (wavelength, intensity, polarization) for optimization of precise spatial and temporal control. While many smart materials exhibit nastic behaviors in response to light, no synthetic material can intrinsically detect and accurately track the direction of stimuli, i.e., exhibit phototropic behaviors. Other than the phototropic in dynamic equilibrium state, self-sustained oscillation under constant stimuli have recently been reported in liquid crystalline networks system. However, no work can realize the self-sustained oscillation to generate locomotion due to its low operation force under damping environment. We, however, report an artificial phototropic actuator and a self-sustained oscillator by using the same light-sensitive hydrogel system. On one hand, the phototropic behavior of hydrogels can instantaneously aim to incident light in three-dimensional space over broad ambient temperatures. The array of phototropic pillars can successfully harvest solar energy for omnidirectional solar vapor generation, achieving high energy harvesting enhancement over non-tropistic materials by maintaining normal to oblique illuminations. On the other hand, the photo-triggered oscillation showcases large force and long-lasting properties. The photo-regulated soft-swimmer is further made by using the oscillation to self-propel away from light source, showing high-speed and controllable locomotion.

SB01.12.71
Oxidative Chemical Polymerization of Functionalized PEDOT:PSS Erjin Zheng, Priyesh Jain, Hao Dong, Zhiyin Niu, Emerson Chen and Qiuming Yu; University of Washington, United States

Poly(3, 4-ethylenedioxythiophene) (PEDOT) is one of the most successful conductive polymers. The commercial available PEDOT is synthesized by chemically polymerizing 3,4-ethylenedioxythiophene (EDOT) monomer in the presence of polyelectrolyte poly(styrene sulfonate) (PSS), giving the water-soluble PEDOT:PSS. Many applications of PEDOT:PSS have been developed such as solar cells, photodetectors, light emitting diodes, smart windows, biosensors, fuel cells, and wearable electronics. The conventional PEDOT:PSS, however, is lack of functionality. The functionality of PEDOT:PSS can be introduced by replacing the counterion PSS or adding a functional group onto the ethylenedioxy ring in the PEDOT backbone. In order to develop functionalized PEDOT:PSS using oxidative chemical polymerization method, it is crucial to understand the interaction between functionalized EDOT monomer, counterion, oxidant, and catalyst during the reaction.

In this work, we selected three monomers, EDOT, EDOT-methylhydroxyl (-MeOH) and EDOT–methylchloride (-MeCl), and polymerized them using oxidative chemical polymerization. We investigated the interaction between EDOT monomer, -MeOH and -MeCl functionalized EDOT monomer with PSS counterion and Fe^{3+} catalyst during the reaction. For EDOT, monomers and PSS formed micelles with monomers inside PSS shells when dispersed in water. The deprotonated, negatively charged PSS, due to adding an equal molar amount of KOH, attracted Fe^{3+} ions to the micelles, which preferentially polymerized EDOT monomers inside micelles. PEDOT polymers were mostly doped by PSS counterions, resulting in an aqueous soluble product. Adding less or no KOH led to partially negatively charged PSS and thus less attraction to Fe^{3+} ions to micelles. As a result, Fe^{3+} ions polymerized EDOT monomer both inside the micelles and in the water phase, where PEDOT polymers were doped by PSS and SO_{4}^{2-}, respectively. Final products were partially soluble in water. We characterized the thin film morphology, chemical structure, and conductivity of the PEDOT:PSS synthesized with different amount of KOH using AFM, Raman spectroscopy, and four-point probe measurement, respectively. The thin films of PEDOT:PSS synthesized with equal molar KOH to PSSH exhibited smooth morphology, quinoid structure dominated PEDOT backbones with linear-like conformation, and low conductivity of 9.06 × 10^{-4} S/cm. The thin films of PEDOT:PSS synthesized with less or no KOH exhibited rough morphology with large aggregates, benzoid structure dominated PEDOT backbones
with coil-like conformation, and gradually increased conductivity to the highest value of $1.76 \times 10^{-1}$ S/cm with no KOH added.

For functionalized EDOT monomers, the -MeOH group formed hydrogen bonding with PSS, which makes EDOT-MeOH monomers stay inside micelles or closer to PSS. However, EDOT-MeCl monomers tended to be away from PSS due to the electrostatic repulsion. Because of the high electronegativity of both types of the functional groups, the oxidative polymerization occurred with a triple amount of oxidant and catalyst, and no KOH added. PEDOT-MeOH polymers were mainly doped by PSS, yielding a water-soluble PEDOT-MeOH:PSS. However, PEDOT–MeCl were doped by PSS and $\text{SO}_4^{2-}$, resulting in a mixture of water-soluble PEDOT-MeCl:PSS and insoluble PEDOT-MeCl:SO$_4$ precipitates. PEDOT-MeOH:PSS thin films exhibited smooth morphology, quinoid structure dominated PEDOT-MeOH backbones with a linear-like conformation, and a conductivity of $1.17 \times 10^{-3}$ S/cm. PEDOT-MeCl:PSS thin films showed large aggregates on surfaces, benzoid structure dominated PEDOT-MeCl backbones with a coil-like conformation, and a conductivity of $4.71 \times 10^{-4}$ S/cm.

This study provides insights into the polymerization of EDOT with functional groups using the oxidative polymerization method and can be widely applied in designing the oxidative chemical polymerization reaction for synthesizing PEDOT:PSS based conducting polymers.

SB01.12.72
**Designing Hydrogel-Based Solar Evaporators for Seawater Desalination and Water Purification** Xingyi Zhou and Guihua Yu; The University of Texas at Austin, United States

Hydrogel materials with unusual physical/chemical properties are becoming critically important in a wide range of applications from electronics, biomedical devices, renewable energy to environmental technologies. To enable significantly improved or even unprecedented properties, the chemical composition, micro/nanostructures and physical interactions of hydrogel materials need to be delicately controlled. Here we will present our representative works on rational design and molecular engineering of hydrogels and their applications in solar powered water purification. We designed hybrid hydrogels composed of a hydrophilic polymer framework and solar absorption materials to harvest solar energy and remove contaminants. By tuning the micro/nanostructures and chemical/physical interactions between components, the hybrid gels exhibit attractive synergistic characteristics including high solar absorption, reduced energy demand for water evaporation, fast water transport, effective thermal management and antifouling property. I will also discuss our latest work on architecting the highly hydratable polymer networks to tune the water state, activating water molecules and facilitating water evaporation. These works provide fundamental design principles regarding material selection, molecular engineering and structural modification of these emerging hydrogels for the development of next-generation solar evaporators for seawater desalination and water purification.

SB01.12.73
**Development of a Facial Thermal-Releasing Drug Delivery Gold Nanoparticles under Ambient Conditions** Jun Zhu and R. B. Lennox; McGill University, Canada

The emergency of nanotechnology has a profound impact on clinical therapeutics recently. One promising candidate is using gold nanoparticles, which has unique optical property, low toxicity, and in vivo stability. Previous researches are focused on using gold nanoparticles as a drug carrier. In this talk, a thermal labile drug delivery linker is developed, using an endo/exo adducts from furanic and maleimide derivatives, and incorporated onto a model gold nanoparticle surface for drug delivery/releasing. Model drug loads can be effectively released at physiological temperature when endo- linker is applied via a retro-Diels-Alder reaction (rDA). In addition, second-stage controllable temperature dependent drug release can be achieved at elevated temperatures through the rDA of exo-linker. This drug delivery strategy has promising applications for the development of novel drug-delivery and thermal triggered drug releasing. This methodology can be easily extended to other nanomaterials.

SB01.12.74
**Biomimetic Nanoemulsions as a Blood Substitute for Oxygen Delivery In Vivo** Jia Zhuang, Ronnie Fang and Liangfang Zhang; University of California, San Diego, United States

Blood transfusion is oftentimes required for patients suffering from acute trauma or undergoing surgical procedures in order to help maintain the body's oxygen levels. The continued demand worldwide for blood products is expected to put significant strain on available resources and infrastructure. Unfortunately, efforts to develop viable
alternatives to human red blood cells for transfusion have generally been unsuccessful. Herein, a hybrid natural–synthetic nanoemulsion platform is developed which combines the biocompatibility of natural red blood cell membrane with the oxygen carrying ability of synthetic perfluorocarbon. By coating perfluorocarbon emulsion with red blood cell membrane through a facile process, the resulting biomimetic nanoemulsion could serve as a more stable and easy way to store and mimic red blood cells for transfusions. Specifically, the nanoemulsion can be stored for over three months at room temperature and exhibits a high capacity for oxygen delivery, helping to mitigate the effects of hypoxia. In an animal model of hemorrhagic shock, mice are resuscitated at an efficacy comparable to whole blood infusion. Furthermore, uncompromised biosafety profiles with pronounced biocompatibility and minimal immunogenicity are demonstrated owing to the incorporation of red blood cell membrane. By leveraging the advantageous properties of its constituent parts, this biomimetic oxygen delivery system may have the potential to address critical needs in the clinic, especially in places that lack ideal storage conditions, such as remote villages and the battlefield. In general, this biomimetic oxygen delivery system could be a robust candidate for next-generation blood substitute, as well as a versatile platform for a variety of biomedical applications such as ultrasound imaging and photodynamic therapy upon further functionalizations.

SB01.12.76

Molecularly Engineering One-Dimensional Assemblies of Optoelectronic Peptide Nanostructures Herdeline Ardona1, Tejaswini Kale2, Zhe Qi3, Christopher Stanley4, Christopher Jaroniec3 and John D. Tovar2; 1Harvard University, United States; 2Johns Hopkins University, United States; 3The Ohio State University, United States; 4Oak Ridge National Laboratory, United States

The applications of functional supramolecular assemblies continue to expand into a broad range of fields, such as from electronics to tissue engineering. The proper molecular design of monomers for such assemblies can enable the rational engineering of their macroscale material properties. Here, studies on systematically controlling the coassembly behavior and corresponding functional heterostructures formed by pi-conjugated peptidic monomers under completely aqueous conditions will be presented. The influence of (i) local fields due to the flanking peptide moieties, (ii) torsional constraints within the central pi-system core, and (iii) lengths of peptide monomers on assembly behavior were studied using photophysical investigations, solid state NMR (ssNMR) and small-angle neutron scattering (SANS). Our results show that within the coassembly volume of peptide-pi-peptide and peptide-alkyl-peptide triblock monomers, a hydrophilic tripeptide sequence (Asp-Asp-Asp, DDD-) sequence promoted isolation/dilution of minority pi-electron components in the matrix of aliphatic peptides, while a beta-sheet promoting sequence (Asp-Val-Val, DVV-) led to blocks of the two components distributed within larger 1D-nanostructures. To demonstrate that torsional constraints within stacked pi-units may affect the overall nanostructure formation, we used quaterthiophene units with inherently different geometries: relatively planar 2,2':5',2''-quaterthiophene (OT4) and twisted 3',4'-dimethyl-2,2':5',2''',5''',2'''-quaterthiophene (OT4dM). The peptides bearing dimethylated quaterthiophene units showed spectral signatures which suggest minimal interchromophore exciton coupling due to perturbed pi-stacking. Finally, ssNMR and SANS characterization of the polymorphic coassemblies suggest that peptide length matching between the monomer components of peptide heterostructures can affect the degree of co-mixing or self-segregation within the nanostructures formed. These insights on structure-property relationships and assembly principles for optoelectronically-active peptide nanomaterials contribute towards developing more innovative strategies for molecularly designing functional regenerative scaffolds for electrically-active cells, such as neurons and cardiomyocytes.

SB01.12.77

Multiple Tridimensional Janus Peptide Dendrimers with Manipulable and Dramatic Multivalency Uimin Hwang, Sung-ju Choi, Soo Hyun Kwon and Yong-beom Lim; Yonsei University, Korea (the Republic of)

The self-assembly of peptides facilitates the construction of self-assembled peptide nanostructures (SPNs) with chemical composition analogous to those of natural proteins; nonetheless, the structural complexity and functional characteristics of SPNs are far different than those of natural proteins. One of the most fundamental challenges in fabricating more exquisite SPNs lies in developing building blocks that are simultaneously more complex and comparatively easy to synthesize. In this poster, the development of self-assembling Janus peptide dendrimers is reported, which have fully tridimensional structures akin to those of globular proteins. For the trustworthy and convenient synthesis of JPDs building blocks, a solid-phase bifurcation synthesis system is devised. The self-assembly behavior of Janus peptide dendrimers is unique because only the generation of dendrimer and not the weight fraction determines the morphology of SPNs. The co-assembly of two JPD building blocks presents an
opportunity not only to enlarge the morphological repertory in a foreseeable manner but also to discover SPNs with uncommon and interesting morphologies. Because JPD assemblies have dual multivalent property, i.e., supramolecular and unimolecular multivalency, the JPD system facilitates the statistical selection of materials with great avidity for the possibly any target receptors and desired cell types.

SB01.12.78
Preparation of Bioactive Glass-Calcium Phosphate Composites and Evaluation of Their Biodegradation in SBF Zivile Stankevičiute, Gabija Zarembaite, Laurynas Alinauskas, Lauryna Sinusaite, Aleksej Zarkov, Edita Garskaite and Aivaras Kareiva; Vilnius University, Lithuania

Biomaterials for bone repair receive considerable attention worldwide and the global bone grafts and substitutes market is projected to grow over forthcoming years. Bioactive glasses (BGs) are group of biomaterials which show relatively fast dissolution after the implantation. BGs are generally based on various oxides containing calcium, sodium, phosphorous, and silicon. Calcium hydroxyapatite (Ca10(PO4)6(OH)2, HAP) – a biomaterial of calcium phosphates (CaPs) group – is similar to the main inorganic constituent of bone and teeth tissue. Synthetic HAP is applied in constructing artificial bone grafts for long-term usage and drug delivery systems. Contrary to the BGs, the crystalline HAP has the slowest degradation rate compare to the other CaPs.

The fundamental properties of bone grafts are osteogenesis, osteoinduction, osteoconduction, and structural support. Therefore, in this work the synergy between BGs and CaPs as a potential materials for bone scaffold engineering was studied. Herein, BG composed of Na4Ca4(Si6O18) and NaCaPO4 phases was synthesized by a sol-gel method at 700 °C. This semi-crystalline BG was then homogeneously mixed with HAP and pressed mechanically to cylindrical-shaped specimens. Bioactivity of prepared BG-HAP composites (wt% relations of BG:HAP were 100:0, 75:25, 50:50, 25:75 and 0:100) was studied in vitro for 1, 3 and 7 days at 37 °C in a simulated body fluid (SBF). The amount of elements after the dissolution was determined using ICP-EOS technique. Morphological features and elemental distribution of a newly-formed ceramic layer on the BG-HAP composites were evaluated using SEM-EDS. XRD and FTIR spectroscopy analyses revealed the rapid phase transformation of bioactive glass to the amorphous carbonated calcium phosphate upon exposure to a SBF solution. It was also shown that substance dissolution rate and topography of newly-formed ceramic layer depends on the wt% of the bioactive glass. Results indicated that BG-CaP composites produced via biomimetic processing route have potential for the exploration of broader range material properties in the field of regenerative medicine. In order to resemble bone implants as closely as possible the biomimetic bone apatite the coatings of these BG-CaP composites would be very promising for application to bone implants.

This project has received funding from the Research Council of Lithuania (LMTLT), agreement No 09.3.3-LMT-K-712 "Development of Competences of Scientists, other Researchers and Students through Practical Research Activities".

SB01.12.79
Preparation of Antibacterial Hybrid Hydrogels of Polysaccharides (Sacran/CNF) Gargi Joshi, Qiang Han, Maiko K. Okajima and Tatsuo Kaneko; Japan Advanced Institute of Science and Technology, Japan

Hydrogel-type wound-dressing materials require strength and water absorbability appropriate for applying to the injury. However, control of the water absorbability, water retention degree, and mechanical strength of the materials are very important for this application. In this respect, our group is studying cyanobacterial exopolysaccharide, sacran. It has an ultrahigh molecular weight over 10 MDa, high water-retention capability, and anti-inflammatory properties. We have adjusted properties by hybridizing sacran with cellulose nanofibers (CNF) with varying the ratio of sacran:CNF solution. The solvent-casted hybrid films were macroscopically homogeneous and easy to handle. The Young’s modulus of the hybrid film increased with increasing the content of CNF. By thermally annealing by films, physically-crosslinked gel matrices were prepared which showed high swelling ratios. To impart these films with antibacterial properties, aminated silver nanoparticles were synthesized and incorporated in the hybrid solution before solvent casting. The prepared nanocomposite dressing showed high antibacterial activity against both gram-negative and -positive bacteria.

SB01.12.80
Voxelated Molecular Patterning in Three-Dimensional Freeforms Mohsen Tabrizi1, Taylor Ware2 and M. Ravi Shankar3; 1University of Pittsburgh, United States; 2The University of Texas at Dallas, United States
In recent years, there has been an increasing interest in smart structures that can be manipulated by utilizing ambient stimuli. Liquid crystalline polymer (LCP) is, in particular, an interesting candidate for making these structures due to the ability to reversibly generate large work densities through changing the molecular order. The ability to pattern the molecular director enables us to program the shape morphing behavior of LCP structures. In this study, we exploited the combination of anisotropic magnetic susceptibility of the LC monomers and spatially-selective photopolymerization approach by utilizing a digital micromirror device (DMD) in an inverted (bottom-up) 3D printing configuration to fabricate LCP structures at scales ranging from the micro to the macro-scale. This gives us a level of flexibility to vary the orientation of the nematic director in all three dimensions (within and between layers), which is not possible with other methods. We developed and optimized different compositions that can be used for printing light and/or heat responsive structures. This platform enables us to modulate the composition and integrate responses to multiple stimuli. We demonstrated this by building a multi-responsive robotic arm that can deform in two different directions independently, in response to light and heat. The proposed fabrication method breaks out the confines of prior approaches and extends the applications of liquid crystalline polymers in the field of soft robotics, biomedical devices, and optomechanical systems.

**SB01.12.81**

**High-Resolution Electrical Probes with Single Nanoparticle Pick-Up Resolution** Eugene Soh, Benjamin Porter, Judy Kim and Harish Bhaskaran; University of Oxford, United Kingdom

Single particle manipulation opens up the possibility to create new device structures and experimentally test new physics that are currently only possible through computer simulations [1]–[3]. Currently, atoms have been precisely manipulated in a scanning tunnelling microscope at low temperatures and high vacuum [4]. Microparticles are usually manipulated with optical tweezers [5] and microgrippers [6]. However, it becomes increasingly difficult and complicated to manipulate particles in the nanoscale regime, especially in ambient conditions. Most methods use a combination of pushing and pulling of particles on a surface with an atomic force microscope (AFM) [7]. For three dimensional pick up, electric fields have been used [8]. However, clusters of particles are picked up irrespective of probe size or voltage used due to stray fields which extend beyond the probe’s tip.

In this work, we manufacture high resolution AFM probes in-situ through nanoscale phase switching of configurable thin films coated probes. These configurable coatings are germanium-antimony-tellurium (GST) and amorphous-carbon; materials known to undergo electric field-induced non-volatile switching. By forming localized conductive filament(s) through phase transition, we are able to confine the electric field to a nanoscale region at the probe apex. And by using dielectrophoresis, we demonstrate the picking up of nanoparticles with single particle resolution. This results are a promising start to developing a truly three dimensional pick and place technique at the nanoscale in ambient conditions.

**SB01.12.82**
Ultraviolet-C Persistent Luminescence in Pr\textsuperscript{3+}-Activated Silicates

Xianli Wang\textsuperscript{1}, Yafei Chen\textsuperscript{1}, Feng Liu\textsuperscript{2} and Zhengwei Pan\textsuperscript{1}; \textsuperscript{1}University of Georgia, United States; \textsuperscript{2}Northeast Normal University, China

Visible-light and infrared-light persistent phosphors have been extensively investigated and are being widely used as self-sustained glow-in-the-dark tags in darkness. However, persistent tags working in bright environments (daylight and artificial light) are not available. Here we report a persistent phosphor, Pr\textsuperscript{3+}-activated strontium yttrium cyclosilicate, that emits broadband persistent luminescence at solar-blind ultraviolet-C (UVC: 200–280 nm) spectral region. The UVC persistent phosphor can be effectively charged by a standard 254 nm lamp and emits intense, long-lasting afterglow (>12 h) at ~270 nm. The UVC persistent luminescence is easily distinguishable from the ambient light (daylight and artificial light) via a corona camera and can be used as self-sustained glowing tags in bright environments. This is the first use of persistent phosphors in bright environments.

Surface Morphing of Geometrically Patterned Active Skins

Yujin Park and Kenneth J. Loh; University of California, San Diego, United States

The design of high-performance surfaces and structures has been inspired by many nature’s creations, such as shark skins with minimal drag coefficients, self-cleaning hydrophobic lotus leaves, and dry adhesives on a gecko’s feet. In addition, recent advancements in additive manufacturing have opened new opportunities for fabricating unprecedented, multi-scale, architected materials with unique properties. However, most of these architected materials only focus on enhancing a specific material property or functionality. This limitation highlights the difficulty of controlling the individual architected units, as well as the surface topology of architected materials. This study introduces a new class of instability-induced morphable structures, which is within the scope of mechanical metamaterials that exhibit unique functionalities by harvesting their extrinsic instabilities. Herein it is referred to as Active Skins, which enables on-demand, reversible, surface morphing through buckling-induced out-of-plane feature deployment activated by in-plane loading. By taking advantage of a preconceived auxetic unit cell geometrical design, mechanical instabilities were introduced to induce out-of-plane deformations when in-plane strains are applied. Here, geometrical imperfection, or notches, were introduced at judiciously chosen locations in an array of 3D-printed and connected unit cells for eliciting unique patterns of out-of-plane deformations and for controlling bulk Active Skin behavior. These purposefully designed imperfections were employed for facilitating full out-of-plane shape morphing with lower applied tension as compared to unnotched Active Skins, as well as selectively actuating them for applications ranging from camouflage to surface morphing to soft robotic grippers.

Oxytocin-Derived Metal Ion Biosensors

Evgeniy Mervinetsky\textsuperscript{1}, Isael Alshanski\textsuperscript{1}, Arezoo Dianat\textsuperscript{2}, Jörg Buchwald\textsuperscript{2}, Rafael Gutierrez\textsuperscript{2}, Gianuarello Cuniberti\textsuperscript{1,2}, Dominique Vuillaume\textsuperscript{4}, Mattan Hurevich\textsuperscript{1} and Shlomo Yitzchaik\textsuperscript{1}; \textsuperscript{1}The Hebrew University of Jerusalem, Israel; \textsuperscript{2}TU Dresden, Germany; \textsuperscript{3}Dresden Center for Computational Materials Science, Germany; \textsuperscript{4}Institute for Electronics Microelectronics and Nanotechnology, CNRS, France

Peptides are commonly used as recognition elements for biosensing. These peptides are usually attached to surfaces as label-free recognition ligands by multistep processes. The outcome of these tedious processes is a modified peptide that, in many cases, doesn’t preserve many of its features. Using functional groups in native peptides for their assembly on surfaces without affecting their biological activity can facilitate the preparation of biosensors. Herein we present several strategies to modify gold surfaces with peptide layers. Exposure of modified surfaces to metal ions induces conformational changes in the peptide layer and thus can affect the electronic and electrochemical properties of the device. We used this phenomenon for biosensor design. Our approach utilizes the neuropeptide Oxytocin which is a known native metal ion chelator. While one functional group is used to anchor the peptide to Au surface, the peptide still preserves the ion-binding properties. The chelation event was monitored using various electrochemical methods and surface chemistry analysis and supported by theoretical simulations.

Liquid Layer Generator with Excellent Dynamic Icophobicity at Extremely Low Temperature

Feng Wang, Zhiliang Zhang and Jianying He; Norwegian University of Science and Technology, Norway

Ice formation and accretion on road, aircrafts, electrical transmission cables, wind turbines et al can cause huge
problems. A large amount of human source and energy are required to clear ice away. Therefore, designing and deploying material surfaces that can remove ice easily is in great demand. State-of-the-art icephobic surfaces fail at low temperature reaching a threshold of around -50 °C, which can lead to multiple orders of magnitude increase in ice adhesion strength. Strategy for such low temperature is missing, which is critical for the ever increasingly important Arctic area. In this work, with the combination of theoretical and experimental studies, a new strategy, termed liquid layer generator (LLG), were designed and fabricated targeting low ice adhesion strength at unprecedentedly low temperature. The molecular dynamic simulation firstly predicted the great potential of using ethanol as lubricating layer in lowering ice adhesion under extremely low temperature. The carefully designed LLGs were able to constantly release interfacial ethanol that convert ice contact from firm solid-solid to weak solid-liquid-solid mode for more than 250 days, and demonstrated super low ice adhesion strength of ~1 kPa. The liquid layer generator can also overcome the challenges of rough surfaces and surface hydrophilicity, and survive at temperature of down to -60°C, showing great potentials for practical applications.1,2

Non-Equilibrium Morphologies in Stimuli-Responsive Gels Subjected to Topographical Confinement Cathy T. Zhang1, Ya Liu2, Cindy Wang3, Xiaoguang Wang4, Stefan Kolle1, Anna C. Balazs2 and Joanna Aizenberg1; 1Harvard, United States; 2University of Pittsburgh, United States; 3Opalux, Canada; 4Ohio State University, United States

Stimuli-responsive "smart" polymers have generated significant interest for introducing temporal control into the properties of antifouling coatings, smart membranes, drug capsules, switchable adhesives and cell manipulation substrates. Switchable surface morphologies formed by confining stimuli-responsive gels to topographically structured substrates have shown potential for a variety of interfacial applications. However, to date, most studies have focused on exploring the equilibrium morphologies that can be obtained from such materials. We conduct a detailed investigation into the non-equilibrium morphologies that emerge from a composite surface consisting of a temperature-responsive gel cured to a bumpy substrate as it is heated along different heating paths. Through harnessing non-equilibrium behavior in this hybrid, temperature-responsive surface, we can control the assembly kinetics of colloidal particles and microalgae. Confining stimuli-responsive gels to topographically-structured surfaces not only enables temperature-programmable control over the local curvature of the surface, but could also introduce temperature path-dependent dynamics into actutable antifouling, cell manipulation, and liquid manipulation surfaces.

SB01.12.87
Liquid Crystal-Based Composite Materials for Neuromorphic Applications Ik-Jyae Kim, Min-Kyu Kim, Youngjun Park and Jang-Sik Lee; Pohang University of Science and Technology, Korea (the Republic of)

Recently, neuromorphic electronics has attracted much attention as a candidate to overcome the von Neumann bottleneck, due to its energy-efficient and smart data processing ability achieved by the massive parallelism and fault-tolerant properties. While much attention has been paid on neuromorphic electronics, artificial synapses that can exploit diverse synaptic functions are still desirable for bio-realistic neuromorphic electronics, as complex biological functions often require cooperative effects of synaptic functions. Here, we demonstrate liquid crystal-carbon nanotube composites as a resistive switching material that can serve as an active material for artificial synapse. The artificial synapse based on liquid crystal-carbon nanotube composite showed resistive switching characteristics with long retention time by its unique resistive switching mechanism, which is electric-field driven carbon nanotube alignment and aggregation. By properly modulating the stimulation pulse and device structure, diverse synaptic functions such as analog switching, homosynaptic potentiation, heterosynaptic potentiation, and heterosynaptic facilitation were emulated. Moreover, synaptic weight normalization, which is an essential synaptic function in the biological brain, was also emulated by tuning the synaptic plasticity using a modulatory electrode. Artificial synapses that exploit multi-functionality of liquid crystal-carbon nanotube composites will offer a new possibility for uses in next-generation neuromorphic devices.
In Vitro Antimicrobial Activity for Bone Repair Scaffolds Formed by 3D Printing in β-TCP and Borate Bioglass—A Comparison between Autocombustion and Sol-Gel Routes
Carlos Paucar, Natalia Jaramillo, Isabel Moreno, Niza Otero, A. Peláez-Vargas and Claudia P. Garcia; Universidad Nacional de Colombia, Colombia

Pathologies such as dental demineralization, dental resorption, and root canal treatments have a high impact on dentistry. The use of ceramic materials such as calcium phosphates and bioglasses with adequate characteristics of size, porosity, degradability, and compatibility are a suitable option for their solution. Nevertheless; Due to oral lesions, it is necessary to contemplate the behavior of these materials against pathogens oral. These effects can be diminished by doping the ceramic material with elements that have an essential role in bone repair and / or regeneration and that also have an antimicrobial effect, such as magnesium (Mg). Doping also has an effect on the process of reabsorption of the material due to the release of ions.

Here, the antimicrobial activity of two types of ceramic materials was studied, borate bioglass (BGb) obtained via sol-gel and Auto-combustion within the X B2O3 [100-X] system (61SiO2 9 P2O5 30CaO) and of calcium phosphate (β-TCP) with 5% by weight of magnesium (Mg) obtained via Auto-combustion. The characterization of ceramic powders was obtained by X-ray diffraction (DRX) and Infrared Spectroscopy (FTIR). Biological characterization includes an antimicrobial activity of borate bioglass (BGb), β-TCP and β-TCP with Mg+2 (5% by weight), this was evaluated against Streptococcus mutans (ATCC25175) and Candida albicans (ATCC90028) strains and its coculture through the technique of disk diffusion and growth curves in the presence of biomaterials. X-ray diffraction for the bioglass indicates crystalline phases associated with doping with Boron, corroborating the obtaining of a semicrystalline (ceramic) material. The FTIR shown a form associated with the crystallization of β-TCP according to the vibrating bands of calcium phosphates (PO4)³⁻, in addition, the intensity related to Al-OH, Mg-OH, is reduced. The in vitro growth inhibition shown better antimicrobial efficacy of (BGb) obtained by self-combustion than BGb by sol-gel. Against a concentration of 1x10⁸ UFC/ml of C. Albicans, β-TCP without doping had a better effect than β-TCP with Mg. The results that the use of ceramic materials is promising as devices in bone regeneration.

Computational Modelling of Electrical Discharge Machining (EDM) for Tuning Surface Roughness and Curvature
Johan Dag Valentin Bäckemo¹,², Matthias Heuchel¹, Markus Reinthaler¹,³, Karl Kratz¹ and Andreas Lendlein¹,²; ¹Helmholtz Zentrum Geesthacht, Germany; ²University of Potsdam, Germany; ³Charite University Hospital, Germany

Electrical Discharge Machining (EDM) is a processing method to create rough surfaces on metallic substrates. The surface is modified by recurring current discharges between an electrode and a substrate separated by a dielectric. The extent of roughness is dependent on the applied current and the distance between electrode and substrate. The process of EDM provides a stochastic method for creating a randomly generated surface. In order to phenomenologically understand how such certain topographies are generated and what surface parameters may change, a predictive model was created for further understanding.

The model assumes that impacts on an arbitrarily sized surface are stochastic and independent of previous impacts. The underlying shape change during the process was deemed most crucial, thus heat transfer and surface charge were not taken into account. A number of input parameters such as number of impacts, size of impact, depth of impact, volume fraction were chosen. Subsequently, Abbott-Firestone curves were used to evaluate both surface roughness and surface curvature. In addition, equilibria for a given set of parameters were determined – i.e. a surface reaches its final form and undergoes no further significant topographical change.

For each iteration a point was randomly chosen as the point of impact. Subsequently the surface was deformed according to an ellipsoid-torus model for crater formation, which was based on a previously reported model of Micro Wire Electrical Discharge Machining (Micro-WEDM). A fraction of the removed volume was used to form the torus ridge surrounding the crater. This process is then repeated for the given number of impacts. The script for the modelling was written in Python 3.7 with packages NumPy for algebraic calculations and CUDA libraries for parallelization were used for faster computation:

The application of such a computational model may be useful in predicting how a surface is deformed, and what input parameters to use to create a surface with certain desired surface function. Future improvements of the model may include volumetric changes, surface charge and heat transfer.

Multicomponent Soft Material Far from Equilibrium Self-Assembly for Functional Systems
David B. Amabilino, Lluisa Perez-Garcia and Mario Samperi; University of Nottingham, United Kingdom

The self-assembly of cationic gelator molecules can be controlled by the composition of the solvent used for their formation. In these water-ethanol media, the dominance of enthalpy or entropy of formation leads to fibres of very different morphology but identical fibre structure. The route used to make these fibres and the resulting gels can be exploited to incorporate functional molecules - such as drugs for controlled release, dyes for singlet oxygen generation, or molecular switches for responsive materials - in a simple ion-exchange and solvophobic driven assembly route. Emergent properties are seen as a result of this new assembly method. The enhancement of singlet oxygen generation by a chromophore localised precisely in the fibres is observed, and the positioning of the fluorescent molecule determined using a unique method for this kind of material. Also, new results will show a three-component system containing dye and photoswitch, wherein the fibres that are formed by the gelator undergo dramatic changes in their morphology upon irradiation. All components of the system are necessary for the response to light to be observed.

SB01.12.91

First Results of the Mucosa Reconstruction in an Animal Model with a Polymeric Implant Material
Dorothee Rickert1,2 and Andreas Lendlein1; 1Helmholtz-Zentrum Geesthacht, Germany; 2Marien Hospital Stuttgart, Germany

The availability of polymeric biomaterials, whose properties and function can be adjusted to fulfill the anatomical, physiological and surgical requirements, facilitate the development of novel therapeutic options in different medical fields. Recently, multifunctional polymeric biomaterials were designed, which shall modulate regeneration in soft tissue. The increasing number of HPV- (Human Papilloma Virus) induced carcinoma of the upper aerodigestive tract in younger patients requires therapeutic strategies with reduced functional loss concerning verbal communication and deglutition. Both are distinctly reduced in case of a pharyngeal reconstruction by myocutaneous flaps. The reconstruction of the pharynx with a polymeric biomaterial would be a novel therapeutic option in oncological Head and Neck Surgery especially when a fast and complete integration of the material in surrounding tissue would minimize the risk for pharyngeal fistula.

Results
The surgical procedure and the postoperative course were without complications in all animals of the implantation and control group (n=63). Gastrointestinal complications like fistula, perforation or peritonitis did not occur in any animal of the implantation group (n=42) and the control group (n=21). A liquid- and gas-tight anastomosis between the copolymer network and the adjacent stomach wall existed in all animals of the implantation group. The intragastric pressure was measured after explantation of the stomach with maximal dilatation of the stomach by air insufflations in order to test the impermeability between the implant material and adjacent gastric wall. The measurement of the intragastric pressure did not show statistically significant differences between the implantation, the control and the baseline group after 1 week, 4 weeks and 6 months. To investigate systemic responses to inflammation leucocytes and acute-phase proteins α1 -acid glycoprotein (AAG) and Haptoglobin were determined at the different times. No statistically significant differences were found in the number of leucocytes and the concentration of AAG and Haptoglobin between the implantation and control group after 1 week, 4 weeks and 6 months.

Discussion
Pharyngocutaneous fistulas are a serious complication after surgical oncological procedures in Head and Neck Surgery, leading to a severe adverse impact for the patient and social activity. Oncological goals cannot be reached when a radiation therapy cannot be started because of pharyngocutaneous fistula. In this model the mortality of the gastric breakdown of the degradable copolymer network and/or sutures and fistula implying local or generalized peritonitis are comparable to the mortality of insufficiencies and salivary fistula of the pharynx. The adequate chemical, enzymatical, bacterial and mechanical stability of the polymeric material was shown under the extreme conditions of the stomach. The impermeability between the implant material and adjacent gastric wall, the missing
gastrointestinal complications and the concentration of the leucocytes and acute-phase proteins suggest that the polymer network did not induce impairment of the wound healing rather support the tissue regeneration. In further investigations, the mechanisms of the integration of the biomaterial in surrounding tissue as well as the degradation of the polymer and the process of the tissue remodeling should be analyzed. Especially, the correlation of the concentration of AAG and Haptoglobin with intraperitoneal cytokines levels should be investigated.

SB01.12.92
Para-Aramid Nanofiber Sheets—Overcoming the Trade-Off between Mechanical and Thermal Protection
Grant Gonzalez1, Janet Ward2, John Song2, Kathleen Swana2, Steve Fossey2, Jesse Palmer3, Veronica Lucian1, Felita Zhang3, Luca Cera1, John Zimmerman1, John Burpo3 and Kevin Kit Parker1; 1Harvard University, United States; 2U.S. ARMY Combat Capabilities Development Command Soldier Center, United States; 3West Point, United States

Extreme environments require simultaneous protection from multiple threats. For example, astronauts need space suits that can provide both thermal and fragmentation protection to survive in these harsh environments while in outer space. These suits are traditionally made up of several layers of materials working in concert with one another to provide multiple modes of environmental protection. Chief among these are aramid-based compounds, such as Kevlar and Nomex, which were used in the Apollo missions to provide fragmentation and thermal resistance respectively. However, one result of using multiple protection layers is that spacesuits are often complex, and bulky. One way to potentially avoid this is by incorporating multiple functionalities into a single material layer. However, this incorporation is traditionally difficult to achieve in high-performance para-aramid fibers due to a trade-off in protective properties. For example, mechanical protective para-aramid Kevlar fibers are an order of magnitude higher than the thermal insulating meta-aramid Nomex but have orders of magnitude lower thermal insulation. To overcome this trade-off, we hypothesized we could combine the mechanical properties of continuous fibers with the thermal properties of porous aerogels by manufacturing a porous network of aligned fibers with a fiber diameter an order of magnitude smaller than commercial high-performance fibers. Choosing a para-aramid polymer as the base building block due to its high mechanical properties, we spun para-aramid solutions using the recently developed immersion Rotary Jet Spinning platform to fabricate our goal structural material. To ensure continuous fiber formation, we engineered the precursor solution to be fluid like during fiber spinning and solid like during fiber formation. This precursor solution allowed for the fabrication of porous, continuous fiber sheets with diameters and single fiber mechanical properties an order of magnitude lower than commercial para-aramid but had a higher sheet insulation value. With these synergistic properties, the nanofibers sheets act as a multifunctional material that can provide personal protection not only to astronauts but also for those exposed in other extreme environments such as firefighters and warfighters.

Multifunctional Silk Biomaterials for Bioinspired Electronics
Sayantan Pradhan1, Meng Xu1, Francesca Agostinacchio2, Antonella Motta2, Nicola M. Pugno2 and Vamsi K. Yadavalli1; 1Virginia Commonwealth University, United States; 2Università degli Studi di Trento, Italy

Bioinspired materials provide exciting opportunities to develop physiologically compliant bioelectronic systems and scaffolds for tissue regeneration. They can serve not only as the structural, but also as the functional components of such devices. Functional bio-composites with properties of mechanical robustness and flexibility, transparency and importantly, biocompatibility and biodegradability provide a unique palette of properties for biointerfaceing sensors and electronics. Previously, our group demonstrated photopatternable silk inks that can be combined with the conducting polymer PEDOT:PSS to form high resolution microstructures, and flexible micropatterned surfaces.[1-3] We further demonstrated electroactive coating materials for conventional electrodes, flexible electrodes, biosensors, and energy storage devices.[4-7] In recent work, we have been able to successfully fabricate multifunctional designs of this biomaterial leading to engineered elastic behaviors and out-of-plane deformations [8]. This has been facilitated by the use of kirigami inspired cuts in silk films. This biodegradable and biofunctional silk kirigami is mechanically flexible, free-standing, and optically transparent, with precisely defined microscale cuts that can be easily formed using a single-step photolithographic process. We will discuss how, as composites with conducting polymers, intrinsically electroactive, stretchable, and flexible biomaterial sheets can be formed. The silk-kirigami sheets are biocompatible, can serve as substrates for cell culture, and be proteolytically resorbed. The unique properties of the kirigami suggest
a host of applications as transient, “green”, functional biointerfaces and flexible bioinspired electronics.

Morphology, Growth and Defect Dynamics in Cylindrical Colloidal Crystals Nabila Tanjeem, William Wilkin, Christopher Rycroft and Vinothan N. Manoharan; Harvard University, United States

Curvature and topology of a substrate have significant impact on crystal morphology and growth dynamics. For example, it is well known that a crystal that grows on the surface of a sphere incorporates topological defects and closure catastrophe. Topological defects arise due to the Gaussian curvature of the sphere. Closure catastrophe, in which accumulation of defects prevents the crystal from growing, arises due to the finite size of the sphere. To distinguish between the effects of Gaussian curvature and closure catastrophe, we study crystallization on the surface of a cylinder.

A cylinder has a zero Gaussian curvature, but a finite circumference, which requires a crystal to loop back on itself and be content with closure. Cylinders with certain diameters can accommodate a perfect crystal around their circumference. These crystals emerge with different chirality depending on the diameter of the cylinder. Common examples of this type of chiral structures are Carbon nanotubes. Cylinders with other diameters, which fail to accommodate a perfect crystal, satisfy the closure constraint by either incorporating asymmetry in the crystal structure, or by incorporating a line-slip defect. In previous work, it was predicted that line-slip defects satisfy the maximum packing condition in case a perfect crystal fails to form (A. Mughal, PRL, 2011).

We design an experiment in which colloidal spheres with an average diameter of 700 nm self-assemble to form a crystal on the surface of a tapered optical fiber (diameter range 1.5 μm– 5.5 μm). The crystallization is driven by a short-ranged depletion interaction. We observe crystals with different chirality; this observation is consistent with previous theory and experiment on cylindrical crystals. We observe line-slip defects with different chirality as well, which were only predicted in theory previously. A line-slip defect consists of a line of particle pairs where each particle has one less number of contacts, compared to other particles in the crystal.

Surprisingly, we find a new form of a line-slip defect with kinks. The kinks incorporate vacancies that are “fractional” - one full particle cannot be fit in the free volume provided by these vacancies. By observing crystal growth dynamics, we find that the kinked line-slip structures are a result of crystal growth – when a line-slip defect fails to follow the crystal growth, it can appear in a separate, parallel line, incorporating kinks and fractional vacancies. We do not observe relaxation of the kinked defects in experimental timescale. We calculate the equilibrium number of fractional vacancies assuming Boltzmann distribution, which shows that we find a greater number of fractional vacancies in experiment that are expected in equilibrium. This further proves that the kinks and fractional vacancies are kinetic traps and are not equilibrium structures.

Moreover, we find that the line-slip defects that form a larger angle with respect to the cylinder radial axis have fewer number of fractional vacancies compared to the ones forming smaller angles. We explain this observation by modeling and tracking crystal growth in time using Brownian dynamics simulation. Since growth of a crystal is limited in the radial direction due to the finite diameter and unrestricted in the axial direction, line-slip defects that are aligned with the axial direction find it easy to grow without incorporating kinks.
In conclusion, we observe unprecedented crystal morphology and growth dynamics in cylindrical colloidal crystals. We conclude that certain aspects of crystal morphology can only be explained from careful consideration of growth dynamics. This study can further help us understand the growth mechanism of various cylindrical structures that exist in nature and in artificial materials, such as – virus, microtubules, nanotubes, etc.

SB01.12.95

**3D Printed Composites of Polymer and Multiferroic Materials** Emery Utterback, Naga Korivi and Vijay Rangari; Tuskegee University, United States

There is great interest in 3D printing-based fabrication techniques for multi-functional materials. We report on the development of composites of polydimethylsiloxane (PDMS), and nano-particles of barium titanate, and cobalt ferrite by 3D printing for applications in advanced multiferroic devices. The fabrication involved the mechanical blending of liquid PDMS pre-polymer and its curing agent with the barium titanate and cobalt ferrite nano-particles. The blend was subsequently loaded onto an extrusion printing head of a commercial 3D printer and printed on a base plate maintained between 75 – 90 °C to yield solid composite layers. Characterization of the solid composite layers by electrical and magnetic studies, and observations from scanning electron microscopy, transmission electron microscopy, x-ray diffraction, differential scanning calorimetry, thermogravimetry will be presented. To the best of our knowledge, this is one of the earliest reports of a 3D printing approach to fabricate polymer multiferroic composites, and represents a significant technological advance.

SB01.12.96

**Rheological Study on Using Graphene Oxide as Printing Aid to Enable 3D Printing of 2D Materials for Energy Storage Applications** Jiacheng Wang\(^1\), Subrata Ghosh\(^1\), Pei Yang\(^1\), Ian Kinloch\(^1,2\) and Suelen Barg\(^1\); \(^1\)University of Manchester, United Kingdom; \(^2\)National Graphene Institute, United Kingdom

Graphene, a type of 2D materials, with large specific surface areas and high electrical conductivity can be used as electrode materials for high-performance supercapacitors [1–2]. However, the re-stacking of 2D graphene sheets during conventional electrodes fabrication can lead to insufficient use of the surface area and blockage of electrolyte ion transport which degrade the capacitance and rate performance of supercapacitors. 3D printing allows fabrication of 3D graphene electrode architectures with well-tuned porosity and interconnected channels that favour the retention of large electrolyte ion accessible surface area and fast ion transport within the electrodes [3–5]. Graphene oxide (GO) aqueous suspensions in specific concentrations were shown to have not only adequate rheological properties for 3D printing [6] but also the capability to process polymers, ceramics, metals [7] and graphite [8]. A study also showed that the addition of graphene nano-platelets into GO inks enhanced the rate performance of printed electrodes [4]. However, there is a lack of study on using GO to process 2D materials for 3D printing. This work conducts a thorough study of the rheological properties of GO-graphene nanoplatelets (GnP) composite inks. GnP was chosen to represent 2D materials with inert chemistry and a strong tendency to re-stack. The theory can be expanded to other 2D materials. 3D graphene supercapacitors have been printed and their performances have been compared with the conventional graphene supercapacitor cells.

Hydrogel Paints for Repairing Articular Cartilage Defects in Osteoarthritis

Wei Wei, Xudong Yao, Wenyan Zhou, Yuanzhu Ma and Hongwei Ouyang; Zhejiang University, China

Osteoarthritis (OA) is causing pain in millions of people's joints. In clinical, the joints with see partial-thickness cartilage defects on their surface. Partial-thickness cartilage defects can not self-repair due to the avascular, aneural, and alymphatic nature of cartilage. Herein, inspired by painting technique, we designed a new kind of hydrogel system consists of the components of cartilage ECM to treat partial-thickness cartilage defect in osteoarthritis. The resultant hydrogel paint is tissue adhesion, compression resistance, cell affinity, and easy operation. Controlled chemical modification allows each component to achieve the above functions while maintaining biological activity. We found the hydrogel paint support adhesion of stem cell and can maintain phenotype of chondrocytes. In vivo results show that the cartilage was regenerated on the defect site while the control group was developed to osteoarthritis. Therefore, we consider such hydrogel paint is a biomaterial that is promising for repairing partial-thickness cartilage defects.

Smart Membranes

Liang-Yin Chu; Sichuan University, China

Membranes are playing paramount roles for sustainable development in myriad aspects such as energy, environments, resources and human health. However, the unalterable pore size and surface property of traditional porous membranes restrict their efficient applications. The performances of traditional membranes will be weakened upon the unavoidable membrane fouling, and they cannot be applied to the cases where self-regulated permeability and selectivity are required. Inspired by the natural cell membranes with stimuli-responsive channels, artificial stimuli-responsive smart gating membranes are developed by chemically/physically incorporating stimuli-responsive materials as functional gates into traditional porous membranes to provide advanced functions and enhanced performances for breaking the bottlenecks of traditional membrane technology. The smart gating membranes, integrating the advantages of traditional porous membrane substrates and smart functional gates, can self-regulate their permeability and selectivity via flexible adjustment of pore sizes and surface properties based on the "open/close" switch of the smart gates in response to environmental stimuli. This presentation introduces the recent development of stimuli-responsive smart gating membranes, including the design strategies and the fabrication strategies that based on introduction of the stimuli-responsive gates after or during membrane formation, the positively and negatively responsive gating models of versatile stimuli-responsive smart gating membranes, as well as the advanced applications of smart gating membranes for regulating substance concentration in reactors, controlling release rate of drugs, separating active based on size or affinity, and self-cleaning of membrane surfaces. With self-regulated membrane performances, the smart gating membranes show great power for global sustainable development.

Multifunctional Materials with Self-Adaptive Mechanical Properties and Regeneration

Santiago Orrego\textsuperscript{1,2}, Zhezhi Chen\textsuperscript{1}, Decheng Hou\textsuperscript{1}, Urszula Krekora\textsuperscript{1} and Sung H. Kang\textsuperscript{1}; \textsuperscript{1}Johns Hopkins University, United States; \textsuperscript{2}Temple University, United States

Nature provides numerous examples of advanced materials with remarkable properties, synthesized in sustainable ways. Inspired by natural systems, there have been active efforts to understand design principles of natural materials and to synthesize bioinspired multifunctional materials with outstanding properties. We have been inspired by natural structural materials with outstanding mechanical properties such as bone, coral reef, and wood that can adapt to their surrounding environment. For instance, bone can control mineral quantity proportional to the amount of stress. It becomes stronger in locations subjected to the higher mechanical loads, and vice versa. This leads to the formation of mechanically efficient structures for optimal biomechanical and energy-efficient performance.

However, it has been a challenge for making synthetic materials that can change their structures and properties to adapt to the changes of loading conditions. Moreover, materials degrade over time due to fatigue damage occurred during use and damages accelerate the degradation rate, resulting in reduction in the lifetime of the materials and increase of the maintenance costs. If materials can repair damages, we can have more efficient use of materials with reduced associated costs. Synthesizing materials with self-adaptable mechanical properties and regeneration capability can help us to use materials for a broad range of loading conditions with extended lifetime and reduced costs.

To address the challenge, we are inspired by previous findings that bones are formed by mineralization of organic scaffolds using ions from blood. We report a multifunctional material system that triggers mineral synthesis from simulated body fluids onto organic scaffolds upon mechanical loadings and/or damages so that the material can modulate its mechanical properties to adapt to loadings and regenerate upon damages. For example, we observed \(~40\%\) increase in the modulus of the material upon periodic loadings for 3 days. We also observed that the material could repair damages generated by removing \(~5\) \(\mu\)m thick minerals from the matrix, in 7 days. In addition, we demonstrate a simple way of making functionally graded material based on stress distribution within a material that results in graded deposition of minerals. We envision that our findings can open new strategies for making multifunctional materials with self-adaptable mechanical properties and regeneration capability as well as tuning material properties on-demand.

Self-Healable Electronics Based on a Paper-Like Thin PVA/CNC Nanocomposite Film

Jung Wook Kim and Jeong Sook Ha; Korea University, Korea (the Republic of)

Wearable electronics including skin-attachable devices in the form of thin and soft film made for conformal attachment to clothes or skin, are prone to be damaged by external forces during usage. In order to increase the lifetime, there have been extensive efforts to develop self-healing materials that can restore the original properties after being damaged and be implemented to wearable electronic devices.

We report a fabrication of a paper-like thin, foldable and self-healable electronics based on poly vinyl alcohol/cellulose nanocrystal (PVA/CNC) composite film through a facile vacuum filtration method. For self-healing conductive electrodes, polyaniline/multi-walled carbon nanotube and gold nanosheet (AuNS) percolated network are deposited onto the PVA/CNC film. Via contacting the bisected surfaces and spraying water, the damaged area can be self-healed due to formation of hydrogen bonding. By controlling the composition of PVA/CNC film, pH, and temperature, the maximum self-healing efficiency can be optimized. On the PVA/CNC self-healing film, integrated circuit of a supercapacitor and a temperature sensor is fabricated using AuNS interconnections. Both the supercapacitor and temperature sensor show mechanical stability; 100\% recovery of capacitance and sensitivity after 100 repetitive folding deformation and \(>80\%\) recovery of capacitance and sensitivity after 5 repetitive self-healing cycles. These results demonstrate the potential application of our paper-like thin PVA/CNC film based self-healable devices to future highly durable and deformable electronics with longevity.
Living tissues are an integrated, multi-scale architecture consisting of dense cell ensembles and extracellular matrices (ECM) that cooperatively enable the outstanding mechanical properties and rapidly dynamic responsiveness. One key challenge in designing tissue-like materials is to identify cell-like building blocks that can synergistically respond to external stress with existing ECM-like polymer platforms. Therefore, we designed a granular material-enabled hybrid gel, including cell-like starch granules embedded in ECM-like synthetic hydrogel matrices that readily exhibited dynamic reconfigurable effects upon mechanical training. Multi-scale and in-situ characterizations reveal that the synergistic cooperation between nanoscopic (chemical bonding) and mesoscopic (physical friction) interactions from three-dimensional hierarchical architecture give rise to the tissue-like properties, such as rapidly dynamic responsiveness, strain-stiffening, and self-healability. Our results suggest that granular materials, a largely ignored component for biomimetics, could be critical in enabling dynamic behaviors in artificial tissue-like materials, meanwhile it also provides a brand new opportunities for exploring adaptive and active materials.

9:45 AM SB01.13.05
A Theory of Photoactive Nematic Liquid Crystal Elastomers Ruobing Bai and Kaushik Bhattacharya; California Institute of Technology, United States

Liquid crystal elastomers containing photochromophores such as azobenzene can undergo large deformation when illuminated by light of certain wavelength. Since its first discovery in 2001, this phenomenon has attracted extensive research and inspired new applications of large-deformation actuation by light. In such a system, the deformation couples optics, chemistry, and mechanics, leading to a multi-scale, multi-physical process. The process includes the photoisomerization of chromophores, the interaction between mesogens and polymers, and the anisotropic, entropic elasticity of the polymer network. Continuum models have been developed in recent years to study this photochemistry-induced actuation. However, the theoretical studies up to date have been incomplete to fully capture the coupling in the system, which further hinders the discovery of new actuation modes, or exploring the general anisotropic and inhomogeneous material response under complex loading conditions. This talk presents a theoretical modeling on the large deformation of photoactive nematic liquid crystal elastomers actuated by light illumination and mechanical force. The model starts from the statistical mechanics of the photoisomerization, nematic mesogens, and the polymer network. The total free energy landscape is plotted under different light intensities and mechanical loads. We show two generalized actuation modes due to light illumination and mechanical force. The coupling between the two modes induces various deformation. The transition between the two modes gives rise to microscopic stripe domains formed in the material. The opto-chemo-mechanical process readily leads to photomechanical instability.

Integrated Soft Materials Zhigang Suo; Harvard University, United States

An integrated circuit achieves its function by integrating dissimilar components, and so does a living organ. Soft materials—tissues, elastomers, hydrogels, and ionogels—are under intense development for immediate and far-reaching applications. Examples include tissue regeneration, synthetic biology, drug delivery, soft robots, ionotronics, bioelectronics, skin-attached and implanted devices, active textiles, as well as wearable and washable devices. Nearly all applications require the integration of dissimilar soft materials. This talk describes several recent examples of integrated soft materials that achieve unusual functions. Also highlighted are fundamental challenges to the mechanics and chemistry of materials, such as adhesion, fatigue, and seal. Integrated soft materials open opportunities to reinvent our disciplines and ourselves.

11:00 AM SB01.13.07
An Origami-Patterned, Flexible Pressure Sensor Fabricated with Vacuum Forming Kris Dorsey, Mariel Jones, Huiying Huang and Alysha de Silva; Smith College, United States

A common flexible sensor modality employs a change in sensor layout and device capacitance to detect mechanical
deformation. A challenge for this sensor type is in determining what type of deformation (e.g., bending, strain, pressure, torsion) caused the signal. While multiple sensors may be placed in a bridge or rosette configuration to improve selectivity or directionality, the sensor substrate also offers a route to identifying deformation type. Here, we present origami-patterned, polyethylene-based pressure sensors. In comparison to flat polyethylene-based sensors, which can only undergo small strains before plastic deformation occurs, the origami patterns allow the sensors to remain compliant at high strain (>45%) while exhibiting pressure sensitivity. Such sensors may have applications to gesture detection and activity classification, which require flexible and conformal sensors that can distinguish modes of mechanical deformation.

The mechanical properties of origami may be tuned through the material choice, the pattern, and the initial geometry. Paper is most commonly associated with origami, but novel processes such as self-assembly, 3D printing, and casting now enable a wide variety of origami patterns in fabrics and polymers [1]. We directly pattern the material by vacuum forming, which eliminates the multiple steps required to buckle or cure the material in self-assembly fabrication processes. To fabricate the sensors, we designed and generated a 3D printed form with the pattern using a custom Python script interfaced with AutoDesk Fusion 360. We heated commercially available carbon black filled polyethylene (Linqstat, Caplinq) at 60°C for 10 s before placing it onto the 3D printed form and custom vacuum former. The 3D printed form is slightly porous and permits suction of the polyethylene onto the form. After cooling, the conductive polyolefin retains the shape. To fabricate the capacitor, two conductive polyethylene sheets were formed and placed on either side of a formed layer of high-impact polystyrene sheet with a thickness of 0.25 mm.

We characterized the pressure sensitivity of the Miura fold, which is a pattern of repeated chevrons [2], and the double arrow pattern, which is similar to the Miura fold with a taper at the edge of each chevron. The unit cell has a width and length of 20 mm with a height of 7.5 mm. When pressure is applied, the Miura pattern deforms at the pattern folds and flattens out, while the double arrow pattern is stiffer and only deforms at the arrow points. The Miura capacitance increased by 17.8% under a mass of 6.5 g placed on the sensor (5.5 Pa), while the double arrow capacitance increased by 0.25%. As the pattern faces do not appreciably expand when the Miura pattern unfolds, the increase in capacitance may represent both an increase in the fringing field capacitance and a decrease in the electrode separation.

Vacuum forming conductive polymers into origami patterns has the potential for the rapid fabrication of sensors with novel mechanical properties, limited only by the capabilities of 3D printers and the draft angle requirements of the vacuum forming process. Forming conductive polyethylene into other origami patterns, such as those with low bending compliance and high planar compliance, may yield selectivity to other modes of mechanical deformation. This work has implications for designing flexible and multimodal sensing systems for wearable sensing and soft robotics applications.

11:15 AM SB01.13.08
Dry-X Paste for Body-Fluid-Resistant Instant and Strong Wet Adhesion Xinyu Mao, Hyunwoo Yuk and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Tissue adhesives are able to bond wet and dynamics tissue surfaces, yet adhesion on body-fluid-covered wet tissues remains to be a challenge. While there are a wide range of tissue adhesives targeting sealing of damaged tissues, most of commercially available glues and patches only take effect on clean tissue surfaces, and generally completely fail to form adhesion on surfaces covered with large amount of body fluids such as blood and mucus. Conventional hemostatic agents enable adhesion with bleeding tissues, such as hemostatic gauze and topical hemostats. However, their adhesion is based on accelerated coagulation of blood and subsequent formation of blood clots. These conventional approaches are relatively slow and lack robust sealing capability for compromised tissue walls due to weak and unstable adhesion formed by blood clots, both of which may pose several practical challenges and limitations. In this talk, we will present our new a dry-crosslinking (Dry-X) paste for instant, strong, and body-fluid-
resistant adhesion on diverse wet tissues to address all abovementioned challenges. Our Dry-X paste incorporates a unique bio-inspired mechanism and materials design that are distinguishable from all known tissue adhesives as well as hemostatic measures, which yields superior capability of instant and strong adhesion on blood- or mucous-covered tissues. These new capabilities enabled by the Dry-X paste will provide a simple, facile, and effective solution to critical clinical and biomedical applications such as traumatic tissue sealing and hemostasis as well as new opportunities such as a tissue-adhesive drug delivery platform for challenging locations such as GI tract.

11:30 AM SB01.13.09
Bioinspired 3D Microscale Suction Cups for Dry and Wet Adhesion to Human Surfaces
Sangyul Baik, Heon Joon Lee and Changhyun Pang; Sungkyunkwan Univ, Korea (the Republic of)

Research in the adhesive phenomena of natural organisms has inspired developments in biocompatible and skin/organ-attachable adhesives for various medical applications such as wound protection, diagnosis, and therapeutics. Examples of such include gecko feet pads, beetle forelegs, and needle structures of endoparasites, which rely on physical interactions of the multiscale architectures on their topologies. However, such adhesive strategies rely on mechanical interlocking or molecular attractions between surfaces, which suffer upon contact with liquids. The development of adhesives which are easily fabricated and perform robustly and repeatedly under both wet and dry conditions without leaving chemical contaminations on the engaged surfaces has been a major challenge. In addition, achieving high conformity against the three-dimensionally (3-D) rough and curved surfaces of the human body remains difficult for further medical applications of wound protection, diagnosis, or therapeutics. To overcome such challenges, much research in recent years has been focused on octopus suction cups due to their unique anatomical features which enable stable fixation onto rough, dry, and wet surfaces. Although previous reports have presented hypothetical studies for the anatomy of octopus suckers, the detailed mechanisms underlying their enhancement of wet adhesion remain largely unexplored due to the difficulty of precise mimicry. Further detailed investigation of the complex architecture of octopus suckers, including the dome-like protuberance, cup-shaped protruding rim, and soft wrinkles, have revealed their roles in establishing dry and wet adhesion. To mimic the 3D architectures of suction cups, we utilized a facile, solution-based, air-trapping technique within microscale molding without any sophisticated chemical syntheses or surface modifications. Applying these bioinspired architectures as interfacial adhesive layers may benefit the development of skin-attachable or implantable bioelectronics for health diagnosis, controlled drug therapeutics, and multifunctional devices for ubiquitous-healthcare systems.

SESSION SB01.14: Smart Electronic Materials and Sensors
Session Chairs: Ximin He and Zhigang Suo
Friday Afternoon, December 6, 2019

Design Skin-Inspired Electronic Materials and Their Applications
Zhenan Bao; Stanford University, United States

In this talk, I will discuss several design concepts on realizing conductive and semiconductive electronics materials with skin-like properties, such as stretchability, self-healing and both properties. These materials have enabled stretchable circuits, displays and sensors. Several examples of applications will be discussed.

2:00 PM SB01.14.02
Multi-Responsive Flexible and Stretchable Robotic Skin for Soft Robot Hands
Jooyeun Ham, Amy K. Han, Jayoung Kim, Zhiao Yu, Naoji Matsuhisa, Mark R. Cutkosky and Zhenan Bao; Stanford Univ, United States

Recent advances in soft robot hands have demonstrated its unique capabilities, such as handling randomly-shaped or fragile-soft objects, which have been addressed as limitations of conventional rigid robotics. Despite recent progress, the majority of soft robot hands are still limited in dexterous activities, which need tactile and thermal detection for feedback control. Here, we present a highly flexible and stretchable multi-responsive sensory network for soft robot
hand applications. Unlike previously developed embedded tactile systems for soft robot hands, in present work, laser-assisted fabrication techniques allow low-cost and rapid-one-step fabrication of multiple sensors and wires, and modulating the width of a pattern of each sensor and wire enables it to easily tune its sensitivity, sensing range, and expandability. The sensor network further integrated with highly expandable and irregularly-shaped soft robot hands and demonstrated successful tactile sensing performances during grasping actuation of robotic hands undergoing expansion and compression due to high conformity on curved surface and stretchability. The sensor network integrated soft robot hand measured tactile and thermal stimuli distribution, and analyzes multiple stimuli in real time simultaneously in various grasping scenarios. The reproducibility of the sensor network was further evaluated by continuous measurement during repeated grasping action.

2:15 PM SB01.14.03
A Body Area Wireless Sensor Network by Stretchable Passive Tags Simiao Niu¹, Matsuhisa Naoji¹², Xiaodong Chen*² and Zhenan Bao¹; ¹Stanford University, United States; ²Nanyang Technological University, Singapore

Body area sensor network (BodyNET) is a promising platform for next-generation healthcare and realizing its full potential requires seamless hybridization between on-body sensors and both rigid circuits for signal readout, conditioning and wireless transmission components. Rigid sensors based BodyNET has already been demonstrated due to its fabrication compatibility with existing integrated circuit technologies while the integration of soft on-skin sensors into the BodyNET still remains a grand challenge. So far, the integration of rigid silicon circuits and stretchable sensors on a single substrate has only been realized through the introduction of rigid islands and stretchable interconnects. However, the weak interfaces between soft and rigid parts severely compromise the robustness of such systems. Therefore, physical separation of stretchable sensors from rigid readout circuits that completely eliminate all fragile interfaces may be an effective strategy towards an intimate and robust BodyNET system.

Here, we demonstrate a bodyNET system comprised of battery-free and chip-free stretchable sensors attached on multiple skin locations to gather human physiological and movement signals, which are wirelessly operated by silicon readout circuits attached to textiles. The physically-separated stretchable sensors and silicon readout circuit are communicated via passive radio frequency identification (RFID) technologies. The stretchable sensor tags are fabricated via printing intrinsically stretchable materials on elastic substrates, and are completely free from rigid silicon chips and batteries to avoid potential stress concentrated regions and improve system robustness. The main technical challenge encountered here is the strain-induced changes of both sensor antenna inductance and resistance that can affect readout effectiveness. We address this issue by adapting an unconventional detuned RFID tag design and verify its appropriateness by both simulation and experiments. Our design enables the bodyNET system to maintain full functionality even when the on-skin sensors are stretched to 50% strain. To further enable multiple sensors in one RFID tag, we have fabricated and integrated a high frequency intrinsically stretchable rectifying diode and low voltage driven intrinsically stretchable ring oscillators for RF energy harvesting and frequency modulation. Finally, the bodyNET is demonstrated by connecting multiple sensor nodes and smartphone through Bluetooth. Our hands-free bodyNET could continuously, simultaneously and accurately monitor human’s respiration, pulse and body movements. Thus, this platform constitutes a powerful tool in analyzing relevant human activities and physiological signals, hence enabling critically-needed possibility for real-time physiological studies.

Visually Imperceptible Liquid-Metal Circuits for Transparent, Stretchable Electronics with Direct Laser Writing Chengfeng Pan¹, Kitty Kumar¹, Jianzhao Li², Eric J. Markvicka¹, Peter Herman² and Carmel Majidi¹; ¹Carnegie Mellon University, United States; ²University of Toronto, Canada

Electrically conductive films that are optically transparent have a central role in a wide range of electronics applications, from touch screens and video displays to photovoltaics. These conductors function as invisible electrodes for circuit wiring, touch sensing, or electrical charge collection and are typically composed of transparent conductive oxides (e.g. indium-titanium-oxide, ITO), polymers (PEDOT:PSS), metal grids, or nanocomposite
polymer thin-films (graphene, carbon nanotubes). However, most transparent conductors have either poor electrically conductivity or are mechanically stiff and/or inelastic – i.e. stretching the material will cause it to break apart and lose electrical functionality. Such inability to support strain or electrical conductivity greatly limits the role of these existing materials for emerging applications in wearable computing, soft bioelectronics, and biologically-inspired robotics.

Here, we introduce a materials architecture and laser-based microfabrication technique to produce electrically conductive films (sheet resistance = 2.95 Ω/sq; conductivity = 5.65×10⁵ S/m) that are soft, elastic (strain limit > 100%), and optically transparent. The films are composed of a grid-like array of visually imperceptible liquid metal (LM) lines on a clear elastomer. Unlike previous efforts in transparent LM circuitry, the current approach allows for fully imperceptible electronics that have not only high optical transmittance (>85% at 550 nm) but are also invisible under typical lighting conditions and reading distances. This unique combination of properties is enabled with a direct laser patterning technique that results in LM grid patterns with a line width and pitch as small as 4.5 μm and 100 μm, respectively. This yields grid-like wiring on a transparent polydimethylsiloxane (PDMS) elastomer substrate that has adequate conductivity for digital functionality but is also well below the threshold for visual perception. To help adhere the LM and PDMS, a “bi-phasic” architecture is adopted in which a thin metal film – in this case sputter deposited Cr/Cu – was coated on the PDMS prior to LM deposition and patterning. The fabricated LM wiring can be readily interfaced with conventional circuit components (e.g. lead wiring, packaged microelectronics, or LED chips) to enable optically clear digital electronics.

2:45 PM SB01.14.05
Chemo-Mechanical Self-Oscillation Based on Dynamic Buckling Mutian Hua, Cheolgyu Kim and Ximin He; University of California, Los Angeles, United States

Self-oscillating materials have drawn great attention from both fundamental science and application endeavors. Its unique capability of generating sustained motion from static energy source or inputs without intervention has inspired numbers of interesting and impactful applications in the field of energy conversion and robotics. Several attempts for creating self-oscillating materials has been made using chemical oscillators coupled with stimuli responsive hydrogels and liquid crystalline networks. However, these systems suffer from limitations such as of careful molecule alignment within the material, limited choice of materials and high requirements for stimuli (e.g. chemical oscillators, polarization, wavelength). On the contrary, oscillatory patterns occurring in nature are much less restrict with the choice of reaction and materials. Chemical and mechanical dynamics in cell division, cilia motion, cardiac rhythms and peristalsis can perpetually occur from wide selections of rudimentary processes such as acid-base neutralization, metal-protein chelation and ion concentration change.

Inspired by nature, we look into the universal strategy for constructing self-oscillating materials systems out of rudimentary reactions and homogenous/isotropic materials. We demonstrate a self-oscillating materials system based on dynamic buckling. The asynchronized swelling and deswelling of hydrogel in the flow direction of the stimuli leads to a cascade of buckling in the hydrogel strip such that different regions will consecutively go through cyclic deformation in succession. This synergistically leads to the self-oscillation of the material. This provide a new general principle of generating oscillation through self-regulated chemical-mechanical energy transductions. The customizable modular design offers opportunities for creating various other forms of self-oscillatory systems.

Photonic Capsule Sensors—New Platform for Monitoring Microenvironment and Its Spatial Distribution Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Sensor technology based on electronic circuits has led the current IoT era. However, the conventional sensor platform is inadequate for monitoring the microenvironmental condition and its spatial distribution. In the film “Twister (1996)”, a thousand of 10 cm-sized sensor balls are suspended in a tornado, from each of which local information is gathered to provide the spatial distribution. Inspired by the film, we design photonic-crystal-laden microcapsules to make a new sensor platform for monitoring microenvironment and its spatial distribution. As the microcapsule sensors can be injected, suspended, and implanted in any target sites, their array provides the spatial distribution, in a similar manner to the sensor balls yet at the three-orders of magnitude smaller length scale. In this
early stage of development, we aim to monitor microenvironmental temperature and its spatial distribution, which is achieved using thermochromic colloidal photonic crystals.

The microcapsules are produced to have a hollow core and solid shell using microfluidically-prepared water-in-oil-in-water (w/o/w) double-emulsion drops as a template. In the inner water drop, thermoresponsive-responsive colloids composed of a polystyrene core and a poly(N-isopropyl acrylamide-co-acrylic acid) shell are encapsulated in the presence of sodium chloride and depletant of poly(acrylamide-co-acrylic acid) at low concentrations. As the oil shell phase, a thermo-curable silicone precursor is used. To assemble the core-shell colloids, the double-emulsion drops are subjected to a hypertonic condition. The water is selectively pumped out from the core, thereby concentrating the encapsulants. This strengthens the depletion attraction and lessens electrostatic repulsion, resulting in the formation of crystallites with a close-packed array along the interface. Interestingly, the crystallites exclusively have hexagonal close-packed (hcp) lattice rather than face-centered cubic (fcc) lattice. The double-emulsion drops are finally converted into microcapsules with an elastomeric shell through curing of silicone precursor. The microcapsules display a brilliant diffraction color developed by the colloidal crystallites.

The volume change of core-shell particles causes the shift of diffraction color. In particular, the volume change of individual colloids fully influences the change of lattice constant in the close-packed array, resulting in a wide shift. Although the colloidal crystallites are fragile against mechanical stress and chemical impurity, the silicone shell completely isolates the core from the surrounding, making shear- and impurity-free environment in the core. Therefore, the microcapsules show a thermochromic property without degradation of performance. More importantly, each microcapsule reports the microenvironmental temperature through the diffraction color and the array shows the temperature distribution through the color map. We demonstrate this using a convection cell at which temperature gradient causes the flow. The microcapsule sensors can be further developed to measure other conditions or detect small molecules and used for various applications.

Cortisol Immunosensor Integrated in Soft, Smart Contact Lenses for Point-of-Care Testing Minjae Ku, Joohee Kim, Young-Geun Park and Jang-Ung Park; Yonsei University, Korea (the Republic of)

Since psychological stress has been demonstrated to have a direct impact on health, extensive research has been conducted to analyze stress levels quantitatively by measuring stress hormones. Various methods have been reported to detect cortisol, the stress hormone, by means of immunoassay and chromatography. However, this method cannot be used in the point-of-care testing (POCT) because it requires bulky equipment and graph analysis. Thus, we propose a cortisol immune sensor integrated into a soft contact lens that can monitor the cortisol level in tears using the POCT platform. This approach makes it possible for smart contact lenses to measure cortisol levels in real time and transmit the data wirelessly to smart mobile devices. The cortisol sensor uses a channel bonded with cortisol monoclonal antibody (C-Mab) as a transducer and the field effect transistor structure to measure electrical signals according to the cortisol concentration. The limit of detection of the sensor was 1 pg/ml, which is sufficient to detect cortisol level in tears ranging from 1 ng/ml to 40 ng/ml. In this study, we used live rabbits for in-vivo testing, and the results confirmed the reliable, wireless operation of the sensor for in-vivo testing as well as its biocompatibility and its safety with respect to the absorption of electromagnetic energy. A cortisol sensor on a wearable platform that is compatible with smart mobile devices provides a new protocol for self-care.

Multi-Functional and Flexible Energy Storage Devices with High Safety Yang Zhao, Ye Zhang, Yifan Xu, Hao Sun and Huisheng Peng; Fudan University, China

Flexible energy storage devices are critical for the next-generation electronics and have attracted extensive attention. With the fast-growing requirements of portable and wearable electronic equipment, great efforts have been made to develop flexible batteries and supercapacitors. However, the energy densities of these devices are still urgent to be further increased. Furthermore, most of the reported flexible batteries and supercapacitors employ either strong acid/base or toxic flammable organic solutions as electrolytes, which poses potential safety issue for being worn by humans or implanted into the bodies. Therefore, the energy density, safety concerns and compatibility of the flexible energy storage devices are still urgent to be improved to meet the practical application requirements.

Herein, we have developed a new family of multi-Functional and flexible energy storage devices including fiber-shaped aluminum-air battery with superior energy density, self-healing and multi-functional aqueous batteries with high safety, and a novel multi-functional compression-sensing supercapacitor. 1. The all-solid-state fiber-shaped
aluminum-air batteries showed a specific capacity of 935 mAh/g and an energy density of 1168 Wh/kg. They are also flexible and stretchable and can be further woven into a variety of textiles. 2. After breaking, the flexible self-healing batteries can be healed to recover the normal functionality by simply contacting the two breaking parts for seconds. The electrochemical performance of these batteries can be well maintained after repeated cutting and self-healing. 3. The flexible aqueous sodium-ion batteries exhibit high volumetric energy/power density and high flexibility. When the normal saline or cell culture medium is used as electrolyte, these batteries can still work well, indicating an application prospect in implantable electronic devices. 4. The novel compression-sensing supercapacitors can store energy and tolerate and sense the external strain change with high performance. These flexible and multi-functional energy storage devices can be woven into lightweight and flexible electronic textiles to effectively meet the requirement of the modern electronics including electronic skins and advanced bioelectronic devices.

Reversible Humidity-Driven Optical Tuning of PS:PEG-Based Porous Polymer Films in Oxygen Sensors
Soyeon Lee and Jin-Woo Park; Yonsei University, Korea (the Republic of)

Recently, polymers have been used as actuators or energy generators because they have good responsivity to external stimuli such as heat, light or environmental factors due to their flexible chains. In particular, inspired by the various movements and activities of the living organisms, widely existing environmental humidity variation has been vigorously used as an external stimulus for controlling the artificial polymers. However, in a polymer-based wearable sensor, the humidity responsive behavior of polymer may jeopardize an accurate detection of a chemical element other than moisture because there are variations in optical and mechanical properties and gas permeability of the polymers upon exposure to the humid atmosphere. For example, in the wearable luminescent oxygen (O2) sensor, where the sensing film is composed of O2-sensitive dyes embedded in polymer matrices, a sensing signal is obtained based on the changes in light intensity. Under humid condition, the variation in gas permeability of the polymer matrix changes the flux of the O2 molecules inside the sensing films, which varies the photoluminescence (PL) of the films. Simultaneously, the water adsorbed in the polymer matrix changes the reflectance of the films, and both the PL and reflectance variations are detected as a photocurrent signal, which leads to signal drift in O2 concentration. Therefore, there is a need to systematically study the origin of humidity-driven optical changes of the sensing films in addition to the change in O2 permeability. In this study, the humidity-driven optical changes in a porous structured luminescent O2 sensing film were examined in two aspects: changes in O2 permeability and light scattering in the polymer matrix. The luminescent O2 sensing films are composed of an O2-sensitive dye (PtOEP) within porous polymer matrices, where the porous structure is formed via phase separation between immiscible polystyrene (PS) and polyethylene glycol (PEG). Different types of polymer films were made by the drop-casting method and samples are prepared by considering the three main factors: 1) the presence of an PtOEP within the films, 2) the PS:PEG phase-separated porous films and PS-only solid films, and 3) the different rinsing time of porous films in deionized (DI) water. These three factors were established to identify the humidity-driven optical changes in a porous structured luminescent O2 sensing film as a function of the variation of O2 permeability, porosity in films and hygroscopicity of PEG inside the pore. Here, the porous structured polymeric films were identified by the FE-SEM image, and the amount of PEG inside the polymeric films was identified by absorption peak intensity in FT-IR spectra based on the Lambert-Beer law. Finally, with comparisons of the polymeric films by in-situ measurement of both the photocurrent signal and diffused reflectance under different relative humidity (RH) levels ranging from 20 to 80 % RH, a decrease in light scattering intensity is a major contributor to the humidity responsive photocurrent decrease of 22.5% in our porous structured sensing films. In the phase-separated porous
structured polymer film, the hygroscopic PEG distributed inside the polymer matrix swells and fills up the pores as the RH level increases. Therefore, the light refraction at the polymer matrix-air interface was replaced by the polymer matrix-swollen PEG interface, which reduced the Mie scattering coefficient and increased the light transport mean free path, and finally reduced the light scattering of the porous films. The fully reversible humidity-driven tuning of the light scattering properties in porous polymeric films will make various applications possible, such as dual monitoring of O2 and RH in wearable sensors, responsive coating or smart windows that require optical tuning without extra energy.

4:45 PM SB01.14.10
New Oxygen Sensors and Pressure Sensitive Paints Based on PDMS-Containing Block Polymers Jiayan Shi,
Ke Zhong and Yanqing Tian; Southern University of Science and Technology, China

In wind tunnel and aircraft experiments, it is important to know the aircraft’s surface pressure, which provides the aerodynamic performance of aircrafts[1]. In traditional pressure test, punching holes on the model surface and installing pressure transducers into these holes are required. Though this method is simple and accurate[2], the pressure information obtained in this way is non-continuous, and the measurement is also limited by the model structures and the interference/interval between adjacent holes[3]. To alleviate these drawbacks of traditional pressure test method, a non-contact and non-destructive measurement technique is needed. Pressure sensitive paint (PSP) provides a non-destructive method for air pressure measurement by using oxygen sensitive probes in suitable matrices, which is based on the oxygen quenching principle[4]. The distribution of air stress on the sample surface can be deducted from the emission changes of PSP. Compared with the traditional pressure measuring method, this type of optical measuring technology has the following advantages: high spatial resolution, no damage to the model surface, short test cycle, high economic benefits, and being able to get continuous measuring results[5]. Almost all of the polymers used for PSP studies belong to random polymers in previous reports. In this study, we reported new PSP materials derived from block polymers. And we investigated the influence of polymer structure on oxygen sensing activity.

The new PSPs with block polymeric structures were prepared by using a kind of controlled living polymerizations - atom transfer radical polymerization (ATRP). Polymers composing of polydimethylsiloxane-b-poly(isobutylmethacrylate) (PDMS-b-PolyIBMA)s act as the matrices for the platinum porphyrin-based phosphorescence probes, which were copolymerized in the matrices. The polymers were characterized by using ^1H-NMR and GPC. The sensitivity and response time to oxygen and/or pressure were investigated. Results showed that copolymers with suitable compositions can have higher sensitivity. The influence of polymer structures on oxygen sensing activity was also investigated. Results showed that polymer structures have no significant effect on their oxygen sensing performance. This is the first time to apply PSPs with block polymer structures, which will broaden the PSP functional materials’ design.

Unraveling the Effect of Morphological Features and Hierarchy on the Performance of Diatoms-Inspired Structures
Flavia Libonati1,2, Filippo Gallina1, Daniele Origo1, Kai Guo2, Laura Vergani1 and Markus J. Buehler2;
1Politecnico di Milano, Italy; 2Massachusetts Institute of Technology, United States

Diatoms are single-cell algae that form a hard silica/organic composite with a honeycomb-like structure. The fascinating and sophisticated structure of these algae, which is responsible for the multifunctionality of these organisms, has attracted several scientists and engineers for various reasons. Multiple functions and properties (e.g., mechanical, chemical, and optical) are achieved through a combination of different factors, such as compositions, geometrical features, and hierarchy. A characteristic feature of the diatoms is the protective shell, which has an optimal strength-to-weight ratio, especially if compared to other biological materials, offering enough resistance to predators’ attacks and preventing sinking. These characteristics make the shell an interesting biomimetic model for the design of lightweight structural materials. Here we focus on one of the most relevant and interesting diatom species, the Coscinodiscus, that is a centric diatom with radial symmetry. Keeping the effective density constant, we use numerical modeling, experimental testing, and additive manufacturing study the effect of systematically varying the size of the relevant geometrical features on the overall bending stiffness. The overarching hypothesis of this work is that the morphological features, like pores and hierarchical layers, drive the mechanical response of diatoms exoskeleton and are designed by Nature to simultaneously fulfill different functions. We build a simplified FE-model of a diatom-inspired architecture and we study the mechanical behavior under three-point bending and compressive loading. We evaluate the effect of the hierarchical level and the effect of material distribution amongst the hierarchical level on the overall bending stiffness and resistance to buckling. The numerical simulations are validated through experimental tests, carried out on polymeric geometries fabricated using multi-material 3D-printing. The results of this study reveal how the natural geometry is optimized to simultaneously provide lightweight, bending stiffness, and structural integrity, limiting local buckling and providing different dissipation mechanisms to absorb energy, thus preventing catastrophic failure. Ongoing studies are carryout on the effect of the pore distribution on both the mechanical behavior, with particular attention to fracture, and on the fluid-dynamics properties. Ultimately, this research offers an innovative perspective in terms of design and fabrication of multifunctional diatom-inspired materials for diverse applications, from drug delivery to membrane filtering and solar cells. Moreover, given the large diatom diversity and the plethora of architectures, there is great potential of applying machine learning algorithm for the design of novel diatom-like topologies with a novel set of properties.

Engineering Microbes to Produce Water-Processable, Biodegradable and Coatable AquaPlastic
Anna Duraj-
Thatte; Harvard University, United States

Over 335 million tons of plastic is produced globally every year and nearly 80% of it have accumulated in landfills and water-bodies. Contamination of non-biodegradable plastics and microplastics (<5 mm fragmented particles) are causing potentially irreversible damage to our ecosystems and global health, including that of humans. Herein, we report AquaPlastic, a new class of microbiologically produced biodegradable bioplastic that is water-processable. We genetically engineered *E. coli* to fabricate AquaPlastic with minimal processing steps. AquaPlastic is entirely water-processable and aqua-healed by the addition of water. Additionally, it can be aqua-welded to create robust three-dimensional architectures by using water as a glue. It also readily forms well-adhered coatings on a wide variety of surfaces and is resistant to strong acid/base and organic solvents. AquaPlastic films can be imprinted with surface patterns with topographical features as small as a few tens of nanometers. These unique features of AquaPlastic are believed to inspire further exploration and the development of much-needed alternatives to conventional plastics.

8:30 AM *SB02.01.03
Biomimetic Nanocomposites for Biomedical Technologies Nicholas A. Kotov; University of Michigan, United States

Design of stimuli responsive and structurally versatile materials with finely controlled combination of properties represent the key bottlenecks of nearly all biomedical technologies. The central challenge for the design and realization of biologically inspired materials with such demanding set of properties is harnessing the processes of self-organization involving molecular, nanoscale, and microscale components. This challenge can be addressed using integration of several methods of self-assembly producing hierarchically structured composites.

Replication of load-bearing and functional nanocomposites will be described for three examples of bioinspired nanomaterials: nacre; enamel and cartilage. Nacre-like composites allow for multidimensional design of materials properties: toughness, stiffness, strength, transparency, ion transport, and biological response. These type of hierarchical nanocomposites resulted in biomimetic neuroprosthetic implants. Replicating tooth enamel, we recently learn that the mechanics and other properties of this material can be replicated combining out-of-plane nanoparticle assembly into columns and molecular-scale self assembly of polymers between them. These composites reveal remarkably high vibrational damping unusual for stiff materials that imparts them resilience to aging. Replication of cartilage gives example how to nature reconciles load-bearing and transport properties. Versatile cartilage-like nanocomposites based on aramid nanofibers (ANFs) will be discussed in details.

9:00 AM SB02.01.04
An Introduction to the Cephalopod Protein Reflectin for Biomedical Applications Atrouli Chatterjee and Alon Gorodetsky; University of California, Irvine, United States

Cephalopods possess unrivaled camouflage and signaling abilities that are enabled by their sophisticated skin, which alters the texture and coloration of their skin to blend into their surroundings. The color-changing capabilities of cephalopods, in particular, are enabled by multiple dermal layers, which contain chromatophore pigment cells (as part of larger chromatophore organs) and different types of reflective cells called iridocytes and leucophores, which function synergistically to alter the appearance of the cephalopods for both communication and signaling. The optical functionality of these cells (and thus cephalopod skin) critically relies upon subcellular structures partially composed of a class of unusual structural proteins known as reflectins. Reflectins have been found to have a unique amino acid sequence, but very little secondary structure. We will highlight studies that have investigated reflectins’ structure-function relationships, within the context of cell-reflectin interactions. We will also discuss these proteins’ multi-faceted material properties, associated challenges, and future potential. Our findings hold relevance for the development of biomedical technologies based on and inspired by reflectins.

9:15 AM SB02.01.05
Biomimetic Thermally Responsive Self-Assembled Hierarchical System Ju Hun Lee1,2, Seungwook Ji3,2, Byoung Duk Lee1,3 and Seungwuk Lee1,2; 1University of California at Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States; 3Samsung Display, Korea (the Republic of)
Out-of-equilibrium self-assembly of biomolecules is one of key processes to forming organisms in nature. Spatial and temporal activation energy switches the biochemical properties of biomolecules, and altering the interactions between biomolecules results in self-assembled structures and, eventually, the construction of a functional organism. To explain the self-assembly mechanism in nature, biophysicists have constructed a variety of theoretical and experimental models. These models assume no interactions between biomolecules in general because it is not trivial to design an interaction-controllable system; this basic assumption, however, is highly simplified and does not represent the reality of nature. We demonstrate our recent efforts to design a biomimetic interaction-controllable self-assembly system. M13 bacteriophage possesses a long fibrous shape with a helically-arranged protein surface, analogous to naturally existing basic building blocks such as collagen, cellulose, and chitin. As a result of amplification through bacterial infection, M13 bacteriophage is identical, homogenous, and can be easily genetically engineered to make M13 bacteriophage a promising biomaterial in designing a biomimetic system. In this study, we genetically engineer M13 bacteriophage to install a thermally responsive peptide (TRP) at the end of the major capsid protein p8 to tune interactions between biomolecules during self-assembly. TRP phage self-assembles into a highly ordered structure with increasing temperature that is counter-intuitively inverse thermal response than usual liquid crystals. The temperature dependent phage transition of TRP-phage in solution is investigated by a macroscopic turbidity measurement. The phage transition temperature is decreased with increasing TRP phage concentration and ionic strength of solution. The microscopic nucleation and growth of TRP phage’s helical, fibrous, and smectic structure is observed by polarized optical microscope. To evaluate the temperature dependent orderedness of the TRP phage structure, small angle x-ray scattering measurement of (100) peak is utilized. TRP phage in solution shows 7.8 nm interspacing at 42°C, and this peak is decreased to 6.9 nm at 68°C, while there is no peak from room temperature to 42°C. From atomic force microscopy and He-ion microscopy, the final nanostructure is the helically assembled TRP. The role of individual amino acids, especially valines in different positions, is also investigated through the turbidity measurement by inducing point mutations.

9:30 AM SB02.01.06
Environmental Remediation and Biofuel Production through Nanoparticle Stimulation of Yeast Shalmalee Pandit, George Sun and Angela Belcher; Massachusetts Institute of Technology, United States

Artificially photosynthetic systems aim to store solar energy and chemically reduce carbon dioxide. These systems have been developed in order to use light to drive processes for carbon fixation into biomass and/or liquid fuels. We have developed a hybrid-biological system that manages both genetically controlled generation of products along with the photoactivability of a semiconductor system. We show an increase in the production of ethanol, a common biofuel, through the electron transfer stimulated by biologically produced cadmium sulfide nanoparticles and light. This work provides a basis on which to improve the production of many metabolites and products through endogenously produced nanoparticles.

9:45 AM SB02.01.07
Mechanical Energy Transmission in Collagen Segments Mario Milazzo1,2, GangSeob Jung1, Serena Danti1,2,3 and Markus J. Buehler4; 1Massachusetts Institute of Technology, United States; 2Scuola Superiore Sant'Anna, Italy; 3University of Pisa, Italy

Collagen is the most abundant protein in humans and animals with more than twenty-five different variations. Among them, Collagen Type I (COL1) is the main component of bone and skin. Owing to its structural nature, previous studies have investigated different mechanical perspectives, including strength, elasticity, toughness and viscoelasticity. An interesting avenue of research, still poorly understood, is the capability of collagen to transfer mechanical energy when exposed to impulsive displacement loads. This topic is particularly relevant due to the tremendous implications for developing new biomimetic and bioinspired materials to be employed in bioengineering. Specifically, the energy transfer applications in the auditory apparatus are most interesting since this organ possesses abundant collagen and its physiological role is specific to mechanical energy transmission from sound waves. In this work, we study a collagen peptide (with GXY triplets) at the molecular level to understand the role of hydration in the material behavior under impulsive loads. We employ molecular dynamics simulations to investigate wave speeds and energy dissipation. We prepare a (GPO)_{20} collagen peptide with Triple-Helical collagen Building Script with a length of about 180 Å. Both dry (DS) and the wet (WS) structures are equilibrated via LAMMPS aiming at relaxing the topology and
reaching a convergence of the potential energy and RMSD (Root-mean-square deviation).

To study the behavior of COL1 along and perpendicularly to the helix axis, wave transfer analyses are performed on both the DS and WS by fixing the peptide at one end and by applying two different impulses: longitudinal case (LC) and transversal case (TC).

As for the LC, we load the free end with an axial impulsive displacement of 10 Å. In contrast, for the TC, we perform a preliminary slow stretching of the triple helix at the free end (up to 10% of the tensile strain) before applying a transversal impulsive displacement of 10 Å.

Our results for the LC show higher wave speeds for the DS than the WS’s (3082 m/s vs. 2190 m/s) with correspondent Young’s Moduli of 8.05 GPa and 4.07 GPa.

We discover that the kinetic energy is markedly dissipated, similarly for the DS and WS, and it results annihilated before the travelling wave reaches the fixed edge. We estimate for both the DS and WS a relaxation time in the order of 100 ps.

Concerning the TC, instead, the material behavior is strongly affected by the pre-strain applied before the impulsive load. We compare the results with the vibrating string analytical model to study the relationship between the wave speeds at different tensile strains and the Young’s Moduli. Our results show a monotonically increase of the travelling wave speed with the tensile strain (up to 1400 m/s and 829 m/s for DS and WS, respectively). A direct comparison of the Young’s Modulus vs. strain curves with previous works confirms the validity of our approach.

Concerning the dissipating phenomena, our results show a quasi-elastic propagation of the wave along the DS with a dissipation about five times smaller than the WS’s in the same loading conditions (i.e., relaxation time: 429 ps vs. 80 ps). We believe that, during transversal perturbations, water plays a key role in enhancing the kinetic energy dissipation, otherwise driven by only hydrogen bonds.

This study represents a first step in understanding collagenous material properties under transient loading conditions in view of applications related to bone physiology and replacement, and to the auditory apparatus where COL1 is abundant.

This work has received funding from the European Union’s Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement COLLHEAR No 794614.

Core-Shell Carriers for the Controlled Release of Multiple Active Pharmaceutical Ingredients Dina M. Silva¹, Anabela F. Gonçalves², Andre da Costa³, Andréia Gomes³, Raul Machado³, Jitraporn Vongsivivut³, Mark J. Tobin¹ and Vitor Sencadas¹,²,¹,⁴; ¹University of Wollongong, Australia; ²University of Minho, Portugal; ³Australian Synchrotron (ANSTO), Australia; ⁴Illawarra Health and Medical Research Institute, Australia

Drug delivery systems have been extensively investigated for the last decade, with research in the field of microparticles, nanoparticles, micellar, lipid and hydrogel vesicles [1-4]. Unlike traditional drug formulations which typically consist of a raw drug dispersed within a matrix, encapsulating reservoirs present the advantage of sustained drug release with high efficacy, in an attempt to alleviate the risks of toxic side effects and overcome the challenges of providing an optimised therapy both in space and time [1, 5]. Such challenges are the driving force behind the design of novel drug delivery systems aiming to revolutionise the way drugs exert their actions. One example is the modification of the release behaviour of core-shell carriers for the combined administration of drugs, within a safe therapeutic window [1, 6].

This work presents a novel route to process polymer-based core-shell microparticles, composed by an outer shell of poly(vinyl alcohol) (PVA) encapsulating ciprofloxacin (CPx), and a core comprising a curcumin (CM) loaded poly(e-caprolactone) (PCL) particle. The obtained core-shell particles size was in the range of 1 – 6 μm, making them ideal candidates for inhalable drug delivery systems.

The release patterns for both CM and CPx from the simple PCL or PVA particles took less than 72 h to being fully
released. The core-shell microparticles, on the other hand, presented a biphasic release pattern, showing that the CPx was released over the first 24 h followed by the release of the curcumin from the core PCL particle, being the last one fully released after 15 days. Thus, the polymer layers worked as a physical barrier, preventing drug-drug interaction and modulating the release behavior.

Attenuated total reflection Fourier transform infrared (ATR-FTIR) spectroscopy coupled with synchrotron infrared (IR) beam was used to obtain the chemical mapping of the drug distribution within the individual core-shell particles. This technique demonstrated that the PCL particles were inside of the PVA layer, and that there was a distinct and traceable distribution of the both drugs inside the particles. Finally, the bioactivity and compatibility of the formulated particles were confirmed by antimicrobial and viability assays. These novel polymer-polymer core-shell systems proved to be biocompatible and able to deliver, in a controlled fashion, two different drugs without compromising their bioactivity, hence offering unique properties for multidrug therapies.

Statement of Purpose: Cancer related deaths are the second leading cause of death with more than 10 million new cases each year. Conventional treatment often affect both healthy and cancerous cells, causing severe adverse side effects. Moreover, systemic delivery of chemotherapeutic drugs requires higher doses of drugs which lead to higher toxicity to healthy cells. Therefore, biomaterials have been used to enable localized and effective delivery of therapies to avoid side effects and reduce the effective dose. Biomaterials engineering was used to develop a variety of drug delivery vehicles for different chemotherapeutic drugs. We hypothesize that by incorporating single walled carbon nanotube (SWCNT)-liposome complexes in hydrogels, a drug delivery system capable of controlling timing and sequence of multiple drug deliveries can be developed. Utilizing near infrared (NIR) lasers, SWCNTs can be preferentially heated to disrupt liposomal bilayers, resulting in drug release. Since NIR absorbance spectra of SWCNTs is dictated by their \((n,m)\)-chirality, e.g. distinct Gaussian profiles with \(~15\) nm full-width at half maximum (FWHM), multiple formulations of single-chirality SWCNT-liposomes can be developed for the multiplexed release of drugs triggered by different NIR lasers. Finally, these SWCNT-liposome complexes will be retained in 3D hydrogel structures, enabling the localized delivery of chemotherapeutic drugs.

Methods: Single-stranded DNA was used to wrap the SWCNTs and disperse them in aqueous solutions. For each dispersion, 1 mg of raw HiPco nanotubes was added to 2 mg of desalted ss(GT)\(_{15}\) oligonucleotide with 1 mL of 100 mM NaCl. The mixtures were then ultrasonicated using a 1/8" tapered microtip for 2 hours at 40% amplitude, with an average power output of 8 W, in a 0 °C temperature-controlled vial. After sonication, the dispersion was ultracentrifuged for 30 min at 250,000 xg and the top 80% of the supernatant was extracted. 1,2-dioleoyl-sn-glycerol-3-phosphocholine (DOPC) and 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) were mixed at a 1:1 molar
ratio in chloroform at 10 mM and rotary evaporated to form a thin lipid film. 10 kDa FITC-Dextran was dissolved in DI water at 1 mg/ml and used to hydrate the lipid film for 5 minutes. The solution was then vortexed and extruded through polycarbonate membranes with 200 nm pore size to form unilamellar positively charged liposomes. DNA-wrapped SWCNTs were mixed with the liposomes using two-barrel syringe and syringe pump to form SWCNT-liposome complexes. Different ratios of SWCNT to liposome were used to minimize aggregation (measurable by polydispersity index (PDI)). These SWCNT-liposome complexes were further encapsulated into alginate hydrogels. Dynamic light scattering (DLS) was used to characterize the SWCNT-liposome structures. Confocal fluorescence microscopy was used to verify the homogenous distribution of SWCNT-liposome structures in the alginate hydrogel.

**Results & Conclusions:** We verified the fabrication of SWCNT-liposome complexes using dynamic light scattering (DLS) to measure the size and zeta potential of these structures before and after fabrication. Different ratios of SWCNT to lipid were used and the optimal ratio for minimizing aggregation was identified. Furthermore, cryo-transmission electron microscopy (Cryo-TEM) was used to visualize the structure of SWCNT-liposome complexes. Confocal fluorescence microscopy demonstrated the retention of model drug in the complexes over a two-week period. In summary, SWCNT-liposome complexes were fabricated, characterized and their retention in a 3D hydrogel scaffold was demonstrated. Furthermore, drug retention in these complexes over a 14-day period was verified and drug release vs. time was quantified. We believe that these complexes can be useful for controlling the drug release by using NIR lasers. More studies need to be conducted to analyze the effect of different NIR wavelengths on release profiles.

Cardoso¹,²; ¹Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; ²Universidade Estadual de Campinas (UNICAMP), Brazil

Over the last 20 years nanomedicine has drastically evolved with consequent approval of 51 FDA nanomedicines which are currently in the market. Most of these nanomedicines are applied intravenously, although oral administration propitiates comfort to patients, reduced infection risks and invasiveness, easy application, and low cost. Therefore, one critical challenge that remains in the pharmaceutical industry is the development of nanomedicines that can be orally administered.

Intestine is likely the key barrier facing oral administration-based medicines. Thus, the interaction and transport of nanoparticles (NPs) across this barrier is of paramount relevance. Currently, intestinal barriers production resembling human tissues involves the co-cultivation of human colon carcinoma epithelial (Caco-2, non-mucus secretion) and human colorectal adenocarcinoma (HT-29, high mucus secretion) cells at 9:1 ratio, respectively. While this co-culture leads to production of intestinal epithelia that mimics the human intestine with higher reliability, few reports have assessed the passage of nanomedicines across non-ideal models of intestine either dealing exclusively with Caco-2 cells or with non-optimized Caco-2:HT-29 ratios. Further drawbacks in these works include the use of NPs undergoing aggregation in biological environment and/or protein-free culture media, which lead to intestinal transport results of low biological relevance. Herein, we quantify the transport of stable fluorescent silica nanoparticles (SiO₂NPs) in complex culture medium across an optimized model of intestinal epithelium (Caco-2:HT-29).

SiO₂NPs were synthesized from the mixture of rhodamine B isothiocyanate dye precursor, tetraethyl orthosilicate (TEOS) and ammonia catalyst in ethanolic solution. A silica shell was produced around the pre-formed fluorescent cores and the resulting particles have approximately 90 nm-size according to electron microscopy. These particles remained stable for more than 24 h of incubation in DMEM supplemented with 10.0% fetal bovine serum enabling reliable analyses of the SiO₂NP transport across the intestinal epithelium since aggregates can prevent this passage and hide accurate quantitative results.

The artificial intestine was formed by co-cultivation of Caco-2 and HT-29 at 9:1 v/v ratio and confocal images confirmed the structure of the intestine. SiO₂NPs at 0.5 mg mL⁻¹ were added on the top of the transwell allowing NPs to interact with intestine. After 24 h, samples from top and bottom (after passing through intestine) compartments were monitored by fluorescence spectroscopy. Quantitatively, 19 ± 2% (n=3) of the SiO₂NPs crossed the intestine through paracellular and transcellular pathways, 44 ± 8% remained at the top of the transwell, whereas roughly 37% were retained either in the transwell polycarbonate membrane or inside intestine cells. Cell viability assays further revealed these SiO₂NPs are non-toxic to intestine cells.

In addition to high stability and low toxicity, the SiO₂NP transport assays were performed using optimized intestine model. The obtained results are important towards a more reliable comprehension on the behavior of SiO₂NPs when
in contact with intestinal barriers, then contributing for new advances related to the development of oral nanomedicines.

Micromotors Set in Motion by Disassembling Polymer Multilayers Marina Fernandez Medina1, Xiaomin Qian1, Ondrej Hovorka2 and Brigitte Stadler1; 1Aarhus University, Denmark; 2University of Southampton, United Kingdom

Micro and nanomotors are entities extensively present in nature where they perform complicated tasks in a simple way, making their artificial development interesting as it holds promise in a wide range of applications in the biomedical context, food science or environmental monitoring. Artificial micro and nanomotors are micro or nanoscale sized devices able to exhibit motion in response to different stimuli or power sources. These motors can either employ fuels to move1 or they can require external energy.2 However, they still need to overcome some difficulties, in the former case often toxic compounds in high concentrations were used to propel motors with high thrust. Biocompatible systems with high enough operational lifetimes and speeds to perform their envisioned tasks remain scarce.

We have designed a polymer-based system to address the latter challenge.3 It consists of micromotors formed by polymer-multilayers assembled through hydrogen bonds via the layer-by-layer technique. They exhibit pH-dependent disintegration that results in micro-motors motion, outperforming the Brownian randomization expected for swimmers of these sizes.

The mobility properties of these micromotors have been assessed experimentally and theoretically based on their trajectories and velocities with the aim to yield micromotors with high thrust. We demonstrated their self-propulsion and directed motion for steep pH gradients, while more shallow gradients resulted in random enhanced motion. Interestingly, velocities were predominantly increased for lower micromotors masses, and higher amounts of adsorbed polymer multilayers in their surfaces. All these characteristics as well as their shape and time related dependence have been summarized.

Micromotors capabilities were further evaluated biologically based on their toxicity and mucus penetration ability within cells. We demonstrated an improvement in cell uptake for micromotors compared with their uncoated counterparts.

These micromotors can exploit the existence of different pH regions in the human body. Their high thrust at short times and their biocompatibility make them suitable to cross biological barriers.

Ultra-Deformable Platelet-Like Particle Promote Hemostasis and Improve Wound Healing Ashley Brown1,2; 1North Carolina State University and the University of North Carolina at Chapel Hill, United States; 2North Carolina State University, United States

Platelets perform a variety of functions during the wound healing process, including targeting to wound sites,
binding fibrin and promoting clotting following injury. Following cessation of bleeding, platelets also release cytokines and antimicrobial peptides and reorganize the fibrin clot through a process known as clot retraction. Clot retraction significantly decreases clot size, alters clot organization and increases clot stiffness, thereby promoting ongoing wound repair. The fibrin clot acts as a provisional matrix for cellular infiltration and tissue remodeling during the inflammation, proliferation, and migration stages of wound healing, and platelet-mediated reorganization of the fibrin network after hemostasis may be an important factor in promoting cellular infiltration. In cases of traumatic injury or disease, platelets can become depleted or dysfunctional, impairing their ability to promote hemostasis and contribute to subsequent healing. To that end, we have developed a biomimetic platelet-like-particle (PLP) that mimics native platelets by homing to injury sites in vivo, augmenting clot formation at sites of injury, and recapitulating platelet clot retraction in a tunable process. We hypothesized that PLPs would stiffen clot matrices as a result of this ability to induce clot retraction. Increased matrix stiffness has been shown to promote cell migration. Therefore, we also hypothesized that PLPs would subsequently improve in vitro cell migration and in vivo wound healing responses when incorporated into fibrin matrices. In these studies, we evaluated the ability of PLPs to reorganize fibrin clots, increase clot stiffness, and enhance cell migration and healing outcomes in healthy healing models, as well as in combinatorial therapies, infection models, and a deficient healing (hemophilia) model. We evaluated our base PLP design and an antimicrobial PLP design. Finally, PLPs were also applied in combination with ultrasound in order to determine whether this combinatorial therapy could be used to minimize the time required to bring about clot structural changes, as well as minimize the therapeutic dosage of PLPs required for treatment. To create PLPs, ultralow crosslinked poly(N-isopropylacrylamide) microgels co-polymerized with acrylic acid were synthesized using precipitation polymerization and following purification, were conjugated to a fibrin-specific IgG antibody through EDC/NHS coupling. Antimicrobial PLPs were also created by incorporation of nanogold or nanosilver into the base PLP design. The effect of PLPs on clot structure and stiffness were evaluated using confocal microscopy, cryogenic scanning electron microscopy, and atomic force microscopy. The influence of PLP-mediated clot retraction on cell migration was evaluated within 3D in vitro models of wound healing in both normal and hemophilia-B like conditions of deficient healing. The ability of antimicrobial PLPs to decrease bacterial burden was evaluated in a colony forming unit assay using both Escherichia coli and Methicillin-resistant Staphylococcus aureus. Finally, the ability of PLPs to augment hemostasis following trauma and promote healing were evaluated in a mouse liver laceration model and a full-thickness dermal injury model, respectively. Incorporation of PLPs into fibrin matrices increased clot density, stiffness, fibroblast migration in vitro, and markers of wound healing in vivo. Both normal and antimicrobial PLPs significantly decreased blood loss in vivo. Antimicrobial PLPs decreased bacterial burden in vitro and in vivo. Finally, co-application of ultrasound and PLPs increased clot density, stiffness, cell migration, and wound healing markers, but at lower dosages and time scales relative to those required with PLPs alone. Overall, these results demonstrate that PLPs are beneficial for augmenting hemostasis and promoting healing.
The vortex configuration of spins emerges in anisotropic magnetic nanomaterials with certain dimensions in the absence of an external magnetic field (MF). This configuration enables rapid control over a particle’s magnetization direction and magnitude. Nanoparticles supporting vortex spin configuration possess near zero net magnetization in the absence of MF, which affords greater colloidal stability in suspensions. This property makes magnetic vortex particles uniquely suited for applications in biological systems. Guided by micromagnetic simulations, we predict and experimentally demonstrate magnetic vortex states in an array of colloidally synthesized magnetite nanodiscs (MNDs) 100–250 nm in diameter. The vortex state in MNDs was measured directly via electron holography. Following phase transfer into physiological solutions, we applied these MNDs for remote control of activity of sensory neurons with weak (7–26 mT), slow-varying (1–5 Hz) MFs. The latency of this magnetomechanical neuronal excitation was correlated to the MND volume and the applied MF amplitude and frequency. Consistent with MNDs geometry and magnetite chemistry, MNDs exhibit direction-dependent hysteresis loops, which results in their hysteretic heating in high-frequency (100s kHz) alternating MFs. We determined MNDs capability of heat dissipation with efficiency (specific loss power) up to 1000 W/g in MFs with frequencies of 75-150 kHz. This is on par with record reported efficiencies for the isotropic magnetite nanoparticles, but observed at 10-50 times lower particle counts owing it to the MND volumes. This characteristic allows for targeted activation of heat-gated ion channels in neurons upon application of high-frequency alternating MFs. With their large induced magnetic moments in slow-varying MFs and high heating efficiencies in alternating MFs, MNDs allow for multiplexed stimulation of neurons by selectively activating mechanoreceptors or thermoreceptors.

Flame Nanoparticle and Device Engineering for Biomedicine Georgios A. Sotiriou; Karolinska Institutet, Sweden

Nanoscale materials show great potential in the biomedical field as they can serve as superior bioimaging contrast agents, diagnostic and therapeutic tools while a key element for the successful implementation of nanoscale materials in clinical applications is multi-functionality. However, the two main bottlenecks for the successful commercialization of such nanotechnologies, that are often neglected in studies, are scalability and reproducibility. Here, a few recent examples will be shown of how flame nanoparticle synthesis, a nanomanufacture process famous for its scalability and reproducibility, may be employed for the production of sophisticated nanoscale materials to tackle important medical challenges.

We focus on nanoparticle formation by flame spray pyrolysis, a highly versatile nanomanufacture process and advance the knowledge for synthesis of complex nanoparticles and their direct integration in multi-scale biomedical devices. We place specific emphasis in multifunctional and responsive nanoparticles that may be used either as transducer elements or as diagnostic probes to monitor biological processes.

We synthesize nanoparticles with high purity and controlled sizes as a basis for functional nanoparticles. We have demonstrated functionalization of luminescent nanoparticles with targeting proteins, whose receptors are overexpressed in cancer cells, and detected them by fluorescence cell imaging. We have also recently explored the potential of flame-made nanoparticles in H2O2 biosensing, using enzyme-mimetic luminescent CeO2:Eu3+ nanoparticles that exhibit catalase-mimetic activity and decompose H2O2. We have also shown the potential of stimuli-responsive nanoparticles as both photothermal agents by near-IR irradiation as well as superparamagnetic nanoparticles for the enhanced triggered-drug-release from alginate beads by hyperthermia. Flame aerosol reactors for nanoparticle synthesis are a powerful toolbox for the scalable and reproducible production of sophisticated nanoparticles with properties not easily attained by other nanomanufacture processes. Their systematic employment in biomedicine has the potential to open up several avenues for nano-enabled solutions to medical challenges.

An Electrochromic Paper-Based Device as a Diagnostic Test for Cystic Fibrosis Elvira Fortunato and Rodrigo Martins; FCT-UNL, Portugal

Cystic Fibrosis (CF) is an inherited disorder affecting more than 70000 people worldwide, especially Caucasian populations with a carrier prevalence of 1/3000. Currently, it has no cure but an early diagnosis remains a critical issue for an optimistic prognosis. Sweat chloride test has been the gold standard to diagnose CF since the affected present higher sweat chloride concentrations than healthy individuals (≥ 60 mM). In this work, a planar electrochromic point-of-care device, based on WO 3 nanoparticles produced by microwave assisted hydrothermal synthesis, was developed for CF low-cost diagnostic testing especially in resource-limited environments. For electrodes patterning, a CO 2 laser technology was used in a PET/ITO sheet. The device presents a design that allows the NaCl-based electrolyte deposition, used as artificial sweat, only on time of usage directly on the nanoparticles or in a paper pad. By applying an operating voltage of 3 V for 1 min, the nanoparticles change their optical properties according to NaCl concentration, presenting a blue colouration with different intensities for different NaCl concentrations. The device is able to differentiate between a positive and negative diagnosis within few minutes, obtaining an RGB channel ratio of 1.37±0.03 for 60 mM of NaCl, when imaged.

Size- and Functionalization-Dependent Transport of Silica-Based Drug Delivery Vehicles across Cellular Barriers Using an Optimized Class of Cell-Penetrating Peptides Isabel Gessner, Annika Klimpel, Merlin Klußmann, Ines Neundorf and Sanjay Mathur; University of Cologne, Germany

While the translocation of cargos across biological barriers is the key issue for therapeutic applications, cell-penetrating peptides (CPPs) have demonstrated to be highly useful for the transport of molecules and even nanomaterials into cells. Herein, we studied how the intracellular delivery of silica nanoparticles can be modulated after decoration with differently active CPPs. The latter were obtained after an Ala scan of the recently developed CPP sC18. Out of the 16 peptides obtained, two were selected for further studies: the first displayed a higher positive net charge and enhanced amphipathicity resulting in significantly higher internalization rates than sC18. The second one demonstrated reduced cellular uptake efficiencies, and served as a control. Attachment of these CPPs to silica nanoparticles of different sizes (50, 150 and 300 nm) was performed electrostatically to preserve the secondary alpha-helical structure of the peptides, which was confirmed by CD-spectrometry. Flow cytometry studies showed that all conjugates were efficiently internalized into HeLa cells revealing a particle size-dependent uptake. Moreover, similar to the free peptides, a peptide-dependent internalization could be observed according to the position of the alanine residue in the biomolecular sequence. These results demonstrate the huge potential of sequential fine-tuning of CPPs and provide more insights into their interaction with inorganic nanocarrier surfaces.

Engineered Nanomaterials as Medicines for Traumatic Brain Injuries Ester J. Kwon; University of California at San Diego, United States

Traumatic brain injury (TBI) affects ~1.7 million Americans every year and is the largest cause of disability-adjusted life-years lost worldwide. Treatments available in the clinic remain palliative, with no strategies that address the long-term brain health of patients. There is therefore an urgent need for new therapeutics. One hallmark of TBI is vascular damage, which is observed through clinical imaging modalities such as magnetic resonance imaging and X-ray computed tomography. We are engineering nanometer scaled materials to exploit this vascular damage in order to gain access to the injured tissue for the delivery of both diagnostic and therapeutic payloads. In addition, we are interested in studying and developing strategies to target nanomaterials to specific cell-types and structures within the injured brain.

We first explore the time window in which vascular damage allows the infiltration of nanomaterials into the brain tissue, and determine that we can deliver material into the brain when delivered hours after injury. Furthermore, we can exploit this transient window of vascular disruption to deliver targeted nanomaterials that carry therapeutic nucleic acids with neuronal specificity. We next explore the size range of materials that can infiltrate the brain after injury and find that similar to the enhanced permeation and retention (EPR) effect observed for nanomaterials in cancer, there is an optimal size for materials to accumulate in the injured brain. We leverage this accumulation in the injured brain for the delivery of a diagnostic payload that generates signal in response to an enzyme that has elevated and deleterious activity in brain injuries. We observe increased activation of this nanosensor in the context of TBI compared to uninjured brains. Collectively, we are engineering nanomaterials that provide diagnostic and therapeutic capabilities to provide new medicines for TBI.

Design of High-Aspect-Ratio Nanoneedle Arrays with Tunable Sharpness for Interfacing and Influencing Biological System Hyejeong Seong, Stuart G. Higgins, Jelle Penders, James P. Armstrong, Axel C. Moore and Molly Stevens; Imperial College London, United Kingdom

Bioengineered systems often employ physical cues arising from intrinsic properties of the substrate in order to mimic specific physiological conditions. In particular, materials with micro- and nanoscale topographies are known to be regulators of cell adhesion, morphology, migration, proliferation, and differentiation. Of these topographies, high-aspect-ratio nanostructures have emerged as versatile platforms for facilitating drug/biomolecule delivery, and intracellular sensing.1,2,3

Here, we present a new approach for the microfabrication of high-aspect-ratio, nondegradable silicon nanoneedle arrays that can support the long-term culture of human mesenchymal stem cells (hMSCs).4 Through a combination of different etching processes, we were able to finely control the sharpness of the nanoneedles from 20 to 700 nm. This enabled us to investigate the influence of the nanoneedle tip diameter upon the phenotype of interfaced hMSCs. High-content, image-based profiling of 100,000 individual cells cultured on different nanoneedle arrays revealed that the nanoneedle tip diameter could be used to influence cell shape, nuclear size, and actin alignment in a controllable manner. In particular, the polarization of actin on sharp nanoneedles was found to be mediated by the Rho-GTPase pathway. Mechanoresponsive cell behavior, including altered expression of lamins, Yes-Associated Protein (YAP) target genes and focal adhesion genes, could also be tuned by altering the tip diameter. These results were correlated to increased nuclear membrane impingement by the sharp nanoneedles, as shown by volumetric, superresolution imaging using focused-ion beam scanning electron microscopy (FIB-SEM).

Taken together, these observations demonstrate the importance of nanostructures for controlling the cell interface and phenotype. Our method of fabricating high-aspect-ratio nanostructures will be broadly applicable to the design of nanotopographical interfaces for biomedical devices, such as bioelectrodes and diagnostic platforms.

Renal Clearable Catalytic Gold Nanoclusters for In Vivo Disease Monitoring Colleen Lovnachan¹, Ava Soleimany², Sangeeta Bhatia² and Molly Stevens¹; ¹Imperial College London, United Kingdom; ²Massachusetts Institute of Technology, United States

Ultra-small gold nanoclusters (AuNCs) have emerged as agile probes for in vivo imaging, as they exhibit exceptional tumour accumulation and efficient renal clearance properties. However, their intrinsic catalytic activity,¹ which can enable increased detection sensitivity, has yet to be explored for in vivo sensing. By exploiting the peroxidase-mimicking activity of AuNCs and the precise nanometer size filtration of the kidney, we designed multifunctional protease nanosensors that respond to disease microenvironments to produce a direct colorimetric urinary readout of disease state in less than 1 h.²

Our nanosensor is comprised of renal clearable catalytic AuNCs (< 2 nm) tethered to a larger protein carrier via peptide linkages, that is disassembled in response to dysregulated protease activity at the site of disease. We demonstrated that the peptide-templated AuNCs can be filtered through the kidneys and excreted into the urine with high efficiency and retain catalytic activity in complex physiological environments. To demonstrate the modularity of the system, we synthesized functionalized peptide substrates shown to be specifically cleaved by either the serine protease thrombin or the zinc-dependent matrix metalloproteinase 9 (MMP9), which play a critical role in cardiovascular disease or cancer, respectively. We demonstrated the response of our protease nanosensors both in vitro and in vivo, achieving sensitive disease detection with a rapid, colorimetric urinary readout using our MMP-responsive nanosensors. We monitored the catalytic activity of AuNCs in collected urine of a mouse model of colorectal cancer where tumour-bearing mice showed a 13-fold increase in colorimetric signal compared to healthy mice. Nanosensors were eliminated completely through hepatic and renal excretion within 4 weeks after injection with no evidence of toxicity.

Our system exhibited a dual amplification platform: leveraging both in vivo protease activity and inorganic catalytic activity of AuNCs to provide a visual readout of disease state directly in urine. With this method, we demonstrate that these AuNCs are small enough to be filtered efficiently through the kidneys and retain catalytic activity in cleared urine, thus providing a versatile disease detection platform that is compatible for deployment at the point-of-care (PoC). Our adaptable nanocatalyst amplification platform should be applicable in low-resource settings for rapid detection of a diverse range of diseases by exploiting their specific enzymatic signatures and will democratize access to advanced and sensitive diagnostics.

Therapeutic Applications of Graphene Quantum Dots for Central Nervous System Disease Byung Hee Hong¹, Je Min Yoo², Donghoon Kim², Hanseok Ko³ and Kyungsun Kang¹; ¹Seoul National Univ, Korea (the Republic of); ²Biographene Inc., Korea (the Republic of); ³Johns Hopkins University, United States

Graphene quantum dots (GQDs) are 2–3 nm sized nanoparticles that have a hydrophobic 2D graphitic domains with hydrophilic oxygen-containing functional groups along the edges. The carboxyl groups on GQDs can be modified to amine groups through simple organic chemistry to be decorated with many different small molecules. In our recent study, the application of GQDs as a therapeutic agent has been demonstrated to alleviate Parkinson's disease by degrading pre-existing α-synuclein fibers as well as by preventing its fibrillization. It is also proven that GQDs have negligible long-term toxicity in animal models as they are excreted through urine in a few weeks (D. Kim et al., 2018, Nat. Nanotechnol., 13, 812-818). Thus, GQDs are gaining growing interests in the field of nanomedicine by virtue of such novel capability to prevent or remove undesirable aggregation of biomolecules that causes various diseases. In this talk, we will introduce our recent finding that GQDs treatment considerably decreases the accumulation of intracellular cholesterol through physical interactions both in vitro and in vivo, resulting in a therapeutic effect against impaired functions in Niemann-Pick type C disease (NPC). The GQDs are found to induce...
autophagy to restore compromised autophagic flux, which eventually reduces the atypical accumulation of autophagic vacuoles. Moreover, GQDs injection prevents the loss of Purkinje cells in the cerebellum with decreased microglial activation. The finding that GQDs alleviate impaired functions in NPC provides a promising potential for the treatment of NPC and related lysosomal storage disorders (LSDs). In addition, it will be shown that the aggregation of amyloid beta and tau protein fibrils related to Alzheimer's Disease has been successfully prevented by GQDs in vitro. We suppose that the thermodynamic equilibrium can be repositioned by adding GQDs as they interfere with aggregating molecules in terms of enthalpy and entropy, leading to the change the Gibbs free energy to block or reverse the fibrosis. We expect that this new thermodynamic approach to treat the central nervous system disease would be expanded to other fibrosis diseases in liver, lung, and kidney in the future.

4:45 PM SB02.03.10
Engineering the Cas9 Protein via a Chemical Route for Nonviral Delivery Hyun Jung Chung and Yoo Kyung Kang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The CRISPR/Cas9 system has been one of the most innovative tools for genome editing. For therapy, viruses expressing Cas9 and sgRNA have been used, but show limitations in safety due to off-target effects and difficulty in viral packaging. Recently, strategies for nonviral, in vivo delivery have been developed, however problems reside due to the need of using excess carrier amount which causes toxicity. To solve this problem, we have developed conjugate systems of the Cas9 ribonucleoprotein, to safely deliver the cargo in vivo. Cas9 from Streptococcus pyogenes (SpCas9) was covalently conjugated with cationic polymers or lipids, to enhance delivery by increasing the net charge or hydrophobicity of the ribonucleoprotein. Mixing the Cas9 conjugates with sgRNA resulted in the formation of nano-sized complexes, which showed enhanced cellular uptake and genome editing efficiencies compared to the native complexes, demonstrated in various human cell lines and bacteria. To improve the versatility of Cas9 as a platform for chemical modification, we have also generated a bioorthogonal Cas9 protein by incorporation of unnatural amino acids. Incorporation of azidohomoalanine could increase the number of functionalities for further modification, while azidophenylalanine allowed site-specific conjugation. Our platform technologies present a versatile platform for engineering the Cas9 ribonucleoprotein using a chemical route, which can be used as a therapeutic for various human diseases, such as cancer, infections, and genetic disorders.

Graphene Based Health Monitoring Dmitry Kireev and Deji Akinwande; The University of Texas at Austin, United States

The modern healthcare and biomedical systems show a clear trend towards personalized, predictive, and preventive medicine. Development of the concept, commonly known as mobile health (mHealth), means that a huge shift in the paradigms of medical device architectures is to be expected in the near future thanks to the increased portability of medical devices as well as increase in number of specific mobile-based apps. An ideal wearable device should possess a set of important requirements, such as (i) low cost of fabrication, (ii) being conformable and compatible with human skin, and (iii) multifunctionality. The latter is of special importance if the goal is to build not just a single specific device, but to rather develop a technology and basis for scalable fabrication of devices that are capable to detect a plurality of vital signals (HR, EEG, ECG, hydration, galvanic response, etc.). In order to develop the universal technology that meets all three requirements mentioned above, we propose to utilize graphene in combination with epidermal technology. The conventional epidermal biosensors are based on metal and silicon based thin films that are patterned into special structures for softness and stretchability and embedded into soft biocompatible polymers. The choice of two-dimensional materials is the most natural due to their ultra-thinness, allowing extreme flexibility, transparency, and conformability to almost any rough surface, including skin [1]. Graphene based passive electrodes have been successfully used to epidermal sensing of electrocardiograms (ECG), electromyogram (EOG), electroencephalogram (EEG), skin temperature, and skin
hydration [1], [2]. It is important to emphasize that the research work is based on large-area CVD-grown graphene, allowing us to develop low-cost, wearable, and fully conformable to skin devices. Furthermore, large area fabrication gives an ultimate promise for future devices fully based on 2D materials to be available on market. In terms of possible applications, the proposed technology can be easily expanded towards other fields of healthcare biosensing, such as in vivo electrophysiology, UV exposure sensing, pressure sensing, or even towards building electronic skin, and prosthetics.

8:15 AM SB02.04.02/SB05.04.02/SB07.03.02
Multifunctional Fiber Based Neural Probes with Integrated Neurotransmitter Detection Atharva Sahasrabudhe1, Tural Khudiyev1, Tomo Tanaka1,2, Kyoungsuk Jin1, Marc-Joseph Antonini1,3, Andres Canales1, Yoel Fink1,1, Karthish Manthiram1 and Polina Anikeeva1,1; 1Massachusetts Institute of Technology, United States; 2NEC Corporation, Japan; 3Harvard-MIT Division of Health Science and Technology, United States

One of the major challenges in deciphering the fundamental principles of cognition is the lack of appropriate tools for seamless interfacing with neurons across all their signaling modalities. Gaining holistic understanding of neural circuits and their control of behavior requires invention of neural probes that can simultaneously record and modulate electro-chemical activity of neurons while evoking minimal inflammatory response for periods ranging from minutes to years. Multifunctional fibers have recently emerged as a promising platform for integrating multiple functional elements to probe and control neural activity that also minimizes the foreign body response.

In my presentation, I will describe our efforts in further expanding the multifunctionality of polymer-based fiber probes by incorporating an electrochemical sensor that enables real-time tracking of neurotransmitter dynamics in behaving animals. This is achieved by introducing a carbon nanotube (CNT) based electrocatalytic electrode within the multifunctional fiber-based probes during their fabrication via thermal drawing process. The resulting devices can be implanted chronically and perform electrical recording and stimulation of neurons, light delivery through waveguides for optogenetics, drug and gene delivery via microfluidic channels, and voltammetry via the CNT electrodes for dynamic detection of dopamine. We envision that these multimodal, miniature, and mechanically compliant probes will facilitate understanding of the neurophysiological underpinnings of dopamine-dependent behaviors including reward, addiction, and motor control.

Chronic Recordings from Behaving Animals Using Microwire-CMOS Technology Nicholas Melosh; Stanford University, United States

Mammalian brains consist of billions of neurons operating at millisecond time scales, which current recording techniques only capture a tiny fraction. Recent advances in CMOS device design have led to high-recording quality planar probes, with diminishing sizes to ameliorate the extent of tissue damage. Matching these powerful silicon electronics to the inherently three dimensional architecture of the brain has remained challenging however, as devices are constrained to the planar two dimensional surfaces required for silicon processing. Here we describe a chronic interface using arrays of microwires read out by CMOS-based devices with a low-tissue damage, and controllable, three dimensional distribution of recording sites. The core concept is using a bundle of insulated microwires mated to a large-scale CMOS microelectrode array, such as found in modern camera chips or displays. We show recent results on the mechanics and tissue damage from microwire insertion scales strongly with wire diameter. Microwires with <25µm diameters are shown to have minimal to no vascular disruption or bleeding, as opposed to more conventional 75 to 100 µm devices. These microwires are then arranged into bundles to control the spatial arrangement and three dimensional structure of the distal (neuronal) end, while providing a robust parallel contact plane on the proximal side which is interfaced to a planar pixel array. The modular nature of the design enables a wide array of microwire types and size to be mated to a variety of different CMOS chips, making the same
fundamental platform scalable from a few hundred electrodes to tens of thousands. We thus link the rapid progress and power of commercial multiplexing, digitisation and data acquisition hardware together with a bio-compatible, flexible and sensitive neural interface array. We present recent massively parallel recording using mouse and rat models, showing both spiking activity from single neurons and local field potentials within both chronic and acute settings.

9:30 AM *SB02.04.05/SB05.04.05/SB07.03.05
Membrane Curvature at the Interface between the Cell Membrane and Nanoscale Electrodes Bianxiao Cui; Stanford University, United States

The interaction between the cell membrane and the measuring electrode is crucial for crucial for sensitive measurement of cell electric activities. We are interested in exploring nanotechnology and novel materials to improve the membrane-electrode coupling efficiency. Recently, we and other groups show that vertical nanopillars protruding from a flat surface support cell survival and can be used as subcellular sensors to probe biological processes in live cells. The nanopillar electrodes deform plasma membrane inwards and induce membrane curvature when the cell engulfs them, leading to a reduction of the membrane-electrode gap distance and a higher sealing resistance. As an electrode sensor, nanoelectrodes offer several advantages such as high sensitivity, subcellular spatial resolution, and precise control of the sensor geometry. Furthermore, we found that the high membrane curvature induced by nanoscale electrodes significantly affects the distribution of curvature-sensitive proteins and stimulates several cellular processes in live cells. Our studies show a strong interplay between biological cells and nanoscale topography, which is an essential consideration for future development of interfacing devices.

Engineering Skin-Like Soft Electrical Interface with Biological Systems Zhenan Bao; Stanford University, United States

In this talk, I will discuss several projects related to engineering conductive materials and developing fabrication methods to allow electronics with effective electrical interfaces with biological systems, through tuning their electrical as well as mechanical properties. The end result is a soft electrical interface that has both low interfacial impedance as well as match mechanical properties with biological tissue. Several applications of such electronics will be presented.

Soft Materials in Wireless Closed-Loop Neuromodulation Systems for Treating Organ Dysfunction John A. Rogers; Northwestern University, United States

Bioelectronic medicines targeted at the peripheral nervous system have the potential to address a wide variety of diseases, from diabetes to bladder dysfunction. The foundational concepts have existed for decades but implementation has been limited and fraught with persistent challenges, including lack in target specificity, nerve interface biofouling, and inability to acquire real time physiologic signals for conditional delivery of corrective stimuli, leading to excess and unnecessary stimulation. Here we present a set of materials, a treatment strategy and supporting technology platform that address many of these challenges, using bladder control as model system. Specifically, we report capabilities for continuous monitoring of bladder function using an ultralow modulus, stretchable strain gauge to measure dimensional changes, real-time data analytics to identify pathological behavior based on the resulting data, and automated, closed-loop optogenetic neuromodulation of bladder sensory afferents to normalize bladder function in the context of acute cystitis, with generic applicability to many other organ systems and conditions.

11:30 AM *SB02.04.08/SB05.04.08/SB07.03.08
Miniature, Wireless Bioelectronics by Harvesting Energy from Magnetic Fields Jacob T. Robinson; Rice University, United States

Miniature, wireless bioelectronic devices enable less invasive surgical implantation and the ability to target tiny nerves or brain areas. However, as these neural stimulators become smaller, we must engineer new ways to deliver
power. Conventional power deliver relies on long wires to deliver power from an implanted battery or subcutaneous antenna. These leads can limit device placement and cause device failure due to lead breakage or infection. Conventional wireless power delivery through biological tissue is difficult when devices are miniaturized and placed deep in the body. Here we show that magnetic materials can effectively harvest energy from magnetic fields and power millimeter-sized bioelectronics. These materials show excellent power densities even as the devices are made small allowing them to be fully implanted and wirelessly powered. We demonstrate that these mm-sized wireless devices can be used to power different types of conventional stimulation electrodes when implanted in rabbits, pigs, and freely moving rats. Furthermore, these miniature electrical stimulators can be adapted to power many individually addressable stimulation channels while still maintaining a small overall device footprint.

SESSION SB02.05: Bioelectronic and Biomedical Devices
Session Chairs: Ritchie Chen and Yoonkey Nam

1:30 PM *SB02.05.01
Soft Electronics for Health Monitoring—From the Skin to Below the Skin Sheng Xu; University of California, San Diego, United States

Soft electronic devices that can acquire vital signs from the human body represent an important trend for healthcare. Combined strategies of materials design and advanced microfabrication allow the integration of a variety of components and devices on a stretchable platform, resulting in functional systems with minimal constraints on the human body. In this presentation, I will demonstrate a wearable multichannel patch that can sense a collection of signals from the human skin in a wireless mode. Additionally, integrating high-performance ultrasonic transducers on the stretchable platform adds a new third dimension to the detection range of conventional soft electronics. Ultrasound waves can penetrate the skin and noninvasively capture dynamic events in deep tissues, such as blood pressure and blood flow waveforms in central arteries and veins. This stretchable platform holds profound implications for a wide range of applications in consumer electronics, sports medicine, defense, and clinical practices.

2:00 PM SB02.05.02
Stretchable, Patch-Type Calorie-Expenditure Measurement Device Based on Pop-Up- Shaped Nanoscale-Crack Based Sensor Kiyoon Kwon and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Demands for precise health information tracking techniques are increasing, especially for daily dietary requirements to prevent obesity, diabetes, etc. Many commercially available sensors that detect dynamic motions of the body lack accuracy, while novel strain sensors at the research level mostly lack the capability to analyze measurements in real life conditions. Here, we demonstrate a stretchable, patch-type calorie expenditure measurement system that integrates ultra-sensitive crack-based strain sensor and Bluetooth-enabled wireless communication circuit to offer both accurate measurements and practical diagnosis of motion. The crack-based strain gauge transformed into pop-up-shaped structure provides reliable measurements and broad range of strain (~100%). Combined with the stretchable analysis circuit, the skin attachable tool translates variation of knee flexion angle into calorie expenditure amount, using relative resistance change (R/R0) data from the flexible sensor. As signals from knee joint angular movement translates velocity and walking/running behavior, the total amount of calorie expenditure is accurately analyzed. Finally, theoretical, experimental and simulation analysis of signal stability, dynamic noises and calorie expenditure calculation obtained from the device during exercise are demonstrated. For further applications, we expect our devices to be used in broader range of dynamic motion of the body for diagnosis of abnormality and for rehabilitation.

2:15 PM SB02.05.03
Fabric-Reinforced Elastomer Composites for Neo-Aorta Application in Normothermic Heart Perfusion Devices Dinara Zhalmuratova, Thanh-Giang La, Katherine T. Yu, David Nobes, Darren Freed, Chun-il Kim and Hyun-Joong Chung; University of Alberta, Canada
An ex-vivo heart perfusion device preserves the donor heart in a warm beating state during transfer between extraction and implantation surgeries. One of the current challenges includes the use of rigid and noncompliant plastic tubes, which causes injuries to the heart at the junction between the tissue and the tube. The compliant and rapidly strain-stiffening mechanical property that generates a J-shaped stress-strain behavior, is necessary for producing the Windkessel effect, which ensures continuous flow of blood through the aorta. In this study, we mimic the J-shaped and anisotropic stress-strain behavior of human aorta in synthetic elastomers to replace the problematic noncompliant plastic tube.

Firstly, we measured the mechanical properties of human \( n = 1 \) and porcine aorta \( n = 14 \) to quantify the nonlinear and anisotropic behavior under uniaxial tensile stress from five different regions of the aorta. Here, the human and porcine aortas demonstrated the J-shaped strain-stiffening in uniaxial tensile testing and were stiffer in the longitudinal direction when compared to the circumferential direction. In terms of location dependence, we observed that the porcine aorta appears to be stiffer at the distal sections from the heart when compared proximal regions.

Secondly, fabric-reinforced elastomer composites were prepared by reinforcing silicone elastomers with embedded fabrics in trilayer geometry. The knitted structures of fabric provide strain-stiffening as well as anisotropic mechanical properties of the resulting composite in a deterministic manner. By optimizing the combination between different elastomers and fabrics, the resulting composites matched the J-shaped and anisotropic stress-strain behavior of natural human and porcine aorta. In order to find the optimal combination between the elastomeric matrix and the fabric reinforcement, the uniaxial tensile properties of various commercial elastomers and commercial fabrics/textiles were tested and the data were archived. Here, neat elastomer materials could not mimic the J-shape, nor the anisotropy. Among composite elastomers, knitted rayon/spandex fabric sandwiched by the two layers of Ecoflex 0050 was the best in mimicking both the strain-stiffening and anisotropy features of the aorta. Here, the knitted fabrics played a role of anisotropically crumpled elastin and collagen, which enable low moduli at low strains and a rapid stiffening at high strains.

Thirdly, improved analytical constitutive models based on Gent’s and Mooney-Rivlin’s constitutive model (the elastomer matrix) combined with Holzapfel–Gasser–Ogden’s model (the stiffer fabrics) were developed to describe J-shaped behavior of the natural aortas and the fabric-reinforced composites. Overall, the elasticity of natural aorta at low strains is attributed to the elastin (Mooney-Rivlin and Gent) and stiffening of the curve at higher strains originates from collagen contribution and \( k_1 \) and \( k_2 \) parameters (Holzapfel). In the fabric-reinforced elastomers, the low elastic modulus at low strains comes from the elastomer matrix and the stiffening at higher strains comes from embedded fabric. Moreover, the values of the main parameters, namely \( \mu, k_1 \) and \( k_2 \) for Gent’s model, and stress-like parameters \( C_{10}, C_{01}, k_1 \), and \( k_2 \) and for Mooney-Rivlin’s were very similar between the natural aorta and our fabric-reinforced composites. These support the aorta-like behavior of the developed fabric-reinforced composites.

In a broad context, J-shape and anisotropy are general properties of many soft biological tissues. We anticipate that the suggested design criteria and our proposed analytical models can be helpful in designing biomaterials that mimic properties of complex soft biological tissues with synthetic materials. The material design concept can also be used in emerging engineering fields such as soft robotics and microfluidics, where the Windkessel effect can be useful in regulating the flow of fluids.

**Tunable, Implantable Materials that Enable Structural Repair and Functional Augmentation in the Heart**

Ellen T. Roche; Massachusetts Institute of Technology, United States

The enhanced design and fabrication of cardiovascular devices relies on technological advances in implantable materials. In this talk I will discuss the importance of tunable and optimized materials for realizing implantable cardiovascular implants for structural repair, active assistance and biological therapy. I will discuss representative devices, and their component materials, in each of these three areas, each addressing an identified shortcoming of existing technologies. In terms of structural repair devices, I will discuss a minimally invasive delivery system that uses a biodegradable, photo-activated adhesive for atraumatic repair of intracardiac defects. Moving to active assist devices I will discuss the modelling and design of a bioinspired soft active material technology that enabled the fabrication of a robotic direct cardiac compression device whose design mimics the orientation of the heart muscle. In vivo testing of this device has demonstrated that it is possible to improve cardiac output without the need for a
blood-contacting approach in an acute heart failure animal model. Building on the platform of soft robotic approaches to enhance organ function, I will discuss pediatric cardiac assist devices and mechanical devices to enhance respiratory function. Lastly, to illustrate examples of enhanced biological therapy, I will discuss the use of biomaterials as vehicles for cell delivery and a targeted, refillable bio-implant for increasing retention of therapy in the heart, which enables repeated local administration of biological or pharmacological delivery, and some preliminary steps to combine these mechanical and biological therapies in order to improve delivery of drugs and modulate the host response.

3:00 PM BREAK

3:30 PM *SB02.05.05
Engineering Materials for Bioelectronics Molly Stevens; Imperial College London, United Kingdom

An important aim of regenerative medicine is to restore tissue function with implantable, laboratory-grown constructs that contain tissue-specific cells that replicate the function of their counterparts in the healthy native tissue. In this talk I will describe our recent work in the development of materials for bioelectronics including polymers and functionalised nanoneedles. I will also describe our new imaging technologies for monitoring and elucidating the cell-material interface.

4:00 PM SB02.05.06
Bioelectronics for Tissue-Wide Electrophysiology and Cell-Type-Specific Electrophysiological Remodeling Jia Liu; Harvard University, United States

Tissue-wide electrophysiology with single-cell and single-spike spatiotemporal resolution, and cell-type specificity is critical for heart and brain studies. In this talk, I will first discuss the creation of cyborg organoids: the three-dimensional (3D) assembly of soft, stretchable mesh nanoelectronics across the entire organoid by the cell-cell attraction forces from 2D-to-3D tissue reconfiguration during organogenesis. We demonstrate that stretchable mesh nanoelectronics can migrate with and grow into the initial 2D cell layers to form the 3D organoid structure with minimal impact on tissue growth and differentiation. The intimate contact between the dispersed nanoelectronics and cells enables us to chronically and systematically observe the evolution, propagation and synchronization of the bursting dynamics in human cardiac organoids through their entire organogenesis and maturation. Second, I will discuss a general concept of genetically-targeted functional assembly in tissue--in this case through a convergence of protein engineering and polymer chemistry that genetically instructs specific living neurons to guide chemical synthesis of conductive polymers onto the plasma membrane. Conductive polymers were assembled in vivo at genetically- and subcellularly-targeted locations per design specifications, and were demonstrated to achieve intended functionality in the form of newly-created electrical conduction pathways. Imaging, electrophysiology, and behavioral analyses confirmed that in vivo conductive polymer assembly preserved neuronal viability, remodeled cellular membrane properties, and elicited cell-type-specific behaviors in freely-moving animals. In the end, I will discuss the prospects for future advances in bioelectronics to overcome challenges in neuroscience and cardiology.

4:15 PM SB02.05.07
Understanding Ion Dynamics in Organic Semiconductor by In Situ NMR Spectroscopy Yanting Jin, Evan Wenbo Zhao, Christopher Proctor, George G. Malliaras and Clare Grey; University of Cambridge, United Kingdom

Organic semiconductors are widely applied in bioelectronic devices, such as organic electrochemical transistors (OECT) and ion pump for drug delivery. This is largely due to their mixed electronic/ionic conductivity, which enables strong coupling between these two charge carriers in the bulk of the material. While electronic charge carrier transport in these materials is rather well understood, the transport of ions has not been studied to equal depth. NMR spectroscopy is a powerful nuclei-specific technique that can provide atomic structural information as well as quantitative and dynamic information of the disordered polymer system. Here, we report on the interaction between the sodium ion and the poly(3,4-ethylenedioxythiophene) polymer doped with poly(styrene sulfonate) (PEDOT:PSS) using $^{23}$Na NMR spectroscopy. The structure of PEDOT:PSS is heterogeneous, and it mainly consists of PSS-rich region and PEDOT:PSS nano-domains (known as “pancakes” due to the non-sphere shape revealed by X-ray scattering measurement). We found that Na absorbs in the pancakes gives rise to unique NMR patterns due to the strong quadrupolar interaction between the Na and the polymer. Thus, we are able to distinguish Na in aqueous NaCl solution and Na absorbed in the polymer. Then we selectively monitor the absorption and desorption
of the Na⁺ and Cl⁻ ions in the polymer when it is biased to different voltages, in order to elucidate and quantify the species within the polymer. Lastly, the Na⁺ dynamics (self-diffusion coefficient and ion drift mobility) is probed by pulsed-field gradient NMR. The result suggests a fast Na⁺ mobility in the hydrated polymer with notable anisotropy possibly due to the preferred orientation of the PEDOT:PSS nanodomains. This work demonstrates the application of in-situ NMR to probe ion-polymer interactions and to correlate the microstructure of the polymer to ion mobility, which improves our fundamental understanding of mixed conductors and our ability to optimise the performance of their devices.

Hybrid Scaffolds Based on PEDOT:PSS/Collagen or Carbon Nanotubes for the Next Generation of 3D Cell Culture Janire Saez, Chrysanthi-Maria Moysidou, Donata Iandolo, Charalampos Pitsalidis and Roisin Owens; University of Cambridge, United Kingdom

3D cell cultures in biomimetic environments are finding numerous applications in drug discovery, regenerative medicine, among many other fields. 3D cultures often rely on scaffolds, typically made of polymeric materials, which support cell attachment and favour tissue development. These scaffolds possess certain structural and mechanical properties, such as porosity and stiffness, that mimic the extracellular matrix providing a similar microenvironment to that found in vivo. However, these scaffolds are typically passive, merely providing a templated support. We have been focusing on a synthetic biology approach where we are integrating additional functionality into cell culture scaffolds, by using electroactive scaffolds capable of monitoring cell growth and differentiation. Porous conducting polymer scaffolds made of PEDOT (poly(3,4-ethylenedioxythiophene): PSS were obtained by the freeze-drying method. This method allows the addition of different components to tune mechanical and biochemical properties (e.g., collagen), to enhance conducting properties (e.g., carbon nanotubes), thereby fine-tuning the chemophysical properties of the scaffold to render the system suitable for a variety of biological applications. We demonstrate that these scaffolds support cell growth of a variety of cell and tissue types and that the electroactive properties of the scaffolds can be used to monitor cell growth. Current work is focusing on understanding the role of electrical stimuli on cells growing in the scaffolds, in addition to the typical mechanical and biochemical cues present.

4:45 PM SB02.05.09
Electroconductive Gelatin-Graphene Composite Nanofibrous Scaffolds for Cardiac Tissue Engineering Ebrahim Mostafavi and Thomas J. Webster; Northeastern University, United States

Cardiovascular disease (CVD) is the most leading cause of mortality and morbidity in the USA and costs $300 billion per year. Myocardial infarction (MI or a heart attack) is currently one of the most frequent types of CVD in the world. Among diverse technologies for rebuilding the infarcted myocardium, cardiac patches can adequately and simultaneously meet the biochemical, electrical and mechanical demands of the native heart tissue to promote regeneration following MI. Here, we first engineered a gelatin-based porous scaffold by electrospinning technique. We then incorporated graphene nanofibers (GNFs) to the acellular porous matrices to fabricate a conductive electrospun composite scaffold. The gelatin-graphene fibrous composite scaffolds were engineered by dissolving 10% (w/v) of gelatin from porcine skin into various concentrations of GNFs in the range of 0 to 0.5% (w/v) in hexafluoro-2-propanol (HFIP) and electrospinning of resulting solutions. The effects of GNFs on physical properties (such as mechanical properties, degradation, swelling, surface energy, etc.), electrical conductivity and in vitro cytocompatibility of the scaffolds were evaluated. The results revealed that by increasing the amount of GNFs from 0 to 0.5% there was no significant difference in elongation of the scaffolds, while the tensile modules was increased from 3.2 to 7.02 MPa. Moreover, incorporation of GNFs can bridge the electrically resistant pore walls of the matrices, to support and facilitate the internal electrical interactions between adjacent CMs. Co-cultures of primary
cardiomyocytes isolated form neonatal rats and cardiac fibroblasts grown on gelatin-graphene patches exhibited remarkably better contractile profiles compared to pristine gelatin control, as demonstrated by over expression of the gap junction protein connexin 43. In the next step, some epicardial-secreted factors such as paracrine factors and proteins was incorporated into the conductive patches obtained from the previous stage, with the aim of promoting the myocardial regeneration. It is expected that the integration of conductive GNFs and epicardial factors within 3D scaffolds may improve the therapeutic value of current cardiac patches and will open new avenues for engineering cardiac tissues.

SESSION SB02.06: Poster Session I: Biomedical Sensors, Actuators and Devices

SB02.06.02
Biomaterials of Nylon 6.6 and Trimetaphosphate with Antimicrobial Properties for Dental Applications
Francisco N. Souza Neto¹, Danilo M. dos Santos², Leonardo A. de Morais¹, Thayse Y. Hosida¹, Emerson R. Camargo³, Elisabete Frollini³ and Alberto C. Delbem¹; ¹State university of São Paulo, Brazil; ²University of Sao Paulo, Brazil; ³Federal University of São Carlos, Brazil

Advances in material science during the last decades resulted in a new class of nanocomposite materials through the combination of polymeric matrices and a large number of different nanoparticles. In this context, nylon 6,6 (N6) is one of the most important engineering plastics in biomedical applications and has been investigated as a bone tissue scaffold. Trisodium trimetaphosphate (STMP) can be used as potential candidates for dental applications due to the anticaries action of STMP when present in a biocompatible scaffold as N6. Therefore, the insertion effect of different STMP concentrations in a N6 polymeric matrix was evaluated and correlated to the physicochemical and microbiological properties of nanocomposites. STMP nanoparticles were prepared by mechanical milling for 48h. N6 and its nanocomposites were prepared by electrospinning technique, while, the N6/STMP nanocomposites were processed by adding 2.5, 5 and 10% w/w (TMP:N6). The milling processing reduced the particle size of the STMP powders without affecting its crystalline structure. Particle size was reduced of micrometric to nanometric scale after mechanical milling producing particles with ~70 nm and spherical morphology. The phase structure was analyzed by XPS technique and nuclear magnetic ressonance spectroscopies in solid state. ¹³C NMR all chemical shifts were well resolved and were assigned according to N6. XPS results demonstrated that phosphate groups were bound to C=O groups on N6 by covalent bonds, showing that, STMP was incorporated in N6. The morphology it was analyzed by Scanning Electron Microscopy (SEM) technique. SEM images showed the formation of nanofibers in N6 and its nanocomposites with ~150 nm of thickness for N6 and thickness higher for N6-STMP nanocomposite, showing the presence of STMP homogeneously distributed over the nanofibers. The thermal behavior was analyzed by TGA technique. Thermogravimetry analyses demonstrated improved thermal stability of N6-STMP nanocomposites with higher TMP concentration according to its barrier effect. The mechanical properties were evaluated, and N6-STMP -2.5% nanocomposite presented higher elastic modulus, elongation at rupture and tensile strength, presenting as a potential candidate in dentistry. Additionally, the concentration of the cariostatic agent solution and its microbial effect were positively observed, where the inhibition halos corresponding to Saforide® against S. mutans showed the largest inhibition zone, with 4.18 mm and the nanocomposites were not cytotoxic in the concentrations evaluated. These findings showed a new approach to add STMP nanoparticles by electrospinning in a polymeric matrix, forming stable nanofibers with potential application in dental biomaterials. With this methodology, it was possible with this methodology to insert the STMP nanoparticles in a polymeric matrix and increase the physicochemical properties of the nanocomposites formed.

SB02.06.03
Coaxially Nanostructured Chitosan-Based Nonwovens as a Potential Drug Release Platform for Periodontitis Treatment
Danilo M. dos Santos¹, Paulo A. Chagas¹, Iliáli S. Leite², Natália M. Inada², Sarah R. de Annunzio³, Carla Fontana², Sérgio P. Campana-Filho⁴ and Daniel Correa¹; ¹Embrapa Instrumentação, Brazil; ²University of São Paulo State–UNESP, Brazil; ³University of Sao Paulo, Brazil; ⁴University of Sao Paulo, Brazil
Periodontitis is a chronic dental infection caused by a complex bacterial microbiota that can lead to the progressive destruction of periodontal tissue and loss of teeth. Antimicrobial agents are frequently administrated to prevent/treat bacterial infections in periodontal defects and the development of controlled release drug systems based on nanostructures appears as a promising alternative to enhance the efficiency of such treatment. Here we report the preparation of core-shell nanofibers via coaxial electrospinning by using chitosan as shell layer and poly (vinyl alcohol) (PVA) containing tetracycline hydrochloride (TH) as core layer as a potential system to treat periodontitis. Chitosan samples possessing different average degrees of deacetylation (DD = 82% and 93%) were prepared via ultrasound-assisted deacetylation reaction of β-chitin extracted from squid pens. PVA was chosen because it is a biocompatible, biodegradable and easily electrospinnable polymer, while TH, a broad-spectrum antibiotic presenting activity against both Gram-positive and Gram-negative bacteria, was chosen as model drug. The effects of degree of deacetylation of chitosan and the post-electrospinning genipin crosslinking on physicochemical and biological properties of resulting nonwovens were evaluated. Defect-free and geometrically uniform nanofibers with diameters in the range of 100–300 nm were obtained, and transmission electron microscopy (TEM) revealed the core-shell structures of the produced nanofibers. The mechanical properties and stability of nonwovens in aqueous medium were greatly improved by genipin-crosslinking. As a consequence, a sustained release of TH from these structures was possible for 14 days. The degradation rate and the release profile of TH in the presence of lysozyme can be controlled by properly selecting the chitosan to be used in the shell layer of nanofibers, as the degradation and TH release rate was higher the lower the average degree of acetylation of chitosan. Further in vitro antimicrobial activity demonstrated that the cross-linked nonwovens containing TH showed strong activity against bacterial strains associated with periodontal disease. Additionally, the nonwovens did not demonstrate cytotoxicity toward fibroblast (HDFn) cells, indicating the potential of this novel drug delivery platform for periodontitis treatment.

The authors thank the financial support from FAPESP (grant number: 2017/20973-4), CNPq, MCTI-SisNano, FINEP, and Embrapa AgroNano research network.

SB02.06.04
Controlled Drug Release System from PLGA Nanoparticles Responding to NIR Irradiation
Ryo Yamashita, Ha Sita, Minwoo Kim, Ruda Lee and Takuro Niidome; Kumamoto University, Japan

Controlled drug release responding to external stimulus is an important technique to focus area of drug eluting, and to reduce side effect of the drug at normal tissue. Previously, we modified double stranded DNA on gold nanorods that can be heated by near-infrared (NIR) light irradiation. After heating the gold nanorods by NIR irradiation, single stranded DNA was released [1]. Thus, we succeeded in constructing controlled release system responding to NIR irradiation. However, capacity of loading drugs (DNA) was limited on surface of the nanoparticles. Chu et al. prepared gold nanorods-coated PLGA nanoparticles and achieved controlled release of drugs from the nanoparticles responding to NIR [2]. Large amount drugs could be encapsulated in the PLGA as a payload, but disruption of PLGA by the photothermal effect of the gold nanorods was limited on their surface. Here, we prepared PLGA nanoparticles encapsulating drugs in the nanoparticles and the release efficiency was evaluated. Gold nanorods were coated with disulfiram and dispersed in dichloromethane. The gold nanorods and PLGA were mixed in chloroform, and then added to 1% PVA aqueous solution with sonication. After washing resultant nanoparticles by water, gold nanorods-encapsulated in PLGA nanoparticles (GNR-PLGA NPs) were obtained. TEM observation revealed that some gold nanorods were encapsulated in one PLGA nanoparticles. Mean diameter of GNR-PLGA NPs was about 300 nm. When GNR-PLGA NPs dispersion in water were irradiated by continuous wave (CW) near-infrared laser, dispersion temperature increased and destruction of PLGA nanoparticles was observed. In case of pulsed near-infrared laser, the gold nanorods were converted to spherical form in PLGA nanoparticles by strong heating effect by the pulsed near-infrared laser; however, no temperature increase was observed. After changing the shape, the gold nanospheres have little absorption band at NIR region, therefore, they could not be heated anymore. Next, drug release from the gold nanorods-encapsulated PLGA nanoparticles responding to the CW laser was examined. Curcumin as a model drug was encapsulated in the GNR-PLGA NPs. When the nanoparticles were irradiated by CW NIR laser, release of the curcumin was observed, while little release was observed when the laser had been turned off. We constructed the controlled drug release system responding to NIR laser from GNR-PLGA NPs. Heating from inside of PLGA nanoparticles and destruction of the whole nanoparticles will be advantageous in high contrast on/off control of drugs release.

Disposable Ink-jet Printed Interdigitated Electrodes Modified with Biomass-Based Composite for Detecting C Reactive Protein
Beatriz A. Vessalli¹, Aline M. Faria¹, Waldir A. Bizzo² and Talita Mazon²; ¹Center for Information Technology Renato Archer - CTI, Brazil; ²University of Campinas – UNICAMP, Brazil, Brazil

Capacitive biosensors, combined with inexpensive fabrication technologies and low cost materials, may provide simple, sensitive devices for detecting clinically relevant cardiovascular disease biomarkers. Herein, we report a novel platform for detecting the C reactive protein using low-cost ink-jetted interdigitated electrodes modified with biomass-based composite. First, a comb-like interdigitated silver electrode was inked on a Kapton sheet substrate by using an ink jetting Dimatix. Different parameters were tested: tension (20 to 30V), substrate heating temperature (273.15 to 333.15K), distance between nozzle and substrate (100 to 500mm) and number of printed layers (01-15) for obtaining good electrical characteristics. The electrodes were characterized by SEM and resistivity measurements. The best parameters were set 30V, 313.15K, 300mm and 01 layer. A simple synthesis was used to prepare the biomass carbon derived from bamboo and its composite with ZnO nanorods. The biomass carbon derived from bamboo was prepared by direct pyrolysis of the ground sample at 750°C for 4 hours. For preparing its composite, a quantity of biomass carbon derived from bamboo was added a hexamethylenetetramine and zinc nitrate in the proportion 1:1 in a Polytetrafluoroethylene (PTFE) vessel. The PTFE vessel was placed in silicone bath. The solution was stirred and heated at 90°C for 2 h, aiming to promote the growth of ZnO NRs on the surface of the biomass carbon. The samples were characterized by FTIR, RAMAN, EDX and SEM microscopy. The biomass-based composite consisting of bamboo derived biomass carbon with a high degree of graphitization and ZnO nanorods were deposited on silver electrodes to aid in the immobilization of C reactive protein antibody. Immobilization of the anti-C reactive protein was proven by immunofluorescence confocal microscopy and FTIR. The capacitance was measured in a frequency range of 1 Hz to 1 MHz and diverse analyte concentrations. The modification of the electrode with biomass-based composite significantly improved the analytical performance of the immunosensor. The biosensor exhibited high reproducibility and relatively low limit of detection.

SB02.06.07
Efficient and Targeted Delivery of the CRISPR Plasmid Using Carbon Dot Nanoparticles for Nonviral Genome Editing
Juhee Lee and Hyun Jung Chung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Gene therapy is a promising technology for treatment of human diseases due to the versatility and specificity in designing the drug according to the target. The CRISPR/Cas9 system has been greatly attractive as a gene therapeutic since the target gene can be reprogrammed with high efficiency and selectivity. Non-viral gene delivery methods that can effectively transport the carrier to a target site are important for addressing the safety concerns of viral delivery methods, due to their low toxicity. Herein, we used polyethyleneimine carbon dot nanoparticles (PEI-Cdots) to deliver the CRISPR plasmid efficiently to cancer cells. An all-in-one CRISPR plasmid expressing Cas9 and GAL4UAS-luciferase sgRNA was prepared and allowed to form a complex with the PEI-Cdot by electrostatic interaction. The complexes were then functionalized with hyaluronic acid (HA) to stabilize the complexes and specifically target CD44 overexpressed on tumor cells. HA-functionalized PEI-Cdot/plasmid complexes were characterized by dynamic light scattering and zeta potential measurements. Delivery of the HA-functionalized PEI-Cdot/plasmid complexes into tumor cells were investigated by using an all-in-one plasmid to CD44-overexpressing cancer cell lines. The cellular uptake of the complexes and subsequent knockout of the target reporter gene were determined by confocal microscopy.

SB02.06.08
Ni-Free, Built-In Nanotubular Drug Eluting Stents—Experimental and Theoretical Insights
Alaa M. Soliman¹, Sarah A. Tolba¹, Icell M. Sharafeldin¹, Mohamed A. Gepreel² and Nageh K. Allam¹; ¹School of Sciences and Engineering, The American University in Cairo, Egypt; ²Egypt-Japan University for Science and Technology, Egypt

Stents used for cardiovascular applications are composed of three main elements; a metal, polymer coating and the specific drug component. Nickel-based metals and polymer coatings currently used in the stent market have
increased the recurrence of in-stent restenosis and stent failure due to inflammation. In this study, a Ti-8Mn alloy was used to fabricate a nanostructured surface that can be used for drug eluting stents to overcome the hypersensitivity of metals that are currently used in stent making as well as introducing a new built-in nano-drug reservoir instead of polymer coatings. Two different systems were studied: titanium dioxide nanotubes (NTs) and Ti-8Mn oxides NTs. The materials were characterized using field emission electron microscope (FESEM), energy dispersive X-ray spectroscopy (EDX), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), roughness, wettability and surface energy measurements. Nanoindentation was used to evaluate the mechanical properties of the nanotubes as well as their stability. In-vitro cytotoxicity and cell proliferation assays were used to study the effect of the nanotubes on cell viability. Computational insights were also used to test the blood compatibility using band gap model analysis, comparing the band gap of the materials under investigation with that of the fibrinogen, in order to study the possibility of charge transfer that affects the blood clotting mechanism. In addition, the drug loading capacity of the materials was studied using acetyl salicylic acid as a drug model.

**SB02.06.09**

**Novel Nanoprobe-Combined Fluorescence In Situ Hybridization for Detection of Ampicillin-Resistant *E. coli***

Wang Sik Lee1,2 and Jinyoung Jeong1,2; 1Korea Research Institute of Bioscience and Biotechnology, Korea (the Republic of); 2University of Science and Technology, Korea (the Republic of)

Antibiotic-resistant bacteria present a global threat because they are increasingly difficult to treat. Therefore, it is highly important to develop advanced methods for the identification of antibiotic resistance gene in the virulent bacteria. Here, we report the development of novel nanoprobes for fluorescence *in situ* hybridization (FISH) and the application of the nanoprobe for detection of ampicillin-resistant *Escherichia coli* (*E. coli*). The nanoprobe was prepared by the modified sol–gel chemistry and consisted of fluorescent dye-loaded poly(d,l-lactide-co-glycolide) (PLGA) and silica nanoparticles. The synthesized nanoprobe showed strong fluorescent signals and pH stability even under natural light condition. For the double-identification of bacteria species and ampicillin-resistance with a single probe *in situ*, the nanoprobes were conjugated to the two kinds of biotinylated probe DNAs; one for *E. coli*-species specific gene and the other for a drug-resistant gene. By using the nanoprobe-DNA conjugants, we successfully detected the ampicillin-resistant *E. coli* through the FISH technique. We anticipate that the nanoprobe-based FISH method will be employed for the detection of various kinds of pathogenic bacteria, and diagnosis of the emergence of the infectious drug-resistance bacteria.

**SB02.06.10**

**On the Structure of Lipid-Based Nanoparticles for Drug Delivery**

Demi Pink1, Jayne Lawrence2 and Christian Lorenz1; 1King's College London, United Kingdom; 2University of Manchester, United Kingdom

Solid lipid nanoparticles (SLNs) have a crystalline lipid core which is stabilised in solution by interfacial surfactants. They are considered favourable candidates for future drug delivery vehicles as they are capable of storing and release bioactive molecules. However, when stored over time it is thought that the lipids undergo polymorphic transitions which result in the premature expulsion of the drug molecules. To date, significant experimental studies have been conducted with the aim of investigating the physicochemical properties of SLNs, including their long-term stability, but as-of-yet, no molecular scale investigations have been reported on the behaviours that drive SLN formation and their subsequent polymorphic transitions. Using a combination of small angle neutron scattering (SANS) and all-atom molecular dynamics simulations (MD) we have generated a detailed, atomistic description of the internal structure of an SLN formed from the triglyceride, tripalmitin, and the Brij O10 surfactant. In addition to studying the SLN, we have performed further experiments and molecular-dynamic simulations on the formation of a triolein-based liquid lipid nanoparticle (LLN) which is stabilised by the same Brij O10 surfactant. LLNs are, like SLNs, of interest for their potential applications in drug delivery. This has allowed us to characterise the structure of the LLN in a similar manner to the SLN and to compare the two contrasting nanostructures in order to better understand the relationship between a nanoparticle’s internal structure and its role in drug delivery. As well as studying the structure and formation of the nanoparticles, we have conducted molecular dynamics simulations and experiments to characterise and compare the processes involved in the encapsulation and localisation of a steroidal drug, testosterone propionate, by both the SLN and the LLN.

**SB02.06.11**

**Optimisation of 5-Fluorouracil Releasing Graphene Oxide/Chitosan/PVP Electrospun Composites**

Jamie J. Grant1, Suresh C. Pillai1, Tatiana Perova2, Sarah Hehir1, Steven J. Hinder3, Marion McAfee1 and Ailish Breen1;
Electrospun chitosan offers an attractive platform for biomedical applications such as wound healing, drug delivery etc. However, chitosan is an extremely difficult material to electrospin and there are few systematic reports of process optimisation for electrospinning chitosan. Graphene-based materials have potential applications in biomedical engineering, due to its large surface to volume ratio and superior mechanical properties but can show poor biocompatibility. Studies have shown that the biocompatibility of graphene-based materials is improved with the addition of chitosan, which also serves to increase the drug loading capacity of the material.

It is hypothesised that blending graphene oxide (GO) with chitosan (CS) and polyvinylpyrrolidone (PVP) would improve the biocompatibility of the graphene and increase its drug loading capacity, whilst also improving the processability of the CS. The research aimed to investigate if a CS / PVP / GO composite could be electrospun and to test the efficacy of this construct for drug release of an anti-cancer drug.

Solution and process parameters were optimised to perform electrospinning of CS/ PVP and these scaffolds were then characterized. PVP was fixed at 6 wt% concentration while CS concentration varied from 0 wt% to 4 wt%. A solvent system of trifluoroacetic acid and glacial acetic acid in a 9:1 ratio was used. SEM analysis showed that the sample containing 4% CS 6% PVP had a homogenous structure with a mean fibre diameter of 0.653μm. XPS analysis of the surface showed that there were no significant chemical shifts present as CS increased, possibly due to masking of the CS by PVP. Raman and FTIR analysis proved the existence of intermolecular interactions (via H-bonding) between PVP and CS molecules, which increases with the increase of CS content in PVP. This is shown through a meaningful downshift of the carbonyl band in Raman analysis (by nearly 13cm⁻¹) along with the linear increase of the ratio of integrated intensities of CH stretching bands (A₂₉₃₀/A₂₉₈₁) versus CS content in x%CS/6%PVP composites (with x = 0, 1, 2, 3, and 4). In FTIR spectra, the contribution of CS to CS/PVP scaffolds was also confirmed by the less dramatic downshift of a C=O band and by the linear increase of intensity of C-O stretching bands of chitosan at 1034 and 1076 cm⁻¹ with increase of the CS content.

GO was integrated into the system to construct GO/4%CS/6%PVP composites in a concentration range of 0, 0.1, 0.2 and 0.7 wt%. Cell viability testing was performed on A549 cells using a neutral red assay. There was no statistical difference in cell viability between constructs loaded with 0 wt%, 0.1 wt% and 0.2wt% GO. With this, a composition of 0.2%GO/4%CS/6%PVP was chosen for drug studies. The anti-cancer drug 5-Fluorouracil (5-Fu) was loaded in concentrations of 10, 5, 1 and 0.1mg/mL to construct electrospun 5-Fu/0.2%GO/4%CS/6%PVP composites. In this case, a significant decrease in cell viability between 10 mg/mL and 5 mg/ml drug loaded samples compared to control of cells only after 48 hours of exposure was detected. At the same time, no statistical difference was observed between control cells and 1mg/mL and 0.1mg/mL samples, showing the drug released was only significant at higher concentrations and had toxic effects on the cells.

The study concludes that electrospun constructs of 0.2%GO/4%CS/6%PVP were successfully fabricated and showed good biocompatibility; capable of releasing a bioactive drug to cells. Current research is aimed at optimising the drug release system and further assessing cell toxicity.

SB02.06.12
Label-Free Nanosensing Platform for Breast Cancer Exosome Profiling Elvira Fortunato and Rodrigo Martins; CENIMAT|I3N, FCT-UNL, Portugal

Breast cancer accounts for 11.6% of all cancer cases in both genders. Even though several diagnostic techniques have been developed, the mostly used are invasive, complex, time-consuming and can’t guarantee an early diagnosis, something that is key when it comes to the tumour treatment success rate. Exosomes are extracellular vesicles that carry biomolecules from tissues to the peripheral circulation, representing an emerging non-invasive source of markers for early cancer diagnosis. Current techniques for exosomes analysis are frequently complex, time
Raman spectroscopy interest has risen lately due to its non-destructive analysis and little to no sample preparation, while having very low analyte concentration/volume, due to surface enhancement signal possibility (SERS). However, active SERS substrates are needed, and commercially available substrates come with a high cost and low shelf life. In this work, composites of commercial nata de coco to produce bacterial nanocellulose and in situ synthesised silver nanoparticles are tested as SERS substrates, with a low cost and green approach. Enhancement factors (EF) from $10^4$ to $10^5$ were obtained, detecting rhodamine 6G (R6G) concentrations as low as $10^{-11}$ M. Exosome samples coming from MCF-10A (non-tumorigenic breast epithelium) and MDA-MB-231 (breast cancer) cell cultures lineages were tested on the synthesized substrates and the obtained Raman spectra were subjected to statistical Principal Component Analysis (PCA). Combining PCA with Raman intra and inter variability in exosomal samples, data grouping with 95% confidence was possible, serving as a low cost, green and label free diagnosis method, with promising applicability in clinical settings.

SB02.06.13
Paper as a Colorimetric Biosensing Platform for the Detection of Tetracyclines in Milk
Elvira Fortunato and Rodrigo Martins; FCT-UNL, Portugal

Tetracyclines (TCs) are a type of antibiotic that exhibits activity against most gram-positive and gram-negative bacteria. These antibiotics are often added at subtherapeutic levels to the feedstock to act as growth promoters. Since they can cause allergic and toxic reactions and also can lead to an increased antimicrobial resistance, several countries implemented a maximum level of residues for TCs of 0.1 µg/mL in milk, 0.2 µg/mL in cattle muscle, 0.6 µg/mL in cattle liver and 1.2 µg/mL in cattle kidney. The current available methods of TCs detection are based on inhibition tests but most of them are time consuming, expensive and inadequate for field analysis.

In the present work a colorimetric biosensor was developed using paper as platform with gold nanoparticles, for the detection of four types of TCs, presenting an alternative in the performance of point-of-care tests. The construction of the sensors was performed using Lab-on-Paper technology and is based on the synthesis of gold nanoparticles by reducing a gold salt precursor for which tetracyclines constitute the reducing agent itself. Different concentrations of tetracyclines were tested and analyzed using image software, allowing to obtain linear calibration, that correlates the concentration of antibiotics in a range between 0.1 and 10 µg/mL with the color intensity of the gold nanoparticles.

Validation tests of the sensors developed with tetracycline (TC) in milk were also performed., confirming that it is possible to detect this type of antibiotic in pre-treated milk.

SB02.06.14
Polymer-Derivatized Cas9 Conjugates as a Nonviral Genome Editing System for Therapeutic Applications of CRISPR
Yoo Kyung Kang and Hyun Jung Chung; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

The CRISPR-Cas9 system is a very robust platform for genome engineering and has a great impact on applications of gene modulation in various organisms. For their delivery, viral vectors are commonly used which have been shown high efficiency and persistent expression of the edited gene. However, the risk of insertional mutagenesis, immunogenicity and off-target effects, disclosed in clinical trials, poses serious safety concerns. Alternatively, CRISPR-Cas9 can be delivered in the form of ribonucleoprotein (= RNP) to reduce these side effects. Most of the recently reported non-viral delivery methods of Cas9 RNP involve the non-covalent encapsulation in carrier materials, which show limitations due to the cytotoxicity by the need of treating at high doses because of the low packaging efficiency. In this study, we introduce a polymer-derivatized Cas9 by direct covalent modification of the protein with cationic polymer, for subsequent complexation with sgRNA and ssODN. Nano-sized CRISPR complexes (= Cr-Nanocomplex) were successfully formed, in which the functionality of Cas9 endonuclease was well maintained. After characterization of the complex, the Cr-nanocomplex was treated to various types of mammalian cells, which showed enhanced cellular uptake and nuclear localization of both Cas9 and sgRNA compared to the native complex or lipofectamine control. Furthermore, we generated a fluorescent reporter cell line to determine HDR efficiency, through which the Cr-nanocomplex was shown to induce effective and precise genome editing, exhibited by phenotypic changes in the reporter cells. Treatment of the Cr-nanocomplex even at high doses did not cause any cytotoxicity problem, which has been a major hurdle for application of conventional lipid-based formulations. In conclusion, the covalent modification of Cas9 with a cationic polymer shows great potential for the application CRISPR complexes as therapeutics for treating a variety of diseases such as cancer and genetic disorders.
Sub-Nanogram Level Biomarker Detection by Using Nanoporous Microneedle Patches

Ye-eun Kang\textsuperscript{1}, Ye Chan Lee\textsuperscript{1}, Keum-Yong Seong\textsuperscript{1}, Sang-Gu Yim\textsuperscript{1}, Seung Chul Kim\textsuperscript{2}, Beum-Soo An\textsuperscript{1} and Seung Yun Yang\textsuperscript{1};\textsuperscript{1}Pusan National University, Korea (the Republic of);\textsuperscript{2}Pusan National University School of Medicine, Korea (the Republic of)

Minimally invasive microneedle (MN) patches have shown its potential for the rapid detection of biomarkers toward diagnostic point-of-care testing. However, achieving sufficient detection sensitivity for target molecules is a significant challenge. Here we present a highly sensitive detection platform using nanoporous MNs, enabling a rapid capturing of biomarkers present at sub-nanogram level. The uniform nanopore arrays on the MN surface was prepared by a controlled anodization process and then the nanoporous MNs were functionalized by the immobilization of biomarker-specific antibody to detect a target biomarker based on an immunoassay method. The bio-functionalized MN patch showed a rapid capture of estradiol (E2) known as a biomarker of preeclampsia following 1 min incubation time and exhibited a concentration-dependent change in fluorescence intensity over the E2 range of 0.5 to 1000 ng mL\textsuperscript{-1} after treating fluorescent detection antibodies. Additionally, multiple biomarker detection using a single MN patch was investigated to improve the accuracy of preeclampsia diagnosis. The nanoporous MN platform can be employed to detect diverse biomarkers including metabolites and proteins and could be integrated into a handheld system for point-of-care clinical diagnostics.

Synthesis of Highly Sensitive and Biodegradable Soft Foam Sensors for Human Motion and Soft Robotics Applications

Vitor Sencadas\textsuperscript{1,2}, Charbel Tawk\textsuperscript{1,1} and Gursel Alici\textsuperscript{1,1};\textsuperscript{1}University of Wollongong, Australia;\textsuperscript{2}Illawarra Health and Medical Research Institute, Australia

Skin-mountable and wearable electronic devices have potential scientific and technological applications due to their facile integration, interaction with the human body and long-term monitoring capabilities\textsuperscript{1}. Up to now, efforts in the development of polymer-based strain sensors was performed with a synthetic elastomeric matrix like polydimethylsiloxane (PDMS)\textsuperscript{1}, Ecoflex\textsuperscript{2}, Dragon Skin\textsuperscript{1}, or butadiene-styrene copolymers\textsuperscript{3}. These materials are not biodegradable, and their disposal after usage raises critical issues related to the increasing amount of electronic waste generated and its negative impact on the environment. Polyglycerol sebacate (PGS) which is an elastomer obtained from the polycondensation of glycerol and sebacic acid, has tremendous potential for biomedical applications since it is both biodegradable and biocompatible.

In this work, we showed a novel route to manufacture sustainable porous piezoresistive sensors with an outstanding performance by adding multiwall carbon nanotubes (MWCNTs) to the PGS prepolymer, followed by the curing the elastomeric matrix at 120 °C, during 96 h under low pressure (100 mTorr). The sensors before biodegradation reveal high sensibility, with a Gauge Factor (GF) up to –9, very fast response (≤ 3 ms), negligible mechanical and electromechanical hysteresis, reliability and very long lifetime under cycling loading (> 1,200,000 cycles), and a differential pressure sensibility of 34 Pa. Due to their porous structure, they can detect low and high frequency vibrations (up to 300 Hz), small forces (200 mN) covering from the low detection limit of metallic strain gauges up to the large strains characteristic of elastomeric-based nanocomposites. Overall, these characteristics closely match the properties of the human fingertip and hence pave the way towards tactile and compliant sense elements embedded in prosthetic devices.

After biodegradation in a simulated body fluid (SBF) at physiologic conditions (37 C), a loss in the sample weight of 15% was observed after 8 weeks of incubation. While their GF or hysteresis behavior was not dramatically affected, a decrease in the nanocomposite density and an increase in the sample cross-linking was observed. Furthermore, their vibration detection limit decrease from 300 Hz for the as processed sample down to 50 Hz, after one week of incubation in the SBF solution. These sensors presented no detectable cytotoxic effects against normal human skin fibroblasts, revealing the great potential of these sensors for the fabrication of wearable electronics.

Overall, this work demonstrates prospective applications of novel sustainable soft resistive foam sensors that meet the future challenges of soft robotic systems\textsuperscript{4,5}.

References
Graphene quantum dots (GQDs) are 2–3 nm sized nanoparticles that have a hydrophobic 2D graphitic domains with hydrophilic oxygen-containing functional groups along the edges. The carboxyl groups on GQDs can be modified to amine groups through simple EDC/NHS chemistry to be conjugated with many different small molecules. Recently, the application of GQDs as a therapeutic agent has been demonstrated to alleviate Parkinson's disease by degrading pre-existing α-synuclein fibers as well as by preventing its fibrillization. It is also proven that GQDs have negligible long-term toxicity in animal models as they are excreted through urine in a few weeks (D. Kim et al., 2018, *Nat. Nanotechnol.*, 13, 812-818).

On the other hand, kidney disease occurs due to the weakening of the filter function of a glomerulus, and while it can be cured by early diagnosis, a full recovery is almost impossible when CKD (Chronic Kidney Disease) proceeds. When the symptom gets severe, dialysis or even transplantation is required. About 15% of adults in the US are suffering from CKD, and the population has been steadily increasing (National Chronic Kidney Disease Fact Sheet, 2017). When a kidney is injured, it loses tubular cells and to fill in space, an excess amount of ECM (Extracellular Matrix) is synthesized, which results in fibrosis. EMT (Epithelial-Mesenchymal Transition) occurs during fibrosis, and myofibroblasts make more ECM proteins, causing the kidney to become stiff and lose its function. Renal fibrosis is a typical and inevitable histological symptom of CKD.

Herein, we develop a method to employ GQDs as a therapeutic agent to prevent or reduce renal fibrosis. GQDs was treated to human kidney cells at the concentration of 5~200 μg/ml and did not show significant cytotoxicity according to the MTT assay. rTGFβ was added to TECs (Tubular Epithelial Cells) to provoke fibrosis and measured whether GQDs can alleviate this process. After rTGFβ treatment, the level of fibronectin and collagen (I), which are major components of the ECM were increased. When GQDs was treated at 2~10 μg/ml, a decrease in the ECM proteins was observed from the immunofluorescence. The increase in E-cadherin confirmed GQDs' role in preventing cell death. Collagen (I) monomers were incubated for 24 hours with and without GQDs, and thicker collagen (I) fibers were formed when GQDs was treated. GQDs quenched the emission of photoluminescence of collagen (I), showing a physical interaction between the protein and particles.

A UUO (Unilateral Ureteral Obstruction) mouse model was used for generating AKD (Acute Kidney Disease), and GQDs were intravenously injected at the concentration of 20 mg/kg. The level of fibronectin and collagen (IV) were significantly reduced after GQDs treatment, while an increase in E-cadherin was observed. TGFβ, as a key profibrotic factor, is linked with diverse signaling pathways, and we focused on the TGFβ-Smad pathway. Smad2/3 promotes fibrosis by directly binding to the promoter region of collagen and triggers its production. Smad7 is an inhibitory regulator that suppresses TGFβ via negative feedback. GQDs were shown to decrease the level of Smad2/3, and increase Smad7, which correlates with the less formation of the fibrotic region as confirmed by histological staining. Overall, we demonstrate that GQDs can be used as a therapeutic agent for renal fibrosis, which is expected to provide an alternative route to treat CKD patients without pain.
oleylamine. And ligand exchange process via citric acid were performed to yield water soluble nanoparticles under basic environment (pH >7). These synthesized nanoparticles are characterized by UV-Vis-NIR spectroscopy, fluorescence spectroscopy, XRD, TEM, etc. are also heavily relevant in producing stable and uniform hybrid nanoparticles that lack physical impurities. By further optimizing synthesis conditions, such as altering growth temperatures and precursor reagent ratios, functional hybrid magnetic nanoparticles can be obtained for MRI and other multimodal biomedical applications. Correlations between fluorescent lifetime and sizes, compositions, shapes of hybrid nanoparticles have been studied further as well.

*In Situ Nanomechanics of Biomimetic and Biomedical Materials*  
Praveena Manimunda, Douglas D. Stauffer and Asif Syed; Bruker Nano Surfaces, United States

Drug-eluting stents (DES) are favored over bare metal stents due to the low risk of angiographic restenosis. To improve the adhesion strength of drug emitting polymer coatings, surface chemical treatments are often adopted. However, to optimize surface modification, it is important to understand the interface phenomenon and mechanical properties of polymer coatings in a greater detail. Here, a new methodology was adopted where, in situ confocal imaging in combination with nanoDMA and nano-scratch tests were used to determine the mechanical and adhesion strength of polymer coatings on stents that contains pharmacologic agents. Force modulations and real-time contact images are correlated to understand adhesion characteristics. Further, the methodology was extended to characterize the mechanical properties of biomimetic materials.

*Towards the Construction of Strong Physical Hydrogels—Translating Single-Molecule Behaviors to Macroscale Hydrogel Mechanical Properties*  
David S. Knoff and Minkyu Kim; University of Arizona, United States

Artificial protein hydrogels have immense potential as functional biomaterials, incorporating the intrinsic mechanical and bioactive properties of proteins in the polymer network. However, current artificial protein designs are limited in their ability to translate protein nanomechanics to macroscale materials due to inefficient crosslinking density or weak crosslinkers. Chemical crosslinkers are strong but, in general, the lack of specificity or uncontrollable binding kinetics can lead to a spatially inhomogeneous crosslinking density within the polymer network. Physical crosslinkers have specific self-associations with temporary bonds, capable of rearranging in a timescale dependent on their dissociation constants to form a relatively homogeneous network. However, their low rupture strength limits possible applications due its effect on mechanical properties of the material. With many self-oligomerizing proteins that form quaternary structures available in nature, there is great potential for finding physical protein crosslinkers with high affinity and specificity. Streptavidin, well known for having one of the strongest protein-ligand interactions with biotin, is utilized in diverse biotechnology applications ranging from molecular identification to drug delivery. Four streptavidin monomers naturally self-associate with high affinity physical bonds to form a tetramer quaternary structure. Here, we used streptavidin as a strong and specific physical crosslinker to model its effect on the spatial homogeneity and mechanical strength of artificial protein hydrogels. In addition, biochemical methods and single-molecule studies revealed that biotin binding to streptavidin enhances the thermal and mechanical stability of the tetramer structure. We analyzed how the stabilizing effect of biotin on streptavidin tetramers translates from the single-molecule scale to macroscale hydrogel mechanical properties.

*The Application of 3D Printing of Biodegradable Polymers*  
Jane Wang, June-Yo Chen, Yu-Ming Chen and Kaiser A. Villalobos Gorday; National Tsing Hua University, Taiwan
The rising prevalence of organ loss and failure due to acute and long term illnesses, and the lack of available therapies and organs for transplantation has been one of the most critical unmet needs in medicine worldwide. In order to meet this critical need in tissue, the field of tissue engineering has emerged over the last several decade with major efforts focused on the liver, lung, kidney, and heart. However, for any organ regeneration, consistent supply of blood to the targeted regeneration sites is considered the most essential criteria for the initiation as well as continuous regeneration. Most engineered tissues, particularly highly metabolic tissues or those with poor oxygen diffusivity, require an intrinsic microcirculation that reaches to within 100 – 200 m of every cell in the construct. This requirement has spurred the development of angiogenesis induction to create capillary beds. Such approaches are promising but face challenges including the long-term robustness and viability of the vessels and integration with larger vessels in the construct and in the host. As an alternative, this work presents biodegradable scaffolds containing bifurcated microchannels designed to replicate the fluid mechanics and transport properties of organ vasculature through 3D printing of glycerol-based polymers. Vasculatures of varying sizes ranging from aortic to micro-vasculatures are successfully printed and are proven robust for repeated flow. Intrinsic micropatterns from 3D printing are shown to facilitate cell adhesion for vasculature regeneration. This work shows potential in advancing the developments in microfluidics and microfabrication technology enabling the supply of nutrients and waste removal for regenerated tissue.

Rapid Manufacturing of Elastic Biohybrid Tissue-Engineered Heart Valves for Transcatheter Pulmonary Valve Replacement Christophe O. Chantre1,2, Sarah Motta1,2, Huibin Chang1, Luca Cera1, Qihan Liu1, Emanuela Fioretta7, Maximilian Emmert2, Simon Hoerstrup7 and Kevin Kit Parker1; 1Harvard University, United States; 2University of Zurich, Switzerland

Valvular heart disease is one of the leading causes of death worldwide and is projected to increase because of our aging population and the lack of effective treatments. Current heart valve bioprostheses are engineered from chemically-fixed animal tissues and are therefore prone to calcification and structural degeneration over time. To overcome these limitations, tissue-engineered heart valves (TEHVs) based on cell-free polymeric scaffold materials have emerged as a promising replacement alternative, as they are designed to leverage the regenerative and self-remodeling capabilities of the host to regrow a living, native-like tissue. Such cell-free approaches can furthermore rely on predictable and low-complexity manufacturing methods, thus further addressing the cost and variability of cell-based TEHVs. However, despite recent advances in synthetic scaffold manufacturing, there remains a lack of automated and scalable platforms for the rapid production of biomimetic TEHVs. We previously designed a nanofiber rotary jet spinning process capable of rapidly fabricating (<15min) fibrous biohybrid heart valve scaffolds. In a proof-of-concept preclinical acute study, we confirmed TEHVs functionality up to 15 h in the pulmonary valve position of a sheep model. Here, we propose to utilize this spinning process to manufacture in a single-step biohybrid TEHVs comprising physiologically-shaped leaflets using a newly synthesized elastomeric polymer. We demonstrate that controlled material composition, mechanical properties, and biocompatibility of TEHVs are essential to promote in-vitro cellular infiltration, as well as sustain in-vitro valve functionality at physiological pulmonary conditions. Future in-vivo acute and chronic studies will demonstrate the feasibility to implant such newly designed TEHVs via transcatheter approaches in a preclinical animal model and confirm long-term functionality and remodeling.

Aminolysis-Based Biofunctionalization of Polyesters Nanofibers for Tissue Engineering Applications Oliwia Jeznach, Dorota Kolbuk and Pawel Sajkiewicz; Institute of Fundamental Technological Research, Polish Academy of Sciences, Poland

Aliphatic polyesters nanofibrous scaffolds are very attractive from the perspective of tissue regeneration, because they can mimic structure of native extracellular matrix. Moreover, they have good mechanical properties and can degrade inside the body. However, the main problem is unsuitable scaffold-cells interaction, due to lack of
biological cues and scaffold hydrophobicity. Immobilization of cell-adhesive proteins, such as gelatin or fibronectin on the scaffold surface can improve biological response. Aminolysis-based biofunctionalization is one of the effective approaches.

Three different aliphatic polyesters - poly(caprolactone) (PCL), poly(L-lactic acid) (PLLA), and copolymer PLA-PCL (70:30) (PLCL) in a form of electrospun nanofibers were investigated. First step of functionalization – aminolysis was conducted at 30°C using various ethylenediamine/isopropanol solution concentrations at various time to find optimum process parameters. Then, chosen samples were subjected to activation process with glutaraldehyde solution and immobilization of two types of proteins – gelatin and fibronectin. Effectiveness of aminolysis process was characterized via colorimetric ninhydrin test. Amount of proteins on the surface was evaluated using bicinchoninic acid assay (BCA assay). Modified samples were characterized via SEM observations, mechanical testing, WAXS and water contact angle measurements as well as examination of cells-material interaction.

SEM microscopy observations showed diverse impact of aminolysis conditions on nanofibers morphology, for instance reaction with 10% w/v concentration of diamine at 30 min led to unbeneficial PLCL and PLLA nanofibers fragmentation, while the same conditions did not cause any change of morphology of PCL nanofibers. Ninhydrin test results indicated that aminolysis reaction was the most effective in the case of PLLA nanofibers, and the least in the case of PCL nanofibers – difference of one order of magnitude in the amount of free amino groups on the surface for 10% w/v concentration of diamine at 30 min. Our hypothesis is that PCL needs much stronger conditions of reaction, due to its higher crystallinity on the surface of nanofibers, which hinders aminolysis process. Finally it was shown that optimized conditions of aminolysis and protein immobilization led to obtaining nanofibrous scaffolds with suitable mechanical properties and improved material-cells interaction.

This study shows results of optimization of aminolysis-based biofunctionalization process for three types of electrospun nanofibers and confirms that this kind of modification is an effective way to enhance cellular response to nanofibrous scaffold.

AFM Method for Studying the Basal Extracellular Matrix in Apical Polarity Cells Applied to the Osteoblast Collagen Matrix Marcos Penedo1, Kiyo-aki Ishii2 and Takeshi Fukuma1; 1Nano Life Science Institute, Kanazawa University, Japan; 2Kanazawa University Graduate School of Medicine, Japan

The extracellular matrix (ECM) is a macromolecular network existing within all tissues. It provides physical scaffolding for the cell while initiating crucial biochemical and biomechanical processes required for tissue morphogenesis, differentiation and homeostasis. Therefore, the study of the ECM is essential to understand the former processes.

Some cells present apical-basal polarity, where the ECM is mainly created on the basal side of the cell. More specifically, in the case of culturing cells with apical polarity, the ECM lies underneath the cells in direct contact to the substrate, which makes it difficult to access it for direct measurements.

In the last years, atomic force microscopy (AFM) was successfully used to study both cells and their ECM. However, when the ECM is synthetized on the basal part of the cell culture, lying between the substrate and the single or multi-layered cell culture, it becomes challenging to introduce the cantilever tip through the cell layer(s) to measure the ECM underneath the cells.

In order to overcome the above, we have developed a novel technique: culturing cells in a standing thin membrane with holes. First, cells are cultured on one side of the membrane and then, the structure is flipped upside-down to measure the ECM produced on the basal side of the cells and spread through the membrane holes. This technique demonstrates that AFM measurements can be performed on unaltered ECM, without any fixation, chemical or temperature treatment. Using this method, we have successfully studied the collagen matrix produced by osteoblasts.
Exploring the Relationship between Material Geometry and Chemistry on Immune Cell Responses Using Three-Dimension ChemoArchiChips and Two Photon Lithography

Le Ma; University of Nottingham, United Kingdom

Two-photon lithography (2PP) is a method of creating three-dimensional micro-structures on photosensitive materials. One of the key capabilities associated with 2PP is the ability to create sub-micrometer resolution materials with intricate shapes and features that are impossible to create using other fabrication techniques. Here we demonstrate a 2PP based approach to create a wide range of 3D structures and geometries to efficiently screen phagocyte cell responses on a range material chemistries (polymers).

Phagocytic cells (including monocytes, macrophages and neutrophils) play a key role in the response to invading pathogens and particulate matter as well as large foreign body implants such as medical devices. Upon encountering such materials in the body these cells will activate and attempt to engulf the foreign material. The physical dimensions and shape of these structures has been identified to play a key role in the response of these immune cells to engulf and encapsulate foreign materials. Therefore the aim of this study is to develop a high throughput screening approach to efficiently study the effect of surface structure size, geometry and complexity on phagocyte interactions and responses.

Initial data shows that complex biocompatible structures down to the micron level can be created which differentially drive the attachment of human monocytes. Up to 90 different chemistries with different micron-size complex structures can be tested in one batch to investigate the combinatorial effect of 3D geometry, shape, chemistry and architecture on cell fate. Furthermore, cells appear to completely remodel their morphology and cytoskeleton as part of this complex interaction with the 3D structures. Further studies are ongoing to understand the effect of these different geometries and chemistries on other cell processes including; differentiation, cellular polarisation and cytoskeletal changes. This fabrication method is fast and economical making it an ideal tool for developing large screening platforms of polymer surfaces and complex surface structures.

Biomaterial Templated Genetically Tractable 3D Models of the Human Brain

Halil Tekin, Sean Simmons, Beryl Cummings, Linyi Gao, Xian Adiconis, Cynthia C. Hession, Sourav Choudhury, Joshua Z. Levin and Feng Zhang; Broad Institute of Massachusetts Institute of Technology and Harvard, United States

Elucidating genetic mechanisms of brain diseases requires tractable in vitro models of the human brain. Three-dimensional (3D) neural tissues are compelling systems to investigate brain diseases, but it has not been shown before how encapsulating materials of these tissues impact the transcriptome of neurons and how these changes relate to the human brain. Understanding how biomaterials and 3D culturing parameters affect the RNA-signature of in vitro neural tissues can help to develop model systems better approximating the gene expression profiles of the human brain.

Herein, we developed 3D human neural tissues using cells directly derived from human embryonic stem cells and characterized how scaffolding materials and wide variety of 3D culturing conditions impact their transcriptome in comparison to that of the human brain. We demonstrate that altering crosslinking density of composite hydrogels of alginate and basement membrane matrix tunes the transcriptomic correlations to particular regions and stages of the developing human brain. Single-cell sequencing revealed that our 3D tissue system transcriptionally recapitulates cell types in the human brain. Finally, we show that our biomaterial-templated 3D tissue system is compatible with CRISPR gene editing and delivery tools to interrogate disease-associated genes. This study interfacing biomaterials engineering with genomics will support the development of more effective models of neurological diseases.

In Vitro Model of the Human Blood Vessel Wall

Jaroslaw Jacak¹, Sandra Mayr¹, Boris Buchroithner¹, Philipp Mayrhofer¹ and Bianca Buchegger²; ¹University of Applied Sciences, Austria; ²Johannes Kepler Universität Linz, Austria

Tissue engineering is a rapidly growing field during the last decade. Cells within an artificial tissue need structural support and guidance for growth. For this purpose, we fabricate polymeric bio-compatible scaffolds by multi-photon lithography (MPL).
In MPL, a femtosecond-pulsed laser focused into a photosensitive resin solution initializes polymerization solely within the focal volume of the laser beam. Hence, sub-micrometer resolution can be achieved in three dimensions. Recently lateral and axial resolution of MPL of below 200nm and around 500 nm have been demonstrated respectively. Hence, its flexible additive manufacturing performance makes MPL a well suited technique for 3D-structuring of biocompatible materials for tissue scaffolds.

The challenge herein is the development of a photosensitive resin that is biocompatible, mechanically stable and can be structured high writing speed. Herein we demonstrate a 2D and 3D biocompatible scaffolds structured onto cell culture membranes, which can be combined with microfluidics. For biocompatibility testing the scaffolds are seeded with cells. In order to promote cell adhesion, we developed strategies to functionalize the scaffolds with biomolecules like antibodies, DNA-linkers or RGD-peptides. This 3D structured cell scaffold within a microfluidic device are seeded with human endothelial cells models of a blood vessel wall. In the future molecular processes like transportation of bio-microparticles or macromolecules will be addressed with our platform.

Cell-Biomaterial Interface Visualized at the Nanoscale Laura Matino, Paola Scognamiglio, Valentina Mollo and Francesca Santoro; Istituto Italiano di Tecnologia, Italy

Cell instructive biomaterials interact directly with biological systems, modifying their behavior by fine-tuning the crosstalk at cellular level. Cell spreading, polarization and cellular mechanical tension are only few examples of interface dynamics consequences. Great consideration has been given to the role of the cell membrane and the surface tension induced by the topology of the material in contact with it. In this context, many efforts have been focused in the last decade to characterize the cell-membrane interface, at the relevant scale. Beside the standard optical acquisition that allows imaging with major limitations in resolution (~ 100 nm), electron microscopy based-acquisition exceeds that limit. However, high resolution electron microscopy procedures require long specimen preparation processes as well as the imaging and processing of hundreds of specimen sections. Here, we present an advanced microscopy method (scanning electron microscopy/focused ion beam) based on ultra-thin resin plastification which uniquely allows the visualization of the interface between cells and materials with 5-10 nm resolution (1,2,3). This technique allows for the visualization of a region of interest where the cell is in contact with the biomaterial underneath. The use of focused ion beam allows foretching through a variety of materials. In fact, here we will present relevant adhesion process of cells in contact with organic and inorganic materials, pseudo 3D materials (vertical nanostructures) and 3D scaffolds. Our results could give new insights in designing new efficient 3D structures for tissue engineering purpose and their interaction and effect on cellular ultrastructures at the cell-biomaterial interface.

Next Generation Scaffolds—Induced Pluripotent Stem Cell-Derived Matrix for Diabetic Foot Ulcer Treatment Francesco Santarella1,2, Rukmani Sridharan1,2, Milica Marinkovic1,2, Ronaldo do Amaral1,2, Brenton Cavanagh1, Avi Smith3, Fergal J. O'Brien1,2,4, Jonathan Garlick1 and Cathal J. Kearney1,2, 1Royal College of Surgeons, Ireland; 2Trinity College Dublin, Ireland; 3Tufts University, United States; 4Advanced Materials and Bioengineering Research Centre, Ireland

Diabetic foot ulcers (DFU) are chronic non-healing wounds that often lead to lower leg amputations1. The gold standard therapy includes surgical debridement and topical antibiotic treatment. Omnigraft (a tissue engineered...
Human pre- and post-iPSF cells were seeded at 16,000 (low) and 64,000 (high) cells/cm², with the addition of 3D porous scaffolds utilizing the 2D matrix; and finally (4) tested the biological function of the scaffold.

Ascorbic Acid (AA) and Macromolecular Crowders (MMC)) that improve and scale-up production; (3) fabricated we have (1) analysed matrix components in 2D matrices from Pre- and Post-iPSF cells; (2) explored factors (e.g., progressive mineralization of the PDL fibers while preventing the downgrowth of gingival epithelial cells are interface. Enabling remineralization of dentin lesion and promoting the regeneration of acellular cementum by analysis of different collagens (Col1, 3 and 4) revealed that Ficoll did not significantly affect their expression. Together, these results suggest that high density, high AA concentrations and the addition of Ficoll increased matrix production in pre- and post-iPSF cells without affecting its composition. In order to fabricate a functional scaffold, we blended equal amounts of the pre- or post-iPSF derived matrix with additional Collagen 1 and freeze-dried the resulting slurry following previously established protocols. The scaffolds had a porous micro-architecture, held their shape when rehydrated and successfully promoted fibroblast migration and proliferation. Ongoing work is focused on assessing the functional capabilities of post-iPSF scaffolds in vascularization and wound healing assays, with the hypothesis that the foetal-like matrix will promote tissue repair. Together, this study has shown that matrix production from post-iPSF cells can be scaled up with optimized cell density, AA concentration and with the use of MMC to successfully produce sufficient amounts of matrix for fabricating porous free-dried scaffolds towards the treatment of DFUs.

Our results demonstrated that post-iPSF cells produced an increased ratio of COL3/COL1 and increased production of fibronectin and LAMA5 compared to pre-iPSF cells, confirming the formation of a matrix with foetal characteristics, known to promote wound healing.

High AA concentration and high cell density enhanced matrix production from both pre and post-iPSF cells, with a 3 fold increase compared to controls. These culture conditions also increased COL1, COL3, COL4, FN1, and LAMA5 production in post-iPSF cells compared to pre-iPSF cells (p<0.05). Moreover, the amount of GAGs was increased in the post-iPSF cells while the overall amount of collagenous proteins was unchanged.

Macromolecular crowders are known to enhance matrix production by aiding in increased collagen deposition. Accordingly, addition of Ficoll in combination with high concentration of AA significantly increased matrix production and collagen deposition in both pre- and post-iPSF groups after three weeks. Moreover, RT-PCR analysis of different collagens (Col1, 3 and 4) revealed that Ficoll did not significantly affect their expression.

Periodontal disease, periodontitis, is a progressive destruction of periodontium including the gingival tissues, cementum, periodontal ligaments and alveolar bone. It is caused by infections, trauma, orthodontic tooth movement as well as certain systemic and genetic diseases. If left untreated, periodontitis leads to wide range of health problems from early tooth loss to severe systemic infections. Current clinical settings focus on stabilizing diseased tissues by removal of local debridement and conditioning with demineralizing agents. While these treatments generally have a positive effect on healing, they often lead to colonization of epithelial cells resulting in the formation of long junctional epithelium that prevents the regeneration of periodontium. A concerted effort in the past 20+ years has developed guided tissue regeneration strategies using bone grafts, cell sheets, tissue scaffolds, and growth factors. Although partially effective, these approaches have not yet led to predictable outcomes, mainly due to their inability to restore the structure and function of cementum and cementum-periodontal ligament (PDL) interface. Enabling remineralization of dentin lesion and promoting the regeneration of acellular cementum by progressive mineralization of the PDL fibers while preventing the downgrowth of gingival epithelial cells are...
requisites of connective tissue regeneration. In this study, the goal has been to adapt machine learning (ML) tools and high-throughput (HTP) screening methods into functional peptide design platform, first, to derive a set of peptides from periodontium related-proteins to form acellular cementum-like hybrid peptide-mineral complex, and then use these peptides with cell attachment/signaling functions to interface with PDL cells to guide cell attachment, proliferation and differentiation leading to generation of acellular cementum (aC) and aC-PDL junction. Using Amelogenin, the key protein in enamel mineralization, we have reported the development of set of Amelogenin-Derived Peptides (ADPs) with mineralization and hydroxyapatite (HAp) binding properties. In particular, using ADP5, we had previously demonstrated the formation of structurally and functionally integrated mineral layer on dentin and enamel tissues with mechanical properties similar to that of cementum. In addition, attachment and proliferation of PDL cells on cemento-mimetic layer has been demonstrated. Towards regenerating the acellular cementum (aC) and aC-PDL junction, the next steps included identification of protein-derived peptides from cell with signaling functions and incorporate them into the newly formed layer in hetero-functional form chimerized with ADP’s as heterofunctional biomolecular constructs that enable to form hybrid peptide-mineral tissue interface facilitating periodontal tissue regeneration. The preferential attachment and differentiation of PDL cells induced by the hybrid peptide-mineral tissue interface within a mixed culture including gingival epithelial cells, are demonstrated. The outcomes of this study provides a practical and effective approach towards the regeneration of periodontal connective tissues. This work is supported by UW-School of Dentistry Spencer Funds.

Exploiting Peptide Self-Assembly for the Design of Functional Materials for Tissue Engineering Applications
Aline Miller¹ and Alberto Saiani²; ¹Manchester BIOGEL, United Kingdom; ²University of Manchester, United Kingdom

The use of non-covalent self-assembly to construct materials has become a prominent strategy in material science offering practical routes for the construction of increasingly functional materials for a variety of applications ranging from electronic to biotechnology. A variety of molecular building blocks can be used for this purpose, one such block that has attracted considerable attention in the last 20 years is de-novo designed peptides. Peptides offer a number of advantages to the material scientists. The library of 20 natural amino acids offers the ability to play with the intrinsic properties of the peptide such as structure, hydrophobicity, charge and functionality allowing the design of materials with a wide range of properties. Synthetic peptides are chemically fully defined and easy to purify through standard processes. Being build form natural amino acids they result usually in low toxicity and low immune response when used in-vivo and can be degraded and metabolised by the body. Self-assembling peptide-based hydrogels in particular have encountered increasing interest in the recent years as scaffolds for 3D cell culture or for controlled drug delivery. One of the main challenges is the fine control of the mechanical properties of these materials. The bulk properties of hydrogels not only depend on the intrinsic properties of the fibers but also on the network topology formed. In this work we show how fiber–fiber interactions can be manipulated by design to control the final hydrogel network topology and therefore control the final properties of the material. This was achieved by exploiting the design features of β-sheet forming peptides based on hydrophobic and hydrophilic residue alternation and exploiting the ability of the arginine’s guanidine side group to interact with itself and with other amino acid side groups. By designing peptides based on phenylalanine, glutamic acid, lysine, and arginine, we have investigated how fiber association and bundling affect the dynamic shear modulus of hydrogels and how it can be controlled by design [Biomacromolecules, 18, 826–834 (2017)]. Subsequently the fine tuning of the mechanical properties allowed us to design a family of functional hydrogels able to direct cellular behaviour from neurite sprouting of neuronal cells for nerve repair [Advanced Healthcare Materials under review 2019] and co-culture of oesophageal cells for Barrett’s oesophagus treatment [Advanced Functional Materials, 27, 1702424 (2017)] to direct differentiation of mesenchyme stem cells into osteoblasts for bone repair [Journal of Tissue Engineering, 7, 2041731416649789 (2016)].
Nanophotonic materials promise non-invasive, high-fidelity sensing and imaging of biological processes, provided they can exhibit biocompatibility, longevity in dynamic, aqueous environments, and improved targeting capability. Here we present our research developing nanophotonic imaging tools for bacterial identification, cellular mapping, and inter-cellular force visualization. First, we combine Raman spectroscopy and deep learning to accurately classify bacteria by both species and antibiotic resistance in a single step. We design a convolutional neural network (CNN) for spectral data and train it to identify 30 of the most common bacterial strains from single-cell Raman spectra, achieving antibiotic treatment identification accuracies exceeding 99% and species identification accuracies similar to leading mass spectrometry identification techniques. Our combined Raman-CNN system represents a proof-of-concept for rapid, culture-free identification of bacterial isolates and antibiotic resistance. Second, we describe a new technique for high-resolution vibrational spectroscopy in the TEM: electron-and-light-induced stimulated Raman scattering (ELISR). Unlike conventional stimulated Raman measurements, our technique uses a laser source as the pump and the electron beam as the broadband Stokes excitation. A small plasmonic nanoparticle amplifies the local Raman signature, with the spatial resolution determined by the electron beam spot size and the nanoparticle size. We show how this technique can enable molecular mapping at the nanoscale, en-route to an “atlas” of cellular receptors. Finally, we introduce a new class of \textit{in vivo} optical probes to monitor biological forces with high spatial and temporal resolution. Our design is based on upconverting nanoparticles that, when excited in the near-infrared, emit light of a different color and intensity in response to nano-to-microNewton forces. The nanoparticles are sub-30nm in size, do not bleach or photobleach, and can enable deep tissue imaging with minimal tissue autofluorescence. We present the design, synthesis, and characterization of these nanoparticles both in vitro and in vivo, focusing on the forces generated by the roundworm \textit{C. elegans} as it feeds and digests its bacterial food. Chronic cytotoxicity assays are used to confirm biocompatibility. Our force measurements are coupled with electrical measurements of muscle contractions in both wild-type and mutant animals, providing insight into the interplay between mechanical, electrical, and chemical signaling \textit{in vivo}.

**Designing Quantum Dots for \textit{In Vivo} Use—Copper Indium Sulfide as a Test Case**  
Joshua Kays\(^1\), Alexander Saeboe\(^1\), Reyhané Toufanian\(^1\), Danielle Kurant\(^2\) and Allison M. Dennis\(^{1,1}\);  
\(^1\)Boston University, United States; \(^2\)Brigham and Women’s Hospital, United States

Near infrared (NIR) emitting quantum dots (QDs) have long held promise as probes of biological systems due to their brightness, deeper penetration depth, and narrow emission profiles, allowing the tagging and multiplexing of many targets simultaneously. However, after several decades of research, there has been limited translation of QD technology to meet biomedical problems. Two key barriers have hindered their use \textit{in vivo}: the accumulation and persistence of QDs in essential organs over months to years, and the use of toxic materials (e.g. lead, arsenic, cadmium) in traditional QD compositions.

To address the latter barrier, copper indium sulfide (CIS) QDs have emerged in the last decade as a non-toxic alternative to traditional QDs.\(^1\) However, all \textit{in vivo} studies thus far have been confounded by the presence of a zinc sulfide (ZnS) shell,\(^2,3\) which traps the core CIS material by preventing degradation and causing accumulation in vital organs. Additionally, the ZnS shell can act as a mask that hides the toxicity of the core material: in hepatocytes, CdSe cores under irradiation cause clear dose-dependent toxicity, while the same QDs with a ZnS shell cause no such toxicity.\(^4\) This bioaccumulation and masking greatly limits potential for clinical translation: of the \~50 FDA approved nanomedicines in the clinic today, all are biodegradable and clear from vital organs quickly.
For the first time, we assess the biodistribution and toxicity of unshelled CIS in a murine model at 1-day, 7-day, and 1-month time points. We show that bare CIS QDs breakdown quickly, with >75% of the initial dose being cleared by 1 month. Surprisingly, we also demonstrate a significant toxic response to these QDs as measured by organ weight, blood chemistry, and histology, in contrast to previous literature on this system. Specifically, we find that CIS particles induce severe hepatotoxicity and splenotoxicity. We also find that CIS particles alloyed with zinc ions before injections demonstrated significant, but lower, toxicity compared to bare CIS, while also degrading slower in several organs, suggesting that the release rate of ions correlates with increasing toxicity. Finally, we explore a new copper based semiconductor material that fully degrades in under a month without significant toxicity.

Overall, our data suggests a shift in perspective in interfacing QD platforms with biological systems. Firstly, QD cores and shell materials must be tested in vivo separately to truly assess the biocompatibility of the materials. Secondly, intentionally designing QDs to break down into biocompatible ions may be the key to future translation of QD platforms for biomedical challenges.

Artificial-Nose Inspired High Dimensionality Fingerprinting of Biological Samples Using Surface-Enhanced Raman Spectroscopy Nayoung Kim1, Michael R. Thomas1, Mads S. Bergholt1, Isaac J. Pence1, Hyejeong Seong1, Patrick Charchar2, Nevena Todorova2, Anika Nagelkerke1, Alexis Belessiotis-Richards1, David J Payne1, Amy Gelmi1, Irene Yarovsky2 and Molly Stevens1; 1Imperial College London, United Kingdom; 2RMIT University, Australia

Label-free platform diagnostic technologies hold great promise, capitalising upon their independence of target-specific binding structures and the associated burden of their discovery, complex conjugation and production procedures. Among a number of targeting-free sensing technologies, label-free surface-enhanced Raman spectroscopy (SERS) has attracted considerable attention, enabling direct profiling of physicochemical properties of endogenous biomolecules. Despite the promise of sensitive fingerprinting, reliable label-free SERS sensors are infrequently realized for biological samples due in part to the challenges of highly overlapped signatures in complex environments. Here, we present an artificial-nose inspired approach using an array of differently functionalised plasmonic surfaces to achieve increased output-data dimensionality in a label- and wash-free regime. Supported by molecular dynamics simulation, we propose that each self-assembled monolayer can provide a different physicochemical interface that promotes a diverse range of molecular interactions, resulting in modulated SERS signatures. As an artificial-nose-like sensing approach, the value of the increased information was illustrated using cell lysates where we achieved reliable improvements in mean discriminatory accuracy towards 100% with each additional surface functionality. The versatile, label-free artificial-nose based approach lays the groundwork for a broad range of biomedical applications where complex signatures of differing pathologies could be established through unguided compositional fingerprinting.

Photonic Materials for Delivering and Generating Light for Biomedical Applications Seok-Hyun Yun1,2; 1Massachusetts General Hospital, United States; 2Harvard Medical School, United States

Light offers attractive ways to visualize and modulate biological systems. However, due to limited light penetration in tissues, many applications require solutions to deliver and generate light deep in the tissue. Here we present some
of those solutions using biomaterial waveguides, bioluminescence energy transfer, and intracellular lasers.

**4:00 PM SB02.09.05**

**Stretchable Optical Fiber Photometry for Recording Neural Circuit Dynamics** Siyuan Rao, Xinyue Liu, Shaoting Lin, Cindy Shi, Atharva Sahasrabudhe, Xuanhe Zhao and Polina Anikeeva; Massachusetts Institute of Technology, United States

Holistic study of neural dynamics in behaving subjects often demands simultaneous recording of neural activity across multiple organs in the nervous system. However, currently available techniques for the chronic recording of activity of specific neuronal ensembles are unsuitable for mobile regions of the nervous system such as the brain stem or spinal cord due to the rigidity of the probes.

Here we present a stretchable optical photometry platform that allows chronic recording of calcium signals as a proxy for neural activity across multiple regions of the nervous system in freely moving rodents during behavioral assays. We achieved simultaneous photometric readout from genetically identifiable neuronal populations in mice correlated to social interactions over a period of more than 6 months. Furthermore, we integrated microfluidic channels within these stretchable probes to realize chemical perturbation concomitant with optical recording. In targeted regions of the nervous system with high mobility, the stretchable fiber photometry platform provides an extended time window to record neural dynamics underlying complex behavioral phenotypes. We anticipate that the stretchable photometry probes will facilitate investigation of neural circuits across central and peripheral nervous systems in freely moving subjects.

**4:15 PM *SB02.09.06**

**Chemical and Mechanical Interrogation of Biological Systems—And Beyond** Periklis Pantazis; Imperial College London, United Kingdom

In recent years, advances in imaging probes, microscopy techniques and bioinformatics image analysis have markedly expanded the imaging toolbox available to probe biological systems. Apart from conventional phenotypic studies, complex biological systems are increasingly investigated in vivo with improved accuracy in time and space and more detailed quantitative analyses down to the single-cell level (reviewed in1). To get more insight into the elaborate chemical and mechanical dynamics that underlie development and disease progression, my laboratory addresses the growing imaging needs of the biological community by developing assays2, imaging technologies3-5, and reagents6,7 for carrying out imaging with i) high spatiotemporal resolution at the single-cell level and with ii) sensitivities down to individual proteins. Such newly introduced and future imaging tools can then be used as a means of performing qualitative and quantitative imaging in order to mechanistically dissect development, disease progression, and tissue regeneration in vivo.

**4:45 PM SB02.09.07**

**Mapping 2D- and 3D-Distributions of Metal/Metal Oxide Nanoparticles within Cleared Human Ex Vivo Skin Tissues** George J. Touloumes¹, Herdeline Ardon¹, Evan K. Casalino¹, John Zimmerman¹, Christophe O. Chantre¹,
An increasing number of commercial skincare products are being manufactured with engineered nanomaterials (ENMs), prompting a need to fully understand how ENMs in these products interact with their major biodistribution entry route: dermal barriers. Although animal studies show that certain nanomaterials can cross the skin barrier, physiological differences between human and animal skin, such as the lack of sweat glands, limit the translational validity of these results. Current optical microscopy methods have limited capabilities to visualize ENMs within human skin tissues due to the high amount of background light scattering caused by the dense, ubiquitous extracellular matrix (ECM) of the skin. We hypothesized that organic solvent-based tissue clearing (“immunolabeling-enabled three-dimensional imaging of solvent-cleared organs”, or “iDISCO”) would reduce background light scattering from the skin’s ECM to sufficiently improve imaging contrast both for 2D mapping of unlabeled metal oxide ENMs and also 3D mapping of fluorescent nanoparticles. Here, we demonstrate successful mapping of the 2D distribution of label-free TiO$_2$ and ZnO nanoparticles in cleared skin sections using correlated signals from darkfield, brightfield, and confocal microscopy, and micro-spectroscopy. Specifically, hyperspectral microscopy and Raman spectroscopy confirm the identity of label-free ENMs which we mapped within human skin sections. We also present measurements of the 3D distribution of fluorescently labeled Ag nanoparticles in cleared skin biopsies with wounded epidermal layers using light sheet fluorescence microscopy. Overall, our results represent a novel strategy for quantitatively mapping ENM distributions in cleared ex vivo human skin tissue models using multiple image modalities. By improving imaging contrast, we affirm label-free 2D ENM tracking and 3D ENM mapping as promising capabilities for nanotoxicology investigations.

**SESSION SB02.10: Poster Session II: Biomolecular and Polymeric Materials and Computation**

**Computational Design of Dendron-Grafted Soft Materials-Based Nanoparticles**

Akash Banerjee and Meenakshi Dutt; Rutgers, The State University of New Jersey, United States

Many drug delivery strategies demand the need for the adsorption and transport of charged, therapeutic biomolecules. These requirements can be met by nanoparticles (NPs) encompassing multiple molecular species that endow electrostatically-induced interfacial binding of specific biomolecules. We are interested in understanding the role of the architecture and composition of the molecular species on the morphological characteristics of the NPs. We study multicomponent NPs encompassing phospholipids and amphiphiles bearing hyper-branched polyelectrolytes (namely, polyamidoamine (PAMAM) dendrons) via the Molecular Dynamics simulation technique used in conjunction with a coarse-grained force field. We examine the impact of dendron generation and relative concentration on the mechanisms and processes dictating the morphology of NPs. Furthermore, we examine the theory underlying the organization and conformation of the hyper-branched polyelectrolytes.

**Controlling the Shape and Mechanical Stiffness of DNA Origami Nanostructures by Module-Based Design Approaches**

Chanseok Lee, YoungJoo Kim, Jae Young Lee and Do-Nyun Kim; Seoul National University, Korea (the Republic of)

The development of scaffolded DNA nanotechnology has enabled the self-assembly of various 2D and 3D DNA nanostructures with nanometer scale precision. The basic principle of DNA origami is the sequence programmability of multiple DNA strands and uniqueness between them. It uses a long scaffold DNA as a template, and hundreds of staple strands programmed to hybridize with the specific binding locations of the scaffold. By utilizing its excellence in shape design with high precision, a number of design methods based on the lattice-packing or lattice-free rules have been established. By contrast, a method for controlling the mechanical stiffness of the DNA origami structures
has been rarely investigated, although the importance and the demand of it has been increased for their various biological application.

Here we provide two design approaches to effectively control the mechanical stiffness of DNA origami nanostructures. The first method uses stiffness-tunable modules consist of up to 11 staple strands. By revising the staple connectivity within the selected module, the location, stiffness, and included angle of hinges can be controlled precisely. Therefore, it enables the construction of dozens of single- or multiple-hinge structures with the minimized replacement of staple strands. The second method uses multiple engineered defects, consist of one to five-nucleotide (nt)-long single-stranded segments as stiffness design components. Systematic spatial distribution of these local mechanical defects with controlled lengths and positions can weaken the stiffness of the entire structure up to 70% while preserving overall structural integrity. Since our methods shown here are based on the basic principle of scaffolded DNA origami, it is anticipated that they are compatible with existing lattice-based or algorithmic routing shape design rules, as well as commonly used design program (caDNAno) and computational shape prediction platform. Therefore, our module-based stiffness design approaches can be widely adopted to biological application such as intracellular delivery carriers and templates of functional nanomaterials for therapeutics.

This work was supported by the National Research Foundation of Korea (NRF) grants funded by the Korea government (NRF-2017M3D1A1039422 and NRF-2019R1A2C4069541).

Dissipative Particle Dynamics Simulations Reveal Micelle Shrinkage of a Pluronic Polymer upon Encapsulation of Ibuprofen Gokhan Kacar; Trakya University, Turkey

The encapsulation of hydrophobic drugs at the hydrophobic core of a micelle gives superior properties in drug delivery, such as drug biocompatibility, better solubility and longer circulation times. Pluronic micelles are one of the widely used polymeric materials in drug encapsulation processes. In this work, we employ coarse-grained Dissipative Particle Dynamics simulations with the hydrogen bonds added explicitly to study the drug encapsulation property, structure and interactions of Pluronic L64/Ibuprofen combinations at different mixing proportions. The coarse-grained simulations reveal that the computed total drug encapsulation efficiency is around 80%, where the hydrophobic drug Ibuprofen is mainly kept in the hydrophobic core of the micelle. As for the micelle structure, the simulations show a decrease in the micelle size upon encapsulation of the drug in line with the experimental literature. The computed Radial Distribution Functions point out that the micelle shrinkage can be caused by an increased local packing of the hydrophobic-hydrophilic units around each other, and the absence of water molecules inside the micelles when there are drug molecules present in the system. Overall, the coarse-grained DPD simulations predict the structural and drug encapsulation properties of a polymeric system consistent with the experiments, whereby bringing new insights to its molecular understanding in terms of micelle shrinkage upon inclusion of Ibuprofen. The results confirm the promising role of the simulation procedure reported in this work to study the drug encapsulation, molecular structure and interactions of polymeric micelles used as drug delivery materials.

SB02.10.04
Effect of pH on the Initialization of Ca-Deficient Hydroxyapatite to β-Tricalcium Phosphate Nanoparticles—A Route to Low-Temperature Synthesis Feray Bakan1 and Ibrahim B. Misirlioglu2,1; 1Sabanci University SUNUM, Turkey; 2Sabanci University, Turkey

Calcium phosphate (CaP) nanoparticles are preferred in many applications owing to their excellent biocompatibility, bioactivity and chemical affinity towards biological molecules. Stoichiometric or non-stoichiometric hydroxyapatite (HA or CDHA), β-Tricalcium phosphate (β-TCP) and biphasic calcium phosphates (BCP, mixtures of HA and β-TCP in a variety of ratios) are the most widely used CaP compounds. Non-stoichiometric Ca-deficient hydroxyapatite (CDHA) is the main inorganic component of hard tissues and its synthetic forms are extensively utilized in a large spectrum of bio-applications ranging from hard tissue repairment and scaffolds to targeted drug delivery and gene therapy. Among all CaP compounds, β-tricalcium phosphate (β-TCP) exhibits better
biodegradability hence it can be absorbed better and aid in the generation of new hard tissue or effective release of the nanotherapeutic molecules and/or drugs in the targeted tissue. β-TCP is also a forthcoming structure enabling highly effective osteointegration. In synthetic wet-chemical processes, β-TCP cannot be directly precipitated but only be transformed from CDHA at relatively high temperatures (≥900°C) where it apparently gets stabilized irreversibly upon cooling. Low-temperature sintering of β-TCP, on the other hand, is desired for use as a biocompatible coating on alloy-based load bearing implant structures inside the body, acting as the osteointegration agent between the host tissue and the implant. In this work, we report on a procedure to obtain β-TCP phase from CDHA at temperatures as low as 720°C where the transformation already starts. Low calcination temperatures are favored in order to obtain pure β-TCP phase with finer morphology in adapt to natural skeletal tissue. However, whether or not adjusting pH can be an effective means to allow so has partly remained elusive. We, therefore, decided to systematically explore the range of pH that we thought would allow the low-temperature transformation of CDHA to β-TCP. A full transformation of CDHA to β-TCP at 750°C in under 3 hours from Ca++ and PO₄³⁻ precursor solutions prepared under a pH of 5.5 was observed. The lower temperatures and the shorter sintering time reported herein allow for a fine nanostructured morphology along with high crystallinity, a sought outcome for effective osteointegration. The effect of synthesized β-TCP particles on the cell viability of human osteoblast-like cell line MG-63 was also assessed by using MTT colorimetric assay for verifying the biocompability of the obtained nanomaterials. We finally note that such a substantial lowering of the sintering temperature, when used as a coating on metallic implants, also aids in minimizing the high-temperature corrosion of the substrate alloy as most metals are prone to oxidation at elevated temperatures in addition to changing the intended fatigue-resistant microstructure.

SB02.10.05 Enhanced Silver Nanoparticle Synthesis by Recombinant E. coli Cells Transformed with Metallothionein Gene Qunying Yuan, Brittany Batiste, Oluwafolakemi Meroko, Quenland Pogue and Zhigang Xiao; Alabama A&M University, United States

In this study, the metallothionein gene of Candida Albicans was assembled by PCR, inserted into pUC19 vector, and further transformed into E. coli DH5α cells. The capacity of these recombinant E. coli DH5α cells to synthesize silver nanoparticles was tested. Our preliminary data obtained by UV-Vis spectrophotometer and SEM analysis suggested that the metallothionein gene transformed E. coli DH5α cells were able to synthesize silver nanoparticles earlier and faster than DH5α cells transformed with pUC19 vector. The composition and morphology of the nanoparticles will be further characterized using Fourier-transform infrared spectroscopy (FTIR), energy-dispersive X-ray spectroscopy (EDS), and high-resolution transmission electron microscope (HRTEM). The capacity of metallothionein gene transformed bacteria to produce other metallic nanoparticles will be tested. The details of biosynthesis of nanoparticles and the analyzed results on the bio-synthesized metallic nanoparticles will be demonstrated and reported.

SB02.10.06 Multiscale Analysis and Modeling of DNA Origami Nanostructures Jae Young Lee, Chansook Lee, YoungJoo Kim and Do-Nyun Kim; Seoul National University, Korea (the Republic of)

Structural DNA nanotechnology has proposed a bottom-up approach to assemble various complex structures with the nanoscale resolution based on complementary self-assembly principles. DNA origami method is used to design higher order structures by programming complementary base sequences of DNA strands and the inter-helical connectivity between DNA strands. Accordingly, in order to precisely design and analyze DNA nanostructures, it is important to characterize and model the material properties of DNA structural motifs such as base-pair steps, which is the smallest unit of DNA helix, and Holliday-junctions connecting helices. Here, we first quantitatively investigated the sequence-dependent characteristics of DNA structural motifs at the base-sequence level using the molecular dynamics simulation. The atomic fluctuation of structural motifs consisting of base-pairs was reduced to intrinsic configuration and covariance matrices, providing the elastic properties as mechanical rigidities and coupling coefficients. A significant difference in material properties was observed with respect to the base sequences, suggesting that consideration and modeling of the sequence-dependent properties may play a crucial role in designing and analysis of the DNA origami structures. Furthermore, we developed a finite element model that can consider the base level properties of structural motifs driven by molecular dynamics simulation. It was confirmed that the proposed model was in good agreement with the previous experimental or simulation results, suggesting detailed and accurate insights into complex and highly deformable structures. Our study demonstrates the
importance of characterizing material properties of DNA by atomic simulations, and their proper modeling can contribute greatly to the mechanical analysis of DNA nanostructures. This multiscale strategy developed for DNA origami nanostructures could potentially be applied to various biomolecule system, indicating its generalizability.

Single-Chain Atomic Crystals as Extracellular Matrix-Mimicking Material with Exceptional Biocompatibility and Bioactivity Jin Woong Lee1, Sudong Chae1, Jung Heon Lee1,2,3 and Jae-Young Choi1,2; 1Sungkyunkwan University, Korea (the Republic of); 2Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); 3Biomedical Institute for Convergence at SKKU (BICS), Korea (the Republic of)

In this study, Mo3Se3− single-chain atomic crystals (SCACs) with atomically small chain diameters of ∼0.6 nm, large surface areas, and mechanical flexibility were synthesized and investigated as an extracellular matrix (ECM)-mimicking scaffold material for tissue engineering applications. The proliferation of L-929 and MC3T3-E1 cell lines increased up to 268.4 ± 24.4% and 396.2 ± 8.1%, respectively, after 48 h of culturing with Mo3Se3− SCACs. More importantly, this extremely high proliferation was observed when the cells were treated with 200 μg mL−1 of Mo3Se3− SCACs, which is above the cytotoxic concentration of most nanomaterials reported earlier. An ECM-mimicking scaffold film prepared by coating Mo3Se3− SCACs on a glass substrate enabled the cells to adhere to the surface in a highly stretched manner at the initial stage of cell adhesion. Most cells cultured on the ECM-mimicking scaffold film remained alive; in contrast, a substantial number of cells cultured on glass substrates without the Mo3Se3− SCAC coating did not survive. This work not only proves the exceptional biocompatible and bioactive characteristics of the Mo3Se3− SCACs but also suggests that, as an ECM-mimicking scaffold material, Mo3Se3− SCACs can overcome several critical limitations of most other nanomaterials.

Synthesis of Biocompatible Silver Nanoparticles and Nanotoxicity in Aquatic Ecosystems Jousen A. Merced, David Medina-Suarez, Gabriela M. Mercado-Guzman and Sonia J. Bailon Ruiz; University of Puerto Rico in Ponce, United States

Silver nanoparticles (Ag NPs) have unique optical, electrical, and thermal properties and are being incorporated into products that range from photovoltaics to biological and chemical sensors. The new generation of silver nanoparticles brings potential applications for antimicrobial coatings, biomedical devices, molecular diagnostics, photonic devices between others. The production of silver nanoparticles has been increasing worldwide in the nanotechnology industry due to the variety of applications mentioned and are very likely to reach aquatic ecosystems damaging them. Due to their small size and high surface area to volume ratio of NPs, they can strongly interact with life cells and cause damage to tested animals. Based on the mentioned previously, it is necessary to evaluate the silver nanoparticle nanotoxicity in aquatic ecosystems to prevent possible ingestion or transfer to humans. Also, the research will benefit aquatic systems due to less pollution around aquatic organisms. The objectives of this research included: i) production and characterization of stable silver nanoparticles in water, ii) characterizing the optical properties by UV-Vis spectroscopy, morphology by HR-TEM, crystalline structure by X-Ray Diffraction (XRD) and the nature of the surface by Infrared spectroscopy. Additionally, Electron Diffraction and Energy Dispersive X-Ray analyses were also evaluated for Ag NPs. iii) Optimize the synthesis of silver nanoparticles by changing the molar ratio of silver/citrate and, iv) evaluate the toxicity of silver nanoparticles in aquatic organisms, i.e Artemia salina. Results obtained evidenced that AgNPs showed absorption peaks in a range of 410 nm and 440 nm. These peaks are due to the phenomenon called surface plasmon resonance (SPR) that are responsible for a variety of phenomena, including nanoscale optical focusing, negative refraction, and surface-enhanced Raman scattering. Also, the concentration of nanoparticles was dependent of the reaction time. HR-TEM measurements evidenced the spherical form of the nanoparticles and its small size at around 12-14 nm and it was confirmed by XRD. In addition, Electron Diffraction analyses suggested the composition of the nanoparticle, which contained only Ag. The toxicity assays were evaluated using different concentration of Ag NPs and a control test. The effect and cytotoxicity of these nanoparticles were studied in the nauplii state of Artemia salina. During the toxicity assay, it was demonstrated that the Artemia salina was able to uptake silver nanoparticles and store it into

Patterned Amyloid Materials Integrating Robustness and Genetically Programmable Functionality
Yingfeng Li, Ke Li and Chao Zhong; Shanghai Tech, China

The precise manipulation, localization, and assembly of biological and bioinspired molecules into organized structures have greatly promoted material science and biomanufactoring. Further technological innovation calls for new patternable soft materials with the long-sought qualities of environmental tolerance and functional flexibility. Here, we report a Patterned Amyloid Material (PAM) platform for producing hierarchically ordered structures that integrate these material attributes. This platform, combining soft lithography with generic amyloid monomer inks (consisting of genetically engineered biofilm proteins dissolved in hexafluoroisopropanol), along with methanol-assisted curing, enables the spatially controlled deposition and in situ reassembly of amyloid monomers. The resulting patterned structures exhibit spectacular chemical and thermal stability and mechanical robustness under harsh conditions. The PAMs can be programmed for a vast array of multi-level functionalities, including anchoring nanoparticles, enabling diverse fluorescent protein arrays, and serving as self-supporting porous sheets for cellular growth. This PAM platform will not only drive innovation in biomanufacturing but also broaden the applications of patterned soft architectures in optics, electronics, biocatalysis, analytical regents, cell engineering, medicine, and other areas.

Hyaluronic acid-Amphotericin B Nanocomplexes—A Promising Anti-Leishmanial Targeted Drug Delivery System
Ricardo Carvalho1, Catarina Gonçalves2, Ana Isabel Bourbon2, Lorenzo Pastrana2, Pier Parpot3, Ana Tomás4 and Miguel Gama1; 1CEB – Centre of Biological Engineering, University of Minho, Portugal; 2Food Processing group, International Iberian Nanotechnology Laboratory, Portugal; 3Centre of Chemistry, University of Minho, Portugal; 4I3S - Instituto de Investigação e Inovação em Saúde, Universidade do Porto and IBMC - Instituto de Biologia Molecular e Celular, Universidade do Porto, Portugal

Leishmaniasis has been classified as one of the most neglected tropical diseases, causing 50 thousand deaths and 1.5 to 2 million new cases every year, according to the World Health Organization. This disease, promoted by protozoan parasites of the genus Leishmania, has a high incidence affecting 89 countries worldwide. Nowadays, current treatment strategies still rely on the antifungal agent amphotericin B (AmB) but are rather inadequate due to the high prevalence of the disease within low-income population of sub-developed regions, the intracellular location of the parasite and the emergence of parasite resistance. Thus, other strategies have been pursued to improve the therapeutic efficacy and to reduce the toxicity of AmB such as the use of biocompatible polysaccharides as carriers. In this work, a simple and inexpensive production process using hyaluronic acid (HA, 50 kDa) was used in order to develop water-soluble hyaluronic acid-amphotericin B nanocomplex (HA-AmB). HA is the main ligand of CD44 receptor, thus being favorably internalized by macrophages that overexpress this receptor upon infection. Therefore, HA arises as a suitable polysaccharide to target the AmB delivery to the leishmania-infected macrophages. The nanocomplex, obtained by simply processing the mixture of the polysaccharide with the drug in a nanospray dryer (HA-AmB SD), was characterized in terms of size/zeta potential (DLS) and morphology (SEM and Cryo-SEM). Furthermore, an HPLC-MS detection method was optimized and used to determine the AmB content in the nanocomplex. Also, to ascertain the interaction between AmB and the HA, FTIR, DSC and PXRD analysis were performed. Cytotoxic and hemolytic effects were assessed on different cell lines through the resazurin test and in dog’s blood, respectively. Anti-leishmanial activity was assessed in vitro in axenic cultures of Leishmania by resazurin and in infected bone marrow-derived macrophages (BMMΦ) stained with different fluorescent probes using high-content microscopy.

Our results shown that the produced material has a spherical morphology in aqueous solution with a mean hydrodynamic diameter of 318.4 ± 34.7 nm and low polydispersity (0.239 ± 0.02). Moreover, this material that presents an AmB content of 13.56 ± 3.49 %, has a good colloidal stability due to the highly negative surface charge (-39.45 ± 1.12 mV). DSC and PXRD analysis strongly suggested the formation of an amorphous inclusion complex between AmB and the complex polysaccharide chain networks, explaining the high solubility of the drug in water. The in vitro assays showed that compared to free-AmB, the nanocomplex had significantly less cytotoxicity against BMMΦ and HEK293T cell lines, significant less hemolytic effect and inhibited the infection in the Leishmania-infected BMMΦ. Exploratory in vivo assays are being conducted in mice. In conclusion, this work has shown that the hyaluronic acid-AmB nanocomplex is a promising system for the treatment of Leishmaniasis, possessing similar
effects to the free-AmB against Leishmania-infected macrophages and Leishmania axenic cultures, with reduced cytotoxicity. Given the affordability, simplicity, low-toxicity and facile scale up of the developed formulation, the hyaluronic acid-AmB nanocomplex may represent an alternative to the expensive nanoformulations available.

The authors would like to acknowledge the Portuguese Foundation for Science and Technology (FCT) for supporting this study under the scope of the strategic funding of UID/BIO/04469 unit and COMPETE 2020 (POCI-01-0145-FEDER-006684) and BioTecNorte operation (NORTE-01-0145-FEDER-000004) funded by the European Regional Development Fund under the scope of Norte2020 - Programa Operacional Regional do Norte. RNA Delivery via DNA-Inspired Janus Base Nanotubes for Extracellular Matrix Penetration  
Ian Sands, Jinhyung Lee, Wuxia Zhang and Yupeng Chen; University of Connecticut, United States

RNA delivery into deep tissues with dense extracellular matrix (ECM) has been challenging. For example, cartilage is a major barrier for RNA and drug delivery due to its avascular structure, low cell density and strong negative surface charge. Cartilage ECM is comprised of collagens, proteoglycans, and various other noncollagenous proteins with a spacing of 20nm. Conventional nanoparticles are usually spherical with a diameter larger than 50-60nm (after cargo loading). Therefore, they presented limited success for RNA delivery into cartilage. Here, we developed Janus base nanotubes (JBNTs, self-assembled nanotubes inspired from DNA base pairs) to assemble with small RNAs to form nano-rod delivery vehicles (termed as “Nanopieces”). Nanopieces have a diameter of ~20nm (smallest delivery vehicles after cargo loading) and a length of ~100nm. They present a novel breakthrough in ECM penetration due to the reduced size and adjustable characteristics to encourage ECM and intracellular penetration.

JBNTs are comprised of self-assembled supramolecular structures which are further broken down into guanine and cytosine DNA base pairs. The hollow channels formed by these nanotubes are ideal for drug loading and the six-member rosette comprised of hydrogen bonding is essential for its low cytotoxicity profile. By controlled assembly between our nucleic acid cargos (in this case siRNA) with JBNT solution, long segmented Nanopieces are synthesized. They can be further separated via a regulated sonication process. Nanopiece with formulations were assembled and their material properties were studied using DLS and Zeta potential measurements. Their morphological characteristics and distributions were analyzed by TEM (transmission electron microscopy) imaging. The RNA delivery abilities of Nanopieces with different formulations were determined in vitro using human chondrocytes. Nanopiece binding and ECM penetration was also studied in vitro using fluorescence and confocal microscopy. Results of this study provide in-depth characterizations of these Nanopieces along with evaluating their abilities of RNA delivery. Our data also determines how Nanopieces bind with and penetrate into cell ECM to understand their delivery mechanism.
of non-serum media to replace the fetal bovine serum (FBS) containing media, the non-serum media has their limitations including the lower cell activity and adhesion rates.

In order to overcome those limitations, nano-materials coated tissue culture polystyrene (TCPS) plates, which are commercially available, are suggested as a novel lab-ware to improve cell adhesion on culture plate. However, we suggest a compatible alternative, the single-walled carbon nanotube (SWCNT), which is a seamless cylinder comprised of a graphene sheet with diameter of the order of a nanometer and has no toxicity when it is properly functionalized and treated to mammalian cells [3].

The aim of this study is 1) the fabrication and characterization of SWCNT film based scaffolds having an optimal property for ADSC culture in non-serum media and 2) the analysis and evaluation of ADSC adhesion mechanism on the SWCNT film based scaffolds in this culture condition.

Controlled Growth of Bacterial Cellulose Films in Laser Printed Micro-Scaffolds Adriano J. Otuka, Rafael R. Domeneguetti, Debora T. Balogh, Sidney Ribeiro and Cleber Mendonca; 1University of Sao Paulo, Brazil; 2Sao Paulo State University, Brazil

Several materials have been developed to meet the growing demand of the technological applications. For instance, biological systems require functional materials with specific features, such as biocompatibility and non-toxicity. Hybrid materials are good candidates for this purpose because it combines the advantages of organic compounds with those of inorganic components, creating a variety of new materials. In this work, aiming potential applications in biological platforms, we prepare liquid hybrid materials which can be sculpted using laser micromachining systems. The host sample is prepared using equal proportions of a silane compound (3-(trimethoxysilyl) propyl methacrylate) and an acrylate monomer (dipentaerythritol pentaacrylate), mixed with an acylphosphine oxide photoinitiator (ethyl-2,4,6-trimethylbenzoyl phenylphosphinate). To produce these biological platforms we used a Ti:Sapphire laser oscillator, centered at 780 nm, operating at a repetition rate of 86 MHz and delivering 100 fs pulses. The laser beam is focused through a microscope objective (10X, NA=0.25) into the sample and scanned in the x-y direction using a pair of galvanometric mirrors, while in the z direction we can move the sample aided by a motorized stage. The biological viability of the three-dimensional micro-scaffolds fabricated was tested from the growth analyses of prokaryotes organisms. We inoculate the bacteria *Gluconacetobacter xylinus* (ATCC 23760) into the microenvironments, receiving all the necessary conditions for their development. These bacteria are responsible for the production of bacterial cellulose, which has emerged as an interesting candidate to fabricate advanced biomaterials, aiming applications in tissue engineering and drug delivery systems. We evaluate the bacterial cellulose growth daily, for one week. As result, we obtained films with different thickness, depending how long the bacteria were inoculate on the platforms. All formed biofilms were characterized morphologically and structurally by scanning electron microscopy, infrared spectroscopy and Raman spectroscopy. The structure and composition of grown bacterial cellulose in the microenvironments are similar than those grown in macro systems. In addition, the grown biofilm also exhibits a nanofibrous porous network highly moldable, with high strength and low density. The results obtained in this work demonstrate that, in respect to the bacteria *Gluconacetobacter xylinus* (ATCC 23760), the hybrid platforms developed in this work are biocompatibles and non-toxicity. Moreover, the use of these matrices do not restricted to gram-negative bacteria, open new opportunities to studies with others prokaryotes and eukaryotes organisms.

Design Strategies to Control the Mechanical Properties of Tyrosine Photocrosslinked Hydrogels Christopher Camp, Ingrid Peterson, David S. Knoff, Zhaoyinqian Li, Anne Wertheimer and Minkyu Kim; University of Arizona, United States

Chemically crosslinked polymeric hydrogels are promising biomaterial solutions in many tissue engineering applications due to their more permanent structure compared to physically crosslinked gels, but often lack the spatially homogeneous crosslink density of physical hydrogels due to the uneven mixing of gelators. However, photocrosslinked chemical hydrogels can offer improved homogeneity because the solution can be completely
mixed before the gelation is initiated. Much attention has been given to tyrosine photocrosslinking in polymeric hydrogels because tyrosine photocrosslinking is rapid and more specific compared to other protein chemical crosslinking methods, which is especially important for designs that incorporate proteins that are critical for cell or tissue functionalities: specific tyrosine crosslinking reduces unintentional, random crosslinking on the incorporated proteins that can result in the loss of protein functionality. However, thorough studies of tyrosine crosslinking and the design of tyrosine incorporated polymers taking into account parameters such as potentially toxic photoinitiator and catalyst concentrations for biocompatibility, tyrosine spacing, polymer length, and their effects on hydrogel rheology are not available.

We present a systematic study of tris(bipyridine)ruthenium(II) chloride and ammonium persulfate mediated dityrosine crosslinking using a biologically synthesized polypeptide construct with various parameters. Typically, photoinitiators are used in excess in gelation procedures for rapid crosslinking and better mechanical properties, but we optimized the hydrogel formulations and used rheology to show the effects on mechanical properties. In addition, we used biomolecular engineering to show the effects of spacing between tyrosine residues and polymer length on the hydrogel mechanical properties while maintaining the same molarity of tyrosine residues and tyrosine percentage in each construct. We also showed the photocrosslinked chemical hydrogels can be prepared to have no cytotoxicity for up to 7 days when in culture with human primary fibroblasts and low endotoxin levels. This study guides a biomaterial design that maximizes the benefits of dityrosine crosslinking while controlling mechanical properties and limiting the use of photoinitiators for increased biocompatibility.

Effect of Self-Assembled Molecules on Cardiac Differentiation of Induced Pluripotent Stem Cells  
Ozgen Ozturk Oncel1, Carlos Heras-Bautista2, Lokman Uzun3, Deniz Hur4, Kurt Pfannkuche2 and Bora Garipcan1;  
1Bogazici University, Institute of Biomedical Engineering, Turkey; 2University of Cologne, Neurophysiology, Germany; 3Hacettepe University, Department of Chemistry, Turkey; 4Eskisehir Technical University, Department of Chemistry, Turkey

Surface chemistry plays an important role in regulating cellular behavior, in vitro. Recent studies showed that functional groups on biomaterial surfaces regulate cellular adhesion, migration, proliferation and differentiation. Self-assembled molecules (SAMs) form organized structures and with these molecules, desired surface properties can be easily generated. In the present study, we aimed to prepare polydimethylsiloxane (PDMS) substrates in natural myocardium-like stiffness range and investigate the effect of their surface modifications with SAMs, having two functional end groups (-CH3 and –NH2) and different wettability properties, on cardiac differentiation of murine induced pluripotent stem cells (mIPS). PDMS (Sylgard 184) substrates were prepared with different ratios of silicone elastomer base and curing agent (10:1 – 70:1) and spin coated on glass slides. Young’s moduli of substrates were characterized with nanoindentation. In low resolution XPS survey spectra of all unmodified and modified PDMS, four characteristic peaks were found as O1s, C1s, Si2s and Si2p at 533, 286, 155 and 104 eV, respectively. -CH3 functionalization of PDMS substrates lead to a remarkable increase in the carbon peak, due to high carbon content of the molecule, whereas N1s peak appeared after modifications with APTES at 401 eV. WCA analysis showed hydrophobic nature of native and –CH3 modified PDMS (104.1±5 and 112.7±5, respectively) and hydrophilic properties of –NH2 modified PDMS (61.9±4). MTT analysis of mIPS cells on these substrates showed no statistical difference between SAMs modified PDMS. Both modified substrates showed higher viability when compared to native PDMS (p<0.05). Western blot analysis results were given in Fig.1 on day 12 of differentiation. Similar to viability analysis, both functional end groups enhanced cardiac differentiation significantly, when compared to native PDMS. Cardiac marker Troponin-T expressions were higher in hydrophilic -NH2 groups. Conventional SAMs modified PDMS substrates in myocardium-like stiffness range were confirmed to be nontoxic to mIPS cells and also these modifications enhanced cardiac differentiation of mIPS cells on PDMS substrates.
We fabricated an artificial oral mucosa using a fish scale-collagen scaffold for clinical applications of oral mucosa defects. Fish derived collagen is appropriate for human use due to zoonotic-free biomaterial. The intrinsic wavy papillary structure of in vivo oral connective tissues was patterned to the collagen scaffold by soft lithography. The soft lithography mold was fabricated from an initial mold fabricated via Si anisotropic/isotropic etching process with the error less than 5%. The histology of artificial oral mucosa with the fish scale-collagen patterned by soft lithography (150 µm in height and 300 µm in pitch) showed a differentiated stratified epithelial layer, similar to the native oral mucosa. Soft lithography can be applied to fabricate a negative molds to create the micropattern mimicking the intrinsic wavy papillary structure of oral mucosa, suggesting a useful technique for developing the proposed biomimetic artificial oral mucosa.

As a remedy of oral mucosa defects, transplantation of the oral mucosa substitutes has been clinically applied. Although collagen scaffolds derived from animals have been proposed, the use of animal derived-collagen may cause infectious diseases by foreign contaminants. Instead, attention has been paid on fish scale-collagen because there is no risk of disease transmission from fish to human [1]. In addition, previous studies on a skin epithelial regeneration revealed that undulating microstructure of the scaffold enables to create the specific microenvironment for epithelial cells. [2] However, microstructuring of the fish scale-collagen has not been reported. In this study, we applied soft lithography to fabricate an artificial oral mucosa using a fish scale-collagen mimicking the topographical structure between oral mucosa epithelium and the underlying the connective tissue. Our proposed artificial oral mucosa with the micropatterned fish scale-collagen facilitates the regeneration of oral mucosa epithelium in vitro.

The microstructure was designed to obtain the wavy papilla structure of oral connective tissues. [3] A polydimethylsiloxane (PDMS) was used as a material for soft lithography mold. First, a Si initial mold was prepared via anisotropic deep-reactive ion etching with a photore sist mask. Subsequently, Si isotropic wet etching was performed to fabricate the wavy structure. The PDMS was molded after applying a release agent on the initial mold by dip coating. Second, a solution of fish scale-collagen was poured and structured by soft lithography with the PDMS mold. Finally, the artificial oral mucosa was constructed by culturing oral keratinocytes on the micropatterned fish scale-collagen tissue.

Results of scanning electron microscope observation showed that the initial mold was successfully patterned with the error less than 5% from the designed value. This result indicates the anisotropic/isotropic etching process enables to fabricate the undulating microstructure similar to oral connective tissue. Furthermore, it was confirmed the PDMS mold was replicated from the initial mold with the error less than 5%. Moreover, our histological examination of the artificial oral tissue revealed the formation of the stratified epithelial cell layer on top of the micropatterned collagen scaffold. The papillary structure with 150 µm in height and 300 µm in pitch was successfully fabricated. The histology of artificial oral mucosa was similar to an in vivo oral mucosa tissue. Consequently, soft lithography can be a useful technique for developing the proposed biomimetic artificial oral mucosa to create micropatterns mimicking the intrinsic wavy papillary structure of oral mucosa.

surface and topological features of the extracellular matrix and as well as support the formation of new viable tissue. However, there are an excessive variety of scaffolds and some of them improve biochemical properties but lack from mechanical strength. Nowadays, fibrous scaffolds have demonstrated excellent potential due they mimic the in vivo physiology, where cells grow and interact according to the spatial and mechanical conditions provided. Here, we prepared a scaffold that incorporated bioglass nanoparticles into the polymeric matrix of electrospun nanofibers. Bioglass nanoparticles were loaded and studied at different concentrations, to induce osteogenic differentiation of human fetal osteoblastic cells (hFOB). Further, we produced a bio-adhesive scaffold, based on mussel-inspired polydopamine (PDA) coating of bioglass-loaded nanofibers. This scaffold not only enhances cell adhesion but also improve its mechanical strength. The chemical composition and morphology of these hybrid composite scaffolds were characterized using Fourier-Transform Infrared Spectroscopy (FTIR) and Scanning Electron Microscopy (SEM), respectively. SEM micrographs showed highly interconnected pores, a suitable characteristic for cell penetration and showed the PDA coating transition as a function of time. After the fabrication, mechanical tests were performed, and the properties of the scaffolds were evaluated. Immunostaining assays were conducted to study cell adhesion and differentiation of hFOB cells. Our results indicate that our bio-adhesive and bioactive composite could support tissue growth and is proposed as a scaffold for bone tissue regeneration.

Novel Polymeric Fibrous Material Based on Gum Karaya for Biomedical Applications Martina Rihova1, Ahmet Erdem Ince1, Ludek Hromadko1,2, Lucy Vojtova1 and Jan M. Macak1,2; 1Central European Institute of Technology, University of Technology, Czechia; 2University of Pardubice, Czechia

The human skin prevents our bodies against an entry of various microbes. Once the skin is damaged, its infection can occur via anaerobic and aerobic bacteria. The necessary skin wound dressing must fulfil some properties, such as to create a sufficiently moist environment, to prevent further infection, absorb the wound fluids and exudates, to decrease the wound skin necrosis and to prevent the skin against external harsh conditions. Bandages should be elastic, non-antigenic and biocompatible materials. To further increase their healing functions, they are loaded with antimicrobial, antibacterial and anti-inflammatory agents (1, 2). However, these compounds are also present in some biopolymers, such as chitosan and oxyccellulose, which are used in the form of nanofibers for wound covers (2, 3). Biopolymeric nanofibers possess in general a high porosity, large specific surface area, variable pore size, excellent breathability and also biocompatibility (1). The most common technique to produce nanofibers so far has been electrospinning (4). This technique enables synthesis of various nanofibers with diameters in the range of dozens to hundreds of nm. However, it possesses several drawbacks, such low production rate, sensitivity on temperature and humidity, incomplete utilization of spun solutions. In addition, electro spun fibers often have residual electrostatic charge, which renders their handling difficult. More recent spinning method, known as centrifugal spinning (5), uses only centrifugal force, which eliminates drawbacks of electrospinning. The centrifugal spinning also broadens the pool of fibers to allow spinning of even non-conductive materials (polymers). In this work, deacetylated natural polysaccharide Gum Karaya (GK) was used as the main material for the centrifugal spinning. This biocompatible and biodegradable polysaccharide can be prepared into 3D foams of fibrous materials with great prospects in regenerative medicine (6). Fiber blends of Gum Karaya with other biodegradable polymers, such as poly(ethylene oxide) (PEO) and poly(vinyl alcohol) (PVA), were also investigated. Obtained fibers from aqueous blended from GK/PVA and GK/PEO were characterized by various means (Fourier-transformed infrared spectroscopy, scanning electron microscopy and swelling behaviour). Most importantly, they were characterized for biomedical effect using antibacterial testing and commercial skin analyzer. We show that the newly prepared fibers represent very promising material for the skin wound dressing.

The work was supported by Technology Agency of the Czech Republic (project TJ02000329), Ministry of Education, Youth and Sports of the Czech Republic (project LQ1601).

**From Microtissues to Organs-on-Chips—Multi-Scale In Vitro Models for Screening Engineered Nanomaterial Toxicity**

Herdeline Ardona1, John F. Zimmerman1, Feyisayo Eweje1, Seungkuk Ahn1, Blakely O'Connor1, Thomas Grevesse1, Johan Lind1, Karla Rivera1, Dimitrios Bitounis1, Philip Demokritou1 and Kevin Kit Parker1; 1Harvard University, United States; 2Concordia University, Canada; 3Technical University of Denmark, Denmark

While engineered nanomaterials (ENMs) have emerged as important components of various consumer products, human exposure to ENMs has been associated with negative health outcomes, such as cardiovascular diseases. To better understand and quantify the pathophysiological effects of exposure to different ENMs, there is a pressing need to develop in vitro models that faithfully recapitulate the native form and function of cells and tissues. In particular, two platforms developed for screening ENM effects in the cardiovascular space will be presented: 1) micropatterned cell pairs as a minimalistic model of the endothelial barrier; and 2) fiber-based cardiac microphysiological devices for contractile stress measurements. These models allow for a multi-scale assessment of the effects of nano-bio interactions at different stages of ENM biodistribution—from the translocation of ENMs across barrier tissues such as the endothelium, to their delivery towards target tissues such as the myocardium. Geometrically-controlled endothelial cell pair microtissues were produced via protein micropatterning, which allows for a systematic assessment of ENM-induced changes in multiple cellular-level parameters related to vascular barrier integrity. These measurements included changes in cellular morphology, junction protein expression, intercellular gap formation and cytoskeletal network organization upon ENM exposure. On the other hand, our “chip-based” platform can be used for measuring changes in tissue-level cardiac function, such as contractile stress and beat rate, during ENM exposure. Aligned polydopamine (PDA)/polycaprolactone (PCL) nanofibers were used as a tissue scaffold for this device in order to mimic the 3D architecture of cardiac microenvironments under physiological conditions. An instrumented version of this platform with embedded strain sensors will also be presented, which provides a way to continuously and non-invasively monitor the effects of ENM on cardiac tissue contractility at different time points. Together, these next generation in vitro and analytical testing platforms provide physiologically relevant 2D- and 3D-models of ENM exposure routes towards a more comprehensive evaluation of microvascular and cardiac response profiles to different nanomaterials.

**SB02.11.10**

**Endothelial Cell Pairs as a Reductionist Model for Studying the Effects of Engineered Nanomaterials on Vascular Barrier Integrity**

Herdeline Ardona1, Feyisayo Eweje1, John F. Zimmerman1, Blakely O'Connor1, Seungkuk Ahn1, Thomas Grevesse1, Johan Lind1, Karla Rivera1, Dimitrios Bitounis1, Philip Demokritou1 and Kevin Kit Parker1; 1Harvard University, United States; 2Concordia University, Canada

Engineered nanomaterials (ENMs) are being increasingly used in a variety of products due to their unique physicochemical characteristics. However, the potential hazards that ENMs pose to human health are still not fully understood. These materials are delivered to target tissues by following several biodistribution routes across multiple biological tissue barriers, with different microenvironments that vary from one another. Of particular interest is their impact on the vascular endothelium, which is an important selective barrier that regulates the exchange of materials between the blood and tissues throughout the body. Current studies of ENM toxicity towards the endothelium are conducted using endothelial cell monolayers, which are low throughput and not particularly amenable to quantitative image analysis of changes in local structural features upon ENM exposure. To address this issue, we have used a micropatterning technique to isolate endothelial cell pairs as a reductionist model of the vascular barrier. Cell pairs, or two cells with a shared junction, serve as the basic functional repeating unit of a continuous biological tissue such as the vascular endothelium. The micropatterned cell pair in vitro model enables both higher throughput ENM
toxicity studies, as well as the measurement of a series of quantitative parameters, such as changes in cellular structure, junction protein expression, and cytoskeletal network reorganization (e.g., transition from predominantly cortical actin to 24 stress fiber formation), which are all relevant to barrier function. We used the cell pair assay to evaluate the dose-dependent changes in induced by a library of ENMs (Au, Ag, TiO₂, ZnO, CuO, Fe₂O₃, SiO₂, Al₂O₃, and 2 nanocellulose polymorphs) from 10 to 100 μg/mL exposure dosage. The summative ENM-induced changes in these endothelial structural features were then assessed for their correspondence to effects on cellular viability and tissue-level barrier function. We found that endothelial exposure to some of these materials, such as Ag and TiO₂, induce changes with negative implications on barrier function, including increased formation of actin stress fibers, reduced junction protein expression, and increased intercellular gap formation. Here, a similarity index scoring method is also implemented to quantitatively compare the extent by which a cell pair deviates from the unexposed “healthy” phenotype after an acute 24-hour ENM exposure. Collectively, these results demonstrate that our cell pair assay represents a viable new method for standardizing ENM endothelial toxicity screening.

Miguel Gama¹, Elvira Fortunato², Aureliana Sousa³, Carolina Marques², Salomé Leal¹, Sara Silvestre² and Cecília Cristelo¹; ¹Minho University, Portugal; ²New University of Lisbon, Portugal; ³I3S, Portugal

Paper fluidics is based on patterning hydrophilic paper with channels bounded by hydrophobic barriers. Fluids move along channels by capillarity. Several methods are available for patterning paper, with different costs/resolutions. Paper patterning for microfluidics also used the embossing technique to design open-channel microfluidic devices, fabricated by compressing the sheet of paper with the help of 3D plastic printing moulds. These approaches are adopted in this work to develop a multiwell-microplate paper-based microfluidic, aiming the creation of organs-on-chip, combining complexity and miniaturization. Bacterial Cellulose (BC) represents a source of highly pure and biocompatible cellulose, with huge technological potential in many fields - biomedical, composites, textiles, food and cosmetics textiles - but currently still rather underexploited [Gama et al, 2016; Klemm et al, 2018]. This work describes a novel approach towards the development of a nanostructured and multifunctional cellulose-based device for the continuous culture of animal cells and tissues. A multilayered system of modified BC (hydrophobized and electroconductive) was used to assemble the skin-on-chip, a microfluidic platform, using the lab-on-paper technology intended to mimic vascularization, with controlled flow, to introduce external stimuli, such as electrical or mechanical, and to support multicellular growth.

This chip serves a multifactorial purpose, aiming the control of each part that make up the overall complex 3D system, including dynamic control of physical, chemical and gaseous gradients, ensure mimetic vascularization, introduce favourable stimuli and co-culture of skin cells. This model sustains cell growth and allow real time and in a high throughput manner to assess cellular phenomena, such as cell-cell crosstalk, paracrine factor exchange, ECM production, as well as tissue homeostasis in the presence of chemical, mechanical, electrical and biological stimuli, and also kinetics of substance delivery on/through the skin.

BC hydrophobization was achieved using a new strategy for the surface modification of BC through the combination of oxygen plasma deposition and silanization with trichloromethyl silane. The combined use of the two techniques modifies both the surface roughness and energy and therefore maximizes the hydrophobic effect obtained. These modified membranes were characterized by SEM, water contact angle measurements, FTIR-ATR and XPS, and its cytotoxic potential was investigated using both indirect and direct contact studies with cells. Importantly, this surface modification revealed no short-term cytotoxic effects on L929 and hDNFs cells. This material was used for the construction of a BC-based well plate for cell culture, which can be supplied continuously with culture medium in long term studies (ranging from days to weeks), using a two-layered 3D full-thickness skin equivalent consisting of an epidermal and a dermal tissue layer, cultivated in alginate scaffolds, that can be maintained and studied as a skin surrogate on the SkinChip [Maia et al, 2014].

**Investigation of Dental Pulp Stem Cells Differentiation Behaviors on Polybutadiene-Polystyrene Nanopattern Substrate**

Ya-Chen Chuang¹, Meirav Grajower², Ilana Sacolick³, Jessica Hofflich¹, Miriam Rafailovich¹ and Marcia Simon¹; ¹Stony Brook University, United States; ²Yeshiva University High School for Girls, United States; ³Hebrew Academy of the Five Towns and Rockaway, United States

Understanding the triggers of stem cell differentiation furthers the field of tissue engineering and contributes to the applications for implantation and bioprinting. Substrate mechanics and topography effects have been widely studied as factors to trigger stem cell differentiation. In our previous studies, we have shown that monodispersed polybutadiene (PB) is able to form biocompatible thin film with adjustable substrate mechanics depending on film thickness, to which the cells can adhere without additional coatings. A threshold was determined at 2.3 MPa when large amounts of biomineralized deposits were observed after 28 days on substrates with mechanics higher than this value. [1] In this study, we explored the understanding and analyzing how dental pulp stem cells (DPSC) respond to both surface moduli and topography effects in nanoscale. In order to achieve this nanopattern, a mixture of Polybutadiene (PB) and Polystyrene (PS) was used in a 3 to 1 ratio for spin cast. Due to the repulsion between two polymers, phase separated nanopattern was created with mechanics and topography differences on different domains, where PB formed flat and soft film with rounded domain of hard PS forming spikes of ~ 100 nm height. DPSC were cultured onto this substrate and were monitored over 28 days. Through the analysis of the images from the confocal microscopy and SEM at first week, DPSC grew slower on pattern substrate compared to the cells cultured on the pure PB substrate. Furthermore, DPSC appeared to be skinny and elongated, seeming to avoid attaching the spikes of PS on pattern substrates. It suggests that DPSC preferred to attach on PB rather than on PS. The cell moduli were also tested at first week through Atomic Force Microscopy with SMFM mode, where we found three different groups of cell moduli instead of two different moduli for the substrates, indicating that DPSC behaved more complicated in response to external triggers. On day 28, biomineralization were observed by SEM and Raman microscopy, where we found fibers templated mineralized deposits on the substrates. RT-PCR was also performed to determine differentiation pathway with selected markers: Alkaline Phosphatase(ALP), Runt-related transcription factor(Runx), and late markers, Dentin Sialophosphoprotein(DSPP) and Osteocalcin(OCN).

This research explored the combination of substrate mechanics and topography effects for DPSC differentiation, which is important for applying printed scaffolds as dentin/tooth regenerative biomaterials, which surface is rough and the mechanics is not homogeneous.

**3D Patterning of Micro-Nano-Hydrogel Fibres towards Replicating Extracellular Matrix Cues for Tissue Assembly**

Elisabeth Gill, Yan Yan Shery Huang and Iek Man Lei; University of Cambridge, United Kingdom

The extracellular matrix (ECM) environment of tissues permits 3D cell growth in a complex fibrous protein architecture with delicate mechanical properties. Existing biomaterial fabrication techniques struggle to simultaneously attain: micro/nano-scale fibril feature resolution, low fibre stiffness and the 3D organisation crucially provided by the ECM without comprising cell motility. This work utilises 3D printing and low voltage electrospinning patterning synergistically to address these conflicting engineering challenges and act as a minimalist guide for self-directed 3D cell growth. Low voltage electrospinning patterning was adapted as a sequential process on a modified 3D printer. Applied voltage and 3D printed geometry can modulate the suspended behaviour of hydrogel fibres that span between 3D printed support pillars, a parametric study characterised threshold conditions and established a predictive model for patterning suspended fibres. Applications in 2D fibre patterning and 3D cell culture on suspended fibres were explored, including the creation of in vitro glomerulus membrane, and fibre guidance of glioblastoma cell aggregate outgrowth.

Internal Design and Fabrication of Tissue Scaffolds
Ozlem Yasar and Deldrys Gomez Reynoso; City University of New York, United States

In the field of tissue engineering, design and fabrication of precisely patterned, highly porous scaffolds/matrixes are required to guide overall shape of tissue growth and replacement. Although Rapid Prototyping fabrication techniques have been used to fabricate the scaffolds with desired design characteristics, controlling the interior architecture of the scaffolds has been a challenge due to CAD constrains. Moreover, large thick tissue scaffolds have reported limited success primarily due to the inability of cells to survive deep within the scaffold. Without access to adequate nutrients, cells placed deep within the tissue construct die out, leading to non-uniform tissue regeneration. This study aims to overcome these design and fabrication limitations. In this work, research has been expanded to design of scaffolds which have inbuilt micro scale fluidic networks. In this procedure, inbuilt channels serve as material delivery paths to provide oxygen and nutrients for the cells. First of all, negative of a cylindrical shape with a single channel was designed with AutoDesk Inventor and printed with a 3D printer to be used as a mold. Then, 3D printed mold was filled out with Poly(ethylene glycol) diacrylate (PEGDA) which is a photo-curable solution to fabricate the cylindrical hydrogel. Once PEGDA was exposed to UV light with the wavelength of 365nm, polymerization completed in about 3 minutes. After that, the same procedure was repeated for cylinders with two and three channels respectively. Then, their mechanical characterization tests were done to compare the compressive strengths of the scaffolds that has different internal architectures. Our preliminary results indicate that, 3D printing and polymerization techniques can be used together to control the interior architectures as well as the compressive strengths of scaffolds.

Production-Scale Fibronectin Nanofibers Promote Wound Closure and Tissue Repair in a Dermal Mouse Model
Christophe O. Chantre1,2, Patrick Campbell1, Holly Golecki1, Adrian Buganza3,4, Andrew Capulli1, Leila Deravi1,3,4, Stephanie Dauth1, Sean Sheehy1, Jeffrey Paten1, Karl Gledhill5, Yanne Doucet5, Hasan Abaci5, Jeffrey Ruberti4, Simon Hoerstrup2, Angela Christiano1 and Kevin Kit Parker1; 1Harvard University, United States; 2University of Zurich, Switzerland; 3Purdue University, United States; 4Northeastern University, United States; 5Columbia University, United States

Severe wounds result in the formation of stiff and fibrotic scars. During embryogenesis, fetal wounds have however the capacity to restore skin tissues to their native scarless configuration. Although the underlying mechanisms of this process are still incompletely understood, several spatiotemporal differences have been observed in fetal and postnatal wounds that provide unique insight for regenerative scaffolds design. Biomaterials that attempt to recapitulate the biophysical and biochemical properties of fetal skin have accordingly emerged as promising pro-regenerative strategies. The extracellular matrix (ECM) protein fibronectin (Fn) in particular is believed to play a crucial role in directing this regenerative phenotype. Accordingly, Fn has been implicated in numerous wound healing studies, yet remains untested in its fibrillar conformation as found in fetal skin. Here, we show that high extensional and shear strain rates in a nanofiber manufacturing system, termed rotary jet spinning (RJS), can drive high throughput Fn fibrillogenesis, thus producing fibrous scaffolds that are used to promote wound healing. Förster resonance energy transfer first confirmed the fibrillar conformation of Fn attained using RJS. Next, when tested on a full-thickness wound mouse model, Fn nanofiber dressings not only accelerated wound closure, but also improved tissue restoration, recovering dermal and epidermal structures and promoting regeneration of skin appendages and adipose tissue. Together, these results suggest that bioprotein nanofiber fabrication via RJS could set a new paradigm for enhancing wound healing and may thus find use in a variety of regenerative medicine applications.

Muscle Tissue Engineering in Fibrous Gelatin—Implications for Meat Analogs Luke A. MacQueen, Charles Alver, Christophe O. Chantre, Seungkuk Ahn, Luca Cera, Grant Gonzalez, Blakely O'Connor, Daniel Drennan, Michael Peters, Sarah Motta, John F. Zimmerman and Kevin Kit Parker; Harvard University, United States

Bioprocessing applications that derive meat products from animal cell cultures require food-safe culture substrates that support volumetric expansion and maturation of adherent muscle cells. This is important, because meat consists of muscle, fat, and connective tissues proportioned according to tissue source, each containing a diverse array of nutrients produced by constituent cells. Cell types composing meat can be cultured in vitro but production scale-up is limited by the anchorage dependence of these cells, which require attachment to culture substrates for survival, proliferation, and maturation. This requirement is especially stringent for muscle maturation, where alignment of densely packed muscle fibers is observed. For this reason, controlling cell phenotypes in volumetric cultures is a key challenge for adherent cell bioprocessing, including emerging strategies for meat production. Here we demonstrate scalable production of microfibrous gelatin that supports cultured adherent muscle cells derived from cow and rabbit. As gelatin is a natural component of meat, resulting from collagen denaturation during processing and cooking, our extruded gelatin microfibers recapitulated structural and biochemical features of natural muscle tissues. Using immersion rotary jet spinning, a dry-jet wet-spinning process, we produced gelatin fibers at high rates and, depending on process conditions, we tuned fiber diameters to values comparable to natural collagen fibers. To inhibit fiber degradation during cell culture, we crosslinked them either chemically or by co-spinning gelatin with a microbial crosslinking enzyme. To produce meat analogs, we cultured bovine aortic smooth muscle cells and rabbit skeletal muscle myoblasts in gelatin fiber scaffolds, then used immunohistochemical staining to verify that both cell types attached to gelatin fibers and proliferated in scaffold volumes. Short-length gelatin fibers promoted cell aggregation, whereas long fibers promoted aligned muscle tissue formation. Histology, scanning electron microscopy, and mechanical testing demonstrated that cultured muscle lacked the mature contractile architecture observed in natural muscle but recapitulated some of the structural and mechanical features measured in meat products. Our results demonstrated that gelatin fibers provide a suitable scaffold to study muscle cell aggregation or formation of 3D aligned tissues. The general nature of cell adhesion to gelatin, and its recognition as a safe edible material, suggest these scaffolds can support a variety of adherent cell types with utility for food bioprocessing. With further research and development, we believe that muscle bioprocessing and tissue engineering will play increasingly important roles in food science.

A Tissue-Engineered Scale Model of the Heart Ventricle Luke A. MacQueen1,1, Sean Sheehy1,1, Christophe O. Chantre1,1, John F. Zimmerman1,1, Francesco Pasqualini1,1, Xujie Liu2, Josue Goss1,1, Patrick Campbell1,1, Grant Gonzalez1,1, Sung-Jin Park1,1, Andrew Capulli1,1, John Ferrier1,1, Turgut Fettah Kosar1, Lakshminarayanan Mahadevan1,1,1, William Pu3,1 and Kevin Kit Parker1,1,1; 1Harvard University, United States; 2Boston Children’s Hospital, United States

Laboratory studies of the heart use cell and tissue cultures to dissect heart function yet rely on animal models to measure pressure and volume dynamics. Here, we report tissue-engineered scale models of the human left ventricle, made of nanofibrous scaffolds that promote native-like anisotropic myocardial tissue genesis and chamber-level contractile function. Inspired by the fibrous extra-cellular matrix of myocardial heart muscle, we produced ellipsoidal 3D ventricle chambers based on blended polycaprolactone (PCL):gelatin fibers with average fiber diameter ~500 nm and circumferential fiber alignment achieved by collecting fibers on a rotating mandrel. Ventricle scaffold porosity enabled cardiomyocyte infiltration and fiber alignment controlled cardiomyocyte shape and tissue alignment. Incorporating neonatal rat ventricular myocytes or cardiomyocytes derived from human induced pluripotent stem cells, the tissue-engineered ventricles had a diastolic chamber volume of 0.5 mL (comparable to that of the native rat ventricle and approximately 1/250 the size of the human ventricle). We measured tissue coverage and alignment, calcium-transient propagation, and pressure-volume loops in the presence or absence of test compounds. Proof-of-concept structural arrhythmia disease modelling demonstrated that stable, pinned spiral waves could be generated by inflicting geometrically controlled injuries. Moreover, we describe a bioreactor for modular assembly of tissue engineered ventricles with optional valves and ventricular assist, providing a path towards inline automated experiments. The model ventricles can be evaluated with the same assays used in animal models and in
clinical settings, suggesting future use in pre-clinical cardiology where patient-derived models are preferred to animal models.

Rational Design of Twisted DNA Nanostructures through Mechanical Perturbation Programming YoungJoo Kim, Chanseok Lee, Jae Young Lee and Do-Nyun Kim; Seoul National University, Korea (the Republic of)

Through self-assembly of multiple DNA strands with rationally programmed sequences, DNA nanotechnology enabled us to construct various two- or three-dimensional structures at nanoscale with intricate structural shapes such as bending and twist [1, 2]. These structural features have proved their utility in broad fields including optical metamaterials [3], liposome synthesis [4], drug delivery [5], and synthesis of chiral colloidal liquid crystal [6]. The structural features could be achieved by applying engineered mechanical perturbations induced by geometrical mismatches neighboring helices at inter-helix junctions [2]. Contrary to well-developed techniques for curvature control, however, the resolution of twist rate still remains unsatisfactory lagging the development of optimized twisted structures for target functionality.

Here, we present a mechanical perturbation programming approach for fine control of twisted DNA origami nanostructures [7]. To this end, first, we program mechanical perturbation distributions through just determining the location of inserted or deleted base-pairs. This method can make different twist rates without change in the number of insertion or deletion used. For demonstration, a fine adjustment of twist angle in six-helix bundle was achieved with mean increment of 1.77 degree per a 21-base-pair-long unit block. Also, we found that different twist mechanism occurred depending on engineered mechanical perturbation through molecular dynamic simulations. Second, we locally relaxed the strain energy due to mechanical perturbations by introducing short unpaired nucleotides, which can broaden the range of achievable twist rate varying their length or density.

Our approach is expected to contribute to expanding design space of DNA nanostructures with high structural accuracy and accelerating utilization of various benefits derived from structural twist into the DNA nanostructures. Employing our method, for example, one can design plasmonic nanostructures with tailored optical response or macroscopic soft materials with controlled structural and physical properties and resolve unintended distortions of hierarchically assembled DNA nanostructures.

**VSEPRnet—Structure-Based Encoding of Biomolecules for Functionality Prediction**

Siddharth S. Rath¹,¹,¹, Jonathan Francis-Landau¹,¹, Ximing Lu¹,¹, Roman Gutin¹,¹, Jacob Rodriguez¹,¹, Oliver Nakano-Baker¹,¹, Burak B. Ustundag¹,² and Mehmet Sarikaya¹,¹,¹; ¹University of Washington, United States; ²Istanbul Teknik Universitesi, Turkey

Predictively designing peptides for executing materials science and technology relevant functionalities offers great potential to custom design materials systems with desired physicochemical properties at ambient conditions. While the functionality displayed by the biomolecules, such as peptides and proteins, are dependent on their conformation, traditional bioinformatics tools have largely used sequences of letters and implicit assumption of their physicochemical and structural features. Although heuristically interpretable, upon utilizing letter-based encodings in machine learning algorithms for predictively designing functional sequences for engineering applications, implicit physicochemical and structural features are unseen by the data-driven machine agents. Furthermore, transferring learned models from sequence-based molecules to non-sequence based conjugated biomolecules such as peptidolipids, peptidoglycans, peptide-nucleic acids, and even simple sugars and small molecules becomes impossible. Here we explore and demonstrate structure-based encodings inspired from valence shell electron pair repulsion structures (*VSEPR*), functional groups, and signal-processing to train machine learning algorithms that learn latent features which are transferable to other biomolecules of interest. Our results demonstrate clear progress over state-of-the-art similarity matrix approaches, as well as convolutional neural network approaches which are based on strings of letters. Fingerprints developed herein are peptide length invariant and are generalizable to heterogeneous molecules. We demonstrate the capabilities of VSEPRnet in predicting peptide-epitopes as well as peptidolipids binding to major histocompatibility proteins as well as solid binding peptides with binding and surface assembly characteristics. Such models will be applicable in predictively designing drugs, antimicrobial coatings, chimeric constructs and for sensing applications in disease diagnostics. The research is supported by NSF-DMREF program through the grant DMR-1629071 as part of the Materials Genome Initiative.

**Structural DNA Nanotechnology—A Foundation for Programmable Biological Materials**

Eike-Christian Wamhoff, Remi Veneziano, Hyungmin Jun, Tyson Moyer, Sakul Ratanalert, Xiao Wang, Matthew Stone, Darrell J. Irvine and Mark Bathe; Massachusetts Institute of Technology, United States

Structural DNA nanotechnology is the only synthetic materials paradigm that offers the ability to position molecules in nearly arbitrary 3D spatial patterns on the 1 to 100 nanometer scale. While the basic rules for this synthetic materials paradigm have largely been in place for over a decade, only now are computational and synthetic procedures reaching a tipping point at which broad adoption of this materials paradigm by the biological and materials science communities is enabled. For this reason, the next decade should witness an increasing number of researchers engaged in the application of this technology to explore its unique potential in diverse scientific domains. Here, I will begin by presenting advanced computational procedures that now offer the fully automated, top-down geometric design of nearly arbitrary 2D and 3D nanoscale assemblies using DNA. I will also review single-stranded DNA synthesis strategies needed to produce the raw material needed for the fabrication of programmed DNA assemblies, including bacterial, enzymatic, and solid-state approaches. I will then present the application of structural DNA nanotechnology to control the spatial organization of HIV antigens that reveals fundamental aspects of immune cell activation, with potential implications for novel vaccine development.

**9:30 AM SB02.12.04**
DNA nanotechnology allows to create programmable and precisely controlled molecular and nanoscale architectures due to the specific Watson-Crick base-pairing and molecular plasticity. In particular, the superior control over DNA origami structures has opened new venues for biomedical applications such as biosensing and drug delivery. However, protecting the integrity of DNA origami structures in complex biological fluids has remained a major challenge. Here, we demonstrate that hybrid peptoids can decorate 3D DNA origamis and provide an effective protection under different ionic and bio-active conditions. We have investigated two types of hybrid peptoid architectures, “brush” and “block” that were built from positively-charged moieties and oligo-ethylene glycol. We find that the brush-like peptoid design exhibits the best protection of DNA origamis against the damaging factors. Our detailed simulation study reveals the crucial role of electrostatic interaction between peptoids and the DNA backbone for the observed protection effect. Moreover, our systematic study shows that the interactions depend on the peptoid sequence, and that the oligo-ethylene glycol motifs contribute to the rigidity of the duplex DNA. Thus, the architecture of these hybrid peptoids can be optimized for desirable “coating” of DNA origamis. We have applied the developed strategy for creating peptoid-coated origamis that reduce a release of anti-cancer drug, doxorubicin and slow down trypsin digestion of proteins encapsulated in the nanostructure. As a proof of concept, we further show that alkyne-modified peptoids can be conjugated with fluorophores and antibodies. This new approach offers a functional and physiologically stable DNA origami-based for targeted biomedical applications.

Keywords: DNA nanostructure, DNA origami, peptoid, electrostatic interaction, molecular protection, molecular coating, drug release

Self-Assembled Hybrid Peptide-DNA and Protein-DNA Nanostructures Nicholas Stephanopoulos; Arizona State University, United States

The ultimate goal of nanotechnology is to build structures on the 10-100 nm length scale, with control of matter down to the atomic level. In recent years, DNA has emerged as a powerful molecular building block for the construction of nanostructure materials due to the specificity of Watson-Crick pairing. However, DNA nanostructures are limited by the physical and chemical properties of oligonucleotides, which can be a hindrance for biological applications, or for attaining higher resolution placement of synthetic functionality. Proteins and peptides, by contrast, are the natural “language” of biology, possess a greater diversity of chemical groups, and can position materials sub-nanometer precision. In this work, we present the novel integration of two self-assembling polypeptide motifs with DNA nanostructures: 1) the coiled-coil, and 2) hetero-trimeric proteins. We have synthesized peptide-and protein-DNA conjugates with high site-specificity, allowing us to integrate these components with self-assembled DNA structures with high precision. DNA tiles, wireframe cages, and DNA origami were modified in specific locations with one of two heterodimeric coiled coil peptides that bind with sub-nanomolar affinity. The coiled coil interaction drove the hierarchical assembly of these components into dimers and one-dimensional nanofibers, providing an orthogonal assembly “code” to DNA hybridization. In addition, we will demonstrate the assembly of hierarchically-ordered 3D cages comprised of trimeric protein vertices with tunable DNA arms linking them. These materials are the first to our knowledge to integrate synthetic, self-assembling peptide/protein-DNA hybrids with well-established DNA motifs, and demonstrate the potential of protein-DNA nanotechnology.
candidates are solid-binding peptides selected for specific inorganic solids by directed evolution techniques. Specifically, these dodecapeptides have been shown to spontaneously form long-range ordered assemblies on two-dimensional solid surfaces, such as graphene. The conformation of the solid-binding peptide is dynamic in solution and depends on the solution conditions, such as pH, temperature, and salt concentration. As self-assembly of biomolecules relies heavily on the molecular conformation of the monomer, we show that it is possible to direct the formation of the equilibrium assembly structure by controlling the labile nature of the peptides in solution via environmental preconditioning. This environmental selection process entails the molecular tailoring of the aqueous peptides’ conformational states towards specific assembly structures at the solid interface. Based on structural kinetic analyses, molecular dynamics simulations and a scanning probe energetic analysis (dubbed Intrinsic Friction Analysis), our results demonstrate that (i) peptide-graphite binding can be tailored via thermal selection of specific conformational states and that the same binding state can be reached for even altered amino-acid sequences, and, (ii) the resulting assembly structure is specific to the most prominent peptide solution conformations. That the thermally selected solution conformation persists upon adsorption will be illustrated with a rational redesigned peptide sequence. Based on these findings, environmental processing of biomolecules may allow for the bottom-up fabrication of active bio-nano interfaces for multifarious applications from bioelectronic devices, biosensors, biomolecular fuel cells, to logic switches. The research was supported by NSF-DMREF program through the grant DMR-1629071 as part of the Materials Genome Initiative.

10:45 AM SB02.12.07 Sugar-Derived poly(D-glucose carbonate)s Block Copolymer Solution Assembly for Functional Nanostructures Jee Young Lee1, Daniel Beltran-Vellegas1, Yue Song2, Karen L. Wooley2, Arthi Jayaraman1 and Darrin J. Pochan1; 1University of Delaware, United States; 2Texas A&M University, United States

Designing the new sugar-derived poly(D-glucose carbonate)s (PGC) is motivated by a need to develop sustainable materials in response to a long-term environmental impact of traditional petroleum-based polymers. A recent work on the self-assembly of glucose-based molecules demonstrates they can assemble into various nanostructures including micelles, nanofibers and vesicles with tunable size and surface charge. Motivated by their potential for building blocks for functional nanostructures, in this work, PGC amphiphilic block copolymers (BCP) with targeted block compositions, chain lengths and side chain chemistries (cationic and anionic) are synthesized by organocatalyzed ROP and assembled into various nanostructures for an in-depth characterization. Their assembly behavior in water is investigated by developing CREASE, an algorithm that reverse-engineers assembled micelle structures based on calculated micelle features (e.g., aggregation number, core size, corona chain structure) from the experimental small-angle neutron scattering (SANS) intensity profile. We further explore the assembly behavior of PGCs using a range of solvent environment (e.g., solvent compositions and pH variation). We find that the PGC BCPs display a unique chain packing that is dependent on the degree of side chain ionization and can transition from micellar to fibrous nanostructures. These findings allow us to discover a variety of robust nanostructures that can be achieved by non-traditional polymers and their potential to be used in various scientific disciplines.

11:00 AM SB02.12.08 Peptide Materials Design via a Hybrid Computational Approach Srinivas Mushnoori, Kassandra Schmidt, Ethan Zang and Meenakshi Dutt; Rutgers, The State University of New Jersey, United States

The area of peptide-based materials has seen a recent surge in interest due to its wide range of potential applications including targeted drug delivery, cancer treatment, tissue engineering, nanoelectronics and batteries. The 20 amino acids, the building blocks of peptides, yields an enormous molecular parameter space which can be used to design peptides with a wide variety of sequences. A fundamental understanding of the impact of peptide sequence on the structure-activity relation of these biological materials will accelerate their development and use, thereby advancing diverse disciplines. We use a hybrid computational approach, which integrates molecular simulations with analytical techniques, advanced sampling and computing tools, to study and develop new biological materials with desired sequence-structure-activity properties in a more time- and cost-efficient way. The biological materials are formed via the self-assembly of amphiphilic ultrashort peptides encompassing aromatic amino acids (namely, diphenylalanine and phenylalanine-asparagine-phenylalanine). The extended spatiotemporal scales connecting molecules to materials is addressed via the use of coarse-grained representations of the molecular species (S. Mushnoori, et al Organic & Biomolecular Chemistry 2018, 16, 2499). The dynamics underlying the self-assembly of these peptides is resolved via the classical Molecular Dynamics simulation method.
11:15 AM SB02.12.09  
**Self-Assembly of Single Random Heteropolymers** Shayna Hilburg and Alfredo Alexander-Katz; Massachusetts Institute of Technology, United States

With inspiration from proteins, we investigate synthetic random heteropolymers through molecular dynamics simulations. We explore the behavior of single macromolecular chains and can relate the impact that monomeric chemistry and sequence have on their morphologies to protein folding. Examination of globule formation and the resulting conformations illuminate how the chains may interact and enable random heteropolymer multifunctionality which has been experimentally shown. By emulating the heterogeneity seen on the surfaces of some biological proteins, hydrophobic and hydrophilic polymer segments create a rich energy landscape, allowing for a variety of dynamic conformations and enabling its unique behavior.

**Coarse-Grained Model of DNA Translocation in Nano-Fluidic Channels** Giovanna Bucci¹,², Karim Gadelrab¹, Christopher Johnson¹ and Alfredo Alexander-Katz²; ¹Bosch Research Center, United States; ²Massachusetts Institute of Technology, United States

There is great potential for genome sequencing to enhance patient care through improved diagnostic sensitivity and more precise therapeutic targeting [1]. To maximize this potential, DNA-sequencing technologies need to be optimized and adapted to clinical requirements. Nano-channel analysis is one of the emerging strategies for non-optical DNA sequencing [2-5]. Each constituent nucleobase is identified via measuring the transverse tunneling current as a single DNA molecule approaches measuring electrodes. Accuracy and throughput are still limited by insufficient control over DNA elongation and transport dynamics. We employ a coarse-grained molecular model, as a robust framework for the simulation of biopolymer dynamics. Our computational model serves as an essential tool for the optimal design of nano-channel platforms offering high-resolution DNA analysis.

The model implementation is targeted towards predicting the degree of linearization of confined DNA molecules, and simulating the DNA uncoiling and entering the nano-channel. Nano-confinement opens the possibility of linearizing much longer DNA molecules that is currently possible. To uniformly stretch DNA chains, the dimensions of nano-fluidic structures should be smaller than the persistence length. (e.g, about 50nm for double stranded DNA in dilute solutions) [6, 7]. Channel size reduction introduces added challenges of DNA loading and fabrication cost. Mediated by channel characteristics and buffer concentration we investigate strategies of micro- and nano-confinement to improve DNA stretching.

In addition to the geometric aspects of sequencing DNA under confinement, controlling DNA electrophoresis is essential to acquiring a clear signal from the sensing device. The frequency of DNA treading can be increased by applying larger voltages. However, this approach can result in DNA transport velocity exceeding the sensor’s sampling rate. Our multiscale approach, combining continuum and coarse-grained models, is informative of the driving forces interplay at various scales. This allows for new design concepts to be numerically studied for feasibility. One strategy to facilitate the transition from a high to a low entropy state consists of introducing structures that provide multiple pathways of increasing confinement for the DNA to unravel [8]. Our systematic study reveals how to design the geometry and applied bias to realize shallow free energy paths for the loading of DNA molecules.

Self-Assembly of Synthetic Collagen and Silk Bio-Composite System for Biomaterial Applications—A Molecular Modeling Investigation

Atul Rawal¹², Kristen L. Rhinehardt¹² and Ram V. Mohan¹²; ¹North Carolina Agricultural & Technical State University, United States; ²Joint School of Nanoscience & Nanoengineering, United States

Bio-composite materials with optimal mechanical and structural properties and capability of cell differentiation are crucial for tissue engineering. Synthetic collagen proteins with lengths of approximately 10 nanometers, along with natural spider silk proteins provide an opportunity for development of an optimal biomaterial for scaffolding applications in tissue engineering. This combines unique mechanical, structural and biological properties of two of the nature’s best polymer proteins. In the present work, we study the binding capability of these proteins at a molecular level via molecular dynamics modeling. Spider silk and synthetic collagen protein molecular models in biophysical saline conditions under standard pressure and temperature are investigated to understand if natural binding occurs between the two without any other external factors. An initial minimum separation of 10 angstroms between the proteins was used. Binding was observed between the two proteins throughout the dynamic simulation. Molecular dynamics simulations are performed for a minimum of 100 nanoseconds for all systems. The radius of gyration and minimum distance between the proteins shows a decreasing separation between the two proteins until a stable distance of 2.5 nanometers and 0.2 nanometers respectively, is achieved. Binding is further identified by binding observed between the proteins via formation of strong and stable hydrogen bonds. A hydrogen bond between collagen Proline-31 and silk Serine-96 was observed to be the most stable and frequent bond between the single collagen and silk system. Results clearly indicate a self assembly behaviour of these two systems illustrating their potential as a biomaterial for tissue engineering.

SESSION SB02.13: Antimicrobial Peptides and Materials

A Series of New Bio-Based Antimicrobial Materials—Poly (3-hydroxybutyric acid) Oligomer and Its Homologues

Ziheng Zhang¹, Jun Li¹, Linlin Ma¹, Xingxing Yang², Bin Fei¹, Polly Leung¹ and Xiaoming Tao¹; ¹Hong Kong Polytechnic University, Hong Kong; ²Hong Kong University, Hong Kong

Bio-based and biocompatible antimicrobial materials have many advantages in term of environmental protection and sustainable development, comparing to common inorganic and organic antimicrobial materials. It has been found previously that fabrics made from bio-based PLA/PHBV blend filament fibers exhibit broad-spectrum bactericidal effects, with no addition of any antimicrobial agents. After extracting and analyzing the antibacterial components, here we first discover that Poly (3-hydroxybutyric acid) (PHB) oligomers with several degrees of polymerization have potent antibacterial and antifungal properties.

Subsequently, two preparation methods for PHB oligomers are described as extraction from biologically fermented PHB polymers and one-step ring-opening polymerization of β-butyrolactone. The topological application of the synthesized PHB oligomer imparts perdurable antibacterial properties to the non-antibacterial fabric.

Furthermore, to test its potential in medical applications, skin sensitization and infected wounds cure of the mice treated with PHB oligomer were observed. The antimicrobial mechanism of the synthesized PHB was revealed as the leakage of intracellular content, inhibition of protein activity and the change of transmembrane potential.

Finally, the antibacterial properties of homologues of PHB oligomer, including polylactic acid (PLA) oligomer and polyglycolic acid (PGA) oligomer, were also discovered incidentally, which has brought a wider map for the exploration of antibacterial materials.
Antibacterial Zinc Oxide—Morphology and Enzyme-Mimicking Activities
Tao Yang1, Alexander N. Zelikin2 and Rona Chandrawati1; 1The University of New South Wales, Australia; 2Aarhus University, Denmark

Zinc oxide (ZnO) particles possess unique semiconductive, photocatalytic, and antimicrobial properties and they have found widespread applications in drug delivery, tissue engineering, and bioimaging. Morphology plays a major role in modulating the properties and activities of ZnO particles; however, gap in knowledge exists in evaluating the effect of capping agents on ZnO growth kinetics. In this contribution, we reported a facile water-based chemical precipitation method to prepare ZnO particles with distinct architectures (i.e. ZnO bowties, flowers, and nests) using zinc nitrate, urea, and polyvinylpyrrolidone (PVP) as building blocks [1]. Our detailed studies uncovered that the preferential adsorption of PVP onto different ZnO facets at different polymer concentration controlled the growth directions of ZnO and hence resulted in varied ZnO morphologies. Serendipitously, we discovered that ZnO particles have enzyme-like activities and demonstrated their ability to decompose exogenous and endogenous prodrugs to produce NO at physiological condition (pH 7.4, 37 °C). We also showed that physiologically relevant NO levels can be realized by varying the concentration of ZnO or NO prodrugs. In addition, we observed that ZnO particles preserved their catalytic capacity even after 6 months when suspended in PBS, which is beneficial for long-term biological applications. NO is a versatile player that participates in nearly every physiological system, such as cardiovascular, immune, central nervous system, and outflow physiology. However, the short half-life of NO in human tissues (approx. 5 s) and its limited diffusion radius (40-200 µm) have hampered the full potential of this molecule [2]. Our findings overcome the aforementioned challenges of NO delivery via utilizing an endogenous NO donor (GSNO) and an enzyme mimic (ZnO). Based on the infinite nature of endogenous NO precursors, NO delivery is therefore “limitless”, and NO can be generated throughout the lifetime of the enzyme mimic.

Bioinspired Design of Redox-Active Peptide-Based Antibacterial Gels to Prevent Implant-Related Infections
Galit Fichman and Joel Schneider; NCI/NIH, United States

Infection of medical implants is a serious ongoing problem worldwide, caused by bacterial adhesion and subsequent biofilm formation on the implant interface. To prevent such infection, we designed a set of catechol-functionalized cationic peptide antibacterial hydrogels that were inspired by the lysine- and DOPA-rich mussel foot protein-5. These advanced supramolecular gels are designed to coat implants providing a barrier to surface colonization and can also be injected during surgery directly to the tissue implantation site to inhibit surgical site infection. Furthermore, utilizing the gels lysine rich amino acid composition and the redox-activity of catecholic residues, these gels kill bacteria by two distinctive mechanisms: via a direct contact mechanism between the polycationic gel and the bacterial cell surface and by DOPA-mediated production of hydrogen peroxide (H₂O₂), a known antibacterial agent. We demonstrated that these gels exhibit high bactericidal activity against clinically isolated gram-positive bacteria, including the notorious multidrug resistant bacteria, MRSA. We further showed how amino acid composition and peptide sequence can modify the amount of generated H₂O₂, and consequently alter the antibacterial activity of the gel. Moreover, we characterized the ability of the gels to act as adhesives at the implant-tissue interface by utilizing lap-shear tensile strain tests. Collectively, these results indicate that DOPA-containing hydrogels hold promise as antibacterial adhesives, suitable for implantation at the tissue-implant interface.
Effect of Surface Polarity and Charge on the Adsorption of Amphiphilic Antimicrobial Peptide Self-Assembled Nanofibrils

Zhou Ye, Alexandra Kobe, Ting Sang and Conrado Aparicio; University of Minnesota, United States

Antimicrobial peptides are promising substitutes for conventional antibiotics with increasing bacterial resistance. Our previous work studied the relationship between self-assembly and antimicrobial activity using a designer peptide derived from a human salivary protein. This 13-amino acid amphiphilic and cationic peptide, named GL13K, can self-assemble to supramolecular nanofibrils in alkaline solutions. In our previous work, the coating of GL13K nanofibrils onto biomedical devices (e.g., Ti implant) and natural tissues (e.g., dentin) modified the surface hydrophobicity and showed a long-lasting antimicrobial activity. The amount of adsorbed GL13K was highly dependent on the surface chemistry and solution conditions, which eventually affected the activity of the coating. For example, the etched Ti adsorbed a much higher amount of GL13K than untreated Ti; the adsorption of GL13K predominated in the mineral-rich region on dentin. Separating and quantifying the effects on peptide adsorption of substrate hydrophobicity, charge, polarity, and roughness is a difficult, but critical task to design and control coating manufacturing and (bio)functionality. We hypothesized that surface negative charge is the main property favoring adsorption of self-assembled GL13K peptides.

In this work, we used quartz crystal microbalance with dissipation monitoring (QCM-D) to study in situ adsorption of GL13K self-assembled nanofibrils. The surface chemistry was controlled by coating Au QCM-D sensors with self-assembled monolayers (SAMs) with different terminal groups, including –COOH, –NH2, and –CH3. The SAM-coated sensors with polar terminal groups (i.e., –COOH and –NH2) were more hydrophilic than the one with a nonpolar terminal group (i.e., –CH3). It was observed that a significantly higher amount of GL13K adsorbed on the sensor with –COOH terminal group compared to the one with –CH3. In the alkaline solution where GL13K self-assembled to nanofibrils, GL13K had negligible adsorption on the sensor with –NH2 terminal group because –NH2 was deprotonated. Notably, adsorption of GL13K was largely favored on the same sensor once it was protonated to –NH3+ in lower pH. Self-assembled nanofibrils were found on sensors with deprotonated –COO– and protonated –NH3+ by atomic force microscopy (AFM). This indicated that polarity, not charge, was the critical factor determining the adsorption of these amphiphilic peptide self-assembled nanofibrils. Thus, we rejected our initial hypothesis.

With a better understanding of the adsorption behavior of GL13K, it is easier to control the coating of antimicrobial peptides on natural tissues. As a proof of concept, hydroxyapatite, the main inorganic component in tooth and bone, was also coated on sensors. Since hydroxyapatite is a very polar and hydrophilic material, GL13K adsorbed extensively on the sensor surface observed by QCM-D and AFM. The findings in this study could lead to better designs of coating amphiphilic peptides with different functionalities on biomedical devices and natural tissues.

2:45 PM SB02.13.06
Sustained Delivery of Antimicrobial Metal Ions via Biodegradable Hollow Drug Delivery Vehicles

Eva Krakor, Isabel Gessner, Sven Santernik and Sanjay Mathur; University of Cologne, Germany

The discovery of penicillin in 1940 is one of the most important medical inventions in reducing human morbidity and mortality but the intensive use of all kinds of antibiotics since then has led to an increase in multi-drug resistant bacteria and shows the necessity for alternative treatment options against bacterial infections. Alternatively to antibiotics, the antimicrobial properties of metals have been used for thousands of years, e.g. vessels made of copper or silver for water disinfection and food preservation. In this work hollow mesoporous silica capsules (HMSC) were synthesized using a hard iron oxide template which was coated with a silica shell through cross-condensation reactions. Afterwards the iron oxide core was removed by acidic leaching. Metallic nanoparticles such as Cu and Ag were incorporated into HMSC through the reduction of their metal salts (Ag@HMSC and Cu@HMSC). The formation of as-prepared rattle-type metal-silica particles was proven by TEM as well as XPS and EDX measurements. To determine the controlled leaching of metal ions under physiological conditions at 37°C, free Ag and Cu ions were complexed with dithizon to allow for their visualization and quantification via UV-Vis analyses at 454 nm and 543 nm. Moreover, INT assays revealed that both particle types exhibit a strong antimicrobial effect against gram-positive (B. subtilis) as well as gram-negative bacteria (E. coli), demonstrating their promising potential as antibiotic alternative in the future.

Nanomaterials Enable Delivery of Genetic Material without Transgenic DNA Integration in Mature Plants
Markita Landry; University of California, Berkeley, United States

Genetic engineering of plants is at the core of sustainability efforts, natural product synthesis, and agricultural crop engineering. The plant cell wall is a barrier that limits the ease and throughput with which exogenous biomolecules can be delivered to plants. Current delivery methods either suffer from host range limitations, low transformation efficiencies, tissue regenerability, tissue damage, or unavoidable DNA integration into the host genome. Here, we demonstrate efficient diffusion-based biomolecule delivery into tissues and organs of intact plants of several species with a suite of pristine and chemically-functionalized high aspect ratio nanomaterials. Efficient DNA delivery and strong protein expression without transgene integration is accomplished in mature *Nicotiana benthamiana*, *Eruca sativa* (arugula), *Triticum aestivum* (wheat) and *Gossypium hirsutum* (cotton) leaves and arugula protoplasts [1]. We also demonstrate a second nanoparticle-based strategy in which small interfering RNA (siRNA) is delivered to mature *Nicotiana benthamiana* leaves and effectively silence a gene with 95% efficiency. We find that nanomaterials both facilitate biomolecule transport into plant cells, while also protecting polynucleotides such as RNA from nuclease degradation. DNA origami nanostructures further enable siRNA delivery to plants at programmable nanostructure loci [2]. Our work provides a tool for species-independent, targeted, and passive delivery of genetic material, without transgene integration, into plant cells for diverse plant biotechnology applications.

9:00 AM SB03.01.02
Real-Time Detection of Wound-Induced \( \text{H}_2\text{O}_2 \) Signaling in Plants with Optical Nanosensors

Tedrick T. Salim Lew\(^1\), Volodymyr Koman\(^1\), Seonyeong Kwak\(^2\) and Michael Strano\(^1\); \(^1\)Massachusetts Institute of Technology, United States; \(^2\)Seoul National University, Korea (the Republic of)

As a consequence of their sessile nature, plants have developed complex signaling mechanisms to cope with the highly dynamic environment that they live in. In response to external stimuli, plants can utilize various signaling pathways for intercellular communication to engage different metabolic and genetic machineries involved in the plant defense system. Among the many signaling molecules recently uncovered, hydrogen peroxide (\( \text{H}_2\text{O}_2 \)) represents one of the most versatile signaling molecule in plants in response to environmental stresses such as mechanical wounding. Here, we develop an optical nanosensor platform using DNA-wrapped single-walled carbon nanotubes (SWNT) to monitor the wound-induced \( \text{H}_2\text{O}_2 \) signaling pathway in plants. This approach enables non-destructive, real-time detection of changes in endogenous \( \text{H}_2\text{O}_2 \) level in plants at a remote distance with portable and inexpensive electronics. We demonstrate the versatility of this method to investigate the dynamics between \( \text{H}_2\text{O}_2 \) and electric signalling pathways in different vegetable crops and plant species. A mathematical model describing the self-propagating \( \text{H}_2\text{O}_2 \) wave mechanism will be presented. Our work provides a promising tool to elucidate the complex plant signaling pathways across species to aid botany research and agronomic applications.

9:15 AM SB03.01.03
A Smart Interface between a Light Sensitive Conjugated Polymer and Plant Cells

Gabriele Tullii\(^1\), Alex Costa\(^2\) and Maria Rosa Antognazza\(^1\); \(^1\)Istituto Italiano di Tecnologia, Italy; \(^2\)Università Statale di Milano, Italy

In latest years the use of smart materials and devices started to attract attention for modulating the growth and functions of plant systems. Very recently, devices based on organic conductors have been object of increasing interest, both as actuators and as sensors. Here, we explore the opportunity to establish a functional interplay between light sensitive, organic semiconductors and plant systems. We chose \emph{Arabidopsis thaliana} as a widely accepted plant model, and we study the effect of a work-horse photovoltaic conjugated polymer, polyhexyllithiophene, on guard cells physiology. Cell viability in presence of the conjugated polymer is evaluated. Effects of polymer optical excitation and cell metabolism are also preliminarily investigated and critically discussed.

9:30 AM SB03.01.04
Plant Membrane-on-a-Chip

Susan Daniel, Han-Yuan Liu and Martin Stuebler; Cornell Univ, United States

The plant cell is protected by a complex polysaccharide cell wall composed primarily of cellulose, hemicellulose and pectin. The cell wall is followed by a semi-permeable barrier, the plasma membrane (PM) that serves two main roles: (1) transport of essential molecules in and out of the cell, and (2) sensory transduction of environmental stimuli as well as adaption to external influences. Considerable progress has been made over the past two decades to understand plant membrane proteins from a genetic perspective, but complementary tools for physiological, electrophysiological, biochemical characterization, and for studying protein function are facing unmet demand. This work highlights a new cell-free platform capturing the properties of the plant PM. This platform consists of a supported proteo-lipid bilayer (SPLB) derived from the plant PM. The main advantage of this platform is the compatibility with state-of-the-art surface, bioelectronic, and biophysical characterization tools. We demonstrates three straightforward ways to obtain proteoliposomes, from plant protoplasts. Three different plants (\emph{Arabidopsis thaliana}, \emph{Nicotiana benthamiana} and \emph{Zea mays}) were successfully used for the formation of SPLBs. This plant based approach enables direct incorporation of transgenic membrane proteins into supported lipid bilayers without using detergents and reconstitution processes and provides a novel tool to isolate and study membrane properties, transport phenomena, membrane-proteins, and protein-lipid interactions. We illustrate here the single molecule tracking of plant membrane proteins using this platform. In the future, we anticipate that this platform will allow studies of the plant membrane characteristics that will enable design of the biotic/abiotic interfaces for new sensing applications that merge plant membranes with electro-active materials.

**10:15 AM SB03.01.05**  
**Long-Term Plant Electrophysiology Using Vapor Printed Polymer Electrodes** Trisha L. Andrew, Jae Joon Kim and Linden Allison; University of Massachusetts Amherst, United States

We vapor print conformal conjugated polymer electrodes directly onto living plants and use these electrodes to probe the health of actively-growing specimens. The conducting polymer PEDOT can be deposited on the surface of living organisms without damaging their health and self-sustenance. A bioimpedance signal can be portably recorded using these vapor printed electrodes, which can reveal detailed information about the health of the organism. Notably, polymer electrodes can be created directly on living plants, meaning that bioimpedance measurements can be performed on-demand, throughout the growth cycle of a plant without being damaged by environmental conditions such as wind, water, temperature changes and UV exposure. Vapor-printed polymer electrodes, unlike their adhesive thin-film counterparts, do not delaminate from microtextured living surfaces as the organism matures and do not observably attenuate the natural growth pattern and self-sustenance of the plants investigated herein. In particular, deep tissue damage caused by UVA irradiation and Ozone exposure can be reliably detected noninvasively. Long-term plant health monitoring can find strategic use in food farming, crop management and biohazard signaling.

**10:30 AM SB03.01.06**  
**Hydroprinting of Liquid Alloy Circuits for Fragile Plants Organism Monitoring** Zhigang Wu¹, Jiajun Jiang¹, Shuo Zhang¹ and Bei Wang¹,²; ¹Huazhong University of Science and Technology, China; ²Uppsala University, Sweden

To precisely monitor the physiology state of plants, this work presents a gentle non-invasive method to transfer functional liquid alloy circuits on living fragile plants using a water-soluble sacrificial layer. This process can print functional electrical circuits in high fidelity on complex irregularity morphology without introducing any external interventions such as heat flow, pressure, acid or base. The data from the circuits on flowers demonstrates this technique is well suitable for monitoring such kind of scenarios.

Internet of things is emerging in sorts of situations, but the access of live plants is rarely studied. With the internet connecting, people could obtain the real-time health state and various behaviors of plants in the practical or stimulus environments. This can further lead to new customized strategies for crop management and even new approaches for botany research. Nevertheless, many of plant organisms, such as flowers and leaves, are fragile with irregular surface morphology, and their growth are easily affected by external constraints. These features make the integration of functional circuits challenging. Existing methods, such as smart patches, press-on buttons, 3D printing, roll-to-roll gravure, flexographic printing and vapor-printing, either impose external loads to the growing plants and hinder the normal growing process, or may easily harm the plants with external intervention during the complicated process.

In this work, a highly biocompatible polyvinyl alcohol (PVA) film was used as a substrate as well as an intermediate sacrificial layer to transfer the original 2-D liquid alloy (Galinstan) circuits to a vulnerable complex 3-D surface under water pressure. Firstly, the circuit was printed on a PVA film by masked deposition with a method developed by our group. Then the circuit with PVA was placed on water surface. When the PVA film was almost completely dissolved, it would become a PVA/water mixture with super flexibility, stretchability and stickiness. More importantly, this mixture could maintain the shape of circuit, which make the transferring process predictable and controllable. Concurrently, the plant organism was gradually immersed through the circuit with a given angle and immersing speed. Consequently, the liquid alloy circuit pattern was transferred and attached to the plant surface by water pressure and Van der Waals force. The whole process can be conducted in minutes, and there is no obviously interference on plants even after three months. To demonstrate the technique, the Galinstan circuits with resolution ~70 um was transferred on complex surfaces with prominent conformalbility, excellent electricity and repeatability. Further, water content sensors and LED circuits were fabricated on rose petals and bean sprouts by this technique. It was found that the measured results could precisely reflect the change of state in different water content, and the sensor could still work well even with an elongation of more than 200% during growth.

**10:45 AM *SB03.01.07**  
**Organic Bioelectronics to Record and Regulate Signaling and Physiology in Plants** Magnus Berggren, Daniel T. Simon and Eleni Stavrinidou; Linkoping University, Sweden

Organic bioelectronics is a unique platform of devices and materials that can serve as the actuator and recorder of signals at the technology-biology interface. In the e-Plant effort, we are exploring organic bioelectronics by
developing devices that can selectively trigger or sense targeted physiological functions and signaling cascades, at high spatiotemporal resolution. With tailor-made organic electronic ion pumps (OEIP), we have managed to deliver phytohormones to regulate the growth rate of the root hairs of Arabidopsis and to provoke the closure of stomata of Tobacco leaves. With PEDOT-based electrodes we have derived efficient bio-photovoltaic electrochemical cells. And, with organic electrochemical transistors (OECT), including immobilized enzymes, we can monitor sugar concentrations from plants in real time. In the future, this sensor-actuator technology promise for a self-powered plant-area network possible to use in plant biology experiments and also in agriculture.

A NanoBioengineering Approach to Developing Living Photovoltaics Ardemis Boghossian; Ecole polytechnique federale de Lausanne (EPFL), Switzerland

Despite their inspiration in improving synthetic photovoltaics, photosynthetic systems suffer from stabilities and efficiencies that limit their direct use in photovoltaics. While they benefit from autonomous repair and reproduction, photosynthetic systems contain light-harvesting machinery that is optimized for evolutionary purposes rather than photocurrent production. Herein we present bioengineered cyanobacteria capable of enhanced photocurrent production. We introduce genetically encoded exoelectronic pathways that serve as electron conduits for interfacing photosynthetic cells with nanomaterial scaffolds. These conduits further enable researchers to electronically rewire the cell metabolism and reprogram biological cells to perform as artificial electronic devices. The ability to improve photovoltaic performance through both nanomaterials engineering and synthetic biology unlocks new possibilities in achieving a viable technology.

2:00 PM SB03.02.02
Enhanced Extraction of Photosynthetic Electrons from Thylakoid-Electrosprayed SU-8 Micro-Pillar Electrodes SeonIl Kim, Yong Jae Kim, Hyeonaug Hong and WonHyoung Ryu; Yonsei University, Korea (the Republic of)

Photosynthetic bio-solar energy conversion using algae or plant cells has been extensively investigated for the last decades. Photosynthesis occurs in the thylakoid membranes (TMs) that contain photosynthetic apparatus such as photosystem I (PS I) and photosystem II (PS II). In photosynthesis, water molecules are split by PS II and high energy photosynthetic electrons (PEs) are generated. Direct extraction of these PEs without a mediator has been investigated over the last decade to maximize the PE currents. Since PEs are transported along TMs, enlarging contact area between TMs and an electrode is a way to enhance PE extraction. Previously, several approaches have been investigated to maximize contact area using various three-dimensional (3D) electrode designs such as multi-wall carbon nanotubes (MWCNTs) modified electrode, sintered AuNPs on screen printed electrode, indium tin oxide (ITO) modified electrode, or micro-pillar electrodes. Then, TMs were usually drop cast on such 3D structured electrodes. However, it is difficult to have uniform and conformal deposition of TMs over the 3D electrodes by the drop casting method. This often results in unreliable performance of the TM-coated electrodes in particular for electrodes larger than a few mm². In this work, we aimed to enhance extraction of PEs from TM-coated 3D micro-pillar electrodes by electrospraying. We fabricated Si micro-pillar (MP) arrays of aspect ratio (AR) of 1, 1.8 with 1um diameter from metal-assisted chemical etching (MAC-Etching). Then, SU-8 MP arrays of 1 cm² size were replicated from the Si MP array as a master mold. To improve adhesion with a metal layer, the SU-8 MP arrays were immersed in 10 mM of 4-aminothiophenol (ATP) ethanol solution overnight. Au layer was sputter-coated on the 4-ATP modified Si micro-pillar electrodes. Then, TMs were electrosprayed uniformly on the SU-8 MP array electrodes. The electrospraying solution contained 1 mg chl/ml of TMs, 3 mM of ammonium acetate, 10% (v/v) of ethanol as a surface tension reducing agent, and 3% (w/v) of sodium alginate as a viscosity modifier. The morphology of TMs, which were electrosprayed over SU-8 photo-anodes, was observed using confocal fluorescence microscopy and SEM to confirm their coating uniformity. TMs were electrosprayed for various spraying times of 0.5, 1, 2, 4 and 10
minutes in order to maximize extraction of PE currents. PE currents were measured using a three-electrode system, under 10 mW/cm² of halogen illumination and bias potential of 400mV vs. Ag/AgCl. The highest PE currents were measured at 4 minutes of TM-electrospraying time. The measured PE currents were 52, 79, and 109 nA/cm² for flat electrodes, MP electrodes with AR of 1, and AR of 1.8, respectively. It was demonstrated that electrosprayed TMs uniformly and conformally covered the entire electrode surface even for MP electrodes with high ARs. It was also shown that higher PE currents were measured from MP electrodes with higher AR values. This indicates larger contact between TMs and individual MPs were formed, resulting in enhanced direct electrochemical contacts.

2:15 PM *SB03.02.03
Biological Solar Cells Using Photosynthetic Machineries of Higher Plants and Cyanobacteria Ramaraja P. Ramasamy¹ and Randy Duran²; ¹University of Georgia, United States; ²NSF, United States

The light reactions of natural photosynthesis can be manipulated towards electricity generation in electrochemical devices called biological solar cells or photo-bioelectrochemical cells (PBEC) that resemble conventional fuel cells in principle without the requirement of a chemical fuel. The device uses a photo-bio anode and a enzymatic cathode that could convert light energy into electricity by photosynthesis assisted oxidation of water. The photosynthetic reactions occur in the thylakoid membrane and involve a complex set of redox reactions that result in the transfer of electrons between protein complexes. The electrons from the photosynthetic reactions can be channeled towards an external electrode for electricity generation by inhibiting the photosynthetic protein complexes in order to divert the flow of electrons towards to desired electron transport path within the photosynthetic membrane. Investigation using site-specific photosynthesis inhibitors revealed that the electrons generated through water oxidation reaction from photosystem II complex can be diverted to the external electrode for photocurrent generation primarily through the plastoquinone pool. Besides site specific inhibition, other approaches to increase photocurrent generation were investigated. One of those approaches is to engineer photosynthetic organisms such as *Synechococcus elongatus* PCC7942 with an outer membrane cytochrome (OmcS) derived from dissimilatory metal reducing bacteria which increase the photocurrent generation at an external electrode by two fold. This presentation will summarize some of our recent work on multiple different approaches to enhance photocurrent generation through an understanding of electron transport reactions in photosynthetic membranes.

2:45 PM SB03.02.04
Bioelectronic Composites from Self-Doped Conjugated Polyelectrolytes Samantha McCuskey, Yude Su and Guillermo Bazan; University of California, Santa Barbara, United States

Anaerobic bacteria routinely interface with abiotic electrodes to catalyze the interconversion of electrical and chemical energy. Integration of materials at the biotic/abiotic interface has improved electron transfer efficiency and cell adhesion, but charge injection/extraction is still largely restricted to the immediate proximity between bacteria and the external electrode. A three-dimensional organization whereby electronic contact extends beyond the confines of the electrode surface would be desirable. Here, we introduce bioelectronic composites comprised of the self-p-doped conjugated polyelectrolyte CPE-K and *Shewanella oneidensis* MR-1. These composites are simple to assemble and biocompatible. Furthermore, testing in three-electrode electrochemical cells show that the composites can generate ~200-fold greater biocurrent density than control *S. oneidensis* MR-1 biofilms. The impact of CPE-K concentration on bioelectronic composite performance will be discussed, along with an evaluation of electroactive surface area and charge transfer resistance.

3:00 PM BREAK

3:30 PM *SB03.02.05
Simple Circuitry for Microbial Extracellular Electron Transfer—Functional Characterization of Geobacter OmcZs Produced in E. coli Miyuki A. Thirumurthy and Anne K. Jones; Arizona State University, United States

Extracellular electron transfer, in which electrons are transferred from the metabolism of a microbe to an extracellular substrate is an intriguing process that may have applications in living electronics, bioremediation, chemical synthesis, sensing, and microbial fuel cells. Although a number of anode-respiring bacteria can exchange electrons with extracellular electrodes, many genetically tractable model microorganisms, especially those used in synthetic biological applications, cannot. Furthermore, the mechanisms by which microbes interact with
extracellular electrodes and the biological components required remain unclear. Among the hundreds of c-type cytochromes found in *Geobacter sulfurreducens*, OmcZs has been shown to have the largest impact on extracellular electron transfer to electrode surfaces. Herein, we overexpressed OmcZs in *E. coli* and defined its function in vitro. UV-vis absorption and florescence assays show that it can reduce riboflavin. Furthermore, electrochemical measurements show that *E. coli* cells expressing OmcZs are capable of extracellular electron transfer, a function not native to *E. coli*. The activity can be enhanced by inclusion of riboflavin in the experiment. Currents produced are comparable to other, more complex *E. coli* circuits reported by others. We conclude that OmcZs and riboflavin alone are sufficient to create a minimal, functional, synthetic pathway in *E. coli* for extracellular electron transfer.

4:00 PM SB03.02.06
**A Kinetic Model for Redox-Active Film Based Biophotoelectrodes**
Darren Buesen¹, Thomas Hoefer¹, Huijie Zhang¹,² and Nicolas Plumere¹; ¹Ruhr-Universität Bochum, Germany; ²University of Leeds, United Kingdom

Photoactive electrodes based on redox-active films are a promising approach to increasing the active area in which enzymes can be deposited and electrochemically accessed via mediated electron transfer. Beside this, these films are able to entrap the deposited enzyme. A great challenge to increase the efficiency arises from different charge recombination pathways, intrinsically connected to the process of the light-induced electron transfer chain from the electrode to the final solar fuel formation or to the charge carrier for electricity production [1]. Experimental investigation based on electrochemical methods and/or product quantification often have the disadvantage, that they cannot distinguish between the catalytic process and the detrimental effect of different short-circuiting processes. We present a general model constructed from diffusion and reaction processes describing redox-active film based biophotoelectrodes [2]. The model predicts the resulting photocurrent-time curve and distinguishes between the main catalytic process and the contribution of the two proposed short-circuiting pathways. It describes the corresponding time dependent concentration profiles of all involved species which can be analyzed to identify bottlenecks present in the solar fuel or photocurrent generation of a given system. The equations consist of dimensionless groups for a straightforward identification of possible limiting processes. The importance of the model for quantitative understanding of biophotovoltaic processes is highlighted with an example of simulation results predicting the effect of the diffusion coefficient of the charge carrier on photocurrent generation for different charge recombination kinetics.

**Direct Functionalization of Plants by Smart Materials for Energy Harvesting in e-Plants**
Samia Zrig¹, Nathalie Bridonneau¹, Vincent Noël¹, Giorgio Mattana¹, Benoît Piro¹ and Eleni Stavrinidou²; ¹Université de Paris, France; ²Linköping University, Sweden

Biofuel cells are one of the most attractive power sources for implantable and microscale devices because of their biocompatibility and ability to operate at near neutral pH and ambient temperature. A typical enzymatic glucose biofuel cell comprises two enzyme-modified electrodes, with Glucose Oxidase (GOx) catalyzing glucose oxidation into gluconolactone at the anode, and Bilirubin Oxidase (BOD) catalyzing oxygen reduction at the cathode. For these enzymes to be recycled, specific redox mediators are necessary, to insure an efficient electron transfer between their active sites and the electrodes. During the process of photosynthesis, vegetal cells use energy from sunlight to convert carbon dioxide and water into glucose and oxygen, which could be both used in a glucose biofuel cell as fuel and oxidant, respectively. Our idea was therefore to integrate the energy harvesting system directly within the structure of a living plant. To achieve this, the direct functionalization of the vascular system containing the plants’ endogenous sugars and oxygen is necessary in order to operate the biofuel cell. The electrodes of such bio-hybrid systems should encompass conductive materials, enzymes and redox mediators.

Our approach is based on the growth of a conductive material (functionalized with enzymes and redox mediators) inside the vascular system of the plant, either through the roots or the leaves. The design, synthesis and characterization of such smart materials will be described and discussed.
We believe that the integration of energy harvesting and storage systems within the living plants could be a major breakthrough for energy applications.

CNT Percolation Network in Thick Photosynthetic Composite Films for Enhanced Harvesting of Photosynthetic Electrons JaeHyounge Yun1, TaeYoep Kim2, Hyeonaug Hong1, Yong Jae Kim1, Yunjeong Park2, Kyunghoon Kim2 and WonHyounge Ryu1; 1Yonsei University, Korea (the Republic of); 2Sungkyunkwan University, Korea (the Republic of)

Photosynthesis produces high energy photosynthetic electrons (PEs) with internal quantum efficiency (IQE) of nearly 100%. Due to this high IQE, bioenergy harvesting using algal cells or photosynthetic organelles such as photosystems (PS I, II) and thylakoid membranes (TMs) has been studied extensively. In the absence of a mediator, the magnitude of harvested PE currents directly depends on an electrical contact between the photosynthetic organelles and an electrode. Thus, thicker deposition of the photosynthetic organelles on an electrode does not increase PE currents despite larger quantity of PEs generated from the thicker photosynthetic film. Even in the presence of a mediator, although a mediator can diffuse between a spot of PE generation and an electrode, PE transportation through the thicker film becomes more difficult.

In this study, we propose formation of electrical percolation networks for PE transport from the surface of the film to an electrode. Electrical percolation network was formed by mixing highly-conductive single-wall carbon nanotubes (CNTs) and thylakoid membranes (TMs). Since CNTs have no charge on the surface, we coated mussel-adhesive protein (MAP) on CNTs to have a positive surface potential due to the exposed amine groups of the MAP. The positive zeta potential resulted in well-dispersed CNTs in an aqueous solution. The exposed amine groups of MAP-CNTs also formed peptide bonds with the carboxyl groups of TMs such that CNTs and TMs were firmly connected. The percolation network in MAP-CNT/TM film was analyzed by cyclic voltammetry (CV), chronoamperometry (CA), electrical impedance spectroscopy (EIS), and linear sweep voltammetry (LSV). CNT percolation networks were achieved when the CNT weight was near 30% of the weight of chlorophyll a (Chl a) in the MAP-CNT/TM composites. Moreover, when the CNT weight was 50% of the weight of Chl a, the composites achieved the highest electrical conductivity without a mediator. Finally, when we increased the amount of TM deposition on an electrode, larger difference of PE current magnitudes was observed between the MAP-CNT/TM and TM-only films. The PE currents from the MAP-CNT/TM composite film became about 100 times larger at the Chl a concentration of 300 μg/cm².
built up smart supramolecular architectures combining multiple enzymes assembled with tailored linkers, which are able to perform manifold functions. Finally, we have explored approaches for integration of RC as the light-responsive material in bio-optoelectronic and electrochemical devices. In particular, we have developed protocols for addressing the RC on thin films of molecular or polymeric semiconductors deposited onto metal electrodes by covalent [6] or weak interactions. Biomimetic polymers, such as polydopamine, have been also investigated as efficient electronic interfaces of RC with electrodes in photoelectrochemical cells.

The lecture will discuss the logic behind designing and synthesizing materials for sunlight photoconversion and for light-triggered bioelectronics, by combination of tailored functional molecules with highly efficient bacterial photoenzymes optimized in billions of years of evolution.

Unravelling the Mechanism of In Vivo Polymerization of a Conjugated Oligomer in Plants Gwennaël R. Dufil, Daniela Parker, Eleni Stavrinidou and Magnus Berggren; Laboratory of Organic Electronics, Sweden

Plants convert radiant energy from the sun into carbohydrates being the primary resource in our ecosystem. Recently, the use of organic electronic materials allowed interaction with plants in a new way: using the vascular system of plant to form electrical circuits and devices targeting bio-hybrid devices. Firstly, a water-soluble conducting polymer, PEDOT-S has been uptaken by the xylem of a rose, forming self-organized conducting wires in the stem. As a next step a conjugated oligomer, ETE-S was developed with bigger versatility in distribution within the plant due to its small size. The ETE-S in-vivo polymerized within the living tissue forming a network of conducting wires from the stem to the flower. It is well known that plant has developed mechanisms for stability and defense that rely on the polymerization of compounds within the cell wall. The major actor in these processes is called the type III peroxidase. This enzyme can proceed with two different catalytic cycles to reduce or increase the cell wall density. The increase of the cell wall density is achieved through the peroxidative cycle that uses peroxide to crosslink phenolic compounds on the cell wall creating a complex network of various polysaccharides such as lignin or extensin. In this work, we demonstrate the involvement of this peroxidative cycle in the polymerization of the ETE-S oligomer by reproducing the reaction in-vitro. We then follow the kinetics of the polymerization reaction while changing the enzyme or substrate concentrations to understand deeper the underlying mechanism. By understanding the mechanism of in-vivo polymerization we can rationally design materials for plant functionalization as well as optimize targeted functionalization.

In Vivo Polymerization of Conducting Polymers in Zebrafish Brain Tissue Xenofon Strakosas¹, Peter Ekstrom², Jennifer Gerasimov¹, David Bliman³, Fredrick Ek², Eleni Stavrinidou¹, Roger Olsson², Daniel T. Simon¹ and Magnus Berggren¹; ¹Linkoping university, Sweden; ²Lund University, Sweden; ³University of Gothenburg, Sweden

Organic bioelectronic devices use conducting polymers as active materials because of their soft nature and mixed ionic and electronic conductivity. Electrode arrays, transistors, and drug delivery devices have taken advantage of the conducting polymers in order to improve their performance for the purpose of diagnosis and treatment. However, the aforementioned devices are commonly being developed by using expensive microfabrication techniques. Moreover, conducting polymers occupy only a part of the whole device geometry, while the rest acts as support. Biology, however, builds biological devices by using its own machinery. Recently, the machinery in plants has shown to polymerize trimers resulting in conducting polymer wires, electrodes, and supercapacitors. Here, we
show *in vivo* polymerization of thiophene based molecules by the machinery in the brain in Zebrafish. Localized areas with conducting polymers exist in different parts of the brain. This process paves the way for the development of self-organized organic electronic devices.

**Development of Printed Solar Biobattery for Use in Bioelectronics** Marin Sawa; Imperial College London, United Kingdom

There is an urgent need to develop a sustainable battery technology that is cheap, environmentally friendly, easy to fabricate and to dispose of, especially to tackle the world-wide increase in illegally dumped electronic wastes. Microbial biophotovoltaic (BPV) technology is a renewable bioenergy system currently being developed at the laboratory scale. It generates electricity from the photosynthetic metabolism of cyanobacteria and microalgae and exploits their ability to convert light energy into electrical current using water as the source of electrons. Innovative approaches are needed to solve scale-up issues such as cost, ease of fabrication (particularly the fabrication of the inorganic and biological (microbes) parts).

In this talk, I will report the feasibility of the thermal-inkjet method to fabricate a thin-film paper-based BPV cell consisting of a layer of cyanobacterial cells on top of a carbon nanotube conducting surface on plain copy paper. The digitally printed thin-film BPV system produced electricity both in the light and dark, with a maximum electrical power output of 0.38 mW m⁻² in one system and the sustained electrical current production over 100 hours in another more fully printed system. I will discuss latest efforts in development of the proof of concept and address limitations and challenges as well possible applications in the area of printed bioelectronics.

**Application of Nanophosphor Particles in Plant Nanobionics** Pavlo Gordiichuk and Michael Strano; Massachusetts Institute of Technology, United States

The concept of a light-emitting plant, or plant exhibiting chemiluminescence powered from its own stored chemical energy, offers promise to advance off grid illumination and other autonomous photonic applications. In this work, introduce and investigate an additional nanoparticle designed to augment plant light emission in the form of silica coated strontium aluminate nanoparticles as nanophosphore elements. These nanoparticles can adsorb and re-emit generated light at longer times, increasing the duration of light emission, where the particles sizes and concentration are the key parameters of plants brightness tunability. Moreover, such nanophosphores can also scavenge additional energy from solar fluence, increasing and augmenting total light emission from the plant. Infiltreted strontium aluminate particles showed homogeneous distribution inside plants leaves in spongy mesophyll region without penetration inside plants cell, preserving their intact structure, as well as efficient particles infiltration deep into the plant’s stem.

**Solar Panels on Yeast—Inorganic Biohybrids for Enhanced Photochemical Production** Neel Joshi¹,², Junling Guo¹,² and Miguel Suástegui¹,²; ¹Harvard Univ, United States; ²Wyss Institute, United States

The intersection between synthetic biology and materials science is an underexplored area with great potential to positively affect our daily lives, with applications ranging from manufacturing to medicine. Inorganic-biological hybrid systems have potential to be sustainable, efficient, and versatile chemical synthesis platforms by integrating the light-harvesting properties of semiconductors with the synthetic potential of biological cells. We have developed a modularbioinorganic hybrid platform that consists of highly efficient light-harvesting indium phosphide nanoparticles and genetically engineered *Saccharomyces cerevisiae*: a workhorse microorganism in biomanufacturing. The InP particles are adhered to the yeast surface using a versatile polyphenol-based chemistry. The yeast harvests photo-generated electrons from the illuminated nanoparticles and uses them for the cytosolic regeneration of redox cofactors. This enables the decoupling of biosynthesis and cofactor regeneration, facilitating a carbon- and energy-efficient production of the metabolite shikimic acid – a common precursor for several drugs and fine chemicals. We observed higher per-cell production of shikimic acid for biohybrids compared to their unmodified counterparts, in a light-dependent manner, and a global metabolic shift toward shikimic acid from other fermentative byproducts, like glycerol and ethanol. Our work provides a platform for the rational design of
biohybrids for efficient biomanufacturing processes with higher complexity and functionality. The biohybrid polyphenol-based fabrication scheme can easily be adapted to virtually any combination of particle and cell type, greatly expanding the range of accessible systems and facilitating the exploration of structure-function relationships. Additionally, the vast toolbox of available genetically modified yeast strains will enable further probing of electron transport mechanisms and applicability to a wide variety of biochemical targets.

11:15 AM SB03.03.07
Semi-Artificial Photosynthesis with Biocatalysts Integrated into Hierarchical Materials for Photoelectrochemical Fuel Synthesis Erwin Reisner; University of Cambridge, United Kingdom

Semi-artificial photosynthesis interfaces biological catalysts with synthetic materials and aims to overcome the limitations of natural and artificial photosynthesis. It also provides an underexplored strategy to study the functionality of biological catalysts on synthetic scaffolds through a range of techniques. This presentation will summarise our progress in integrating biocatalysts in bespoke hierarchical 3D electrode scaffolds and photoelectrochemical circuits. The fundamental insights gained into the function of the water oxidation Photosystem II will be discussed, where (i) unnatural charge transfer pathways have been revealed at the enzyme-electrode interface, and (ii) O₂ reduction that short-circuit the water-oxidation process has been discovered. In contrast to natural photosynthesis, these photoelectrochemical cells allow panchromatic light absorption by using complementary biotic and abiotic light absorbers. As opposed to low-yielding metabolic pathways, the electrochemical circuit provides effective electronic communication without losses to competing side-reactions. Progress in the integration of robust live cyanobacteria in 3D structured electrodes will also be discussed.

PEDOT:PSS-Based Multilayer Bacterial-Composite Films Daniel T. Simon1, Caroline Ajo-Franklin2, Moshe Baruch2,3, Tom Zajdel4, Gábor Méhes1, Eleni Stavrinidou1 and Magnus Berggren1; 1Linköping University, Sweden; 2Lawrence Berkeley National Laboratory, United States; 3Rice University, United States; 4Princeton University, United States

Microbial electrochemical systems provide an environmentally-friendly means of energy conversion between chemical and electrical forms, with applications in wastewater treatment, biofuel production, and environmental biosensing. However, a major challenge to further development, miniaturization, and deployment is the limited thickness of biofilms, necessitating large anodes to achieve sufficient signal-to-noise ratios. In this talk, we present our recent demonstrations of embedding living electroactive bacteria in electrodes based on organic conducting polymers, enabling truly hybrid bioelectronics with a well-defined biological-to-electronic signal pathway. Our method embeds a large, dense biomass of current-producing bacteria inside a three-dimensional PEDOT:PSS matrix, which we call a multilayer conductive bacterial film. The resulting bio-hybrid electrode provides a conformable electrode interface to each bacterium, provides nutrient-permeability, and permits electron transfer via multiple bacterial mechanisms. As a result, it produces 20× more current than a native biofilm grown on the same substrate. We will discuss how this work can both expand our mechanistic understanding of interfacial electron transfer and enable miniaturization and direct incorporation of living biological materials into electronic devices, such as organic electrochemical transistors and microbial biosensors.

Anion Interactions with Vapour Deposited PEDOT

Drew Evans; University of South Australia, Australia

Conducting polymers offer several key advantages over their inorganic counterparts, such as mechanical flexibility, transparency, and material abundance, which can enable low-cost fabrication and novel applications such as printed and flexible electronics. The conducting polymer poly(3,4-ethylenedioxythiophene), PEDOT, is one material which displays (among others) high electrical conductivity [1], enhanced thermal conductivity [2], good electrocatalytic performance [3], as well as thermoelectric behaviour [4]. Enhancing the properties of PEDOT has been achieved through Vapour Phase Polymerisation (VPP), an oxidative polymerization process under vacuum conditions. We report that VPP PEDOT shows interesting interactions with anions, in some examples almost specific ion effects [5]. For example, the uptake of anions from an aqueous solution into electrochemically reduce PEDOT is highly dependent on the anion itself. More interestingly is nitrate is specifically absorbed by PEDOT when present in a mixed electrolyte solution [6]. This selective absorption is hypothesised to originate from anion-π interactions, in part validated by MD simulations [5]. Such interactions, relating to both chemistry and structure, lead to interesting opportunities in energy storage as well as (agricultural) sensing.

All-Inkjet-Printed Humidity Sensors for the Detection of Relative Humidity in Air and Soil—Towards the Direct Fabrication on Plant Leaves

Giorgio Mattana1, Walid Ait Mammar1, Samia Zrig1, Nathalie Bridonneau1, Vincent Noël1, Eleni Stavrinidou1 and Benoît Piro1; 1Université de Paris, UFR de Chimie, Laboratoire ITODYS, France; 2Linköping University, Sweden

Relative humidity (RH) detection and quantification play a major role in both agriculture and floriculture, as the water content in air and soil has a strong impact on the plant’s growth, flowering and fruiting. Nowadays, the crop and floral industry are facing unprecedented challenges, especially because of the combination of the rapid increase of the world’s population with the unpredictable effects of global warming: atmospheric and soil humidity monitoring has thus become crucial to avoid production insecurity problems. Research on air and soil RH sensors for agricultural and floriculture applications is now focusing on the development of devices that are low-cost, low power-consumption and easily portable. These needs may be met by utilising printing techniques to fabricate...
simple capacitive sensors on flexible, plastic foils.
The devices presented in our work are fabricated on polyimide foils (Kapton®) by inkjet-printing a capacitive structure consisting in coplanar, interdigitated silver electrodes; cellulose acetate butyrate is subsequently printed onto the interdigitated comb and used as humidity sensing layer.
Impedance spectroscopy (at fixed RH) was used to identify the frequency range where our sensors exhibit the most stable capacity values; the sensors’ response to different RH levels was fully characterised by performing both static and dynamic measurements.
A particularly innovative aspect of our work is the sensors characterisation in soil: the printed devices were dipped inside potting soil at different humidity levels (measured by means of a commercial electronic sensor) and again both statically and dynamically characterised. Their lifetime inside the soil was also investigated.
Finally, we present the preliminary results of a protocol to fabricate the aforementioned printed RH humidity sensors using directly plant leaves as substrate.
Our results could pave the way for the fabrication of the next generation of low-cost, flexible and environmentally-friendly humidity sensors.

Porous Silicon Fabry–Pérot Interferometer for Highly Sensitive Detection of Mycotoxins in Field Crops Ilana Freidman1 and Giorgi Shtenberg2; 1Bar Ilan University, Israel; 2ARO Volcani Center, Israel

Food and agricultural commodities contamination by various toxigenic molds (fungi) is a serious neglected problem, affecting ~25% of the world’s crops with staggering economical loses [1]. Regardless of decades of extensive research, mycotoxins continue to penetrate the food chain through food and feed crops and pose health risks both to humans and livestock [2]. Mycotoxins may lead to adverse health effects, including cancer, gene mutation, as well as estrogenic, gastrointestinal and kidney disorders [3]. Some mycotoxins are also immunosuppressant which reduce resistance to infectious diseases [4, 5]. Mycotoxins are secondary metabolites produced by specific filamentous fungi species usually belong to Aspergillus, Penicillium or Fusarium that infect crops at the field level and endure on foods during storage. Due to the increased toxicological effects, many countries have set stringent limits for mycotoxins residues in food and feedstuffs particularly with respect to international trade, including developed and developing countries [1]. Thus, it is rather essential to have an accurate, rapid and sensitive method for multiplex detection of mycotoxins in unprocessed food and feed. An oxidized porous silicon (PSi) nanostructures, a Fabry–Pérot thin film, is synthesized and used as an optical transducer element for the detection and quantification of Fumonisin B1 (FB1, target molecule). The nanostructure is modified with specific robust bioprobes for the validation of fungal contamination and its secreted toxins by indirect immunoassay amplified by FB1-horseradish peroxidase (HRP) conjugates. The catalytic activity is monitored in real-time by reflective interferometric Fourier transform spectroscopy (RIFTS). This technique is sensitive to small changes in the average refractive index of the thin-film induced by enzymatic activity products infiltrating the pores. Optical studies reveal high specificity and selectivity towards FB1, presenting LOD of 0.38 ppm. The main advantage of the presented biosensing concept is the ability to detect fumonisin contamination, at environmentally relevant concentrations, using a simple and portable experimental setup.

The Design of Biodegradable Soil Sensors for Precision Agriculture

Madhur Atreya, Karan V. Dikshit, Gabrielle Marinick, Jenna Nielson, Carson Bruns and Gregory L. Whiting; University of Colorado Boulder, United States

Low cost biodegradable sensors for environmental monitoring can enable the collection of large data sets useful for resource optimization in precision agriculture. Therefore, we have developed wireless soil moisture and nitrogen sensors that are printed from solutions of functional biodegradable materials using scalable manufacturing techniques. These sensors will be placed in the field and remotely interrogated, controllably degrading into the soil over time when no longer needed.

The development of biodegradable sensors presents a complex design problem wherein sensor performance must be constant for several months until a prescribed end of life is reached. We leveraged the complex ecosystem of soil in order to more carefully tune degradation rates of electronic devices. We combined enzymatically degradable polymers, such as poly(lactic acid), polycaprolactone, and polyhydroxybutyrate, with benign conductive materials such as magnesium and carbon, to print conductive lines. Similar polymers were also employed as substrates and encapsulant materials. Techniques such as solvent aging and the addition of various composite fillers were explored and optimized for electronic characteristics and degradation rates. We then fabricated wirelessly readable and fully degradable capacitive soil moisture sensors and report on performance shifts due to degradation.

By integrating and modifying existing enzymatic biodegradation techniques, and developing new accelerated testing approaches, we compared degradation rates in continuous flow with traditional batch techniques. We then compared this data with soil-compost mixtures in incubator conditions. Component materials, such as polymers and metals, were tested independently for mass loss and topological changes; and then printed composites and entire devices were tested to investigate performance loss during degradation. In order to ensure the degraded byproducts have a benign impact on the crops being monitored at the local level and on streams and water tables at the systems level, we analyzed the effluent from these accelerated degradation techniques for ecotoxicity.

Control of Stomata in Tobacco Plant Using Organic Bioelectronics

Iwona A. Bernacka-Wojcik1, Miriam Huerta1, Klas Tybrandt1, Michal Karady2, Yusuf Mulla1, David J. Poxson1, Erik O. Gabrielson1, Karin Ljung2, Daniel T. Simon1, Magnus Berggren1 and Eleni Stavrinidou1; 1Linkoping University, Sweden; 2Umeå Plant Science Centre, Sweden

Technologies that allow manipulation of cellular processes with high spatiotemporal resolution can lead to engineering plants that are tolerant of harsh conditions, which is one of the primary goals of modern plant biology. The organic electronic ion pump (OEIP) provides unique means for the electronically-mediated delivery of phytohormones without fluid flow at the cellular scale. Here the OEIP is used to deliver phytohormones at very high accuracy with respect to rate and spatial resolution directly into leaf tissue. Owing to the capillary form factor and the sub-100 µm diameter of the device, there is no significant wound response from the plant benchmarking the OEIP as minimal invasive tool for regulating plant physiology. The delivery of ABA, the phytohormone that mediates plant’s tolerance to stress, induces closure of stomata, the microscopic pores in leaf epidermis that play a vital role in both photosynthesis and transpiration. High performing OEIP mediated delivery revealed surprising kinetics of the ABA-induced signal. This technology offers a new versatile tool for basic plant research but also potential application in agriculture.

Photocontrolled Release Fertilizer System Using Iron(III) Carboxylate Photochemistry for Sustainable Agriculture

Madugamuwe Hewawasam J. Karunarathna, Kerri M. Bailey, Zachery R. Hatten and Alexis D. Ostrowski; Bowling Green State University, United States

Hydrogels with Fe(III) ions and carboxylate-containing polysaccharides such as alginate and pectin were photoresponsive and showed photoreduction to Fe(II) and oxidative decarboxylation of the polysaccharide1. Interestingly, these Fe(III)-polysaccharide hydrogels showed phosphate uptake capability from aqueous solutions for
pH range 4.8 – 11.5. Different hydrogel beads prepared by changing the polysaccharide combination showed a phosphate uptake more than 1 mg g$^{-1}$ at neutral pH of 7. Reclaiming the phosphate from chemical fertilizers and animal manure applied in agriculture is a challenge, and thus we explored the use of these hydrogels to capture phosphate from waste. The phosphate uptake from 100 ppm solutions at pH = 7 was 99% and and~80% from 800 ppm solutions. For raw manure solutions around same pH and with a phosphate content of 340 ppm, the phosphate uptake was 99%. This showed that the uptake behavior was unaffected by the presence of other ions and dissolved solid particles in manure.

These phosphate-loaded hydrogels were also photoresponsive, and the Fe(III)-carboxylate photochemistry slowly degraded the hydrogel network while releasing the phosphate ions. In addition, the amount of phosphate release could be controlled with light intensity. Nutrient uptake by plants (kale and tomato) from the fertilizer-loaded hydrogels was significant. Compared to the controls, plants treated with our fertilizer hydrogel beads showed enhanced plant growth and fruit formation showing the photo controlled nutrient release mechanism. These results show a promising system for reclamation of phosphate from waste solutions and reusing them as a controlled release fertilizer for sustainable agriculture.

**Substrate-Functionalized Carbon Nanotubes as Enzyme Probes for Benchtop and In Situ Study of Soil Health**

Nathaniel Kallmyer, Marshall D. McDaniel and Nigel F. Reuel; Iowa State University, United States

The enzymatic degradation of biomacromolecules is critical to the sustenance of life, whether at the cellular or the ecological size scale. Thus, measurement of hydrolytic enzyme activities is often used to characterize an ecosystem’s capacity to support life, particularly in agriculture, where this rate portends to the long-term return of nutrients and overall health of the soil. While soil hydrolytic activity assays exist, they are often confined to dedicated lab spaces and suffer inconsistencies related to in-house preparation of unstable reagents and variable dynamic ranges. In this work, we present a modular sensor that can be used to evaluate modification of different large, agriculturally-relevant substrates. By suspending semiconducting single-walled carbon nanotubes (SWNT) in an amphiphilic enzyme substrate, we observe enzymatic modification of the substrate through modulation of SWNT fluorescent signal. These substrates may be inherently amphiphilic or may be chemically modified to exhibit hydrophilic and hydrophobic domains. Herein, we demonstrate the throughput and modularity of this nanosensor by measuring proteolytic, cellulytic, and lignin-modifying activity in soil to evaluate health of the soil microbiome. We explore variables including type of crop rotation, microbial carbon content, and soil categorization for each type of enzyme. We also demonstrate this assay’s utility for on-site testing using a custom, portable, battery-powered fluorimeter.

**In Vivo Sugar Monitoring in Trees via Implantable Organic Electrochemical Transistors**

Chiara Diacci$^{1,2}$;  
$^1$Linköping University, Sweden; $^2$Università degli studi di Modena e Reggio Emilia, Italy

During photosynthesis, plants convert light into chemical energy, building sugar molecules, using water and carbon dioxide. Glucose is one of the main products of photosynthesis and it holds an essential role in plants function being the fuel for respiration, growth and development. In order to meet the plants energetic demand sugars are transported from source to sink tissues through the phloem vascular tissue, mainly in the form of sucrose. Although it is well known that sucrose is transported via the phloem, there is evidence of sucrose transport in the xylem vascular tissue, that is adjacent to phloem and it is mainly responsible for water transport. Monitoring sugar transport in xylem, has gain interest in the scientific community since sugars can play a vital role in the wood development; however the current understanding is limited. Apart from being energy source sugars are also important signalling molecules, involved in regulation of physiology including stress responses. Currently there are no methods that allow real time monitoring of sugar transport in plants. Sugar detection is based on enzymatic assays, chromatography and/or mass spectrometry; all of these methods require sample collection and preparation. Organic electrochemical transistors (OECTs) are ideal tools for interfacing with organisms, since they can translate complex biological input to an electronic readout signal. OECT sensors can operate in complex media and they can directly detect products from the biological unit. Recently we demonstrated that OECTs are able to measure the export of glucose in real time, from isolated chloroplasts, with a temporal resolution of 1 min. In this work we develop implantable OECT-based sugar sensors for in-vivo, real time monitoring of sugar transport in poplar trees. OECTs are developed with standard microfabrication techniques, with multienzyme functionalized gate for specificity to glucose and sucrose. The OECTs sensors show high device to device reproducibility, stability.
during the operation in the in-vivo environment and most importantly they do not cause a significant wound response in the plant. We demonstrate that OECT-based sugar sensors are attractive tools for studying transport kinetics in plants, in vivo and real time.

**Single-Bacteria and Virus Identification Using a Bio-Recognition Nanopore**

Makusu Tsutsui¹, Akihide Arima¹, Kazumichi Yokota¹, Masayoshi Tanaka², Masateru Taniguchi¹, Mina Okochi², Takashi Washio³ and Tomoji Kawai¹; ¹Osaka University, Japan; ²Tokyo Institute of Technology, Japan

Solid-state nanopore is a physical sensor capable of detecting single-particles and molecules. The sensing mechanism involves measurements of the temporal ionic current blockade called resistive pulses by an individual object passing through a nanopore. Combing with machine learning to examine difference in multiple features in each ionic current profile, it enables discriminations of analytes by the size, shape, and surface charge states (M. Tsutsui et al., Sci. Rep. 7, 17371 (2017)). In my presentation, I will present our recent research on peptide nanopore approach for adding bioselectivity to the multimodal single-particle analysis. We synthesized recognition probes of various amino acid sequences designed to possess specific affinity to surface proteins of bacteria and/or viruses. We adhered the peptides on Au nanopore wall so as to render antigen-specific perturbation to single-particle translocation dynamics. We found positive correlation between the single-amino-acid-sensitive peptide-analyte affinity and the single-bacteria and -virus translocation time, which was ascribed to longer residence duration of the bioparticle inside the nanochannel with stronger peptide-protein interaction at the wall surface. Multiphysics simulations revealed the intermolecular-interaction-mediated single-antigen translocation mechanism to involve tensile deformations of the soft envelope via electrophoretic forces. Most importantly, we demonstrated multimodal discriminations of flagellated bacteria (Tsutsui et al., Anal. Chem. 90, 1511 (2018)) and influenza types (Arima et al., J. Am. Chem. Soc. 140, 16834 (2018)) in a high-dimensional feature space that revealed the resistive pulse apex as an effective characteristic for distinguishing the intermolecular-interaction-derived difference in the in-pore translocation motions of the two viruses. As the amino-acid sequence degrees of freedom can potentially offer variety of recognition ability to the molecular probes, the peptide nanopore approach can be a versatile single-particle immonosensor that promises wide applications in bioanalysis including environmental monitoring to infectious disease diagnosis.

4:30 PM SB03.04.10
**Nanowire Force Sensors to Probe the Effect of N-acetylcysteine on X. fastidiosa Single Cell Adhesion and Biofilms**

Aldeliane M. da Silva¹, Alessandro Cavalli², Erick Bakkers², Alessandra A. de Souza³, Carlos L. Cesar¹ and Monica A. Cotta¹; ¹UNICAMP, Brazil; ²Technical University of Eindhoven, Netherlands; ³Agronomic Institute of Campinas, Brazil

Probing cell adhesion forces is one of the approaches used to evaluate bacterial motility and surface interactions, which are crucial to the understanding of microorganism behavior. This work presents the application of Indium Phosphide (InP) nanowire arrays as force sensors to investigate the inhibitory effect of N-acetylcysteine (NAC) on adhered cells of the phytopathogenic bacteria *Xylella fastidiosa*.¹,² These bacteria produce extracellular polymeric substances (EPS), which allow them to adhere on a surface and to form biofilms.² NAC is a cysteine analog assumed to disrupt disulfide bonds and therefore remove EPS, among other antibacterial effects. However, the NAC action mechanisms on adhered bacteria are not yet validated experimentally³. In this work we analyzed in real time the effect of NAC on cells attached to the top of InP nanowires. Adhesion forces are measured by optical detection of nanowire deflections due to the forces exerted by bacterial cells, using Confocal Laser Scanning Microscopy. Nanowire positions are determined using a 2D Gaussian fitting of the laser reflection profile. Adhesion forces can be calculated from the measured displacements within the limits of linear theory of elasticity.² Changing bacterial growth time and NAC concentrations in the liquid cell housing the nanowire sensor, we investigated the NAC action on single cells and biofilms. We observed that the measured forces decreased with increasing NAC concentration. Release of cells and biofilms upon NAC addition to the culture are observed in real time; force values on the nanowires decrease once the cells are free. Furthermore, our results suggest a different behavior for the elongated cells bridging neighboring clusters¹; higher adhesion forces keep them attached to the surface after NAC addition, even after biofilm release.

¹P. Sahoo et al., Nano Letters (2016), 16, 7, 4656-4664.
Programmable release fertilizers have been intensively investigated in the last decades to regularly deliver nutrients to plants. The most used approach is to coat the nutrients using a polymeric matrix to slow or/and control their release on the environment [1,2]. However, the matrix may affect the soil properties, as conductivity and pH, depending on its composition, as a result bio-based and biodegradable polymer had been applied to avoid the harm [3]. In response to this, nanofibrillated cellulose (NFC) has been considered due to the presence of hydroxyl groups on its chemical structure. Those groups allow chemical functionalization of the NFC’s surface, giving it an anionic or cationic charge, and enable the interaction with ionic compounds, e.g. the potassium nitrate nutrient (KNO3). As an effect, it should hold the nutrient and delay its release depending on the nutrient charge. Also, the spray drying technique was used because of its advantages as versatility, reproducibility, and flexibility of the process. In this work we use two types of nozzles to understand the relation of the produced particle (capsule or sphere [4]) with the release mechanism in water. First, the NFC has been chemically modified using TEMPO-mediated oxidation [5] and quaternary ammonium salts [6]. Then, the encapsulation was done on a Mini Spray Dryer B-290-BUCH (inlet temperature: 180°C, aspirator: 100%) using two-fluid (flowrate: 9ml/min) and three-fluid nozzle (inner flowrate: 1 ml/min, outer flowrate: 10ml/min, approx.) to attain microsphere and microcapsule (core-shell) structure, respectively. The materials were characterized and compared by their structure (Z-potential, conductivity titration, FTIR and XRD), morphology (SEM), thermal properties (TGA) and the nutrient release profile. The nutrient encapsulated by nanocellulose has shown a lower released percentage (in water) as compared to non-encapsulated nutrient (KNO3). Also, the two- and three-fluid nozzles have formed different structure, as well as the three-fluid nozzle provided a delayed release of nutrients compared to two-fluid nozzle microparticles. Furthermore, the releasing rate dropped from 100% to 45% for the nutrient encapsulate by positively charged nanofibrillated cellulose. The reasons for the slower released are attributed to the charge of the NFC and to the core-shell structure. The content of the positive charges of NFC was determined by conductometric titration of chloride ions with AgNO3 and found to be 0.119 mmol g⁻¹ corresponding to a degree of substitution of 0.02 (AGU). For the negative charges, the value of 1.46 mmol g⁻¹ was obtained by conductometric titration of acid groups with NaOH. The Z-potential of anionic NFC was found to be -60.1 ± 2.2 mV and for the cationic NFC, 36.5 ± 0.8 mV (proofs of positive charges were grafted on NFC). After the encapsulation, the charges of cationic NFC decrease to -8.4 ± 0.8 mV and 6.6 ± 0.6 mV for microspheres and microcapsules, respectively; confirming the interaction between NFC cationic and the KNO3. As a result, the nutrient is bond with the cationic NFC in the core and also surrounded by the additional layer of NFC (shell) postponing its release. Our approach has showed the great potential of functionalized NFCs and core-shell structure in the preparation of environmentally-friend systems for programmable release fertilizers.

Transparent wood is an emerging material with the combination of optical functions and mechanical performances, showing promising prospect in energy-saving buildings, smart windows, and photonics applications. [1] Transparent wood is usually prepared by removing the light-absorbing components followed by successful impregnation with a refractive-index-matching polymer such as polymethyl methacrylate (PMMA).[2]–[4] During the process, the hierarchical wood structure is preserved. The synergy between wood and PMMA is observed for mechanical properties. Optical properties of TW are tunable via control of the fabrication process and doping the host wood matrix with various additives. Wood nanotechnology is an efficient approach to fabricate multi-functional transparent wood. Through wood-PMMA interface modulation, transparent wood with superior high transmittance and low haze is obtained, paving the way for centimeter thick transparent wood preparation.[5] Wood cell wall modification with organic dye Rhodamine 6G (Rh6G) before PMMA infiltration results in luminescent transparent wood.[6] Lasing effect was observed with the dye modified transparent wood, extending the application of transparent wood in the photonic area. By incorporating functional particles or polymers into the wood structure, hybrid transparent wood materials could be obtained, such as luminescent transparent wood, thermal energy storage transparent wood etc.[7], [8]

Additive engineering is a well-known effective strategy to obtain high quality perovskite films, which is critical for successful perovskite-based device technology[1]. Some challenges of unclear mechanism, limited material selection still exist for these bulk-incorporated materials. In addition, the toxicity and cost of the reported additives are often ignored, in fact being one barrier for the future large-scale fabrication. Here, we introduce an extremely low cost and green biomaterial, Ethyl Cellulose (EC) into the perovskite films. Versatile beneficial effects including trap passivation, crystallization kinetic modulation, balanced charge mobility, hydrogen bonding interaction, scaffold behavior, etc., are surprisingly observed in the EC modified perovskite layers[5]. Due to these benefits, the resulting solar cells with EC additive exhibit a remarkably enhanced average power conversion efficiency from 17.11% to 19.27% with the increased of all device parameters including Jsc, Voc and FF. The hysteresis index is found to decrease by 3 times. A pronounced retardation on degradation is also realized where the bare devices with EC retain 80% of their initial efficiencies after 30 days in ambient air under 45% relative humidity, whereas the pristine devices without EC are completely degraded under the same condition.
The work provides a promising way using simple, earth-abundant, but versatile cellulose-based biomaterials as additives to improve both efficiency and stability of the perovskite solar cells.

Developing Fractionation Technologies for Making Quality Renewable Carbon Fibers from Plant Qiang Li, Cheng Hu, Mengjie Li and Joshua Yuan; Texas A&M University, United States

Lignin polymer represents a promising alternative of petroleum-derived polyacrylonitile (PAN) polymer as precursor to synthesize carbon fiber, because of the biorenewability, abundance, low cost, and high carbon content of lignin polymer. Lignin is one of the three main plant cell wall components and a major waste from both paper industry and lignocellulosic biorefinery. Converting lignin waste into carbon fiber has been sought after for several decades with attempt to make cheap carbon fiber and return economics and build sustainability for both biorefining and paper industry. Nevertheless, the poor mechanical performance remains to be a major barrier for commercial applications of lignin-based carbon fiber. We have established that the low mechanical performance was attributed to the chemical heterogeneity of lignin polymer, including diverse interunitary linkages, various functional groups, different molecular weight, and polydispersity. Recent advancements of our group in fractionation technologies showed the great potential to reduce lignin heterogeneity and thus enhance lignin carbon fiber performance. We have developed a series of fractionation technologies to process technical lignin, including 1) partly degradation of lignin using laccase-mediator system and autohydrolysis treatment; 2) solvent fractionation using different organic solvents with different solubility of lignin; 3) physical fractionation by dialysis tube according to lignin molecular weight; 4) lignin precipitation against water with gradient pH values. All these fractionation have trimmed lignin chemistry and reduced lignin heterogeneity by deriving lignin fraction with more β-O-4 linkage, less hydroxyl groups, higher molecular weight, and less polydispersity index (PDI). The resultant carbon fiber was found to have both enhanced mechanical performance and electrical conductivity. Mechanistic study have revealed that the improvement in lignin heterogeneity has improved the molecular interactions of lignin with guest molecules, and thus enhanced the growth of the crystallite structures in carbon fiber, resulting in carbon fibers with improved performances. Overall, fractionation of lignin represents a simple and efficient way to regulate lignin chemistry and boost the quality of lignin carbon fibers, which paved an avenue to transform the sustainability of carbon fiber industry and the bioeconomy of biomass refining.

Structural Biopolymers—From Nanotechnology to Precision Agriculture and Food Security Benedetto Marelli; Massachusetts Institute of Technology, United States

The reinvention of structural biopolymers into technical materials has enabled the design of biomedical and optoelectronics devices with unique and compelling properties that can serve at the interface between the biotic and the abiotic worlds. For example, we have previously shown the use of silk fibroin bioinks for the detection of E.coli contamination in food. Silk fibroin, in fact, is an edible and biodegradable protein extracted from B. mori cocoons that can be engineered in several formats ranging from films to particles, foams, and gels. By exploiting silk fibroin essential properties (i.e. polymorphism, conformability, and hydrophobicity) it is possible to design a water-based protein suspension that assembles in nano- to centimeter thick materials that can be nanofabricated using advanced manufacturing techniques, including e-beam, soft lithography, replica molding, and printing. The so formed materials modulate mass transport (e.g. O2 and CO2 diffusion and water vapor permeability) and preserve the function of biological molecules and micro-organisms outside the cold chain. This is possible by controlling protein polymorphism (i.e. formation of random or beta-sheet structures) during and post material assembly. Here, we show how silk materials can be used to address technological challenges in precision agriculture and food preservation to enhance food security. We will present the design of edible coatings that prolong the shelf-life of perishable food by decreasing water evaporation and regulating O2 and CO2 diffusion, effectively reducing oxidative stresses and cell metabolism. The use of silk fibroin coating can also be expanded to seeds to engineer the inoculation of biofertilizers that can mitigate abiotic stress as saline and arid soils. Finally, we will discuss the possibility to use silk-based materials as a vehicle to deliver phytoactive payloads in plants vasculature to modify plant metabolism.

Spotlight Talk—Multifunctional SiQD-Embedded Transparent Wood Alden Clemments and Ilya Sychugov; Kungliga Tekniska Hogskolan, Sweden

Recent developments in the fabrication of transparent wood (TW) have shown promise in the field on renewable energy. Impregnation of TW with silicon quantum dots (SiQDs) exhibits promise as light-harvesting composite. However, these advancements are hindered by the ability to selectivity control QD distribution and loading within the porous scaffold. Here, we demonstrate that by employing a variety of chemical methods, improvements in QD loading, distribution, and ultimately optical output are drastically improved.

Spotlight Talk—Electronic Functionalization of Roots of Intact Plants via In Vivo Polymerized Conducting Polymer Daniela Parker1,2, Gwennael R. Dufl1,2, Magnus Berggren1,2 and Eleni Stavrinidou1,2; 1Laboratory of Organic Electronics, Sweden; 2Linköping University, Sweden

As our understanding of the surroundings and technology advances so does the way we interact with our environment. Serving as food, improving our health, allowing us material extraction or just decorating our constructions, plants have played a vital role in helping humans thrive to adapt and survive. As new challenges arise, there is still room for creative ways to interact with plants. Recent research has focused on interfacing organic electronics with living plants. Although the plant by itself represents a complex system, the idea is to add an extra functionality.

Initially we demonstrated formation of conducting wires along the xylem vascular tissue of rose cuttings from stem to flower. The wires were formed spontaneously, when the cutting was immersed in aqueous solution of a thiophene based conjugated oligomer, ETE-S. ETE-S comprises key features such as water solubility and small molecular weight for plants to transport through its vascular system. The plant guided the polymerization reaction in the xylem acting as a template and catalyst for the polymerization reaction.

In this work we aim to advance the technology by functionalizing intact plants. We choose the bean as our model system and demonstrate electronic functionalization of roots. The ETE-S polymerizes effectively in the root epidermis forming polymer coating of thickness 1-3um. The functionalized roots exhibit conductivity in the order of 10S/cm and volumetric capacity of 50F/cm3. The plants ability to grow its not impaired from the electronic functionalization, making it an attractive system for biohybrid applications from sensing to energy.

10:40 AM SB03.06.03
Spotlight Talk—Synthesis of a Paracyclophane-Based Conjugated Oligoelectrolyte and Its Interactions with Biological Membranes Jakkarin Limwongyut1,1, Yang Liu2, Gayatri Shankar Chilambi2, Thomas Seviour2, Jamie Hinks2, Yuguang Mu2 and Guillermo Bazan1,1; 1University of California, Santa Barbara, United States; 2Nanyang Technological University, Singapore

Conjugated oligoelectrolytes (COEs) are molecules that can spontaneously interact and modify microbial membrane properties. In this work, a three-dimensional COE containing a [2.2]paracyclophane unit (COE2-3-pCp) in a conjugated framework was synthesized to introduce more dimensionality to the core. Its biological activity was determined within the context of membrane perturbation and biocompatibility in lipid vesicles and microbial cells. Additionally, the effects of COE2-3-pCp in a bacterial membrane model were determined in silico using molecular dynamic simulations. The simulations indicate that, compared to its linear analog (COE2-3C), COE2-3-pCp introduces more lipid disorder with higher extent of membrane thinning. In microorganisms, COE2-3-pCp exhibits...
lower toxicity against *E. coli* K12 and yeast, while maintaining similar levels of membrane permeabilization. These findings suggest a new design of COEs as biocompatible cell permeabilizers.

The Photoelectrochemistry of Photosynthetic Machineries—From Isolated Proteins to Living Cells Jenny Zhang; Univ of Cambridge, United Kingdom

Photoelectrochemistry is a relatively new tool for studying photosynthesis, and the knowledge and tools developed from this platform will form the foundation of emerging technologies utilizing photosynthetic materials for energy conversion. The photoelectrochemistry of purified photosystems have recently benefited enormously from an improved understanding of the interfacial wiring and improved electrode design. Here, I give an overview of this progress with a focus on lessons derived from photosystem II, and show how these lessons can be applied to the photoelectrochemistry thylakoids and whole cells. The systematic comparison of the different components, each being one step removed in metabolic complexity, allows the electron transfer processes at each level to be more effectively teased out.

Bacterial Photosynthetic Reaction Center—Extending the Functionality by Bioconjugation Strategies  
Gabriella Buscemi1, Simona La Gatta1, Francesco Milano2, Roberta Ragni1, Gianluca M. Farinola1 and Massimo Trotta2; 1University of Bari, Italy; 2National Research Council, Italy

Bioconjugation is a process useful for giving natural systems addititional artificial properties belonging to ad hoc newly synthetized organic small molecules or other biomolecules. Protein functionalization is usually achieved via click chemistry reactions or amide synthesis, and the partner molecule can be a lipid, or another protein, a nucleic acid, a polysaccharide or an organic molecule. During the bioconjugation processes, cysteine, tyrosine and lysine residues are typically exploited for anchoring synthetic ligands1. Moreover, if the protein is an enzyme, the creation of a protein-protein or protein-prosthetic assembly can finely modulate the enzymatic activity.

The photosynthetic reaction center (RC) is an ubiquitous protein. Among all the photosynthetic organisms, the RC obtained from the anoxygenic purple bacterium Rhodobacter sphaeroides is often used as a model system, due to its easy isolation and fully charactherized spectroscopic/electrochemical behaviour2. RC is a trans-membrane photoenzyme which efficiently harvests sun-light and converts it in other viable forms of energy by generating charge separated states for fueling cell metabolism.

Biohybrid materials, based on the combination of RC and artificial organic antennas have been already produced to increase the spectral region of the harvested sun light, in order to ameliorate the charge separation aptitude and generation3. Now our research group is focusing on the possibility to covalently link RC with another non photosynthetic protein, the cytochrome c (Cyt C), which is the natural electron donor of these photosynthetic proteins. This is in principle done for ameliorating the electrical communication between RC and Cyt C4.5. This RC-Cyt C bioconjugation is possible by developing a one-step “grafting-to” protocol exploiting specific lysine and organic aliphatic linkers. In a speculative perspective, we will use these biohybrids to better orient RC on devices for
bioelectronic applications.

Flavin-Hybridized Carbon Nanotube Electrode for Selective Biocatalytic Oxyfunctionalizations Da Som Choi¹, Yan Ni², Elena Fernández-Fueyo², Minah Lee¹, Hollmann Frank² and Chan Beum Park¹; ¹Korea Advanced Institute of Science and Technology, Korea (the Republic of); ²Delft University of Technology, Netherlands

Biocatalytic oxyfunctionalization of inert C-H or C-C bonds is of special interest in organic synthesis. In particular, unspecific peroxygenases have gained much interests since they catalyze a wide range of selective oxyfunctionalization reactions; however, their broad application is hampered by oxidative degradation of the heme moiety in the presence of even low concentrations of H₂O₂. Typically, this challenge has been met by in situ provision of peroxygenases with suitable amounts of H₂O₂ by catalytic reduction of molecular oxygen using electrochemical¹, photochemical², or enzymatic³ methods. Photoelectrochemical (PEC) reduction of oxygen is an attractive approach to produce H₂O₂ with the use of abundant solar energy and water, avoiding the accumulation of byproducts in the reaction mixture. In this study, we demonstrated a novel, photoelectrochemically boosted peroxygenase catalysis through in situ generation of H₂O₂ via flavin-hybridized carbon single-walled nanotubes (SWNT) photoelectrodes. Flavins can be easily immobilized on the surface of SWNT electrodes via a simple hybridization process while maintaining their redox-active properties of flavins. The hybridization of flavins with SWNTs occurs through π-π interactions between aromatic isoalloxazine moities and graphitic carbons in addition to hydrogen bondings between adjacent flavin molecules. Compared to a pristine SWNT, the flavin-SWNT hybrid photoelectrode exhibited much higher photocurrent density and a marked anodic shift for oxygen reduction reaction, which is attributed to the facilitative effect on charge transfer to oxygen by flavin photosensitizers. As a result, H₂O₂ production rate is enhanced up to 0.15 mM h⁻¹ at -0.3 V (vs. Ag/AgCl) under illumination, which is 2.28- and 2.48-fold higher than control experiments without light or using a pristine SWNT cathode under light, respectively. We successfully coupled the flavin-SWNT-based PEC platform to peroxygenase-catalyzed reactions, such as ethylbenzene hydroxylation, 2-phenoxypypropanoic acid hydroxylation, and indole oxidation.

Charge Recombination in Semi-Artificial Photosynthesis Nicolas Plumere; Ruhr-Universität Bochum, Germany

The integration of photosynthetic proteins in biophotoelectrodes is envisioned for the production of electricity⁴ or chemical fuels. Redox hydrogels proved particularly suitable as matrices for the immobilization and electrical contacting of photosynthetic proteins to electrodes. We tuned the redox potentials of the electron relays and the properties of the polymeric supporting matrix to enable benchmark photocurrent densities (300 μA cm⁻² for PS1⁵ and up to 400 μA cm⁻² for PS2⁶) at low overpotential⁴. In analogy to the working principle of dye sensitized solar cells, an important feature of biohybrid solar cells for conversion of light to electricity is the charge carriers needed for collection of the high-energy electron from the photosystem⁵. The main limitation in energy conversion efficiency is the recombination of this charge carrier at the photoelectrode, a process that decreases both the photocurrent and the open circuit voltage⁶. Moreover, this charge recombination process is suspected to induce degradation of the photosynthetic protein⁶. We demonstrate that the hydrogel film properties as well as the electrode surface chemistry can be tuned to minimize the various charge recombination pathways.

**Antimicrobial Polymer-Peptide Conjugates Based on Maximin H5 and PEG to Prevent Biofouling of E. coli and P. aeruginosa** Eduardo Nicolau, Valérie Ortiz and Jaime Santillan; University of Puerto Rico, United States

Many pathogens, such as *Pseudomonas aeruginosa* and *Escherichia coli* bacteria can easily form biofilms. The formation of such biofilms in surfaces is known represents a problem for membrane-based water purification techniques, the area of biomedical devices among many others. Aiming to provide a plausible solution to this issue, herein we explore on an antimicrobial peptide (AMP’s) polyethylene glycol (PEG) conjugate that prevents biofouling formation. In this research, the anionic and hydrophobic peptide Maximin H5 (MH5, 2.4kDa), which is
an integral part of the defense system of the frog *Bombina maxima*, is coupled to PEG of different sizes (i.e. 2 kDa and 5 kDa) followed by extensive characterization. Scanning Electron Microscopy (SEM) was employed to evaluate the formation of biofilms and its interaction with these conjugates, showing no biofilm formation. After physical and microbial characterization, MH5 was bio-conjugated to PEG followed by size exclusion purification. The reaction confirmation was achieved by SDS-PAGE and MALDI ToF. Moreover, the antimicrobial activity of the MH5-PEG conjugates was performed via the growth inhibition method and SEM. These conjugates have demonstrated potent antimicrobial activity with high inhibition of bacterial growth after 24 hours. Thus, the prepared polymer-peptide conjugates have the potential to be utilized on applications where an antimicrobial coating is necessary.

**SB03.08.03**

**Modification of Cotton Surfaces with Superhydrophobic Nanotextures for Enhanced Healthcare and Hygiene**

Jun Kyun Oh; Dankook University, Korea (the Republic of)

As a result of frequent outbreaks occurring due to poor hygiene and improper sanitation of processing environments, there has been an increasing demand for the development of material surfaces that intrinsically inhibit and reduce likelihood of potential microbial adherence and biofilm formation. Herein, we report the synergistic utilization of surface nanotexturing and chemical modifications with nonpolar functional groups on cotton surfaces to produce coatings having bacterial super-repellent characteristics. Using these coatings, the attachment of *Staphylococcus aureus* as pathogen surrogates was reduced more than 99.0%, compared to the bare cotton surfaces. Moreover, this method is both versatile and scalable, involving inert and biocompatible building blocks. Overall, this study contributes to the field of biomedical applications through the design and development of novel coatings for achieving improved healthcare and hygiene.

**SB03.08.04**

**A Novel Photothermal Nanocomposite for Reducing Bifofilms Associated with Silicone-Based Devices**

Pedro Sanchez, Stanley Green, Madison Greer, Shaina Yates and Nicole Levi-Polyachenko; Wake Forest University Health Sciences, United States

*Staphylococcus aureus* is a common pathogenic bacterium prevalent in a wide variety of diseases, including progressive blood and tissue infections such as chronic ulcers, sepsis and osteomyelitis. Additionally, there exist many *S. aureus* subtypes which have developed resistance to broad-spectrum antibiotics. Part of the acquired antibiotic resistance may be attributed to the capacity for *S. aureus* to thrive in colonies within a protective matrix of polymers, polysaccharides, extracellular DNA and water (biofilm). Biofilm residing bacteria are known to be many times more resistant to select antibiotics than their planktonic counterparts.

One mechanism proposed for mediating biofilm-associated infections is to disrupt the polymer structure of the biofilm, leading to the release of planktonic bacteria which are more susceptible to antibiotic therapy. Chemical agents have been evaluated for accomplishing this; however, physical means, such as heat or ultrasound can serve two purposes by first disrupting the biofilm structure while also altering individual bacterial cell walls. Physical disruption may be especially advantageous for eradicating biofilms associated with implanted medical devices, alleviating the need for their removal and maintaining device function.

Silicone is a biocompatible elastomer that can either compose an entire medical device (catheters) or be used as a pliable surface coating on metal or ceramic implants. For the generation of heat, we have included photothermal donor–acceptor conjugated polymer nanoparticles based on poly[4,4-bis(2-ethylhexyl)-cyclopenta[2,1-b;3,4-b’]dithiophene-2,6-diyl-alt-2,1,3-benzoselenadiazole-4,7-diyl] (PCPDTBSe). The composite materials were evaluated for the killing of planktonic and biofilm-residing *S. aureus*, in either the presence or absence of the antibiotic gentamicin. In the absence of near-infrared laser stimulation of the composite, addition of the nanoparticles exhibited an unexpected bactericidal effect. Stimulation of silicone alone with 612 J/cm2 of 800nm light had no effect on planktonic or biofilm *S. aureus*, whereas ablative temperatures in the nanoparticle doped composites resulted in a 95-100% reduction in viable bacteria. Sub-ablative temperatures resulted in a 75% reduction in planktonic bacteria treated with gentamicin and a 90% reduction in biofilm-residing *S. aureus*, compared to controls treated with gentamicin alone and no infrared stimulation. The PCPDTBSe nanocomposites were then evaluated in a murine model to simulate biofilm infections associated with subcutaneously placed silicone implants. A luminescent variant of *S. aureus* was used to monitor the bacterial burden in the mice before and after laser stimulation with and without antibiotics, and the burden was quantified by measuring colony forming units.
(CFU) following explantation of the nanocomposite. Depending upon the laser parameters used (1.2-3W/cm² for 10-45s) there was a reduction of 33-94% CFUs following treatment with the heat-generating nanocomposite plus antibiotics. Our results demonstrate the potential for heat-generating biocompatible nano-composites to augment antibiotics used to treat S. aureus biofilms. These results offer a new avenue for the use of photothermal nanocomposites to eliminate challenging medical infections associated with in-dwelling medical devices.

Metabolically Active Cells of the Photosynthetic Bacterium Rhodobacter sphaeroides Encapsulated in Melanin-Like Structure
Massimo Trotta¹, Danilo Vona², Stefania Cicco¹, Roberta Ragni², Marco Lo Presti², Gabriella Buscemi² and Gianluca M. Farinola²; ¹Consiglio Nazionale delle Ricerche, Italy; ²Università di Bari, Italy

Photosynthetic organisms are the primary producers of energy on planet Earth thanks to their ability to harvest and convert light into other forms of energy viable for virtually all the metabolic needs of any living organism. Exploiting this formidable attitude is a very intriguing possibility for developing innovative and efficient sustainable energy sources based on the conversion of solar energy. Garnishing the photosynthetic enzymes [1,3] to produce hybrid systems formed by biological and organic moieties for energy transduction has been shown to be a promising route. On the other side, being able to use the whole, metabolically active, photosynthetic organisms is even more promising [4]. To this purpose, “wiring” the living organism with conductive systems, either organic or inorganic, is of paramount relevance [5] and, yet, has not been fully addressed. Recently, the encapsulation of living yeasts in polydopamine (PDA)-based structures has been demonstrated [6], with the metabolic activity of the cells preserved in this confinement state because of the lack of any detrimental effect of the polymer. We present here the preliminary results of the entrapping and confinement of active cells of the photosynthetic bacterium Rhodobacter sphaeroides into ad hoc engineered melanin-like polymers using a mild approach in water based buffers. Bacterial growth accompanied by cellular division are retained under photosynthetic anoxygenic condition, although some detrimental effects are registered in the case of some of the polymers investigated.

This work was funded by European Commission through the EU project 800926 - HyPhOE (Hybrid Electronics based on Photosynthetic Organisms)

**M13 Bacteriophage Based Triboelectric Energy Generation for Powering Organic Light Emitting Diode**

Han Kim\(^1\), Byoung Duk Lee\(^2\), Jihwan Yoon\(^2\), Jonghyuk Lee\(^2\), Ju Hyuck Lee\(^3\) and Seungwuk Lee\(^3,1,1\); \(^1\)University of California, Berkeley, United States; \(^2\)Samsung Display, Korea (the Republic of); \(^3\)Biological Systems and Engineering Division, Lawrence Berkeley National Laboratory, United States

Development of a clean and green renewable energy source without sacrificing a carbon footprint is one of most challenging issues that mankind faces in the modern society. Triboelectricity is a charge separation induced by friction through the physical contact of materials with different electron affinities. Recently, triboelectricity materials and devices have shown a promising pathway to harvest ubiquitous mechanical energy to charge mobile and portable electronic devices. M13 bacteriophage (phage) is a promising material to develop a clean and green triboelectric material. M13 phage is benign and non-harmful virus to infect only bacterial host cells. It has a filamentous shape with 880 nm in length and 6.6 nm in diameter. The M13 phage is covered by 2700 copies of major coat protein that encapsulates phage DNAs. Through the genetic modification, we can precisely control the chemical and physical structures of the phage coat proteins. The resulting engineered phage can be easily amplified to produce identical copies of the phage in a large scale. Due to the anisotropic rod-shape, we can self-assemble the phage into various of liquid crystalline structures. Here we developed a novel triboelectric energy harvesting materials and devices using M13 phage. We first created a monolayer thin film of M13 phage and characterized triboelectric properties of the M13 phage. Through direct friction between Ti/Pt coated-AFM tip and M13 phages, we generated the triboelectric charge, and characterized them using Kelvin probe force microscopy (KPFM) measurement. Upon friction generation, we could successfully observe the triboelectric charge generation using the KPFM. We then modified the surface charge through addition of different number of glutamic acids on the M13 phage coat proteins. The phage with higher number of glutamic acids showed a higher triboelectric potential than that of fewer glutamic acids. We also characterized triboelectric charge generation depending on the friction conditions and their discharging behavior. We finally fabricated the large area thin film of M13 phage and developed a triboelectric thin film energy harvesting device. Upon the mechanical force application, the phage-based triboelectric devices can generate 3 V and 5x10^-4 mA. The resulting device also could power the organic light emitting diode devices with thin film encapsulation. Our approach to develop a phage-based triboelectric material is useful to understand how friction can induce charges in a biological system in a molecular level and to develop clean and green energy harvesting solutions to charge portable electronic devices and biomedical applications in future.

**An All-in-One Fluorescent Supramolecular Bacterial Sensor Assisted by Transformation of Peptide Self-Assembly**

Youjin Jung\(^1\), Woo-jin Jeong\(^2\), Se-Hwan Choi\(^1\), Hye-soo Lee\(^1\) and Yong-beom Lim\(^1\); \(^1\)Yonsei University, Korea (the Republic of); \(^2\)University of Wisconsin–Madison, United States

An all-in-one fluorescent supramolecular bacterial sensor assisted by transformation of peptide self-assembly is reported.
The essential components of a sensor are receptors, signal converters and detectors. Here we propose an all-in-one bacterial biosensor in the form of supramolecular peptide assembly, which contains all three components by itself. The assembly consists of a double-layered octa-helical tetrameric coiled-coil structure. The outer surface of the assembly shows tetravalent helical bioreceptors for targeting bacteria and the inner core is composed of environment-sensitive fluorophores as detectors. At the connection between them are reversibly self-assembling peptides that play a role in signal transduction. The signal transduction exploits the reversible and non-covalent property of the self-assembled supramolecular system. The multivalent binding of bacteria activates supramolecular transformations, which are transduced into fluorescence changes. Our fluorescent supramolecular biosensors (fSBs) could selectively detect E. coli over other bacteria. Since the fSBs are not denatured by heating, they maintain their capability as a bacterial sensor even at high temperature (50 °C). Based on this research, a variety of responsive supramolecular sensors can be developed to detect diverse biomacromolecules and large biological objects.

SB03.08.11
Spray-Dried Microspheres of Starch as Enhanced Efficiency Fertilizer Materials Camila G. Chiaregato1,2 and Roselena Faez2,1; 1University of Sao Paulo, Brazil; 2Federal University of São Carlos, Brazil

By 2100, the population is expected to reach 11.2 billion people, and agriculture has the challenge to establish strategies to achieve sustainable production of food. Fertilizers are used to increase crop production by replacing the necessary nutrient for the plant and also are the major cause of contamination of underground water and rivers. About 30 to 50 % of the fertilizers applied are lost by lixiviation or volatilization, being necessary to use a higher quantity than the real need. The big question is how to increase fertilizer efficiency and crop yield without compromising natural resources? One of the answers is developing a material that controls the availability of fertilizer in the soil, a technology that enhanced efficiency fertilizer, reducing the loss, the amount of fertilizer applied and, consequently, production costs. To achieve this goal is relevant to use polymers from natural resources with wide availability, and potential to biodegrade, to act as a protection layer. Starch polymer fits all these characteristics and has a low cost. For this purpose, the aim of this work was developed microspheres of starch and micronutrients by spray drying technique. For starch gelatinization, 6 wt. % of food-grade corn starch was added in 100 mL in distilled water and heat in an oil bath at 97 °C during 30 min. After, the gelatinized starch was homogenized in a Turrax for 5 min with 10,000 rpm and during the atomization process kept in magnetic stirring. For starch atomization, we use a 2 - fluid nozzle (0.5 mm diameter) at 130 °C and aspiration rate of 10 % in a Mini spray drying (B290/Buchi) yielding 47 %. The X-ray diffraction pattern of native corn starch exhibited peaks at 15 °, 18 ° and 23 ° (20), which indicates A-type starch crystallinity. After the atomization, the microspheres showed an amorphous pattern, which is a consequence of the drying process. The decrease of nutrient release in water demonstrates the potentiality of spray-dried starch microspheres as an enhanced efficiency fertilizer.

SB03.08.12
Spray-Dried Microparticles Based on Chitosan and Cellulose Nanocrystal as Supporting Material for Controlled Release of NPK Fertilizer Lucas L. Messa1,2,3 and Roselena Faez2,1; 1University of Sào Paulo-USP, Brazil; 2University of São Carlos-UFSCar, Brazil; 3University of California, Davis, United States

The development of microparticles based on natural polymers has attracted great interest for numerous applications, mainly as the release of compounds. It can offer a longer diffusional path, which prolonged release. One of the most potential application of these systems of microparticles is in agriculture, where the main issue presented is the loss of fertilizers, like nitrogen (N), phosphorus (P) and potassium (K). Chitosan (CS) is a cationic polysaccharide frequently used for slow/controlled release due to its biodegradability and availability of functional groups (N-H, O-H) on its surface. Because of the reactivity of the protonated amino group (NH3+), CS is able to interact with anionic compounds such as phosphate ions. In addition, cellulose nanocrystal (CNC), which is produced from acid hydrolysis of native cellulose fibers, has negatively charged groups due to the insertion of sulfate groups from hydrolysis. These groups can bind many cationic ions, such as potassium and ammonium. This work focus on the preparation of spray-dried microparticles and the surface interactions between of both polymers (CS and CNC) and the NPK fertilizer as well. First, the CNC was prepared by acid sulfuric hydrolysis (64% wt., 50°C, 120 min) from sugarcane bagasse cellulose. Then, 4 formulations based on 100 mL of Cs (1 wt.%) and two different mass ratios of CNC (0.1 and 1.0 g) and NPK (2.7 and 16.2 g) to CS were dried on a Mini Spray Dryer B-290-BUCH (inlet temperature: 180°C, aspirator: 100%) using two-fluid (flow rate: 7 ml/min). Microparticles were compacted using a hydraulic press (6 ton, 25°C for 1 min) to produce materials in pellet form. All produced materials were characterized using FTIR, XRD, SEM and releasing tests were carried out to evaluate the CNC effect on release.
property of the composites. XRD confirmed the presence of NPK in the spray-dried microparticles. The interactions between chitosan polymer and ions from fertilizer were confirmed by FTIR results. The non-encapsulated NPK had the fastest release due to high solubility of the fertilizer in water. SEM results showed that CS concentration used in this work was not able to encapsulate the high content of NPK (16.2 g). The fertilizer encapsulated by composites with 0.1 wt.% of CNC showed a slower release profile as compared those with 1.0 wt.% of CNC. This suggests that part of the NPK remains not encapsulated in the presence of CNC high content and can be quickly released from the system. Our work demonstrates one application of CNC and chitosan to bind fertilizers into microparticles that would improve nutrient use efficiency.

SB03.08.13
Single-Cell Drop-Seq Techniques for Genomic Profiling of Microorganisms Abhiteja Konda1,1, Ryan Dohn2, Rebecca Back2, Pavani Vamshi Krishna Nittala2,1, Ralu Divan1, Supratik Guha1,2 and Anindita Basu1,2; 1Argonne National Laboratory, United States; 2The University of Chicago, United States

Single-cell genomics research has gained significant and rapidly growing interest due to its ability to characterize a population of cells at epigenomic, transcriptomic, or proteomic level with a single-cell resolution that is critical to understanding the genomic heterogeneity between individual cells comprising a population for its potential applications in industry and medicine. The existing single-cell techniques have mainly focused on multicellular, complex organisms such as primates, insects, rodents, and fish; however, understanding the heterogeneity in unicellular microbial organisms is important and will be critical in addressing some of the challenges in environment, medicine, and energy-related applications. This heterogeneity in microbes exists as a response to the ever-changing complex environment. Currently, there are no tools or technologies that allow the quantification of this variation. In the present work, a droplet-based approach is used to transcriptionally profile each microbial species at single-cell resolution and high throughput. Emphasis is laid on the lysis of the microbial cell wall which is one of the key challenges to overcome for the success of the project. A suite of different techniques (both physical and chemical) including the use of microelectromechanical systems [MEMS], laser ablation, acoustic waves, plasmon resonance either used independently or in combination are studied for the lysis of the cell wall. The single-cell lysates are then used as input for high-throughput single-cell RNA-Seq. This work will significantly enhance the current technologies and will enable generalized, cost-effective single-cell RNA sequencing in microbes at high throughput and therefore will be vital to advancing science from different fronts for applications in synthetic biology, environmental engineering, energy, and medicine.

Phase-Separating Biopolymer Conjugates in Designing Multicomponent Biomaterials Kristi L. Kiick; University of Delaware, United States

Microstructured hydrogels offer many opportunities in developing therapeutic matrices for guiding cell behavior. This presentation will outline our recent studies in formulating PEG- and (poly)peptide-based conjugates with nanoscale and microscale structures imparted by the controlled phase separation of multicomponent solutions. Resulting microstructured hydrogels can be manipulated on the basis of solution conditions and the composition of the polypeptide. The materials exhibit distinct microscale mechanical properties (1-15kPa) in ranges relevant for the development of synthetic pedicles for vascular grafts and high cytocompatibility over weeks in static and dynamic culture. Given our observations that the activation of fibroblasts and the differentiation of CD34+ stem cells can be directed in substrates with shear storage moduli in this range, our data suggest possible cell-materials platforms for modulating the activities of cells relevant in cardiovascular applications.

8:30 AM *SB04.01.02
3D-Extrusion Printing of Stable Constructs Composed of Polypeptide Hydrogels Robert Murphy and Andreas Heise; Royal College of Surgeons in Ireland, Ireland

The field of tissue engineering and regenerative medicine aims to regenerate damaged tissues rather than their replacement via the creation of well defined, surgically implantable biomaterial constructs. The development of defined three-dimensional (3D) architecture fabrication for tissue engineering has been a recent emergence within the field. In particular, 3D printing represents a promising rapid prototyping technology for the production of intricate bio-inspired scaffolds/constructs. The primary feedstock materials used are polymeric hydrogels, which possess ideal physicochemical properties for these rapid 3D patterning techniques. Hydrogels encompass the capability to augment native tissue due to their comparative 3D nano-architecture while holding the potential to act as a mimic of the extracellular environment. Recent work on 3D rapid prototyping with hydrogels has mainly focused on the use of natural polymers. Polysaccharides such as chitosan have been chemically functionalized and used as carriers within hydrogel inks. Recent reports also detail the fabrication of modified bio-native gelatin hydrogels which were 3D printed into cell laden constructs and self-healing structures respectively. More synthetic approaches have utilized poly(ethylene glycol) or acrylic monomer loaded inks. Despite these efforts, the limited number of suitable bio-inks has been identified as the major barrier to progress and the development of new advanced hydrogel applications.

We present a new family of copolypeptide based hydrogel ink capable of structural microfabrication using 3D extrusion printing. The material comprises an amphiphilic block or star copolymer structure which spontaneously form hydrogels through hydrophobic interaction. The chemical design allows the bulk phase of the hydrogel to remain intact after application of shear due to its self-recovery behavior. It is demonstrated that the composition of the materials is ideally suited for 3D printing; with scaffolds capable of maintaining structural cohesion after extrusion. Post extrusion UV-triggered fixation of the printed structures can be carried out resulting in stable hydrogel constructs. The constructs were found to be degradable, exhibited favorable release of encapsulated molecular cargo and did not affect the metabolic health of the commonly used fibroblastic cell line, Balb/3T3 cells. Moreover, the functionality of the amino acid building block allows the design of intrinsically antimicrobial constructs. In summary, the copolypeptide inks offer a new bioink platform that allow for rapid prototyping enabling the fabrication of defined intricate microstructures, providing a platform for complex scaffold development.

9:00 AM *SB04.01.03
3D Bio-Printed Platforms for Oral and Dental Diseases Stella Alimperti1,2; 1American Dental Association, United States; 2National Institute of Standards and Technology, United States

Traditional treatments for periodontal and dental diseases have severe limitations, including high-cost, non-efficient drug delivery, and aging. For example, patients who receive tooth and gum grafts are subject to lifelong side-effects,
such as increased rates of gum infections and oral malignancies. A solution to overcome these barriers is the integration of oral medicine and bioengineering within a single framework for potential translational and therapeutic purposes of dental diseases. Our lab focuses on identifying new biological targets involved in periodontal disease with the development of multidisciplinary tools, including organ-on-a-chip technologies, oral biology, and 3D printing technology. Our particular focus for today’s presentation is diabetes on oral health. Diabetes is a chronic, incurable disorder characterized by lack of resistance to insulin, leading to an excess of serum glucose, which negatively affects homeostasis of the oral epithelium [1,2]. Alterations or disruptions of the epithelial integrity can ultimately result in chronic inflammation and periodontal disease. We engineered a 3D platform to deconvolute the dynamic contribution of epithelium in diabetic periodontitis. The in-vitro disease epithelium model is a 3D printed microfluidic platform that is comprised of 3D cylindrical channel (diameter 160 µm) embedded within different stiffnesses (0.1kPa, 1kPa, 10kPa) of hydrogel solution of collagen I. Human oral keratinocytes (HOKs) were seeded and allowed to adhere through the collagen I wall. The epo-oral tube was exposed to 11 nmol/ml glucose to mimic diabetic conditions compared to control, 4 nmol/ml glucose under different stiffnesses. In addition, we introduced a pro-inflammatory stimulus into the 3D bio-printed platform, named lipopolysaccharides (LPS) (100 ng/ml) for 1hr. The diffusion of fluorescent dextran (70 kDa Texas Red, Thermo Fisher) (12.5 μg/mL) was imaged in real time with a confocal microscope (LSM 800, Carl Zeiss). The diffusive permeability coefficient ($P_d$) was calculated by measuring the flux of dextran into the collagen gel and fitting the resulting diffusion profiles to a dynamic mass conservation equation [3]. The $P_d$ was increased dramatically in LPS treated diabetic conditions compared to non-diabetic ones. Finally, LPS treatment increases FOXO1 translocation in diabetic HOKs. Collectively, the 3D bioengineered micro-platforms substantially provide insights on periodontitis area by developing sophisticated approaches, based on the 3D printing and organ-on-a-chip technology, avoiding the limitations of the 2D standard cell culture and enabling us to approach potential efficient treatments for periodontal diseases.

9:30 AM BREAK

10:00 AM *SB04.01.04
3D Printing of Transparent and Conductive Heterogeneous Hydrogel-Elastomer Systems Joost J. Vlassak; Harvard University, United States

Interest in stretchable electronics has grown significantly in recent years, driving a need for soft and stretchable materials that can sustain high strains and still fulfill their function in applications such as wearable sensors for health monitoring or feedback sensors in soft robotics. Many stretchable conductors exist including liquid metals, nanowires, and micro-cracked metals. Conventional strategies of incorporating hard components with soft elastomers to attain stretchability often lead to failure of the hard-soft material interface and limited stretchability. The use of gels as soft conductors, where ions are the charge carriers instead of electrons, represents an entirely different approach that has gained popularity recently. Their high stretchability, when combined with recent improvements in toughness and stiffness, enable their use as stretchable electrical conductors, capacitive strain sensors, and chemical/pH sensors. Gel-based ionic circuits thus represent a unique class of devices within stretchable electronics. Fabrication of stretchable electronics using hydrogels requires integrating hydrogels with stretchable dielectrics such as dielectric elastomers; a process thus far achieved primarily via the combination of several different manufacturing techniques. We have developed an extrusion printing technique capable of fabricating an ionic circuit that integrates a LiCl-doped poly(acrylamide) (PAAm) hydrogel with a poly(dimethylsiloxane) (PDMS) dielectric elastomer. By incorporating hygroscopic salts such as LiCl into the hydrogel, we are able to prepare an ionically conductive hydrogel with excellent water-retaining properties. For printing reliability, we have optimized the rheological properties of a high ionic-strength hydrogel precursor using a nonionic rheological modifier. We show that the adhesion between oxygen plasma-treated PDMS and hydrogel increases with time to reach a stable value of 15 J m$^{-2}$ after approximately six days. During that time, the contact angle of water on the PDMS interface remains constant at 30°, suggesting that hydrophobic recovery of plasma-treated PDMS is suppressed by the presence of the hydrogel. Furthermore, a thin viscous layer develops at the interface between PDMS and hydrogel, which results in energy dissipation upon debonding and which allows full recovery of the adhesion after debonding and rejoining. Finally, we demonstrate the viability of silane coupling agents to further enhance the adhesion between PDMS and hydrogel. By introducing a charge-neutral surfactant in the PDMS and adjusting silane concentrations in the PAAm, interfacial adhesion can be increased to the point that the system fails by cohesive failure within the hydrogel, achieving toughness values of up to 193 J m$^{-2}$ for a fully printed PAAm hydrogel-on-PDMS bilayer. This result suggests that an integration strategy with silane coupling agents may enable robust extrusion printing of a wide variety of hydrogel and silicone elastomer chemistries.
Stereolithographic 3D Printing of Self-Adhesive Double Network Hydrogels for Soft Actuators and Microfluidics

Thomas M. Valentin, Eric DuBois, Catherine E. Machnicki, Dhananjay Bhaskar, Francis R. Cui and Ian Y. Wong; Brown University, United States

Hydrogel building blocks that are stimuli-responsive and self-adhesive could be utilized as a simple “do-it-yourself” construction set for soft machines and microfluidic devices. However, conventional covalently-crosslinked hydrogels are unsuitable since they are as static materials with poor interfacial adhesion. Here, we demonstrate ion-responsive interchangeable parts based on composite hydrogels that incorporate both covalent and ionic crosslinking. We use light-directed 3D printing to covalently-crosslink poly(ethylene glycol) diacylate in the presence of anionic poly(acrylic acid) of much higher molecular weight. The addition of trivalent cations acts to crosslink the anionic polymer chains together. Using high cation concentrations drives strong crosslinking, which can result in dramatic hydrogel contraction. Mismatched contraction of layered ion-responsive and non-ion-responsive hydrogels can control bending and twisting actuation, which is utilized for a gripping device. Alternatively, moderate cation concentrations permit strong self-adhesion between hydrogel surfaces. LEGO-like hydrogel blocks with internal channels and external mechanical connectors can be stacked into complex microfluidic device geometries including serpentine micromixers and multilevel architectures. This approach enables “plug-and-play” hydrogel parts for ionic soft machines that mimic actuation, sensing, and fluid transport in living systems.

3D Printing of Biocompatible and Structurally Relevant Hydrogel Scaffolds for Articular Cartilage Tissue Engineering

Mahmoud Amr1, Joshua Kernan2, Alia Mallah1, Terrell Robertson3, Haneen Abusharkh2, Olivia Reynolds2, Arda Gozen2, Bernard Van Wie2, Juana Mendenhall1, Vincent Idone4 and Nehal Abu-Lail1; 1The University of Texas at San Antonio, United States; 2Washington State University, United States; 3Morehouse College, United States; 4Regeneron Pharmaceuticals Inc, United States

Osteoarthritis (OA) is a disease that affects more than 30 million adults in the US, posing a huge economical burden and adversely affecting people’s lifestyle. It is the hallmark of the degradation of Articular Cartilage (AC) lining moving joints, due to systemic, genetic, and injury related causes. One of the most prevalent types of OA is knee OA. Knee OA can cause enormous pain and discomfort and may lead to disability. No current single efficient treatment exists for knee OA. The disease is managed through pain killers, anti-inflammatory drugs, hyaluronic acid injections, and eventually a total knee replacement (TKR). Tissue Engineering (TE) offers an alternative route that is potentially capable of managing or treating OA while avoiding the limitations associated with OA’s traditional treatment routes. In TE, cells are seeded on a scaffold and grown in a bioreactor under a controlled environment in vitro. Ideally, the bioreactor is supplied with nutrients and built to mimic the mechanical shear stress, compression and oscillation pressures present in the knee. The product of interest of a TE approach is a functional AC tissue that mimics the native one in structure and function. AC has a unique structure that consists of three different zones (superficial, intermediate, and deep). Each zone is characterized by its own cellular and protein composition, fibrillar alignment, porosity and mechanical strengths. The variations in the zonal properties allow each zone to serve a specific AC function including lubrication and loadbearing. To our knowledge there is no current AC tissue engineered that mimics the native AC in structure and function. In a step towards replicating the AC unique zonal structure, we hypothesize that a structurally relevant scaffold that mimics the gradated anatomy of the native AC will guide the chondrocytes to create a native-mimicking tissue that can be used as an alternative to traditional cartilage grafts. Onto test our hypothesis, a biocompatible, biodegradable, and structurally relevant graded scaffolds in composition, porosity and mechanics will be fabricated using 3D printing and optimized via testing in a bioreactor for appropriate AC growth. Our scaffolds are hydrogels consisting of Gelatin (GEL), Gum Arabic (GA), and Sodium Alginate (SA) mixed in different concentrations and crosslinked by cooling, Calcium Chloride (CaCl2), 1-Ethyl-3-(3-dimethylaminopropyl)-carboidiimide (EDC) and N-Hydroxysuccinimide (NHS) respectively to achieve a mechanically stable structure. To print the scaffold, we have modified the commercial 3D bioprinter BioX from Cellink with a pressure amplifier and a home-made software control to achieve high printing pressure and time-efficient printing of scaffolds with different printing parameters. With that, we have been able to 3D print scaffolds with line width as fine as 250 µm using a 100 µm nozzle and a pressure of 700 kPa at room temperature using the hydrogel composed of (8.2% GA, 4.2% GEL, 8.2% SA). When bovine chondrocytes were cultured on the hydrogels for 14 days, they were viable. Biochemical assays confirmed that the cells with their pre-mature tissue expressed...
AC-specific biomarkers such as glycosaminoglycan (GAGs) and total collagen. To improve on our current findings, ongoing work aims at characterizing the ultimate tensile strength, elastic modulus, and hardness of the structural scaffolds using a universal testing machine. We hypothesize that the resulting AC tissue will have better native-mimicking AC structure and function when the mechanical properties of the scaffold mimics those of the native AC ECM properties. Ultimately in the future, the 3D printed structural scaffold combined with cell-laden hydrogels will be grown in a unique centrifugal bioreactor to create a mechanically and biologically native-mimicking AC tissue.

11:00 AM SB04.01.07
A Mechanically Enhanced Electroactive Hydrogel for 3D Printing Using a Multileg Long Chain Crosslinker
Yong-Woo Kang, Jaesung Woo, Hae-Ryung Lee and Jeong-Yun Sun; Seoul National University, Korea (the Republic of)

Electroactive hydrogels (EAHs) are receiving attention in soft robotics. 3D printing makes EAHs even more attractive, due to the diversification and elaboration of actuations. However, 3D printing needs a large amount of photoinitiator for faster printing, which makes the printed hydrogels so brittle that they cannot produce large scale 3D printing. Here, we developed a 3D printable EAH based on poly(3-sulfopropyl acrylate, potassium salt) (PSPA) using glycidyl methacrylated hyaluronic acid (GMHA) as a mechanically enhancing multileg long chain (MLLC) crosslinker. The MLLC crosslinking improved the stretchability of the PSPA-based hydrogel to 49% from 28%, while maintaining the same level of electroactivity. Additionally, the fracture toughness of the PSPA-based hydrogel remarkably increased from 11 J/m² to 40 J/m² with crosslinking by the MLLC. Using the mechanically enhanced EAH, i.e., the GMHA-PSPA EAH, the 3D printing of elaborate structures, e.g., ‘Leaning Tower of Pisa’ and a hand, and their electroactuation were successfully demonstrated.

3D Printing of Programmable Microbial Hydrogels
Avinash Manjula Basavanna¹², Anna Duraj-Thatte¹² and Neel Joshi¹²; ¹Wyss Institute for Biologically Inspired Engineering, United States; ²Harvard University, United States

Over the years, 3D printing technology has witnessed the development of numerous inks and bioinks for various applications. Bioinks are especially challenging as it requires biocompatibility, resembling microenvironment that favors cellular viability/adhesion, adequate mechanical properties and the capabilities for chemical/photochemical functionalization. Building on these characteristics and advances, herein, we present programmable living inks comprising of microbial hydrogels. Our innovative strategy provides unprecedented control on the characteristics of the ink as well as the ability to systematically regulate the microbes embedded in the 3D patterns.

11:30 AM SB04.01.09
Nanoscale Hydrogel 3D Printing with Focused Electron Beam
Andrei A. Kolmakov¹, Tanya Gupta¹², Glenn Holland¹, Evgheni Strelcov¹², Joshua Schumacher¹, Yang Yang¹², Mandy Esch¹ and Vladimir Aksyuk¹; ¹National Institute of Standards and Technology, United States; ²University of Maryland, United States

Additive manufacturing of hydrogel scaffolds has become the key technology for tissue engineering, soft robotics, biosensing, drug delivery and biomedical research in general. The progress in the field has been advanced via development of special polymerization initiators coupled with modern additive manufacturing techniques. The current state of the art 2-photon, and stereolithography curing techniques allow for 3D printing of submicron scale hydrogel features. Further advancement in printing time and resolution could be envisioned by using curing radiation with shorter wavelength and larger crosslinking cross-section. Despite of highly developed electron, ultraviolet and X-ray lithography of dry polymers to pattern nanoscopic features, 3D printing from liquid hydrogel precursor solutions is hard to realize due to vacuum incompatibility of liquid samples. In this work we resolve this “pressure gap” impediment and demonstrate a technique for in-liquid hydrogel 3D-sculpturing using fluidic enclosures equipped with electron transparent windows. The principle of the technique, details of the curing mechanism and factors affecting the ultimate feature size (resolution), are described and validated through the comparison of experiments and simulations. The potential of this technique is demonstrated on few selected examples such as live-cell encapsulation, synthesis of nanocomposite hydrogels and microfabrication of mesoscopic 3D-hydrogel structures.
Matrix Assisted 3D Printing of Cellulose Nanofiber Hydrogels Sungchul Shin and Jinho Hyun; Seoul National University, Korea (the Republic of)

In the matrix assisted 3D printing, rheological properties of materials are of importance for the formation of highly resolved structures. The concentration of hydrophobically modified-CNF (Hphob-CNF) and hydrophilic-CNF (Hphil-CNF) hydrogels was fixed at 1%, and petroleum jelly was mixed with liquid paraffin at a ratio of 3:1 for the 3D printing. The viscosity change of hydrogels and petroleum-jelly ink showed a shear thinning behaviour, which was an important parameter for the easy extrusion of ink in direct ink writing. The Hphob-CNF hydrogel continued to show a high colloidal stability without any stabilizer as the Hphil-CNF hydrogels showed. It is considered that the viscosity of CNF hydrogels is mainly determined by the aspect ratio of fibers, the number of ends and the branch of fibers rather than the surface property of high aspect ratio of nanofibers. The sol-gel transfer properties of Hphob-CNF matrix and Hphil-CNF ink exhibited elastic properties over a wide range of shear stress, making it very useful as a printing matrix and a printing ink. Channel forming petroleum-jelly ink also showed the elastic properties confirming the stability in printing. The applicability of the CNF hydrogels embedding microchannels will be introduced in the presentation.

Granular Hydrogels for Biomedical Applications Jason Burdick; University of Pennsylvania, United States

Hydrogels represent a class of biomaterials that have great promise for the repair of tissues, particularly due to our ability to engineer their biophysical and biochemical properties. Hydrogels can provide instructive signals through material properties alone (e.g., mechanics, degradation, structure) or through the delivery of therapeutics that can influence tissue morphogenesis and repair. In recent years, we have transitioned from traditional hydrogels to granular hydrogels that are comprised of smaller hydrogel units (i.e., microgels). Granular hydrogels have advantages in that they can be designed through heterogeneous microgels to introduce complexity to the material, they support cell invasion through the space between microgels, and they can be packed together to act as solids that can be easily extruded through a syringe.

Here, I will give examples of the design and use of granular hydrogels based on hyaluronic acid for use as injectable therapeutics, as well as in 3D printing. Microfluidic devices are used to fabricate the microgels using photoinitated thiol-ene reactions or radical polymerizations for intraparticle crosslinking where crosslinkers can be stable or responsive to local proteases. For cardiac therapeutics, we injected heterogeneous granular hydrogels into the myocardium and showed selective microgel degradation to release factors and introduce porosity for cellular ingrowth. In 3D printing, we jammed together microgels to form shear-thinning and self-healing hydrogels that could be printed either onto surfaces or within other hydrogels. These could be cell-laden or stabilized where necessary with secondary crosslinking. Most recently, we designed these granular hydrogels to be conductive, through an in situ metal reduction process of silver onto microgels and then jamming into solids with high conductivity due to increased surface area when compared to traditional hydrogels. The conductive granular hydrogels were shown to influence electrical tissue bridging in muscle defects and could be 3D printed into conductive lattices. Overall, the granular hydrogel design opens up new opportunities in the design of functional hydrogels in biomedical applications.
response to the implant and development of bacterial biofilms. A multifunctional surface coating that can address all these two issues concomitantly would significantly improve clinical outcomes. We hypothesized that polyarginine (PAR), a synthetic highly cationic polypeptide, can act on macrophages to control innate immune response because arginine is an important component of macrophage metabolism. Moreover, PAR is susceptible to act as an antimicrobial agent due to its positive charges. We developed a new polyelectrolyte multilayer film based on PAR and hyaluronic acid (HA). The layer-by-layer PAR/HA films have a strong inhibitory effect on the production of inflammatory cytokines released by human primary macrophages subpopulations [1]. This could reduce potential chronic inflammatory reaction following implantation. Next, we show that PAR/HA films were very effective to inhibit Gram-positive and Gram-negative pathogenic bacteria associated with infections of medical devices [2] [3]. We demonstrate that exclusively films constructed with poly(arginine) composed of 30 residues (PAR30) acquire a strong antimicrobial activity. Moreover, changing HA by another synthetic or natural polyanion did not provide any more antimicrobial activity. HA is a key component of the system and the mechanism behind this property has been elucidated. The cytocompatibility of the PAR/HA films was assessed with several cell types playing a major role in tissue regeneration. This system can also be fabricated in the form of hydrogel, useful to provide antibacterial properties to porous implants like surgical meshes. In this case, a precise controlled release can be achieved with strong efficiency over multi-infections. Recent developments to render these systems smart and responsive have also been made to obtain a release and activity only when bacteria are closed to the implants.

2:30 PM SB04.02.03
In Vitro Hair Shaft Generation from 3D Cell Aggregate for Hair Regenerative Medicine Rikuma Nakajima1, Akihiro Shimizu1, Tatsuto Kageyama1,2 and Junji Fukuda1,2; 1Graduate School of Engineering, Yokohama National University, Japan; 2Kanagawa Institute of Industrial Science and Technology (KISTEC), Japan

Hair loss is a common concern among numerous individuals. Hair regenerative medicine has recently been attracting attention as a promising treatment approach for hair loss. Hair follicle morphogenesis is triggered by interactions between epithelial and mesenchymal germ layers during embryogenesis, and various approaches for fabricating tissue grafts by recapitulating such interactions in vitro have been examined in the past decade. Since thousands of tissue grafts are necessary for a single patient, approaches for fabricating tissue grafts should be scalable. Herein, we fabricated a microwell array device with oxygen-permeable poly(dimethylsiloxane), wherein epithelial and mesenchymal cells spontaneously formed hair follicle germ (HFG)-like cell aggregates in 3 d of culture. This approach was scalable and >5,000 HFGs were prepared simultaneously by simply seeding the two types of cells and culturing them for 3 d in the device (T. Kageyama et al. Biomaterials, 154, 291-300, 2018). This approach is simple and robust. However, there are still certain issues, including further improvement of hair regeneration owing to the low hair regeneration efficiency when patients’ own cells are employed.

In this study, we propose an approach to screen HFGs based on their hair regeneration potential. HFGs generated herein produced hair shafts in vitro, which sprouted from the HFGs at 12 d of culture and reached ~200 µm in length at 23 d of culture. However, only less than 1% of HFGs (a few/300 HFGs) generated hair shafts. Thus, we optimized culture conditions and found that supplementation of an extracellular matrix hydrogel, Matrigel, significantly increased hair shaft generation. HFGs exposed to Matrigel generated hair shafts at 4 d of culture, which then ~1,400 µm in length at 17 d of culture. Moreover, the efficiency of regeneration was significantly increased (~90%, 275/300 HFGs). Scanning electron microscopy and transmission electron microscopy revealed that the hair shafts have typical morphological features including hair cortices, hair cuticles, melanosomes, and micro-fibrils. HFGs producing hair shafts at 6 d were selected and transplanted into the dorsal and scalp skin regions of nude mice. The hair generation efficiency was 85.4%, which was significantly greater than that of HFGs generated using our previous approach without pre-screening (i.e., 65.0%). The present approach may provide a better strategy for hair regenerative medicine.

Zapping Bacterial Infection with a Fast Setting Biodegradable Hydrogel Daniela Vieira, Samuel Angel, Edward Harvey and Geraldine Merle; McGill University, Canada

Wound infections have been a major challenge especially for military medicine. As the care of casualties continues to enhance survival rates, infectious complications will remain a major cause of morbidity. When bacteria biofilm sus
formed at the wound site, the infection is significantly more difficult to treat, increasing the healing time and the cost of the treatment. Conventional way of treatment is surgical debridement combined with antibiotics to prevent the growth of bacteria in and around wound before infection is established. Because of the misuse and overuse of antibiotics more than 50% of the bacteria are resistant to standard antibiotics. Bacterial resistance has become a serious global problem with a morbidity up to 45% in developing countries. Additionally, antibiotics often have serious negative effects on normal bodily functions. Given these challenging concerns, new strategies to treat bacterial infection are necessary. The use of antimicrobial peptides, polysaccharides and other antimicrobial components are an alternative. However, they are also hemolytic, toxic and easy to lose efficacy. Using electrical current (EC) to break down and destroy bacterial biofilms has been investigated for several years. Our concept is based on targeting the bacteria synergistically on various fronts. The impact of EC associated with antibacterial materials may be more significant. In this work, we designed a bioresorbable hydrogel free of antibiotics able to combat antibiotic resistance and help heal infected wounds. We synthesized an injectable biodegradable hydrogel based on silk fibroin (SF) and silver nanoparticles (Ag-NP) capable of fast setting, transporting EC and killing bacteria. SF solution was prepared following Rockwood protocol. This biocompatible and biodegradable natural polymer contains some tyrosine motifs, which reduce silver ions (Ag+) into Ag-NP with great toxicity against diverse bacteria. Sequentially, AgNO3 was added, mixed and exposed 24 h to incandescent light at room temperature. SF hydrogel and Ag-NPs exhibit an excellent conductivity of 1.2 S cm⁻¹, allowing the electrons to flow. Different conditions were performed to evaluate cytotoxicity and bacteria viability. First, as a control, just cell or bacteria (C/B). Second, C/B in contact with hydrogels (t= 60s). Third, C/B in contact with EC (1mA/60s). And finally, our approach, C/B in contact with the hydrogels combined with EC (1mA/60s). Hydrogels were removed right after from the medium. There is no toxicity on CHO mammalian cells treated with hydrogels or EC, separately or combined. In contrast to the effect in cells, the proposed work has a significant toxicity on E. Coli. Only hydrogels have no significant effect on bacterial killing, and further for EC, with 12.9% and 8.6% of death, respectively. However, the combined effect produced 77.8% of dead bacteria. In order to analyze these effects, Ag⁺ release, and ROS (oxygen species) generation was performed. Treatments with hydrogels and the combined effect presented similar Ag⁺ release, 21.94 ± 2.21 ppm and 19.59 ± 3.32 ppm, respectively. It is not the main cause of bacterial toxicity. However, for ROS generation, a difference of 50% was found between treatments, showing an interesting contribution of EC to produce ROS. Ag-NPs are able to generate ROS, and combined with EC, its ability increased, being more efficient. Furthermore, bacteria require extracellular electron acceptors to realize electron transport in its respiratory chain. Thereby, we believe these hydrogels have an electron extraction ability. It means, it may form a circuit to electron transfer, causing an extraction of electron from the bacteria membranes. Eventually, it causes membrane disruption and, consequently, the bacterial death. These results are promising and unprecedented in literature.

Bioinspired Elastin-Based Adhesives for Surgical Glue Applications Julie C. Liu; Purdue University, United States

A successful biomedical adhesive must be biocompatible, set in a wet environment, match the mechanical properties of the surrounding tissue, and have proper adhesive and cohesive properties. Current technologies do not meet these needs. We developed bioinspired protein-based adhesives that combine adhesion from DOPA residues found in mussel adhesive proteins with the mechanical properties of elastin, which can also coacervate in response to the environment. We demonstrated that these proteins are cytocompatible, provide the strongest bonds of any rationally designed protein when used completely underwater, and can be easily applied underwater because they coacervate in physiological conditions. Recently, we investigated different formulations and crosslinking chemistries in physiologically relevant environments by using pig skin substrates and curing in a warm, humid environment.

4:00 PM SB04.02.06
Bioinspired Self-Healing Protein Materials Abdon Pena-Francesch¹, Huilun Jung², Melik Demirel² and Metin Sitti¹; ¹Max Planck Institute for Intelligent Systems, Germany; ²The Pennsylvania State University, United States

Recent research efforts have focused on developing soft, flexible, compliant materials for medical robotics, biointerfacing, and biosensing applications, with properties matching those of biological tissue. Because of their intrinsic softness, these materials are susceptible to cut, puncture, scratch, and/or tear damage that compromises the
physical integrity of the device/interface. Soft self-healing materials offer a solution to this challenge and improve the long-term reliability, although many of the commonly explored self-healing chemistries are not biocompatible and are time-consuming (long healing times). To overcome these problems, we present biocompatible synthetic protein-based materials, inspired in squid proteins, that self-repair microscopic and macroscopic damage within seconds. The self-healing mechanism relies on the formation of reversible physical crosslinks in an elastomeric protein network. The healing process takes place in physiological conditions and the mechanical properties are recovered after healing. Furthermore, the protein material can be functionalized with biomolecules such as enzymes that maintain their activity after several healing cycles. These protein-based self-healing materials find applications as adaptive actuators for soft robotics, dependable biosensing platforms, and protective textiles against chemical and biological warfare agents.

pH Triggered Drug Release from Hydrogel Layers Integrated in Magnetically Controlled Microdevices
Roberto Bernasconi¹, Bradley Nelson², Salvador Panè², Marinella Levi¹, Filippo Rossi¹ and Luca Magagnin¹; ¹Politecnico di Milano, Italy; ²ETH Zürich, Switzerland

Two of the most crucial topics in modern medicine are medicines administration routes and their relative pharmacokinetics inside human body. The largest part of conventional drug delivery methodologies, like absorption through the gastrointestinal tract or intravenous injection, are generally based on the non-selective distribution of the active substance in the whole body, mediated by blood circulation. With these delivery methodologies, however, most of the drug reaches non-target parts of the body. This implies that higher dosages must be provided to reach the optimal concentration in the target organ, lowering administration efficacy and amplifying drug side-effects.

To overcome these problematic issues, advanced administration strategies based on targeted delivery have been recently developed [1]. More specifically, drugs are released in controlled amounts only in correspondence of the target organ. This approach requires a superior temporal and spatial control over release, which is challenging to achieve. A possible solution to control drug delivery timing can be the use of stimuli responsive polymers [2], which can release therapeutic drugs under the influence of an external stimulus (thermal, chemical, …). By employing this class of advanced materials, medicines can be released upon request and with controlled rates. Conversely, to allow spatial control, a possible key can be the use of magnetically controlled microrobots [3]. These microdevices are able to perform different tasks in-vivo, including for example cell transport [4] and medicine delivery applications [5]. For the latter, they can be covered with drug releasing materials and wirelessly guided inside human body to perform administration only in close proximity of the target organ. Moreover, magnetic field is harmless for humans, allowing a limited invasivity of the microrobots in conjunction with a great manipulation precision.

In this context, we describe the realization of magnetically guidable microdevices integrating a hydrogel layer specifically tailored to perform pH triggered drug release. The microdevices are characterized by a microporous structure, which increases hydrogel loading capability and that is obtained employing additive manufacturing. More specifically, we employ microstereolithography, a highly scalable and flexible 3D printing technique able to yield micrometric sized objects at relatively low cost. To allow magnetic actuation, a CoNiP layer is applied by mean of wet metallization on the 3D printed devices. The same technique is employed also to deposit a gold layer to make the surface biocompatible. Finally, the micropores are filled with an alginate hydrogel modified with click chemistry, in which the drug is binded to the biopolymer chains by mean of a pH cleavable bond. In this way, release takes place only when the device reaches the part of the body presenting the correct pH range. An example of possible application may be drug release in well-defined zones of the gastrointestinal apparatus, which is characterized by different pH levels according to the tract considered [6].

4:30 PM SB04.02.07
Piezoionics as a Mechanism for Sensing in Gels
Yuta Dobashi¹,², Yael Petel², Dickson Yao², Carl Michal² and
Hydrogels have been shown to be effective as transparent electrodes in pressure and touch sensors, forming “ionic skin”. Interestingly, the gels themselves also generate voltage when they are deformed. An ionic sensing effect has long been known in cartilage tissues in which counter ions that balance the charged collagen backbone are redistributed when pressure is applied. In this work, we propose a new mechanisms in which voltage arises from differential rates of ion motion within the gel when pressure gradients are applied. Fluid flow is generated within pores that are so small that ions experience additional drag. Some ions move more slowly than others, leading to voltage generation that is typically in the tens of millivolts.

In this work, we report on our investigation of pressure-induced ion redistribution and electric field generation arising due to differential cationic and anionic mobilities in solid polymer electrolytes. An organic phase solid polymer electrolyte was synthesized by a solution-casting technique using lithium bis(trifluoromethanesulfonyl)imide (LiTFSI), propylene carbonate (PC) and Poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP). The PVDFHFP/PC/LiTFSI gels of varying concentrations (0.1 M ~ 3 M) were subjected to mechanoelectrical transduction tests and the magnitude of generated potentials were recorded. Subsequently, diffusion NMR (pulsed field gradient spin echo) was performed on the polymer electrolytes to determine the self diffusion coefficients of the lithium and TFSI ions. The results revealed that the signs of the voltages generated were largely determined by the ion of higher diffusivity. Subsequently, the mechanotransduction was numerically modelled by coupling Darcy’s flow velocity to the convective flux of the ions, and subsequently computing the Nernst Planck equation. The equation was modified such that for each transport coefficient (diffusion, convection, and electrophoretic), hindrance factors were imposed representing the slowing of each ionic species by the presence of the polymer matrix. The hindrance is relative to solvent flow through the pores in the case of convection, and relative to bulk solution in the case of diffusion. Using measured the ionic diffusion coefficients and the Darcian permeability as the inputs, and using the hindrance factors as fit parameters, the observed mechanotransduction effect is largely in agreement with measurements.

We further show that these sensors, which, like piezoelectrics, do not require any external power beyond the induced mechanical deformation, can readily be formed into sensor arrays. They produce sufficient voltage and current to stimulate nerve and muscle activation – a possible area of application.
We demonstrate that by optimising the chrysophenine doping levels, the actuation strain can be increased to 17%. This is far in excess of analogous systems, e.g., 2-hydroxyethylmethacrylate, ethylene glycol-dimethacrylate copolymers equilibrated in a 0.4% chrysophenine solution displayed photo-actuated strains of under 1% [6]. Moreover, regardless of the fibres’ cross-sectional area, the hydrogel could be stretched up to 4 times its initial length. In conclusion, we demonstrate the successful fabrication of single fibre photo-actuators which amplify the molecular interactions between chrysophenine and the tough PU-PAA IPN, achieving spatiotemporal independence and control.

SB04.03.02
Double Covalent Network—3D Printing of Customized, Complex Hydrogel with Hyper-Elastic, Self-Adhesive and Shape Memory Effect Lei Zhang; Northeastern University, United States

Double covalent network hydrogels have attracted extensive attention as an innovative material having both high-water content and extremely high mechanical strength. 3D printing has revolutionized the way products are developed and customized, as satisfied with the integration of the complex structure and multiple-functions. Here, based on the classical PAMPS/PAAm double network strategy, a new 3D printing method, combined with nanocomposites enhancing mechanism and self-polymerized dopamine modification, is presented for customizing the complex double covalent network architectures.

Double network gels are characterized by a special network structure consisting of two types of polymer components with opposite physical natures: the first component is abundantly cross-linked polyelectrolytes (rigid skeleton) and the second component comprises of poorly cross-linked neutral polymers (ductile substance). The synthesis orders and process are vital to realizing their excellent mechanical performances which comparable to that of rubbers and soft load-bearing bio-tissues. However, tough mechanical feature and the unique crosslinking process make double network gel interesting and challenging on the developing in customization of 3D architectures. Thus, this work reported a simple yet versatile method for establishing a fair balance between the dopamine polymerization and second covalent crosslinking network together with the doped-nanoparticles, which makes the double covalent network hydrogel into the customized, complex 3D architecture with hyper-elastic, self-adhesive, fatigue resistance and shape memory effect. This strategy could potentially expand double network gel’ application in fashion, medical devices, human tissue replacement and engineering.

SB04.03.03
Synthesis, Characterization and Antimicrobial Measurement of BSA Conjugated Silver Nanoparticle Filled Hydrogel Nanocomposite Berhanu Zewde, Olufolasade Atoyebi, Ayele Gugssaa and Dharmaraj Raghavan; Howard University, United States

Nanocomposite hydrogels is attracting significant interest due to their potential use in implants, drug delivery systems, and tissue design scaffolds. This paper reports about the synthesis of precursors (tetrazine-modified polyethylene glycol and norbornene-modified hyaluronic acid) to form crosslinked hydrogels and hydrogel nanocomposite. Click chemistry of precursors in combination with in situ encapsulation of preformed Bovine Serum Albumin (BSA) conjugated silver nanoparticles (Ag/BSA) yielded nanocomposite hydrogel. 1H-NMR of
norbornene-modified hyaluronic acid and tetrazine-modified polyethylene glycol showed characteristic peaks for the vinylic protons of the endo and exo configuration of norbornene and tetrazine unit as well as PEG chains of tetrazine-modified polyethylene glycol, respectively. The Ag/BSA nanoparticles in the nanocomposite, were well dispersed as revealed by SEM and TEM, and were 20-30 nm in size. By TGA analysis, the percent of silver in the nanocomposite was established to be 2%. The interaction between the nanoparticles and the hydrogel was demonstrated by studying the shift in OH peaks of hydrogel via FTIR, changes in binding energy of O1s peak in XPS and measuring the desorption of nanoparticles from the hydrogel nanocomposites of various crosslinked system by AAS. Unlike native hydrogel, the hydrogel nanocomposite showed good antibacterial activity against gram positive/gram negative bactericides, and the loading of nanoparticles had a strong bearing on the extent of antibacterial activity.

Self-Restorable Adhesive Hydrogels Synthesized Using Poly(N-vinylpyrrolidone) and Tannic Acid via Supramolecular Assembly

Myeong-gyun Nam1, Hyeon-Gyun Nam2, Ji-heung Kim1 and Piljin Yoo1;
1Sungkyunkwan University, Korea (the Republic of); 2Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Supramolecular assembly and complexation is a powerful method to impart new functionalities to various organic compounds and is extensively used in biomedical, energy, and surface coating applications. Especially, when strong molecular interactions are exerted simultaneously, interacting molecules suffer the gelation by internal cohesive bonding, triggering a pseudo-crosslinking effect forming a supramolecular gel. Among various substances inducing supramolecular assembly, phenolic substances, e.g. 3,4-dihydroxy-L-phenylalanine (DOPA), are tremendously applied for adhesive materials owing to abundant hydroxyl groups driving supramolecular assembly via hydrogen bonding. However, in spite of the strong adhesive property of monomeric phenol, it is deficient to induce cohesive strength, resulting in rarely forming a supramolecular gel to secure its mechanical properties. Herein, to overcome this drawback, we realized a supramolecular coacervate hydrogel through simple mixing process of poly(N-vinylpyrrolidone) (PVP) and tannic acid (TA), resulting in internal cohesive interactions by virtue of the large molecular size of TA compared to monomeric phenols and enhanced molecular interactions triggered by a tremendous number of galloyl groups with a high density. Additionally, we tried to analyze the rheological and adhesive properties of PVP-TA coacervate hydrogels. Interestingly, on various substrates, remarkably high adhesive property is shown by PVP-TA hydrogel with abnormal self-healing property against extreme deformation. In detail, average adhesion strength of PVP-TA hydrogel shows 3.71 MPa on a glass substrate, which is 4 – 5 times stronger than that of conventional PVP.

SB04.03.05
A Novel Self-Healing Hydrogel with Stretchable, Conductive and Super-Adhesion

Yimeng Wang, Jing Peng and Maolin Zhai; Peking University, China

Multifunctional and adhesive hydrogels show excellent potential for multifarious applications, such as tissue adhesives, sealants, and implantable electronic devices, but most of them still suffer from poor reusable performance, high synthesis complexity, and low conductivity when facing to electronic device adhesives. Herein, based on a fully physical crosslinking network, a novel self-healing hydrogel (named GO,SPNB) with various ratios of graphene oxide (GO) to soluble starch and polyelectrolyte poly(sodium 4-vinylbenzenesulfonate-co-(3-(methacyroyloxy)ethyl)-N,N-dimethylbutan-1-aminium bromide) (PNaSS-co-MOBAB) was synthesized successfully by a simple one-pot γ-ray radiation-induced polymerization. Due to the multi-physical crosslinking network inside the hydrogels among GO, starch and PNaSS-co-MOBAB polymer, such as electrostatic interactions and hydrogen bonds, the resultant nanocomposite hydrogels exhibit fast automatic self-healing ability. In the meantime, the obtained hydrogels show super stretchable ability, non-toxicity, and ionic conductivity about 10.5 mS dm⁻¹. With high adhesive components such as soluble starch and acrylate derivatives inside, it was also endowed with super adhesion to various substrates, including solid materials and biological tissues. For example, the adhesion strength to the copper plates was about 60.5 MPa at room temperature, nearly one magnitude larger than other reversible adhesives that have been reported. Considering the facile preparation and all the advanced properties, the procedure provided here opens up a promising avenue to develop multifunctional hydrogel glues for design and fabrication of smart electronic device adhesives.
SB04.03.06
Design of Tunable Multicolor Fluorescent Materials as Strain Sensors Dong Zhang, Jie Zheng, Yanxian Zhang, Yonglan Liu, Shaowen Xie and Li Tang; The University of Akron, United States

Development of tunable multicolor fluorescent materials is important but challenging for fundamental research and practical applications. In this work, a series of trichromic (blue, green, and red), fluorescent polymers are synthesized by covalently copolymerizing spiropyran-based, naphthalimide-based, and pyrene-based monomer onto hydrophilic poly(acrylic acid-co-acrylamide) chains separately. Due to the dynamic fluorescence resonance energy transfer process between electron donors and acceptors, the tunable rainbow-color fluorescent polymer films and polymer solutions can be effectively fabricated by simply mixing and blending monochrome copolymers. Interestingly, utilizing the abundant carboxyl groups in the macromolecular chains, the thin fluorescent polymer films can also form physical hydrogels in a single step through carboxyl-Zn$^{2+}$ coordination. Furthermore, such dynamic physical cross-linked hydrogels could also be easily loaded onto complex electric driven devices, achieving organic combination of fluorescent hydrogels and actuators based on reversible sol-gel transition. Ultimately, we demonstrated a new strategy to enhance mechanical properties by embedding this mechanically weak fluorescent gel into a brittle alginate hydrogel shell via metal ion (Zn$^{2+}$ ion) diffusion induction mechanisms. We believe that our design principles and the resultant multicolor materials will broaden the design of next-generation fluorescent materials.

SB04.03.07
Stimuli Responsive Shape Recovery Hyaluronic Acid Hydrogel Using Ice-Template Eunsook Park and Haeshin Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Hyaluronic acid (HA), an essential component of the extracellular matrix, has been recognized as a promising building block in cell therapy and tissue engineering due to its excellent biocompatibility and biological properties. Furthermore, HA is versatile in functionalization with various crosslink-moieties and has been easily transformed into hydrogel via chemical and physical crosslinking for cell culture and transplantation. However, cross-linker and photoinitiator, used in the crosslinking reaction, cause chemical and radical induced cytotoxicity. Current catechol modified hyaluronic acid (HA-C) was reported as a novel candidate that overcame these limitation, showing low cytotoxicity and tissue adhesive properties. However, it was inevitable to use a high pH environment or oxidizing agent due to slow catechol oxidation rate. Moreover, the gel had low mechanical properties and was unable to maintain its shape.

In the study, we describe another technique to make mechanically robust HA-C gel using the ice template. When HA-C is frozen, the formation of ice promotes the oxidation of catechol by two mechanism: 1) the increase of the local concentration of HA-C in the unfrozen area, and 2) the increase of buffer pH with decreasing temperature. Initially, an injectable gel is formed but as freezing and thawing cycle are repeated, a solid-like free-standing gel is formed. When compressed, the water trapped in the pore squeezes out and the gels show compressibility due to large porous structure that is prepared by ice. However, when water feeding, the gel present rapid water uptake properties and repeatable water induced shape recovery. In addition to, the large pore structure of the gels improved the permeability of nutrients and cells and biocompatibility. These gels is best mimic bio-tissues (e.g. cartilage) with compressible properties and porous structure, and thus can be used promising building blocks in tissue engineering.

SB04.03.08
The Biocompatible Hydrogel Skin for Long-Term Used Catheter Yueying Yang, Yan Yu, Qing Ling, Jiaxin Wang, Le Lin, Jianfeng Zang and Xuanhe Zhao; 1Huazhong University of Science and Technology, China; 2Massachusetts Institute of Technology, United States

With the rapid development of global science and technology, the average life expectancy of human beings is generally extended, and the social problems caused by the aging of population are also increasing. Due to the rapid increase of diseases caused by aging, such as heart disease, high blood pressure, stroke, etc, the number of hospitalized patients increases rapidly, and the number of bedridden patients also increases continuously, accounting for 30% of hospitalized patients. The catheters used by bedridden patients for long periods of time need to be replaced on average once a week, however it greatly increases the risk of urinary tract infections. The existing catheters made of natural rubber, silicone rubber or PVC, which has high friction coefficient, render patients uncomfortable. Since the external environment is connected with the human body through the catheter, the risk of patients’ infection is increased. In our study, we coat the hydrogel skins on inner and outer surfaces of the Catheter,
the hydrogel skins exhibit tissue-like softness and provide superior low-friction, antifouling, anti-bacterial, to the catheter. In addition, we demonstrate the new catheter’s features through animal experiment.

**SB04.03.09**  
**Fabrication of Photo-Curable Polyurethane-Acrylate for 3D Printing Based on Viscosity and UV Curing Time**  
WonBin Lim and PilHo Huh; Pusan National University, Korea (the Republic of)

Nowadays, 3D printers have been undergone much attention in all fields of industry. The photo-curing resins which ranging from rigid to flexible, are successfully prepared using the synthesis of Polyurethane-Acrylate. It will be used for according to the application through the measurement of flexural strength and hardness. The intrinsic viscosity of the photo-curable monomer and polymer is measured to target the molecular weight of the material. The photo-curing polymer is produced through physical or chemical reaction, and the curing time and physical properties of the material are adjusted according to the purpose. It can be controlled the ratio of the photo initiator and polymer. For example, Thermoplastic polyurethane (TPU) series based on polyethylene glycol(PEG) as a polyol and hexamethylene diisocyanate (HDI) as an isocyanate were synthesized as a function of molecular weight formulation. After that, PU-acryl will be synthesized by attaching hydroxyethyl-methacrylate(HEMA) and used for DLP 3D printing by controlling the content ratio of photo-initiator and addition multifunctional acrylate.

**SB04.03.10**  
**3D-Printed Microbe and Consortia Hydrogels for on Demand Bioproduction and Preservation**  
Trevor Johnston¹, Shuo-Fu Yuan², James Wagner², Xiunan Yi², Abhijit Saha¹, Alshakim Nelson¹ and Hal Alper²,*; ¹University of Washington, United States; ²The University of Texas at Austin, United States

Living materials are composites of polymers and living cells wherein the function of the material is derived from the residing cells. Here, we describe a 3D-printed hydrogel-based system for harnessing the bioactivity of embedded microbes for on-demand small molecule and peptide production in mono-culture and microbial consortia systems. This platform bypasses the challenges of multi-organism consortia by spatially organizing organisms into hydrogel inks to precisely control the final consortium composition and dynamics without the need for synthetic control. Furthermore, we demonstrate that these hydrogels provide protection from preservation techniques (including lyophilization) and can sustain active metabolic function for over 1 year of repeated use. We demonstrate the utility of this approach (compared to traditional liquid-based culturing) for four chemicals and peptide antibiotics using through both mono-cultures and cross-feeding and parallel consortia of yeast and E. coli. In all cases, the printed hydrogel ink’s efficiency in repeated production phases, both pre- and post-preservation, outperformed liquid culture. We envision this technology being a step forward in the ease of use of complex designed biological systems for the expanded, on-demand production of a variety of high-value compounds.

**SB04.03.11**  
**A Supramolecular Hydrogel for Spatial-Temporal Release of Auxin to Promote Plant Root Growth**  
Yao X. Chen; Nankai University, China

So far, synthetic auxins other than indole-3-acetic acid (IAA) have been widely used in both scientific studies and agricultural and horticultural practices. The synthetic auxin 1-naphthalene acetic acid (NAA) is popular because of its relative stability and its lipophilicity, which allows it to freely enter the plant cell. However, because of the rapid diffusion of NAA in agarose hydrogel, the most commonly used technique for physically encapsulating NAA in an agarose hydrogel or hydrogel beads cannot fulfill the need for the spatial release of NAA for plant research. It remains a challenge to develop materials for the spatial-temporal release of auxin for research use. In this study, we demonstrated the effectiveness of an auxin-based hydrogelator linked by a hydrolysable ester bond. Hydrogel I, formed by the gelator (NAA-G’FFY) linked with an ester bond, was able to release 1-naphthaleneacetic acid (NAA), whereas hydrogel II, formed by the gelator without an ester bond (NAA-GFFY), was not. By mixing NAA-G’FFY with Fmoc-GFFY to form a two-component hydrogel, the spatial and temporal release of NAA was achieved, promoting on-site auxin responses including primary root elongation and lateral root formation in the model plant Arabidopsis thaliana. The strategy of using a hydrolysable ester bond to connect drug molecules and self-assembling peptides could lead to the development of supramolecular hydrogels with more controllable drug release profiles.

In summary, we demonstrated that an auxin-based supramolecular hydrogel connected by a hydrolysable ester bond has a good capacity to slowly release NAA into the environment, while the control connected by an amide bond...
cannot release NAA. The spatial and temporal release of NAA could be a useful new tool in the study of auxin-induced plant growth and development.

**SB04.03.12**  
**β-Galactosidase Instructed Supramolecular Hydrogelation for Selective Identification and Removal of Senescent Cells**  
Tengyan Xu; Nankai University, China

Cellular senescence is a natural process to prevent the proliferation of damaged or stressed cells, and it is also believed to be beneficial in wound healing. However, senescent cells tend to accumulate upon persistent damage or during aging, which impairs tissue functions and accelerates aging. Recent studies indicate that the clearance of senescent cells can delay features of aging and counteract the loss of tissue hemeostasis after chemotherapy or chronic damage. It is therefore very important to develop strategies for selective identification and removal of senescent cells.

In this work, we introduced a novel strategy of β-galactosidase (β-Gal) instructed peptide self-assembly to selectively form nanofibers and hydrogels in senescent cells. We demonstrated that the in situ formed nanofibers could alleviate endothelial cell senescence by reducing P53, P21, and P16INK4a expression levels. We also demonstrated that our strategy could selectively remove senescent endothelial cells by inducing cell apoptosis, with an increase in the BAX/BCL-2 ratio and caspase-3 expression. Our study reports the first example of enzyme instructed self-assembly (EISA) by a sugar hydrolase, which may lead to the development of supramolecular nanomaterials for the diagnosis and treatment of many diseases, such as cancer, and for other applications, such as wound healing and senescence.

As a result, this is the first example of supramolecular hydrogel formation triggered by a sugar hydrolase. Sugar hydrolases play important roles in many diseases, and we envision great promise for the diagnosis and treatment of these diseases by sugar hydrolase-controlled supramolecular nanomaterials.

**SB04.03.13**  
**Supramolecular Nanofibers of Drug-Peptide Amphiphile and Affibody Abolish HER2+ Tumor Growth**  
Chunhui Liang; Nankai University, China

Antibody-based medicines and nanomedicines are very promising for cancer therapy due to the high specificity and efficacy of antibodies. However, antibody-drug conjugates (ADCs) and antibody-modified nanomaterials frequently suffer from low drug loading and loss of functions due to the covalent modification of the antibody.

We herein reported on a novel and versatile strategy to prepare supramolecular nanomaterials by the co-assembly of an affibody (antiHER2) and drug-peptide amphiphiles. During the enzyme-instructed self-assembly (EISA) process, the drug-peptide amphiphile could co-assemble with the affibody, resulting in supramolecular nanofibers in hydrogels. The drug loading in the supramolecular nanofibers was high (>30 wt%), and the stability of antiHER2 was significantly improved in the nanofibers at 37 °C (>15 days in vitro). The supramolecular nanofibers exhibited high affinity for HER2+ cancer cells and could be efficiently taken up by these cells. In a mouse tumor model, our supramolecular nanofibers abolished HER2+ NCI-N87 tumor growth due to the good accumulation and retention of nanofibers in tumor.

We demonstrated a novel and versatile method to prepare nanomedicines composed of drug-peptide amphiphiles and antibodies/affibodies by the EISA process. Compared with general ADCs that had very low drug loading, our system possessed much higher drug loading (31.6 and 30.2 wt% of CRB in co-assembled nanofibers with 10 and 15 wt% of affibody). The stability of the affibody could be significantly improved in our supramolecular nanofibers. More importantly, the in vitro and in vivo results indicated the excellent performance of our supramolecular nanomedicines, which possessed good targeting and therapeutic effects for cancer diagnostics and therapy. We also envision the generation of more supramolecular nanomedicines for the diagnostics and treatment of important diseases.

**SB04.03.14**  
**Spiral-Shaped Stimuli-Responsive Hydrogel Actuator for Controlling Compression and Expansion**  
Koki Yoshida and Hiroaki Onoe; Keio University, Japan

Stimuli-responsive hydrogels swell and shrink corresponding to external stimuli such as temperature, pH, light, and chemical compounds. These characteristics are attractive for soft actuators including artificial muscles, biomimetic robotics, and microfluidic components. Current challenges of hydrogel actuators are controlling their displacement...
and deformation direction, since bulk stimuli-responsive hydrogels only swell/shrink isotropically, as determined by the nature of the hydrogel materials. To overcome this challenge, various types of double-layered hydrogel actuator have been developed to controlling deformation direction, however controlling displacement of the stimuli-responsive hydrogel materials has not been achieved.

Here we present spiral-shaped stimuli-responsive hydrogel actuator for controlling deformation direction (compression/expansion). The magnification of deformation and controlling the deformation direction by shrink/swell characteristics can be enhanced just by the shape of spirals without any molecular modification of materials.

Simulation of actuation of the spiral-shaped actuator:
We use finite element simulation (COMSOL) for simulating the actuation of the spiral-shaped actuator. We consider the spiral-actuator with a diameter of gel $D_{gel} = 300 \, \mu m$ and a diameter of spring $D_{spring} = 1000 \, \mu m$. We apply a shrinkage ration of stimuli-responsive hydrogel $\alpha = 0.6$ which determined by measuring a shrinking ration of the stimuli-responsive hydrogel. The Double-layered spiral-shaped actuator behaved as axial compression with winding up. In contrast, when patterned stimuli-responsive hydrogel in the outside of spiral-shaped actuator, spiral-shaped actuator behaved as an axial expansion with winding down.

Fabrication of spiral-shaped stimuli-responsive hydrogel actuator:
We prepared a bevel-tip capillary by cutting a perfluoroalkoxy (PFA) microtube (inner diameter: 200 $\mu m$) at the tip angle to $\sim 20^\circ$. The tube was set horizontally to the liquid surface. By using bevel-tip capillary, a continuous flow of mixed sodium alginate and poly(N-isopropylacrylamide-co-acrylicacid) pre-gel solution was extruded in CaCl2 solution, resulting in spontaneous formation a spiral-shaped hydrogel with a wide range of gradient pitches via buoyancy force. We used double-layer laminar flow for the formation of double-layered spiral-shaped hydrogel composed of stimuli-responsive part and non-responsive part. The resulting spiral-shaped hydrogel has double-layered structures and different pitches.

Results of spiral-shaped actuation:
We applied stimuli to the spiral-shaped actuators in CaCl2 solution by heating at 50°C. The double-layered spiral actuator shrank with large compression. The double-layered spiral actuator was mainly compressed in an axial direction. These results indicate that the spiral structure enhances the magnification of shrinkage of stimuli-responsive hydrogels. Furthermore, expansion of a spiral actuator in the axial direction was achieved by using a double-layered spiral actuator whose boundary between the two layers was parallel to the axial direction of the spiral (outside: stimuli-responsive hydrogel). These results showed that shrinkage of the stimuli-responsive hydrogel was converted to large expansion movement in the axial direction. Therefore, these results indicated that the deformation direction can be controlled by patterning the stimuli-responsive hydrogel.

Conclusion: Compression and expansion motions of spiral-shaped actuator were magnified by forming a spiral shape, which was corresponding to the simulation results. Therefore, it is expected that various multiple complex actuation could be realized by other complex compartmentalization and encapsulating functional materials. The success of multiple complex movements and magnifying the deformation would open new avenues to various microscale biochemical applications such as autonomous soft robots and drug release systems.

SB04.03.15
Aldenronate-Functionalized Poly(2-oxazoline)s with Tunable Affinity for Calcium Cations Maria J. Sanchez Fernandez1,2; 1Radboudumc, Netherlands; 2Radboud University, Netherlands

A library of poly(2-oxazoline)s functionalized with controllable amounts of alendronate, hydroxyl and carboxylic acid side groups was successfully synthesized to create novel polymers with tunable affinity for calcium cations. The affinity of alendronate-containing polymers for calcium cations was quantified using isothermal titration calorimetry. Thermodynamic measurements revealed that the Ca$^{2+}$ binding affinity of these polymers increased linearly with the amount of alendronate functionalization, up to values ($K_{Ca^{2+}} = 2.4 \times 10^5 \, M^{-1}$) that were about 120-fold higher than those for previously reported polymers. The calcium-binding capacity of alendronate-functionalized poly(2-oxazoline)s was exploited to form robust hydrogel networks cross-linked using reversible physical bonds. Oscillatory rheology showed that these hydrogels recovered more than 100% of their initial storage modulus after severe network destruction. The versatile synthesis of alendronate-functionalized polymers and their strong and tunable affinity for calcium cations render these polymers promising candidates for various biomedical applications.

Gels for Bioprinting—Finding, Functionalising, Formulating, Printing and Characterising Gordon Wallace; University of Wollongong, Australia

The ability to create 3D printed structures containing living cells is providing a route to the creation of "living" systems that might be useful for bench top drug testing or implantables that facilitate tissue regeneration.

However, the realisation of a useful printed structure based on hydrogels is not a simple task. While we can build on the extensive knowledge that has accrued through cell-gel interaction studies to date, there are a number of dimensions that add to the challenge.

Central to these is that the gel containing the cells must undergo a reasonably rapid phase transformation. In addition, with some applications multiple cells and other bioactive entities need to be strategically distributed in 3 dimensions. Sterilisation of the components and/or the final structure is also of critical importance and finally knowing what we have created without destroying it remains a challenge.

Returning to the start of this process we encounter perhaps the most neglected aspect - most of the emerging hydrogels finding use in bioprinting are naturally occurring. So where do we find them - how do we ensure a reliable high quality source?

8:30 AM SB04.04.02/SB01.04.02
Novel Hybrid Approach to 3D-Print Graphene/Polymer Composites Xuechen Shen, Taylor J. Morrison, Hani E. Naguib and Tianhao Chen; University of Toronto, Canada

Current 3D printing uses a wide range of plastic, metal, and ceramic materials, with no significant effort to integrate these techniques for multi-material fabrication. We previously developed a novel method to deposit non-viscous ink through a stable continuous jet formed by gearing-enhanced peristaltic pumping. This ink deposition technique was used to deposit graphene oxide (GO) ink in a binder jetting (BJ) process to fabricate GO/polyvinyl alcohol composites. In this technique, ink particles are accelerated to speeds of 2-10ms\(^{-1}\) to overcome surface tension forces tending towards pendant drop formation. Gearing is applied to achieve mechanical advantage (MA)<1, enabling high pump velocity. Motor acceleration made up for the lost torque. In recognizing that gearing could be used to increase torque with MA>1, we realized the potential to perform Direct Ink Writing (DIW) using our ink deposition system. To this end, we DIW-printed viscous graphene/nanocellulose inks. We also recognized that DIW and BJ shared similar layer change, material transport, and gantry motions, allowing the 2 techniques to be implemented in the same system. We designed and built the hybrid 3D printer, implementing transmission to switch gearing ratios. The hybrid printer was demonstrated to print Graphene/polymer composites using both DIW and BJ printing modes.

8:45 AM SB04.04.03/SB01.04.03
Three-Dimensional Printing with Silica Cages Jen-Yu Huang\(^1\), Tangi Aubert\(^1,2\), Ulrich Wiesner\(^1\) and Tobias Hanrath\(^1\); \(^1\)Cornell University, United States; \(^2\)Ghent University, Belgium

Material scientists have now developed an extensive library of nano-sized building blocks, offering a vast panel of properties (optic, magnetic, plasmonic, catalytic, etc.). Nevertheless, combining these building blocks for the realization of multifunctional materials while controlling their structure from the nano- to the micro- and all the way to the macroscale still remains an open challenge in order to fully exploit their potential. In parallel, new material processing techniques such as 3D printing technologies are emerging for the fabrication of macroscopic highly engineered parts and devices. In this work, newly discovered silica nanocages are combined with digital light processing 3D printing technique for the rapid fabrication of mesoporous parts with arbitrary shapes and tunable internal structures. Complementary strategies are then deployed for the implementation and deliberate positioning of various functionalities throughout 3D printed objects with high control on the microstructure and macroscopic
architecture of the superstructures. This approach paves the road for innovative device concepts and designs, that will benefit from the unique properties of nanomaterials and from the micro- and macroscale manufacturing capability of 3D printers.

9:00 AM SB04.04.04/SB01.04.04
Magnetically Navigable 3D Printed Multifunctional Microdevices for Water Quality Control Roberto Bernasconi¹, Elena Carrara¹, Marcus Hoop², Fajer Mushtaq², Bradley Nelson², Salvador Panè³, Caterina Credi¹, Marinella Levi¹ and Luca Magagnin¹; ¹Politecnico di Milano, Italy; ²ETH Zürich, Switzerland

Water contamination, either chemical or biological, is one of the main problems for public healthcare in many parts of the world. Contaminated water is a source of a great number of diseases caused by pathogens or by chemical agents. Many techniques are available to improve water quality, but in many cases these methods are not entirely environmentally friendly. Current research efforts are directed toward the use of harmless substances and safer methods. From the pathogens control point of view, silver is one of the most used non-antibiotic agents. Regarding chemical pollutants elimination, one of the most promising techniques is photodegradation mediated by titania (TiO₂). This material photocatalytically generates reactive radicals able to oxidize pollutants upon exposure to an electromagnetic radiation. Functional layers of silver and titania can therefore be used to provide efficient water remediation.

An interesting approach consists in manufacturing multifunctional materials that exhibit both antimicrobial and photocatalytic activities. A fabrication technique able to yield this type of materials is electrolytic codeposition of particles with metals or alloys [1]. For example, thanks to this wet deposition technique, a matrix of silver with embedded titania particles can be easily obtained. The final composite layer exhibits both antibacterial and photoactive properties. Water cleaning possibilities can be further expanded if the antibacterial and the photodegradation action is performed by microdevices covered with silver/titania composites. An example of such devices are the so-called microrobots [2], which can be wirelessly guided using magnetic field and placed exactly where the water decontamination action is needed. Examples of microrobots presenting photocatalytic [3] or antimicrobial activity [4] are available in literature, but none of them combines these two actions on the same device.

The aim of this work is the realization of cylindrical shaped microrobots combining biokilling and photodegradation thanks to the presence of a bifunctional composite on their surface. Such microrobots are produced using 3D printing, more specifically microstereolithography, and are subsequently metallized using wet techniques. Two functional layers are applied on the surface of the 3D printed device: a CoNiP magnetic alloy and an Ag/TiO₂ composite. The first makes possible the movement of the device under the influence of an external magnetic field, while the latter imparts the biocidal/catalytic activity to the device. We demonstrate that these devices exhibit antimicrobial activity toward methicillin resistant Staphylococcus aureus bacteria. Moreover, from the pollutants removal point of view, we prove that they can efficiently photodegrade a model molecule like rhodamine B when exposed to ultraviolet radiation.

9:15 AM SB04.04.05/SB01.04.05
Macroscale Double Networks—A Universal Method for Improving the Strength and Toughness of Soft Materials Daniel R. King, Tsuyoshi Okumura, Riku Takahashi and Jian Ping Gong; Hokkaido University, Japan

The double network concept has been revolutionary in its ability to turn soft, brittle hydrogels into tough, robust materials with mechanical properties that match the best synthetic elastomers. Double network hydrogels consist of two interpenetrating networks, where each network has a specific mechanical response: the “first network” acts as a sacrificial network, consisting of a rigid, extended network, and the “second network” is a globally percolated, stretchable network. When a double network hydrogel is stretched, covalent bonds of the first network break, dissipating energy; this process continues with increasing strain, until the sacrificial network is completely broken and the second network ruptures. The goal of this research is to demonstrate that the “sacrificial bond concept” is
applicable at length-scales beyond the molecular scale. We aim to incorporate this design concept universally for application in structural and medical devices.

Like double network hydrogels, our system consists of a rigid “first network,” 3d printed polyurethane/polyacrylate grids, embedded in a soft and stretchable “second network,” silicone rubber. We found that when the strength of the matrix exceeds the strength of the grid, local fracture occurs in the grid, and stretching is isolated to the rubber in the fractured region. As stretching increases, the force increases, and when the local force exceeds the global strength of the grid, fracture will occur elsewhere in the composite. This process continues sequentially throughout the sample until all grid fracture sites are exhausted, and the matrix ruptures. By tuning the stiffness of the grid, we can independently control the yield strength and fracture strain of the composite, until a point where the grid strength exceeds the matrix strength, and the multiple fracture process no longer occurs.

We also systematically studied the interfacial interactions between the matrix and the reinforcing grid. Both interfacial adhesion as well as topological interlocking are important towards developing a robust composite. By adhesive interactions alone, only minimal fracture of the reinforcing phase occurs; topological interlocking is required to maximize fracture. Based on this result, we systematically change the grid size to modify the number of fracture events. In the optimized form, an increase in work of extension of ~50% over the neat matrix was achieved, representing a ~70% toughening efficiency versus the calculated maximum toughness. These results demonstrate that macroscale double networks can dramatically increase the toughness of soft materials.

9:30 AM *SB04.04.06/SB01.04.06
4D Printing Thermoplastic Polyurethane Hydrogel-Elastomer Trilayers for Structural Applications Richard S. Trask; University of Bristol, United Kingdom

Hydrogels represent a class of engineering materials that have great promise for integration within the human body; particularly by optimising and functionally grading their biophysical and biochemical properties. The ability to construct complex architectures through 3D printing is now common place but introducing the ability to transform a planar architecture into a new configuration once manufactured opens up the potential to minimise manufacturing complexity but maximising the design potential. This presentation will detail our latest design thinking utilising a multifunctional materials design methodology and 4D printing research for producing a diverse range of complex architectures utilising thermoplastic and hydrogel trilayer constructs. This unique methodology permits the viable construction of dynamically robust and complex bilayer and trilayer origami architectures for a new generation of active structures. In our study the resulting creations transform from flat 2D parts to 3D structures through submersion in water and return to their original configuration through dehydration. This technique uses commercially available materials and printers to enable a controlled and predictable actuation method that is more accessible and affordable than previous examples of hydration triggered 4D printing. We show the ability to create tessellated origami patterns, such as the Miura-ori origami fold pattern and the waterbomb configuration; the latter being a design that has not previously been realised with 4D printing. These new designs demonstrate how the integration of multiple trilayers into a single 3D print enables through-thickness control of actuation resulting in the formation of active structures with complexity beyond what has previously been achieved with 4D printing. The research will now be extended by the generation of curved-layer morphing origami architectures (i.e. individual layers with variable z-component actuation) to enable selective structural buckling; the generation of tubular bilayer/trilayer architectures; and, the generation of sequential actuation through the addition of porogens (i.e. dissolvable particles used to create porous hydrogel structures) such that the rate and magnitude of actuation can be further programmed in the design phase.

10:00 AM BREAK

10:30 AM *SB04.04.07/SB01.04.07
Extreme Hydrogel Technology Xuanhe Zhao; Massachusetts Institute of Technology, United States

While human tissues and organs are mostly soft, wet and bioactive; machines are commonly hard, dry and biologically inert. Bridging human-machine interfaces is of imminent importance in addressing grand societal challenges in health, security, sustainability, education, and joy of living. However, interfacing human and machines is extremely challenging due to their fundamentally contradictory properties. At MIT Zhao Lab, we propose to harness “extreme hydrogel technology” to form long-term, high-efficacy, compatible and seamless interfaces
between humans and machines. In this talk, I will first discuss the fundamental mechanisms to design extreme properties for hydrogels, including extremely tough, resilient, adhesive and anti-fatigue, for long-term robust human-machine interfaces. Then I will discuss a set of novel hydrogel technologies, including i). hydrogel bioelectronics capable of electro-opto-fluidic interrogating single neurons and continuously monitoring gastric physiological conditions over the long term; ii). tissue double-sided tapes that give instant strong adhesion of wet tissues and devices. I will conclude the talk with a perspective on future human-machine convergence enabled by extreme hydrogel technology.

11:00 AM *SB04.04.08/SB01.04.08
Smart Hydrogels from Mechanistic Design to Practical Applications Jie Zheng; University of Akron, United States

Synthetic polymer hydrogels as soft-wet materials, consisting of three-dimensional cross-linked networks and a large amount of water (50–90%), possess many unique properties such as swelling/deswelling, stimuli-responsiveness, shock absorption, and low sliding friction, making them as potential excellent biomimetics for substitution of soft living materials. However, conventional hydrogels often suffer from weak mechanical properties, which greatly limit their extensive uses for many other applications. In this talk, we will present different design strategies to prepare tough and multifunctional hydrogels with unconventional polymer network architectures and extraordinary properties. Guided by our design principle, we will demonstrate different hydrogels with high mechanical properties, self-healing, actuation, antifouling, and/or wound healing to mimic cartilages, artificial muscles, and mussel-inspired glues. In parallel, molecular simulations will be presented to given atomic-details of structure-properties relationship. Finally, several unique aspects for future development of tough hydrogels will be suggested.

11:30 AM SB04.04.09/SB01.04.09
Design and Understanding Dynamic Hydrogel with Hydrazone Crosslinks for 3D Printing Junzhe Lou, Sean Friedowitz, Christopher Lindsay, Sarah C. Heilshorn, Jian Qin and Yan Xia; Stanford University, United States

Dynamically crosslinked hydrogels received increasing interest for their adaptive mechanical behaviors under stress and deformation and wide applications for cell scaffolding and delivery. We present a new concept of modulating the dynamics of hydrogel systems crosslinked by hydrazone bonds via a biocompatible organic catalyst. The catalyst accelerates the exchange kinetics of hydrazone bonds for over two orders of magnitude, resulting in identical network structure with widely tunable viscoelastic behavior. The catalyst control of network dynamics enabled quantitative and unambiguous correlation between the network parameters and mechanical properties of dynamic polymer networks, which can be generalized to provide design principles to engineer their viscoelastic properties. We also applied this system for 3D bio-printing to modulate the dynamic properties of hydrogels at different time points of application to have both high injectability and high stability. The incorporated catalyst enhanced the exchange of dynamic crosslinks to achieve high injectability during printing process, but rapidly diffused away from the hydrogel after ejection to retard the exchange and improve the long-term stability for cell culture.

11:45 AM SB04.04.10/SB01.04.10
Chemical Pumps for Soft Autonomous Robots Junsoo Kim¹, Kai Luo² and Zhigang Suo¹; ¹Harvard University, United States; ²Beijing Institute of Technology, China

Soft robots can be untethered by carrying a chemical fuel of pneumatic actuators. However, it has a fundamental design restriction; the fuel pressure should be higher than the actuator pressure to transport the fuel. Given that the fuel part occupies most of the volume, the robot becomes pressurized as much as the actuating pressure and requires stiffer materials for the fuel part, making entire robots stiffer. Here, inspired by the pit in plants, we decouple the pressures of the fuel part and the actuator while providing a fuel against the pressure gradient by introducing an isolator between them, thereby liberating from the design constraint. This isolator consists of a hydrophilic nanoporous membrane made of a hydrogel and a micro-porous wall made of a nylon mesh, that correspond to the pit membrane and the cellulose wall at the pit respectively. The mechanical integrity of the structure according to the geometry is studied by finite-element analysis to establish a design rule and the pneumatic power is extensively characterized experimentally with various parameters. Finally, the isolator is implanted to the conceptual soft robots.
to demonstrate the merits of the isolator.

SESSION SB04.05: Actuators

Tuesday Afternoon, December 3, 2019
Hynes, Level 3, Room 302

1:30 PM *SB04.05.01
Function-Function Relationships in Multifunctional Soft Actuators Andreas Lendlein\(^1,2\); \(^1\)Helmholtz-Zentrum Geesthacht, Germany; \(^2\)University of Potsdam, Germany

The limitation of classical shape-memory polymers of a stimuli-induced one time shape shift was overcome with the realization of shape-memory polymer actuators (SMPA). SMPA are soft actuators, which can repetitively change their shape reversibly controlled by temperature under stress-free conditions. They possess the unique feature of re-programmability of their actuation capability related to shape changing geometry and switching temperature. The thermally controlled reversible actuation can occur many times [1,2]. Structure-function relationships for SMPA can be derived from datasets, which are generated by comprehensive characterization of the effects caused by systematically varying structural parameters on different length scales. Motivated by potential application, e.g. in the field of robotics or healthcare technologies require additional functions such as self-repair, magnetic controllability or degradability. Besides integrating these different functions in one material system, creation of targeted function-function relations are a major challenge. Orthogonal multifunctionality is realized when several functions can be addressed almost independently from each other. An example for orthogonal functions are soft actuators equipped with a self-healing capability [3]. Sequentially coupled functions enable linking functions according to a domino effect. Sequential multifunctionality relies on a series of functions, where the effect (output) of one function is the input of the next function. The coupling of a stimulus conversion from magnetic to thermal with an actuation capability will be presented as a prominent example [4].

Hydrogels and Other Ionic Conductors in ‘Piezo-Ionic’ Sensors, Actuators and Electrochemical Devices John D. Madden\(^1,2,3\), Yuta Dobashi\(^1,2\), Mirza S. Sarwar\(^1,2\), Dickson Yao\(^1,2\), Saeedeh Ebrahimi Talakoo\(^1,2\), Claire Preston\(^1,2\), Ngoc Tan Nguyen\(^1,3\), Justin K. Wyss\(^1,3\), Bertille Dupont\(^1,2\), Yael Petel\(^1\), Carl Michal\(^1\), Cédric Plesse\(^4\), Giao T. Nguyen\(^5\), Frédéric Vidal\(^1\), Eric Cattan\(^1\), Sébastien Grondel\(^1\), David Shepherd\(^1\) and Geoffrey M. Spinks\(^1\); \(^1\)University of British Columbia, Canada; \(^2\)Faculty of Applied Science and Engineering, University of Toronto, Canada; \(^3\)École Polytechnique de Montréal, Canada; \(^4\)Institut Énergie Matière NANO (IEMN-CNRS), France; \(^5\)Université de Cergy-Pontoise, France

Ionic conductors offer exciting device possibilities, particularly with the advent of highly extensible and easily synthesized hydrogels. Following on from recent work on hydrogel “ionic skin”, ‘piezo-ionic’ sensors and ionic artificial muscle, we present example ionic devices, including stretchable and transparent capacitive sensor arrays, pressure sensors that generate currents upon stretching, actuators that bend or contract when ions are inserted, as well as stretchable electrochrome elements and batteries.

Hydrogels and other ionic conductors offer advantages over metals and semiconductors in being intrinsically stretchable and non-absorbing of visible light. Their moderate to low moduli and non-linear mechanical properties can match those of tissue, and make them of interest for use in human interfacing devices. On the other hand, ions are much less mobile than electrons, ionic conductors don’t have bandgaps, and, unlike electrons and holes, anions and cations don’t recombine. The materials are typically wet, and properties can depend significantly on dimensions, pH and temperature. Given these drawbacks, how can we make practical use of ionic conductors?
In order to avoid being limited by the low mobility of ions, we can take two approaches. One is to implement gels and other ionic conductors in devices that consume very little current – such as capacitive sensor arrays. Even in low current devices, dropping temperatures can dramatically and unacceptably increase resistance, so a careful consideration of RC charging time is important in the design. Another approach to avoid being limited by low mobility is to make the transit distances short. We present bending actuators that can operate hundreds of hertz. Relative speed of ion motion is important in ‘piezo-ionic’ sensors, where application of a pressure gradient leads to differential rates of ion motion between positive and negative ions – and the generation of current. NMR and electromechanical measurements suggest that in hydrogels ions move more slowly than solvent, perhaps hindered by the polymer structure. The small voltages that result are sufficient to stimulate nerves.

Electrochemical devices combine electronic and ionic conductors – for example in batteries, electrochromics and ionic diodes. In such cases, the electrode material is not as stretchable as the hydrogel. We present a symmetric conducting polymer-based electrochromic element that can stretch and change colour, and battery that is robust under extension.

If ionic devices dry out, they will slow or stop. One approach to avoid drying is to use salts that dramatically reduce vapour pressure – but this can come at the cost of conductivity. We instead demonstrate the use of non-volatile ionic liquids to keep a capacitive sensor array working for years without encapsulation. Alternatively, low vapour transmission rate elastomers can keep fast actuators and stretchable batteries functional for months or even years without preventing bending.

2:30 PM SB04.05.03
Electrically Controlled Gel Actuator Using Liquid Metal Spring Ken Matsubara and Hiroki Ota; Yokohama National University, Japan

This report demonstrates an electrically controlled gel actuator by a three-dimensional(3D) helical structure with liquid metal. Previously, core-shell hydrogel microsprings was fabricated using a double bevel-tip nozzle. In this study, liquid metal as conductive material was injected into core part of microspring, which formed liquid metal spring which has 3D helical structure. A rod of a temperature responsive gel was inserted into the center of the liquid metal spring in order to an actuator. Current was applied to the spring to heat the entire actuator. The rod of temperature responsive gel was warmed up, and shrinks together with the spring. As a result, we succeeded in control the actuation of the gel by the liquid metal spring by 16%. Spring structures might be used in a wide range of fields taking advantage of energy absorption and storage. Our gel actuators present an important advancement towards development in several fields including soft robots, microactuators, drug delivery systems (DDS).

Background: Poly(N-isopropylacrylamide) [PNIPAM] is a temperature-responsive polymer that has lower critical solution temperature (LCST) at 32°C. PNIPAM gel exposed to an environment at higher than LCST changes hydrophilic to hydrophobic so that the water is discharged, and its volume decreases eventually. In several fields such as soft robotics and DDS, this characteristics is taken advantage of. However, in terms of an actuator using a temperature responsive gel, they require temperature change in entire environment, which make control of an individual actuator difficult. To improve this individual controllability, we propose a gel actuator that combines a heater using a liquid metal coil which is ultra soft, and a temperature responsive gel. In addition, the coil made of liquid metal has little change in cross-sectional area during the deformation, which leads stability of the resistance change. This helical shape overcomes the problem of changing parameters due to deformation that often occurs in soft actuators and stretchable sensors, and provide electrical control of gel actuation.

Fabrication: In order to create helical structure of gel by imbalance of crosslinking due to inclination of the nozzle, sodium alginate was poured from a bevel-tip nozzle into an aqueous solution of calcium chloride. Core-shell hydrogel helical structure was made by double nozzles held by a 3D printed nozzle joint. In this study, polyvinyl alcohol was used as a core part, and sodium alginate as a shell part. Then, the polyvinyl alcohol was extruded with liquid metal (Galinstan). Eventually, a spiral structure of Galinstan was established. Temperature responsive gel was molded by 3D printer. Then, the rod of the gel was inserted to the liquid metal microspring. Gel actuator with liquid metal coil was established.

Results: Characteristics of liquid metal microspring was investigated. Modules of microsprings filled with liquids metal in core parts were 0.33 N/m. we measured resistance change as a function of elongation of the straight and spiral wiring. The resistance of a straight wiring of the liquid metal increased to 140% by 100 % tension. On the other hand, a spiral wiring of the liquid metal increased to only 1.2%. Therefore, we accomplished the liquid metal
spiral wiring which maintained stable resistance in DC during harsh deformation of a circuit in this study. Furthermore, electrically controlled gel actuation was demonstrated. The gel actuator was heated by supplying 1.4W of power to liquid metal coil. As a result, it contracted 16% in 15 minutes. In summary, we succeeded in producing an actuator that can be controlled by electricity.

2:45 PM SB04.05.04
Design with Supramolecular Hydrogels Hector Lopez Hernandez and Eric A. Appel; Stanford University, United States

Supramolecular hydrogels are appealing for biological applications such as drug delivery, 3D printing bio-inks, and cell therapies. These applications create a diverse set of material requirements which are met by exploiting the broad tunability of the hydrogel’s material properties through modifications to the composition, crosslinking moieties, concentration, and molecular weight. The effects of these variables on the material properties can be complex and difficult to characterize. In addition, the vast parameter space makes it difficult to rationally design the hydrogels for specific applications.

Herein we present the complex rheological and diffusive behavior for supramolecular polymer-nanoparticle hydrogels, comprising hydroxypropyl methylcellulose and poly(ethylene glycol)-b-poly(lactic acid) nanoparticles, from the perspective of designing an injectable controlled release drug-delivery platform. The hydrogel’s associative gel formation dynamics and the strong non-Newtonian rheological behavior, including yield stress fluid behavior and shear-thinning, are presented as a function of variations in the formulation of the polymer-nanoparticle hydrogels. Diffusion, measured by fluorescence recovery after photobleaching (FRAP), is presented to demonstrate the correlation between the mechanical properties of the hydrogels and the transport within the hydrogel. It is shown that formulations created to expand the timescale of release may result in an inadvertent effect of increasing the viscosity and yield stress of the hydrogels, precluding injectability. We also present a design-oriented approach, developed from our systematic rheological and diffusive characterization, which allows for visualizing the effects of each formulation knob on intrinsic material properties and behavior. Furthermore, this approach allows for the generalization of the hydrogel platform and provides a means for engineering formulations for a more diverse set of applications beyond injectable therapeutics, such as 3D printing.

3:00 PM BREAK

3:30 PM *SB04.05.05
Design of Novel Homocomposite and Hierarchically Structured Hydrogels for 3D Printing Orlin D. Velev; North Carolina State University, United States

This talk will present two interrelated approaches to making novel classes of extrudable and responsive hydrogel materials based on special suspensions and multiphasic compositions. The first one uses a method called 3D printing with Homocomposite Thixotropic Paste (HTP). This method was originally developed in our group for 3D printing of ultrasoft silicone structures. The extrudable HTPs are “capillary gels” made of particles and binding liquid with the same chemical composition. At a certain volume fraction the pre-gelled particles jam and make a two-phase thixotropic homocomposite paste. Once this paste is extruded, the gelation of the liquid medium results in a homogeneous and cohesive single-component hydrogel. Its remarkable flexibility and extensivity are based on the strong cohesion of the particles and identical cured liquid. The HTP compositions allow for easy doping with magnetic nanoparticles to make them field-responsive. The mechanical properties of the homocomposite material can be enhanced further by using particles with special morphology and interactions. In the second part of the talk, we will show how the HTP-3DP method was enhanced by using a new class of hierarchically structured soft particles. The morphology of these “dendricolloid” particles is similar to molecular-scale polymer dendrimers, but is two orders of magnitude larger in scale. They are formed as a result of a new process of polymer precipitation in turbulently sheared liquid. The dendricolloids have very large excluded volume, while their nanofiber corona possesses the highly adhesive abilities of the nanofiber-padded gecko legs. The dendricolloids form strong gels at very low volume fractions. They produce even sturdier homocomposite and heterocomposite hydrogels when their medium is molecularly gelled on its own. The investigation of the interactions-structure-property relationship of such HTP 3D printed materials could enable the making of numerous hydrogel architectures with excellent mechanical properties and programmed response and actuation.
4:00 PM SB04.05.06
A Photothermal Responsive Actuator with Self-Monitoring Strain Sensing Capability  Chiao-Yueh Lo, Cheolgyu Kim and Ximin He; University of California, Los Angeles, United States

Soft robots, with their attractive living organism-like compliance and flexibility, have motivated the development of new active materials capable of neuromuscular behaviors. In spite of many new soft sensors and soft actuators, self-sensing materials that can monitor their own motions are highly desirable but proven challenging to realize. In this paper, we present a photothermally-responsive electrically conductive soft material that can serve as a strain sensor and a self-monitorable photothermal actuator, simultaneously owning two key functions essential to artificial muscle materials. This material is a nanostructured conductive hydrogel based on an interpenetrating network of theromoresponsive hydrogel and conducting polymer with enhanced stretchability and responding speed. A variety of complex photo-driven anisotropic locomotion of the homogeneous composite hydrogels can be precisely remotely controlled by near-infrared (NIR) laser illumination. The strain produced from the controlled motion is sensed by the actuator itself in real time. The photothermal response and electrical conductivity allow the hydrogel acts as a photo-triggered switcher. With this unprecedented capability of sensing the magnitude of the strain that the actuator produces, the robust, stretchable, and ultra-sensitive conductive hydrogels will lead to the next-generation soft robots with self-diagnostic feedback-controlled, higher level of autonomy.

Mechanical Characterization of Graded Hydrogel/Polymer Interfaces to Assess Robustness  Andrew A. Tomaschke, Archish Muralidharan, Stephanie J. Bryant, Robert McLeod and Virginia L. Ferguson; University of Colorado Boulder, United States

As our understanding of tissue engineering for cartilage repair has progressed, so has the complexity of scaffolds designed to repair cartilage defects. Early scaffold designs focused on getting cells into the defect using a soft, biocompatible materials like Pluronic and Polyglycolic acid [1]. When outcomes proved undesirable due to inability of soft hydrogels to bear physiological loads, researchers designed scaffolds to mimic the properties of the native tissue [2]. Unfortunately, these stiff scaffolds were highly cross-linked and as a result, had diffusional limitations that limited the ability of the cells to proliferate and create new tissue. Thus, recent approaches now utilize a composite design [3]. These use a stiff polymer skeleton to control strain under externally applied loads and match the stiffness of surrounding tissues when implanted and a soft hydrogel cellular niche for cells to grow and proliferate. For this combined approach to be effective, it relies on the attachment of the soft cellular niche to the stiff skeleton in order to transmit the proper strains to the seeded cells.

Briefly, our approach includes a 3D stereolithography (SLA) manufactured, stiff PEGDA:PETMP structure (target modulus = ~1 MPa) that is infilled with a soft (~50 kPa), PEG-norborene hydrogel. The stiff structure bears load and controls strain, whereas the soft infilling hydrogel can be tailored [4,5] to serve as a cellular niche. To mitigate potential interfacial failure between the stiff structure and soft hydrogel, we have created a graded interface by creating a shell of 13% converted stiff material around a 100% converted core and infiltrating the 13% converted PEGDA:PETMP with PEG-norborene.

Preliminary testing of sharp versus graded interface materials showed that the graded interface more effectively resisted fracture when loaded in tension. However, this analysis lacks context of how specific property gradients (i.e., via spatial control of conversion) can be designed to minimize interfacial failure between the two materials. Thus, this work presents a direct assessment of the material property gradients spanning sharp and a range of graded interfaces. Using nanoindentation testing, the distribution of mechanical properties across the interfaces are characterized. These measures will be used to help explain the role of fracture across gradient conversion interfaces between two dissimilar materials. This work is designed to both validate our existing approach for interface design and serve as a guide to others seeking to utilize composite, SLA-printed scaffolds in their work.

engineering gel structural changes to facilitate cartilaginous tissue production." Biotechnology and bioengineering 86.7 (2004): 747-755.

From Aqueous Graphene Dispersions to Smart Soft Materials Ester Vazquez; UCLM, Spain

The synthesis of different hybrid hydrogels by in situ radical polymerization in the presence of graphene derivatives, is one of the followed approaches to attain three-dimensional nanocomposite scaffolds. The role of the nanomaterial within the polymer network is primarily intended for the reinforcing (i.e. increasing the stiffness and toughness). However, we have shown that the presence of graphene can also enhance features such as biocompatibility, smart behavior based on responsiveness to external stimuli, sensing, or self-healing ability, giving rise to truly hybrid composites.

The preparation of these soft materials requires the production of large amounts of graphene derivatives in water, and for this reason, ball milling approaches developed in our labs, have proven a method of choice for the preparation of graphene starting dispersions. Moreover, aqueous graphene suspensions can be rapidly frozen and, subsequently, lyophilized giving rise to a very soft and low-density black powder which can be readily dispersed in water and in organic monomers allowing the preparation of the hybrid hydrogels.

Artificial Phototropism and Artificial Phototaxis Based on Light-Sensitive Hydrogels Yusen Zhao, Xiaoshi Qian and Ximin He; University of California, Los Angeles, United States

Many living organisms track light sources and adaptively stop their movement when the tracking is achieved. This phenomenon, known as phototropism, occurs as plants self-orient to face the sun perpendicularly throughout the day. While many smart materials exhibit nastic behaviors in response to external stimuli, no synthetic material can intrinsically detect and accurately track the direction of stimuli, i.e., exhibit tropistic behaviors. Other than the phototropism in dynamic equilibrium state, oscillations are also widely found in living organisms to generate propulsion-based locomotion often driven by constant ambient conditions, such as phototactic movements.

However, most man-made oscillations require non-constant energy input and cannot perform environment-dictated movement. Here we report an artificial phototropic and an artificial phototactic system by using the same light-sensitive hydrogel system, respectively, termed sunflower-like biomimetic omnidirectional tracker (SunBOT) and soft swimming robot (OsciBOT). The SunBOT can instantaneously aim to incident light in three-dimensional space over broad ambient temperatures. Phototropism successfully enabled plant-like maximization of energy harvesting through SunBOT-based omnidirectional solar vapor generation, achieving up to 400% energy harvesting enhancement over non-tropic materials by maintaining normal to oblique illuminations. OsciBOT showcases agile life-like omnidirectional oscillatory motion in entire 3D space with near-infinite degrees of freedom. The large force generated by the powerful and long-lasting oscillation of OsciBOT can effectively self-propel away from light source, showing high-speed and controllable phototactic locomotion. The artificial phototaxis opens broad opportunities in maneuverable marine automated systems, miniaturized transportation, and solar sails.
Molecular self-assembly is a key direction in current nanotechnology based material science fields. In this approach, the physical properties of the formed assemblies are directed by the inherent characteristics of the specific building blocks used. Molecular co-assembly at varied stoichiometry substantially increases the structural and functional diversity of the formed assemblies, thus allowing tuning of both their architecture as well as their physical properties.

In particular, building blocks of short peptides and amino acids can form ordered assemblies such as nanotubes, nanospheres and 3D-hydrogels. These assemblies were shown to have unique mechanical, optical, piezoelectric and semiconductive properties. Yet, the control over the physical properties of the structure has remained challenging. For example, controlling nanotube length in solution is difficult, due to the inherent sequential self-assembly mechanism. Another example is the control of 3D-hydrogel scaffold’s physical properties, including mechanical strength, degradation profile and injectability, which are important for tissue engineering applications.

Here, in line with polymer chemistry paradigms, we applied a supramolecular polymer co-assembly methodology to modulate the physical properties of peptide nanotubes and hydrogel scaffolds. Utilizing this approach with peptide nanotubes, we achieved narrow nanotube length distribution by adjusting the molecular ratio between the two building blocks; the diphenylalanine assembly unit and its end-capped analogue. In addition, applying a co-assembly approach on hydrogel forming peptides resulted in a synergistic modulation of the mechanical properties, forming extraordinary rigid hydrogels. Furthermore, we designed organic-inorganic scaffold for bone tissue regeneration.

This work provides a conceptual framework for the utilization of co-assembly strategies to push the limits of nanostructures physical properties obtained through self-assembly.

Biophysics of Complex N-glycan Shields on HIV Pseudovirus Preethi Chandran; Howard University, United States

The surface of cells and pathogens is coated with a layer of carbohydrates called glycans. Majority of glycans on secreted and membrane proteins is produced by the N-glycosylation pathway and are known as N-glycans. N glycans have either (i) core and distal branches of mannose sugars (high-mannose type) or (ii) core of three mannose sugars followed by distal branches of non-mannose sugars that end in sialic acid (complex type). Our goal is to understand in the inherent biophysical design in the choice and placement of the complex N-glycan sugars. Single sugar biophysics obtained with force spectroscopy was integrated to composite N-glycan biophysics by systematically increasing the complexity of sugar presentation in monolayer-monolayer to virus-monolayer to virus-virus experiments. In all systems, there were consistent long-ranged, charge-mediated, and materially 'tough' self-adhesions originating from sialic acid residues. On the other hand there were more short-ranged, hydrogen-bonding mediated, and materially 'brittle' self-adhesions originating from mannose residues. The two sugars did not cross-interact and neither did most other sugars in the glycan shield. Correspondingly in solution, mannose-stabilized gold nanoparticle tightly coated viruses, but sialic-stabilized gold nanoparticle particles aggregated and precipitated viruses. Moreover, the sugar interactions in the glycan shield gave rise to a rate-dependence, with both the virus glycan shield and virus itself being penetrated at low rates but only compressed at high rates. The findings imply that biological surfaces would have different interfacial properties and aggregation propensities based on the sugar composition of the surfaces and the solvent shear.

Vascularized Bone Grafts Prepared with Hydrogel Micro-Dispenser and 3D Mesh Printing Hikaru Akieda, Tatsuto Kageyama, Yohei Noda, Shoji Maruo and Junji Fukuda; Graduate School of Engineering, Yokohama National University, Japan

Large bone defects are serious complications typically caused by extensive trauma, tumors, infections, and congenital musculoskeletal disorders. Current approaches to treat bone defects include autograft and allograft transplantation. However, limited availability of grafts, infections, and immune rejection hinder the widespread application of these approaches. Recently, tissue engineered bone grafts using osteogenic cells and/or osteoconductive materials have emerged as a promising approach for treating large bone defects. However, their therapeutic use remains limited due to the significant time required for ossification and remodeling of large grafts after transplantation. To shorten the required time, pre-vascularization of grafts may be critical, because vasculature delivers not only oxygen and nutrients, but also osteogenic cells for bone formation and subsequent remodeling. In this study, we propose an approach for fabricating vascularized bone grafts containing osteoblasts, bone matrix, and complex vasculature. A unique aspect of our approach is that we first prepare collagen-rich cell aggregates, named bone beads, through the spontaneous constriction of cell-encapsulating collagen drops during a 24 h culture. This spontaneous formation of bone beads facilitated large scale bone bead preparation using a micro-dispenser system. This approach allowed the spotting of 10,000 collagen microgels in 10 minutes. After gelation at 37 °C for 30 min, constructs were collected, suspended in culture medium, and seeded onto a non-cell adhesive dish or spinner flask bioreactor. Interestingly, cells in bone beads showed better osteogenic differentiation, including osteogenic marker expression and bone matrix secretion, compared with conventional spheroid culture after 2 weeks in an osteogenic differentiation medium. We further optimized the stirring rate of the spinner flask bioreactor to maximize osteogenic differentiation of cells in bone beads. In particular, bone matrix secretion was significantly increased by increasing the stirring rate from 0 to 250 rpm. To fabricate vascularized bone grafts, a few hundred bone beads were cultured for 14 days. They were then suspended intermixed with vascular endothelial cells and seeded into non-cell-adhesive flat-bottom dishes. After 1 day of culture, these constructs were stacked into a cell culture insert for 2 days of further culturing. Endothelial cells formed luminal structures in the spaces between bone beads. Fabricated vascularized bone grafts were transplanted into 4-mm-diameter cranial bone defects in nude mice, and bone regeneration efficiency was evaluated by micro computed tomography. Five weeks after transplantation, vascularized bone grafts achieved 83% coverage of the bone defect area, which is significantly greater than that achieved using other approaches, such as the use of beta tricalcium phosphate (β-TCP) powder. Moreover, histological analysis showed newly formed bone at
transplanted sites. Finally, to hold bone beads in place at bone defect sites, we tailor-made β-TCP meshes using a 3D printer. Transplantation of bone-bead-loaded β-TCP meshes showed higher bone regeneration at bone defect sites than transplantation of β-TCP mesh alone. This simple approach using a micro-dispenser and a 3D printer may provide a promising strategy for advancing bone regenerative medicine.

Fabrication of Universal Thermoresponsive Cell Culture Platform—Toward a New Horizon in Tissue Engineering Andrew Choi1, Kyoung Duck Seo2, Hyungjun Yoon1, Seon Jin Han1 and Dong Sung Kim1;
1POSTECH, Korea (the Republic of); 2Wonkwang University, Korea (the Republic of)

Over the course of years, a cascade of studies has engaged in enhancing the health of mankind scrutinized diverse biomaterials (metals, ceramics, polymers, hydrogels, and etc.) for the development of novel and innovative cell culture platforms. And inevitably continued expansion in material selectivity of cell culture platform enabled the creation of diverse cell culture platforms with increased functionalities. One of the most intriguing functional cell culture platforms utilizes the thermoresponsive hydrogel, poly(N-isopropylacrylamide (PNIPAAm), which possesses a prominent behavior of reversibly altering its physicochemical characteristics in response to change in temperature; and consequently, enables the harvest of cell sheets in a scale of $10^2$ mm by altering the ambient condition of temperature above/below low critical solution temperature (LSCT) of 32 °C without any use of chemical treatment. However, its common fabrication method (grafting method) currently confronts several issues due to the instability of grafted polymer chains on the substrate. Depends on the type of the substrate that polymer chains are being grafted and the fabrication methods that are being utilized to graft polymer chains, thermally triggered intermolecular interactions of the grafted polymer chains were found to be all different. And therefore, it is still arduous to achieve stable adhesion behavior of the cells on the fabricated cell culture platform and the inherently constrained geometry of the harvested cell sheet limits the range of its utilization. While the realization of various methods of adopting PNIPAAm on cell culture platform is continuously being pursued to attain in vivo-like heterogeneous or vascularized cell sheets, there are clear fundamental issues in the current ‘form’ of PNIPAAm cell culture platform that hamper maximizing the potential of cell sheet engineering.

In this study, we tailored the polymer network of conventional PNIPAAm through the modification of its substance composition and for the first time introduce a thermoresponsive cell culture platform composed only in a ‘bulk’ form of a PNIPAAm hydrogel having an MPa-scale Young’s modulus. While the initial surface roughness of the bulk PNIPAAm could be modulated by altering the cross-linker concentration, the value of the roughness was found to be changing from nm- to μm-scale above/below the LCST. Through the proper adjustment in the concentration of the cross-linker inside of the bulk PNIPAAm, a stable attachment and easy detachment of diverse cells were allowed. During the incubation of cell lines (C2C12 and NIH3T3) at a temperature condition of 37 °C, all cells were able to be attached on the prepared PNIPAAm cell culture platform with the roughness value of below ~50 nm. On the other hand, the primary cells were found to be only attached on a surface with the roughness value of below ~30 nm during the incubation at the same condition. Moreover, in the act of detaching cell sheet via incubating them at a temperature condition of 20 °C, the cell sheets consists of cell lines were fully detached from the surface with the roughness value of ~10 μm or higher, whereas the cell sheets consists of primary cells were detached from the surface with a roughness of ~19 μm or higher. Based on such behavior of the diverse cells on prepared PNIPAAm cell culture platform, this study successfully optimized the surface roughness value and suggested a universal thermoresponsive cell culture platform which allows the harvest of all types of cell sheets consists of cell lines (C2C12 and NIH3T3) or primary cells (human umbilical vein endothelial cells and keratinocytes). We believe this novel universal cell culture platform could play a powerful and versatile role in igniting a spark to the advancement of cell sheet engineering.

The Visco-Elasticity of 2D Protein Networks—Implication for Stem Cell Expansion at Liquid-Liquid Interfaces Julien Gautrot, Dexu Kong and Lihui Peng; Queen Mary, University of London, United Kingdom

The mechanical behaviour of the extracellular matrix has an important impact on cell phenotype. Despite the importance of mechanotransduction in regulating a wide range of phenotypes, we recently reported the surprising observation that cells (keratinocytes and mesenchymal stem cells) can adhere, spread and proliferate at the surface
of liquids. This observation is particularly surprising as the reinforcement of cell adhesion is thought to require a solid elastic or viscoelastic substrate that can resist cell-mediated contractile forces. Our work has evidenced the formation of protein nanosheets, self-assembled at the liquid-liquid interface, displaying strong mechanical properties that can provide a sufficient mechanical scaffold to promote cell adhesion and expansion. We showed that this is sufficient to regulate stem cell phenotype. However, the parameters controlling the self-assembly and the mechanical properties of protein nanosheets remain poorly understood. In this work we investigate the assembly of polymers and proteins at liquid-liquid interfaces, and the impact of pro-surfactants with a wide range of chemistries. We identify structural features that control the visco-elastic properties of the resulting nanosheets and regulate associated cell phenotype. In this work, we show the importance of parameters such as pH and concentration on protein self-assembly and the impact it has on interfacial mechanics. Importantly, we demonstrate the impact that pro-surfactant-protein interactions play on regulating the assembly and the interfacial mechanical properties of the corresponding interfaces.

Thermoresponsive Hydrogel Scaffolds with Cysteine Pendant Groups Show Enhanced Mucoadhesion Ninad S. Kanetkar and Adam K. Ekenseair; Northeastern University, United States

Introduction: Inflammatory Bowel Disease (IBD) affects 1.9 million people in the United States. Current treatments demand invasive surgery and lifelong immunosuppression that lead to poor quality of life. Systemic stem cell delivery has been shown to regenerate damaged tissues, however cell viability and therefore effectiveness remain suboptimal. In situ forming biomaterial scaffolds can overcome this limitation by sustaining non-invasively delivered cell populations for a longer duration. Poly(N-isopropylacrylamide) (pNiPAAm) is a polymer that forms a gel above a Lower Critical Solution Temperature (LCST) of 32°C due to a shift in the balance between hydrophobic and hydrophilic interactions. pNiPAAm copolymers have been investigated as in situ forming scaffolds due to the proximity of its LCST to body temperature. Previous research has established the ability of p(NiPAAm–co-Glycidyl Methacrylate (GMA)) thermogelling macromer (TGM) to be delivered to the intestine via an airbrush spray and sustain encapsulated cells. Here, cysteine pendant groups were introduced on the polymer to covalently bind to the intestinal mucus, a hydrogel composed of cysteine rich proteins called mucins. This work investigated the kinetics of cysteine conjugation, crosslinking, viability of encapsulated cells, and the impact on mucoadhesion.

Materials and Methods: TGM was obtained by copolymerization of pNiPAAm and GMA in a 10:1 mole ratio. Cys-TGM was obtained by reacting 0.1 equivalents of Cysteine with a 10% TGM solution at room temperature. DSC, GPC, NMR spectroscopy, and rheometry were used for characterization. Mucoadhesion was determined by the pull-off force required to separate two pieces of porcine intestine bound with the polymer.

Results & Discussion: The progress of cysteine conjugation was followed over time using DSC. The peak LCST of Cys-TGM increased from 30.24 to 32.05, and can be attributed to the increased hydrogen bonding in Cys-TGM, requiring higher energy to undergo a coil-globule transition to form a gel. Whereas TGM exhibited fully reversible thermogellation, Cys-TGM formed crosslinked gels which remained insoluble upon cooling below LCST. This network formation was accelerated when the gels were kept in a thermogelled state over several hours as confirmed.
by the net movement of the polymer from sol phase to gel phase. This indicated network formation, which reached a critical point at 4 hours of incubation and was complete after 6 hours. Cysteine conjugated TGM showed superior adhesive strength compared to unmodified TGM and a significant increase compared to a mucus-only control. LIVE/DEAD staining showed cells encapsulated in unmodified TGM initially showed higher death in comparison with the cysteine containing gels. Gels with 30% equivalent cysteine showed similar low death compared to 50% equivalent cysteine gels but showed a higher migratory behavior as opposed to clustered proliferation.

Conclusions: Cysteine modified thermogelling polymers were synthesized, characterized and tested in the context of applicability as an intestinal scaffold. Cysteine-mediated disulfide bond formation was shown to be a promising pathway to enhance scaffold mucoadhesion. Cysteine modification did not hinder the viability of encapsulated cells cultured over a long term.

In Situ Formation of Cell-Containing Hydrogel Sheets Conformal to Full-Thickness Burn Wounds Richard Y. Cheng1, Gertraud Eylert1,2, Jean-Michel Gariepy1, Sijin He1, Marc Jeschke1,2 and Axel Guenther1; 1University of Toronto, Canada; 2Sunnybrook Research Institute, Canada

The current standard of care for treating patients with severe large area burns involves the direct application of a bilayered matrix consisting of a silicone layer for immediate wound coverage and a crosslinked collagen layer as a scaffold for host cell migration. Cell repopulation remains a challenge especially as acellular scaffolds rely on the recruitment of host cells. While emerging treatment options including the delivery of allogeneic or autologous cells via spraying or injection have demonstrated improved wound healing, the consistent delivery of cellularized biomaterials conformal to wound topologies remains a challenge.

Here, we report a handheld instrument for the in-situ formation of cell-containing biomaterial sheets conformal to a burn wound. The mesenchymal stem cell (MSC)-containing, fibrin-based bioink and thrombin crosslinker solutions are delivered through on-board syringe pumps to a microfluidic printhead with internal bifurcated channels. A skin precursor sheet of consistent thickness covered with the crosslinker is obtained at the exit. Wound-conformal delivery of MSC-laden biomaterial sheets was achieved by translating the printhead along the wound surface by a soft silicone wheel, while a two-axis gimbal design allowed it to adapt to the wound topology. We observed that the addition of 1% hyaluronic acid (HA) provided desirable shear-thinning behavior of the bioink (1.2 Pa*s at shear rate 1/s, 0.35 Pa*s at shear rate 100/s), resulting in 83% of the starting thickness to be maintained for deposition surfaces with inclination angles of 45 degrees. Furthermore, these fibrin-HA hydrogels maintained high biocompatibility with the co-delivered MSCs (>94%), in addition to long-term preservation of 3D morphology and cell proliferation as shown with Hoechst/Phalloidin+ immunostaining over one week. To demonstrate the clinical utility of this approach, we uniformly distributed 1x10^6 MSCs/ml of the fibrin-HA hydrogel on a porcine 5cm x 5cm full-thickness burn wound model and quantified a 1.4-fold improvement of macroscopic re-epithelialization speed, a 1.3-fold increase in collagen density in the dermal layer, and a 2.5-fold reduction in CD11b+ inflammatory cell activity after 28 days compared to burn only controls, as observed via microscopic analysis of H&E histological stains. Taken together, these results highlight the utility of in-situ delivering cell-containing bioinks conformal to physiological surfaces, while promoting cell viability and migration to accelerate wound healing in full-thickness burns.

11:00 AM SB04.06.09
Cell-Friendly, Low-Cost and Fast Assembled Orthopaedic Treatment Using Hybrid Polycaprolactone/Alginate Hydrogel 'Bone Bricks' for Refugees Fengyuan Liu; University of Manchester, United Kingdom

Physical, sensory or intellectual impairments affect one in every five refugees, a further one in seven is affected by a chronic disease and one in 20 suffers from injury. A 2016 Handicap International report stated that 53% of injuries were due to the use of explosive weapons, among this 47% of refugees had fractures or complex fractures and this
includes open fractures of lower and upper limbs. Orthopaedic surgical intervention is a priority after blast injuries to align broken bones/fixate, treat infection and implement solutions for the associated bone loss. However, often the only feasible treatment for these injuries is limb amputation. Amputation has associated complications including heart attack, slow wound healing and infection.

This project aims to create a medical implant allowing for non-union bone loss of 10-20 cm in the lower limb able to induce bone regeneration. The research is built on the current treatment of external fixation but with the addition of an engineered internal prosthetic implant to improve patient outcomes, avoid painful limb lengthening and reduce recovery time. The patient specific prosthetic is achieved by constructing the prosthetic implant from modular pieces, “bone bricks”. The bone bricks, are hybrid scaffolds consisting of different biocompatible and biodegradable materials and infection prevention hydrogel, manufactured using multi-head extrusion-based 3D printing technique, come in a pallet of shapes and sizes and fit together in a “lego like” way to form the prosthesis. The prosthesis and paste will prevent infection, promote bone regeneration creating a mechanically stable bone union. The external fixator offers a comfortable support for patients and a strong stimulation to facilitate bone ingrowth.

This paper reports preliminary results using polycaprolactone/alginate hydrogels scaffolds. Scaffolds are extensively characterised in terms of morphology, physical, chemical and biological properties, and the results show that these scaffolds are suitable candidates to treat large bone defects enabling limb salvage as an alternative to amputation, avoiding painful limb lengthening and improving recovery time/functional patient outcomes.

11:15 AM SB04.06.10
Novel Hydrophilic/Hydrophobic Thermo-Responsive Platforms from Citric Acid Crosslinked Methylcellulose Hydrogels Lorenzo Bonetti1, Luigi De Nardo2, Fabio Variola1 and Silvia Fari1,2; 1Politecnico di Milano, Italy; 2National Interuniversity Consortium of Materials Science and Technology (INSTM), Italy; 3University of Ottawa, Canada

Methylcellulose (MC) hydrogels undergo sol-gel reversible transition upon temperature changes. At temperatures higher than their lower critical solution temperature (LCST) they are in a gel, hydrophobic state. Conversely, at T < LCST they are in a sol, hydrophilic state [1]. These hydrogels lend themselves to smart system applications, exploiting the body temperature as a trigger to activate their sol-gel transition [1,2]. However, one of the limiting factors of MC hydrogels consists in their reduced stability and mechanical properties [3]. The purpose of our research is to explore a novel method to crosslink MC hydrogels in order to increase their mechanical properties while preserving their smart behavior.

A crosslinking strategy based on the employment of citric acid (CA) was developed. The thermal response of the gels was studied by using a Design of Experiment approach, analyzing the effect of three independent variables, namely CA concentration [1-5% w/w], crosslinking time [1-15 min], and crosslinking temperature [165-190 °C] on the swelling rate of the hydrogels. This approach allowed to identify three crosslinking conditions (low, medium, high) while avoiding a trial-and-error approach. The resulting crosslinked hydrogels were characterized by a physico-chemical, mechanical and in vitro biological point of view.

Swelling tests in water revealed the effectiveness of CA crosslinking in modulating the water uptake of MC hydrogels. The crosslinking density [4] increased from (0.19 ± 0.02)*10^{-4} to (2.58 ± 0.65)*10^{-4} mol cm^{-3} for low and high crosslinking conditions, respectively. FTIR analysis and acid-base titrations confirmed the efficacy of CA in controlling the crosslinking degree of the hydrogels [5]. Specifically, carboxylic esters increased from 0.05 ± 2.74 to 42.25 ± 3.71 mmol/100 g for low and high crosslinking conditions, respectively. The extent of hydrophilic/hydrophobic transition was assessed by swelling tests in solvents with different polarities (water and 70% 2-propanol solution) and at different temperatures (4, 25, 37 and 50 °C) [6]. These tests showed that both low and medium crosslinking conditions preserved the smart behavior of MC hydrogels. Ongoing studies aim at assessing temperature-induced chemical and nanomechanical variations assessed by Raman spectroscopy and Atomic Force Microscopy. In vitro biological characterization proved the absence of any cytotoxic effect induced by CA or by the crosslinking procedure when extracts were put in contact with L929 cells for 24 h.

The obtained results pave the way for the development of MC smart hydrogels with tunable properties, with potential innovative implications in the field of smart systems, e.g. for drug delivery.

Room-Temperature Formed PEDOT:PSS Hydrogels Enable Injectable, Soft and Healable Organic Bioelectronics

Yihang Chen, Shiming Zhang and Ali Khademhosseini; University of California, Los Angeles, United States

There is an increasing need to develop conducting hydrogels for bioelectronic applications. In particular, PEDOT:PSS hydrogels have gained significant focus due to their excellent biocompatibility and stability [1]. However, injectable PEDOT:PSS hydrogels have not yet been reported. Such syringe-injectable hydrogels are highly desirable for minimally invasive biomedical therapeutics [2]. Here, we demonstrate an approach to enable injectable PEDOT:PSS hydrogels by using room-temperature crosslinked PEDOT:PSS hydrogels (RT-PEDOT:PSS hydrogels). These RT-PEDOT:PSS hydrogels formed spontaneously after syringe-injection, without the need of any thermal treatments. We further demonstrate that these RT-PEDOT:PSS hydrogels can be used for soft and self-healable bioelectronics.

Shining a Light on Mechanotransduction—Photo-Patterned Hydrogels for Tissue Engineering

Phillip Chivers1,2, Simon J. Webb1, Paul G. Genever2 and David K. Smith2; 1University of Manchester, United Kingdom; 2University of York, United Kingdom

The high demand for transplant tissue is a major health concern worldwide. A shortage of donors combined with poor long-term outcomes post-transplant has seen tissue engineering emerge as an alternative therapy. Using a patient’s own stem cells to regenerate lost or damaged tissue could reduce pressure on transplant waiting lists and avoid issues of organ rejection. However, for laboratory research to be translated into clinical applications, the development of biomaterials which stimulate the formation of specific tissues is essential.1

In recent years, hydrogels have become leading candidates as scaffolds for controlled cell growth. Despite this, there is a dearth of literature exploring the applications of low-molecular-weight gels (LMWG) in this field.2 These materials, which self-assemble through non-covalent interactions, are often dynamic – able to modulate their structure and properties in response to their external environment. Such responsive materials have great potential for complex control of stem cell fate through the delivery of spatiotemporally defined cues.

We report the use of LMWG-containing materials for the spatial control of mesenchymal stem cell (MSC) behavior. By combining DBS-CONHNH2 (a LMWG) with a photo-curable polymer gel (PEGDM), we were able to modify the stiffness of the gels with spatial control by exposing specific regions to UV irradiation.3 MSCs grown on stiffer gels were significantly more likely to differentiate into bone cells than those cultured on soft gels. Furthermore, MSCs at each side of an interface between soft and stiff gel showed significantly different behavior, illustrating the potential of these patterned materials to direct stem cell growth. Studies into the controlled release and diffusion of model compounds and biomolecules indicate that these heterogeneously structured materials could be used for spatially-defined presentation of other stem cell directing factors in the future.

Temporal changes in gel stiffness can be used to impart a further level of control over MSC behavior. We are currently developing a family of hydrogels which modulate their mechanical properties through a reversible photoreaction. Using these materials, we aim to understand and exploit the influence of stem cell mechanical memory to develop next-generation biomaterials.

Failure and Fracture of Hydrogels and Hydrogel Composites Michelle L. Oyen; East Carolina University, United States

Hydrogels have gained recent attention for biomedical applications due to their large water content, which imparts biocompatibility. However, their mechanical properties can be limiting. There has been significant recent interest in the strength and fracture toughness of hydrogel materials in addition to their stiffness and time-dependent behavior. Hydrogels can fail in a brittle manner even though they are extremely compliant. In this work, the failure and fracture of hydrogels is examined using a range of mechanical test methods, including compression, tension, mode I fracture and mode III tearing. Spheres of commercially-available sodium polyacrylate were tested to failure in compression as a function of loading rate. The spheres exhibited virtually no load relaxation when compressed to small fixed displacements. The distributions of strength values obtained were examined in a particle fracture framework previously developed for brittle ceramics. Mode I and mode III fracture experiments were conducted for single-component hydrogels and for hydrogel composites reinforced by nanofibers. Even though the fibers were themselves also hydrogels, the composite toughness values were two orders of magnitude greater than those for the component gels. Strength and toughness of composite hydrogels approached values seen in natural soft biological tissues, indicating that a biomimetic approach to microstructure relates to increasing material properties of hydrogels, making them suited for use as tissue engineering scaffolds in demanding load-bearing applications such as articular cartilage in the joint.

Coarse-Grained Model of the Influence of Solvation on the Properties of Electrolyte, Nanoparticle and Polyelectrolyte Solutions Jack F. Douglas; National Institute of Standards and Technology, United States

The aqueous solvation of ions, highly charged nanoparticles and polymers, and the resultant non-trivial interactions between these solvated species, is a ubiquitous, but poorly understood phenomenon that underpins many biological and manufacturing processes. This solvation phenomenon is investigated based on simple, but explicit, model of the solvent that accounts for the high cohesive interaction strength of water based on the constraint that the solvent reproduces the critical temperature of pure water, while the strength of the van der Waals ion-solvent interactions between the ions and the solvent are fixed by the experimentally observed enthalpy of solvation. We find that this coarse-grained model of aqueous ionic solutions reproduces observed trends of the viscosity of water and water diffusivity with specific salt types, along with observed trends in the density, compressibility and surface tension of aqueous solutions. The application of this model to highly charged particles and polyelectrolytes, leads to new phenomena associated with nanoparticle and polymer solvation that are not observed when the solvent is treated as a continuum. In particular, while the counter-ions dissolve into the solvent as in the case of a continuum solvent, they continue to dynamically associate, leading to the formation of a diffuse “polarizable” cloud of counter-ions around the polymers and nanoparticles. We find that the fluctuations of the ions of opposite charge, which are modulated by competitive counterion and polymer/particle solvation, can lead to strong attractive interactions between charged species having a common sign. We argue that these solvation-induced interactions are crucial for understanding the widespread observations of supramolecular assembly in highly charged polyelectrolyte and colloidal solutions in the context of viscoelastic solutions and gels of proteins, and many other naturally occurring polyelectrolytes, and in common charged colloidal viscoelastic materials such as soils, setting concrete, etc. Further development of this type of model for hydrogels, and many other aqueous solution applications, requires improvements in the modeling of ion-ion interactions and van der Waals solvent-polymer or nanoparticle interactions that become large when the

2 Christoff-Tempesta, T.; Lew, A. J.; Ortony, J. H. Gels, 2018, 4, 40
3 Chivers, P. R. A; Smith, D. K. Chem. Sci. 2017, 8, 7218-7227
salt concentration becomes large. Further validation studies of the coarse-grained model for transport coefficients such as ion diffusivity, etc. are also required.

Behavior of Polyelectrolyte Gels in Concentrated Solutions of Highly Soluble Salts Jessica Sargent1, John A. Howarter1, Kendra A. Erk1, Mitchell Brezina1 and Xunkai Chen1,2; 1Purdue University, United States; 2University of California, Berkeley, United States

Hydrogels composed of lightly crosslinked poly(sodium acrylate-co-acrylamide) (P(ANa-AM)) have been investigated as responsive materials for a wide range of applications. This polyelectrolyte network is highly hydrophilic and sensitive to changes in the pH and ionic strength of its environment. Above a pH of ~5, the sodium acrylate moieties dissociate to produce negative charges along the polymer chain, which increases the gel’s swelling capacity due to a further increase in the osmotic pressure difference between the gel interior and the surrounding aqueous solution. However, if the solution in which the gel is submerged contains free cations (e.g., dissolved salt ions), these ions interact with the charged polymer molecules and reduce the gel’s swelling capacity and, consequently, transport properties. P(ANa-AM) gels have been applied in many biological applications and consumer products, and they are also a prime candidate for controlled release agents in internally cured high-performance concrete. The effects of biologically-relevant saline solutions on the swelling properties of these gels have been thoroughly investigated, but little has been reported regarding the performance of P(ANa-AM) gels in concentrated saline solutions (e.g., 10 mM to greater than 1 M) or after cyclical swelling and deswelling in saline solutions. In particular, it is expected that the effect of crystal formation of monovalent and multivalent salts within the gels from these concentrated solutions will have significant impacts on hydrogel behavior as well as offer new avenues for tailoring gel compositions for applications such as controlled crystal growth and recyclable hydrogel materials.

This research probes the effects of concentration, valency, and crystallization of highly soluble salts (e.g., sodium chloride and calcium chloride) on fundamental hydrogel properties including swelling capacity, mesh size, and free volume. In so doing, we seek to develop an enhanced understanding of structure-property-performance relationships in these materials that can contribute to the informed design of responsive hydrogel materials for targeted environments. This work focuses specifically on polymer compositions of 17% and 83% sodium acrylate with 0.5 and 2.0% crosslinker due to their relevance to recent research in high-performance concrete. Investigation utilizes a combination of characterization techniques that span multiple length scales in order to correlate macroscopic changes in performance with the molecular-scale interactions that induce these changes. Specifically, we incorporate bulk measurements (e.g., gravimetric swelling tests), optical analysis, and spectroscopy experiments including x-ray scattering and positron annihilation to elucidate the structural relationships between hydrogel composition (e.g., amount of charged monomer units and crosslink junctions in the network) and effects of high ionic concentrations in solution. X-ray scattering (XRD and SAXS) and positron annihilation lifetime spectroscopy (PALS) are complimentary spectroscopy techniques that allow us to probe both the size and distribution of electron-dense regions (i.e., salt crystals, collapsed polymer coils, and crosslink junctions) via x-ray scattering and the relative abundance and size of void spaces between network components (i.e., free volume) through positron annihilation. Combining these techniques with larger-scale measurements of changes in the gels’ swelling behavior, we aim to provide a complete picture of P(ANa-AM) hydrogel performance in high salinity environments.

Modeling Tetra-PEG Hydrogels with Degradable Crosslinks Vaibhav A. Palkar, Chandan K. Choudhury and Olga Kuksenok; Clemson University, United States

Soft materials with controllably degradable crosslinks constitute an important component of active stimuli responsive platforms for numerous applications. As one example, fast photo-cleavage of crosslinks has enabled the development of a soft material allowing user-directed growth of neural networks. Apart from light, other stimuli such as heat and ultrasound can also be utilized for controlled degradation. Herein, we develop a Dissipative Particle Dynamics (DPD) simulation framework aimed at modeling tetra-arm polyethylene glycol (tetra-PEG) hydrogels with transient crosslinking. This framework allows single parameter control over the crosslink degradation rate. Further, we develop a correspondence of our DPD framework with continuum level modeling and isolate phantom
and affine network conditions with respect to our model hydrogel network. Our results show a good correspondence with prior experimental studies on tetra-PEG gels showing crossover from phantom to affine network models for these systems with an increase in crosslink density. We then focus on adsorption of tetra-PEG nanogels at oil-water interface and on dynamics of confined films of these gels. We show that the cleavage of crosslinks leads to the controlled spreading of nanogels at the interface and to degradation-induced buckling of constrained films.

Ideal Dynamic Covalent Hydrogels for Thermal Stabilization of Biologics Bruno Marco Dufort and Mark W. Tibbitt; ETH Zürich, Switzerland

Recent research in the design and engineering of polymer networks has introduced a new class of hydrogels based on dynamic covalent chemistry, which combines the mechanical properties of both physically and chemically cross-linked materials. Dynamic covalent hydrogels enable the formation of responsive, mouldable, and self-healing materials, as the bonds in the network can break and reform in response to external stimuli [1]. These unique properties are being leveraging in many biomedical applications, such as in responsive drug delivery systems, dynamic scaffolds for cell culture and more recently in our work on the thermal stabilisation of biologics. The macroscale properties of these hydrogels, however, depend on the specific chemistry of the cross-link binding pairs as well as the network topology. Successful application of dynamic covalent gels therefore requires a robust understanding of how these factors influence each other and the emergent properties of the network.

In this work, we related the viscoelastic properties of dynamic covalent networks, measured by dynamic mechanical analysis, to the microscopic behaviour of the reversible junctions, through kinetic NMR studies. Boronic ester-based hydrogels were used as model dynamic covalent gels, since their viscoelastic properties can be tuned over several orders of magnitude by tailoring the chemistry of the acid-diol binding pair or by changing network pH [2]. Oscillatory shear rheometry revealed that these materials behave as ideal dynamic covalent networks, exhibiting both rubber elastic behaviour and time-dependent mechanical properties, which can be modelled by a single Maxwell element with a spring and a dashpot in series. Uniquely, the viscoelasticity in these materials could be linked to the microscopic behaviour at the junctions via 2D ¹H NMR exchange spectroscopy (EXSY), as the relaxation behaviour in these materials at different pH scale with the reaction rates of the diols with the boronic acids. This work, which links dynamics of the junction chemistry in a reversible network to its bulk behaviour, is being used to develop physical models that relate binding pair thermodynamics and kinetics to macroscale properties in order to enable the rational design of hydrogel systems.

In addition, we are applying the knowledge gained from these fundamental studies to the development of a platform material with utility in 3D printing, injectable drug delivery, and for the thermal stabilisation of biologics. We present here new results on the thermal stability of a broad range of biologics; leveraging the ability of these dynamic covalent gels to enable encapsulation, stabilisation, and triggered release of cargo. The ability to protect biologics from thermal stress with a simple material solution presents a useful approach to mitigate the cost and risk associated with reliance on a continuous cold chain for biologic transport and storage.

Structural and Conformational Properties of Bottlebrush Polyelectrolyte Solutions Alexandros Chremos¹, Jack F. Douglas² and Ferenc Horkay¹; ¹National Institutes of Health, United States; ²National Institute of Standards and Technology, United States

Bottlebrush polyelectrolyte solutions have great significance in biology, e.g., aggrecan is a major proteoglycan in the articular cartilage, and exhibit great potential in drug delivery applications, however, there is little theoretical understanding of their behavior compared to their linear polyelectrolyte solutions. We made a comparative investigation of linear and bottlebrush polyelectrolyte solutions with the use of molecular dynamics simulations. In particular, we utilize a previously developed polyelectrolyte coarse-grained bead-spring model that includes an explicit treatment of the charged species and solvent to probe the conformational properties of polyelectrolyte linear and bottlebrush polyelectrolytes at different polymer and salt concentrations. Specifically, we calculate the polymer hydrodynamic radius and radius of gyration along with its eigenvalues. Moreover, we calculate the structure factor
and determine the scaling of the location of the polyelectrolyte peak with polymer concentration. Overall, our findings are in agreement with small angle neutron scattering (SANS), dynamic light scattering (DLS) and osmotic pressure measurements. These complementary experimental and computational techniques probe different length and time scales providing a comprehensive picture of the essential properties of bottlebrush polyelectrolytes.

4:30 PM SB04.07.07
Light-Induced Shape-Morphing Hydrogels—Dynamic Motion and Programmable Assembly Hyunki Kim, Todd Emrick and Ryan C. Hayward; University of Massachusetts Amherst, United States

Small organisms living on the surface of water often rely on the modulation of capillary forces to propel themselves on demand. For example, springtails move at the air-water interface by simply adjusting their posture, which in turn modulates capillary forces. This results in the aggregation of the springtails and migration of individuals between aggregates. Inspired by nature, we developed a dynamic soft material that mimics the behavior of on-demand attraction and repulsion and displays programmable assembly patterns and non-equilibrium capillary motion.[1] Our synthesis of shape-morphing hydrogels used in situ patterned growth of Au nanoparticles (NPs) embedded within temperature-responsive hydrogel films. The patterns of Au NPs yielded spatially non-uniform heating under illumination, and therefore light-induced differential swelling and wrinkling of the hydrogel films. As a result, the three-phase contact line at the air-water-hydrogel interface was distorted dynamically to generate capillary attraction and repulsion. The geometry of these hydrogel nanocomposite films was designed to generate specific wrinkling patterns and resulting configurations of the hydrogel assemblies. Time-varying patterns of illumination led to reconfiguration of the assemblies, allowing them to be ‘annealed’ to reach low-energy structures. Furthermore, an appropriately chosen static pattern of illumination and geometry of the hydrogel actuator induced sustained rotation and translation. This approach provides synthetic tools to control objects in time and space with implications for the design of hydrogel nanocomposite materials and soft robots.

Muscle-Like Fatigue-Resistant Hydrogels by Mechanical Training Ji Liu1,2, Shaoting Lin2, Xinyue Liu2 and Xuanhe Zhao2; 1Southern University of Science and Technology, China; 2Massachusetts Institute of Technology, United States

Skeletal muscles possess the combinational properties of high fatigue resistances (1,000 J/m²), high strengths (1 MPa), low Young’s moduli (100 kPa), and high water contents (70 – 80 wt%), which have not been achieved in synthetic hydrogels. The muscle-like properties are highly desirable for hydrogels’ nascent applications in load-bearing artificial tissues and soft devices. Here, we propose a strategy of mechanical training to achieve the aligned nanofibrillar architectures of skeletal muscles in synthetic hydrogels, resulting in the combinational muscle-like properties for the first time.1 These properties are obtained through the training-induced alignment of nanofibrils, without additional chemical modifications or additives. In situ confocal microscopy of the hydrogels’ fracturing processes reveals that the fatigue resistance results from the crack pinning by the aligned nanofibrils, which require much higher energy to fracture than the amorphous polymer chains. This strategy is particularly applicable for three-dimensionally printed microstructures of hydrogels, in which we can achieve isotropically fatigue-resistant, strong yet compliant properties.

Synthesis of Photo-Activating Acryl-Polyurethane Containing Multifunctional Monomer for High Strength and Biocompatible 3D Printing Materials Jihong Bae and PilHo Huh; Pusan National University, Korea (the Republic of)

A UV curable acryl-polyurethane is successfully prepared by a combination of poly(tetramethylene ether) glycol (PTMG) and 1,4-butandiol (1,4-BD) as polyols, 4,4’-methylene bis(phenylisocyanate) (MDI) as an isocyanate, pentaerythritol triacrylate and triethyleneglycol dimethacrylate (TEGDMA) as multifunctional monomers and benzophenone was used to photoinitiator for UV curing to optimize the physical property of the 3D structure. The crosslinking step of acryl-polyurethane elastomers were processed using the exposure to 385~405nm UV radiation. The structure of the resulting acryl-polyurethane was evaluated by fourier transform infrared spectroscopy (FT-IR), gel permeation chromatography (GPC). The tunable UV absorbance of acryl-polyurethane was adjusted through the material design. The mechanical properties such as tensile strength, elongation and modulus were evaluated by universal testing machine. And flexural strength and hardness were measured by durometer and ISO test machine. The surface resolution-quality of the 3D structure was analyzed by field emission scanning electron microscope (FESEM).

Stability-Enhanced Chitosan-Catechol 3D Bioink by Diatom Frustule Silica Jeehee Lee and Haeshin Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

This study shows the availability of a 3D bioink enhanced by diatom frustules. Diatoms are photosynthetic, aquatic creatures with a skeleton called frustule, mainly composed of silica. Many materials for 3D printing require a liquid to solid transition so that stimuli such as temperature, or UV curing were employed. However, this method is difficult to use in bio printing, which requires printing with live cells. Although there are many conventional biocompatible materials, it should be fulfill requirements: injectable, adhesive to the each layer, and maintainable without spreading after printing. Chitosan-catechol, mussel-inspired adhesive, is a 3D bioink that catechol is conjugated to chitosan, which contains an amine group that plays a synergistic role in adhesion with catechol. Chitosan-catechol is the representative adhesive that best mimics the adhesion of mussel byssus. Rapid complex formation of chitosan catechol with serum proteins is known to be able to form 3D structures. Thus, it is also possible to use it as a bio ink for rapid liquid printing, which is next generation 3D printing, not to be stacked layer by layer. However, while having a good system, the formed chitosan-catechol 3D composites have poor stability after injection and weak mechanical strength after gelation. There have been attempts to overcome this with addition of vanadium, but there are still other issues to address such as in terms of price and in vivo safety as well as performance.

In this study, we significantly enhanced the stability of the bio ink by simply mixing silica microparticles with a charged nanoporous structure. As a model system, we used Melosira nummuloides, because they are relatively bulky at ~ 50 μm in diameter, and numerous nanopores are exposed to the surface, which is likely to increase the chance to form entanglements of the bio-ink polymer to the silica surface. The results showed that the addition of Melosira nummuloides greatly increased the post - injection stability of chitosan-catechol bioink, and confirmed increased storage and loss modulus values and shear thinning rheological properties. Through the Universal Testing Machine data, it was confirmed that it has stronger mechanical tensile strength. In addition, it is verified that cells were viable on this bio ink. By using these properties, it is possible that diatom frustule-reinforced chitosan-catechol bioink can be used for printing directly in the body.

SB04.08.03
Silk Fibroin Based Antimicrobial Hydrogel for Wound Infection Treatment Wenlong Li1,2,3 and Xiaodong Chen1,2,3; 1NTU Institute for Health Technologies, Singapore; 2Innovative Centre for Flexible Devices (iFLEX), Singapore; 3Max Planck-NTU Institute for Artificial Senses, Singapore

Pathogen infection into human beings is a worldwide problem. With the global crisis of multi-drug resistance in bacteria, it is becoming an emerging urgent task in the fighting of bacteria related infections. Wound infection is one
of the easiest ways for pathogen transmission if no proper treatment is engaged. As such, the development of antimicrobial biomaterial is of great importance to interface with pathogenic microorganism. Silk fibroin, a natural protein produced from *Bombyx mori*, can be a promising candidate due to their biocompatibility, biodegradability, low immunogenicity, and tuneable mechanical properties. However, silk fibroin-based hydrogel biomaterial is not bacteria resistant, and its Young’s modulus is not comparative with human skin, hindering its application for infection treatment. Here, we present a facile self-assembly process to prepare silk fibroin hydrogel with the antimicrobial property. Dialyzed silk fibroin is co-assembled with Fmoc-protected amino acids. This procedure has very fast gelation kinetics (within two minutes), which is faster than most of the currently applied silk fibroin gelation methods. It was found that increasing Fmoc-Leu-OH (Fmoc-L) and silk fibroin concentration increased the gelation kinetics. From FTIR study, Fmoc-L transformed silk fibroin secondary structure from random coil to β-sheet. It indicates Fmoc-L promoted β-sheet formation in silk fibroin. This is probably due to the amphiphilic property of Fmoc-L, causing a capping effect on silk fibroin protein. The antimicrobial activity of hydrogel was evaluated by agar plate spreading and LIVE/DEAD staining, which showed that the hydrogel is very effective at killing *B. subtilis* with 108 CFU/mL. In addition, the mechanical property of the antimicrobial hydrogel can be tuned with other PAAm hydrogel co-gelation, making it wearable on the skin. Our results suggest a novel biomaterial candidate for wound treatment on human skin.

**Static and Dynamic Properties of Aggrecan Assemblies** Ferenc Horkay¹, Peter Basser¹, Erik Geissler² and Anne-Marie Hecht²; ¹National Institutes of Health, United States; ²Universite Grenoble Alpes, France

Aggrecan is a bottlebrush shaped high molecular weight proteoglycan. It consists of an extended protein core to which many chondroitin sulfate and keratan sulfate (linear sulfated polysaccharide) chains are attached. This array forms a bottlebrush structure. Aggrecan’s primary biological role is to provide the osmotic properties for cartilage. In the presence of hyaluronic acid (HA) aggrecan molecules self-assemble into a supramolecular structure with as many as 100 macromonomers bound to a HA molecule. The aggrecan-HA complexes govern the load bearing properties of cartilage.

Small angle neutron scattering (SANS), dynamic light scattering (DLS) and osmotic pressure measurements were made on near physiological solutions of aggrecan and aggrecan-HA complexes. SANS reveals that the supramolecular structure of aggrecan assemblies is only marginally affected by the HA molecules. DLS indicates that the dynamic response of the aggrecan-HA complex is slower than that of the corresponding aggrecan solution. The relaxation rates measured by dynamic light scattering is proportional to $q^3$, which is the signature of internal modes in large loosely connected assemblies of smaller units, such as individual aggrecan molecules. This is reflected in the hydrodynamic radius, $R_H$, whose apparent value varies inversely with $q$. With increasing aggrecan concentration $R_H$ increases, which is a consequence of the steric hindrance due to densification of the aggrecan aggregates. HA slows the relaxation rate in agreement with an increase of the friction coefficient owing to the rearrangement of the aggrecan molecules along the HA chain. However, addition of calcium chloride slightly increases the relaxation rate of the correlation function. Osmotic pressure measurements quantify the effects of HA and calcium chloride on the osmotic modulus, which defines the compressive resistance of aggrecan assemblies.

**Development of an Ingestible pH Sensitive Actuator for Edible Devices via One-Pot Synthesis** Alex Keller, Holly Warren and Marc In het Panhuis; University of Wollongong, Australia

Edible devices are an emergent technology which seek to provide researchers and health professionals with tools to monitor the GI tract without the traditional risks of retention as they are constructed from edible materials.

To this effect an ingestible actuator was developed using non-toxic poly(acrylic acid) and calcium hydroxide. Poly acrylic acid and poly(acrylic acid)/calcium hydroxide hydrogels displayed compressive stresses of 0.08 ± 0.02 MPa and 0.10 ± 0.03 MPa, respectively and swelling ratios of 61 ± 3 and 45 ± 2, respectively. However, on exposure to simulated gastric fluid (pH 1.2) for 1 hour the polyacrylic acid hydrogels were destroyed whereas the poly(acrylic acid)/calcium hydroxide hydrogels displayed a compressive stress of 0.16 ± 0.04 MPa and a swelling ratio of 12 ± 2. Furthermore, the poly(acrylic acid)/Calcium hydroxide hydrogels displayed a volume change to 17% ± 2% of it’s original volume.
This demonstrates the ability that the calcium hydroxide provides in preserving the polyacrylic acid in acidic environments such as gastric fluid and that this neutralisation reaction results in a volume change of the hydrogel. In addition to this, the poly(acrylic acid)/calcium hydroxide hydrogels exhibited reversible actuation on submerging in 0.1 M sodium citrate for 2 hours. The poly(acrylic acid)/calcium hydroxide hydrogels where able to restore their compressive stress to $0.19 \pm 0.06$ MPa, swelling ratio to $26 \pm 2$ and volume to $56\% \pm 3\%$ of its original volume.

This work offers new oppurtunities for researchers to further the state of the art for a variety of fields such as drug delivery, 4D printed materials, soft robotics and edible devices.

**SB04.08.06**  
**Strain Sensors Based on Conducting Tough Hydrogels** Matthias Kuenzel, Matthew McRae and Marc In het Panhuis; University of Wollongong, Australia

A simple model system towards an impedance-probing strain sensor based on conducting tough hydrogels is demonstrated.

An easy-to-make poly(acrylamide) (pAAm) hydrogel, cross-linked with N,N-methylene-bis(acrylamide) (MBAAm) was prepared and contacted with carbon fibres for electrical impedance analysis. The conductivity of these LiCl salt-containing hydrogel was determined to be $114 \pm 10$ mS/cm.

Upon stretching the hydrogel samples to their fourfold initial length, the impedance response increased according to a power law. This was used to establish a sensing equation for the relation between the resistive component of the impedance signal and the applied mechanical strain under tension.

Functional capacitance strain sensing devices were constructed the salt-containing hydrogels, carbon ribbons and a dielectric elastomer. The sensors were tested under cyclic loading/unloading. The measured capacitance value of the sensor was found to be linearly dependent on the extension ratio.

Our results contribute to the development of highly stretchable and soft strain sensors for the application in soft robotics or tissue engineering.

**SB04.08.07**  
**Living Electrodes from Green Algae in Hydrogels** Mohammed Al-Mossawi$^{1,1}$, Holly Warren$^{1,1}$, Paul J. Molino$^{1}$, Paul Calvert$^{2}$ and Marc In het Panhuis$^{1,1}$; $^{1}$University of Wollongong, Australia; $^{2}$New Mexico Institute of Mining and Technology, United States

Hydrogels are attracting great interest due to their unique material properties, which have found potential applications in a range of disciplines such as fuel cells, membrane electrode assemblies, neural interfaces and other biomedical applications. A relatively new direction is to combine soft (hydrogel) electrically conducting materials with living entities to create living electrodes.

In this presentation, living electrodes have been prepared by embedding green algae Chlorella Vulgaris within a hydrogel consisting of alginate and cross-linked with a salt charge carrier. We have established various immobilisation techniques to allow high-density algae cultivation. We demonstrate that the algae cells were capable of growing within alginate hydrogels for more than 28 days. Mechanical, rheological, electrical and biological properties of the living electrodes were assessed to investigate the impact of algae growth.

These living (algae-hydrogel) electrode materials are an important stepping stone towards the future development of living electrodes for biomedical and tissue engineering applications.

**SB04.08.08**  
**Decellularized Extracellular Matrix for In Situ Cell Encapsulation for Tissue Engineering** Seth Edwards, Jason Brown and Kyung Jae Jeong; University of New Hampshire, United States

Extracellular matrix (ECM) provides the ideal microenvironment for various tissue specific cellular functions including adhesion, migration, proliferation and differentiation. Using decellularized ECM (D-ECM) as a tissue
engineering scaffold has been proposed to take advantage of the chemical and physical information it retains for the growth of tissue-specific cells, in addition to retention of physical strength of the original tissue. However, introduction of cellular components into D-ECM scaffolds involves injection of cells, significantly damaging the D-ECM structure and resulting in a poor distribution of cells within the ECM. Thus, scaffolds of this nature are unfit for traditional cellular encapsulation. Alternatively, D-ECM can be milled and digested into a solution, and crosslinked to form a homogeneous hydrogel. Although this method enables in situ cell encapsulation, the mechanical properties of the resulting hydrogel are poor due to the low concentration of soluble D-ECM (~2%), and encapsulated cells are trapped in the polymer mesh of the hydrogel, which inhibits cell adhesion, spreading, and proliferation. In addition, the digestion of D-ECM results in a partial loss of molecules important to ECM function, and destroys the 3D microenvironment of the original ECM, which has been shown to be important in promoting proper cell and tissue function. Here, we propose a new method of producing D-ECM hydrogel, by assembling and curing D-ECM ‘microparticles’, allowing for in situ cell encapsulation. Using porcine corneal stroma as a model tissue, D-ECM is first mechanically milled into microparticles by cryomilling, and upon suspension in physiological buffer, particles are chemically crosslinked by microbial transglutaminase (mTG). Due to a high solids concentration, the resulting hydrogel has improved mechanical strength when compared to homogeneous D-ECM hydrogel. Additionally, the macroporous structure allows for a more optimal growing surface for encapsulated cells when compared to homogeneous D-ECM hydrogel, and the negation of a digestion step allows for the partial retention of the original ECM microstructure. This proposed change in methodology introduces a new avenue of research for using D-ECM as a biomimetic scaffold, and can be applied to other relevant tissues.

Wenwen Huang¹,²; ¹The Zhejiang University-University of Edinburgh Institute, Zhejiang University School of Medicine, Zhejiang University, China; ²The 2nd Affiliated Hospital, Zhejiang University School of Medicine, Zhejiang University, China

Fine-tuned programmable shape changing biomaterials are crucial for a variety of task-specific applications ranging from health care to sustainable novel devices. Biocompatible smart actuators with multifunctions and complicated architectures fabricated from natural materials remains a challenge. To generate tailored bio-polymeric materials with predictive functional outcomes, exploiting designs from nature while morphing them towards non-natural systems offers an important strategy. Elastin is a major structural protein abundant in the extracellular matrix, providing reversible extensibility and elastic recoil to the skin, elastic cartilage and blood vessels. The dynamic elastomeric systems based on elastin proteins have gained increasing attention due to their great potential for controlled release and actuating systems. In current research, an integrated modeling-experimental approach were used to rationally design and fabricate stimuli responsive and shape changing silk-elastin-like protein (SELP) hydrogels, which response to environmental stimuli, such as thermal, pH and enzymatic triggers. New stimuli-responsive bilayer hydrogel actuators were also fabricated based on genetically engineered SELP in composite laminate arrangements with cellulose nanofibers (CNF). These hybrid devices were designed to respond to dual stimuli, temperature and ionic strength, around body temperature and salt concentration of 0.5 M to 5 M. The sensitivity of these actuators support intricate morphological transformations in SELP/CNF bilayer designs where pre-patterned control of the materials assembly provides options for diverse applications for these devices. These studies provided further insight into the sequence-function relationship of SELP and bio-actuator design, and therefore accelerated the development of stimuli-responsive biomaterials.

**Responsive Peptide-Based Supramolecular Hydrogels Constructed by Self-Immolative Chemistry**  
Zheng Debin; Nankai University, China

Peptide-based supramolecular hydrogels that are stimuli-responsive under aqueous conditions have many potential biological applications, including drug delivery and sensing. Herein, we reported a series of responsive peptide-based supramolecular hydrogels that respond to glutathione (GSH), nitric oxide (NO) and hydrogen sulfide (H2S), which are biologically important signaling molecules. The responsive hydrogelators were designed by “self-immolative” chemistry and constructed by using self-immolative groups to modify short peptides. The self-immolative capping group could be removed in the presence of a corresponding trigger, thus causing gel–sol phase
transitions. The potential of our responsive hydrogels for drug release was also demonstrated in this study. We developed several responsive supramolecular hydrogels using self-immolative chemistry. The short peptide, GFFY, was modified with self-immolative aromatic groups to yield supramolecular hydrogelators that could form hydrogels. In the presence of small molecules capable of removing the aromatic groups from the peptide, the hydrogels changed to solution.

The potential of our hydrogels in sensing and drug delivery was demonstrated in principle. The hydrogelators were biocompatible to LO2 cells. Our study provided novel responsive hydrogels that responded to biologically important small molecules and could be applied in drug delivery and sensing.

SB04.08.11
Rationally Designed Self-Healable Planar Supercapacitor for Driving an Integrated UV/NO2 Multifunctional Sesonor Minsu Kim and Jeong Sook Ha;1 KU-KIST graduate school, Korea (the Republic of); 2Korea University, Korea (the Republic of)

Recently, there have been extensive efforts to develop self-healable electronics with reliability which can spontaneously restore electrochemical as well as mechanical properties after damages due to external impact or continuous usage. In this work, we report a rationally designed self-healable planar supercapacitor for driving an integrated UV/NO2 multifunctional sensor. As a good self-healable electrolyte in both air-ambient and watery conditions, PVA/Borax/Agarose hydrogel with NaN03 was used. The dynamic network of PVA–Borate provides the hydrogel with ultrafast self-healing property, and the agarose network provides an additional mechanical strength and stability. Bisected hydrogel electrolyte restores 96% of tensile stress and 98% of ionic conductivity after simple physical contact for 30 s without external stimuli. Gold nanosheets and multi-walled carbon nanotubes (MWNTs) transferred on to a PVA/Agarose substrate by vacuum filtration was used as self-healing electrodes. A multifunctional sensor was fabricated by vacuum filtration of MWNTs and Zinc oxide nanowires to detect both UV and NO2. The fabricated self-healable supercapacitor exhibits areal capacitance of 68.7 mF cm-2 at 1 mA cm-2, maximum energy density of 6.1 μWh cm-2, and maximum power density of 1.4 mW cm-2. The supercapacitor maintained 87% of initial capacitance and the UV/NO2 sensor also kept its sensing ability after 5 repetitive healing cycles. Using the stored energy of the supercapacitor, both UV and 10 ppm of NO2 gas could be detected for sufficiently long time. This work demonstrates a high potential of our self-healable planar supercapacitor as an integrated energy storage device in application to high performance self-healable sensor system.

Mineralization-Assisted Additive Manufacturing of Alginate Shubhanga Ballal, Qiaochu Li, Niels Holten-Andersen and Seth A. Cazzell; Massachusetts Institute of Technology, United States

We investigate a novel approach to additive manufacturing using a mineralized alginate hydrogel. By coupling the polymerization of alginate in the presence of calcium ions with the reaction of calcium ions and carbonate ions, the hydrogel is mineralized. This alters the mechanical properties of the hydrogel, making it more suitable as a structural material that can be printed. We explore how the ion concentrations and reaction times affect the properties of the resultant hydrogel. We also determine optimal methods for extruding the gel so that it may be used to form larger structures.

SB04.08.13
3D Printing of Anisotropic Hydrogels with Bioinspired Motion Hakan Arslan, Amirali Nojoomi, Junha Jeon and Kyungsuk Yum; University of Texas, United States

Motion in biological organisms often relies on the functional arrangement of anisotropic tissues that linearly expand and contract in response to external signals. However, a general approach that can implement such anisotropic behavior into synthetic soft materials and thereby produce complex motions seen in biological organisms remains a challenge. Here, we present a bioinspired approach that uses temperature-responsive linear hydrogel actuators, analogous to biological linear contractile elements, as building blocks to create three-dimensional (3D) structures with programmed motions. This approach relies on a generalizable 3D printing method for building 3D structures of hydrogels using a fugitive carrier with shear-thinning properties. This study demonstrates that the metric incompatibility of an orthogonally growing bilayer structure induces a saddle-like shape change, which can be further exploited to produce various bioinspired motions from bending to twisting. The orthogonally growing bilayer structure undergoes a transition from a stretching-dominated motion to a bending-dominated motion during its shape
transformation. The modular nature of this approach, together with the flexibility of additive manufacturing, enables the fabrication of multimodular 3D structures with complex motions through the assembly of multiple functional components, which in turn consist of simple linear contractile elements.

SB04.08.14
Molecular Dynamics Simulations of Nanocomposite Hydrogels with Nanoplatelet Clay Fillers Shoumik Saha, Miriam Rafailovich and Dilip Gersappe; SUNY-Stony Brook, United States

Nanocomposite hydrogels are physical gels formed from a mixture of hydrophilic polymer chains and nanoparticles. They have enhanced properties and can retain higher amounts of water. Despite the large number of experimental studies on this topic, little is known about the mechanism of formation and structure of these gels. Here, we use molecular dynamics simulations to study structure formation in physically associating nanocomposite hydrogels. Nanofillers were modeled as rigid bodies of disk-like shapes and physical crosslinks were simulated by introducing a short-range attraction between the nanofillers and polymer chain ends. The structure, dynamics and mechanics of these polymer gels were studied as a function of nanofiller volume fraction. We model gels both with a single polymer, as well as a binary mixture of polymers to study the effects of polymer chain interaction and assembly on structure formation and gelation of these systems. Our results show that assembly between the nanoparticles is an important determinant of the final properties of the gel. This assembly is mediated by the types and interactions of the polymer used. Our simulations are able to determine local structural information and can determine conditions under which the strength of the hydrogel is optimal.

SB04.08.15
Systematic Characterization of 3D-Printed Polycaprolactone/ Poly (Ethylene Oxide)/ Hydroxyapatite (HA) Scaffolds For Biomedical Devices and Bone Tissue Engineering—Influence of Material Composition and Structure Design Bin Zhang1,2, Alesander Nguyen, Jie Huang and Roger Narayan; 1University College London, United Kingdom; 2University of North Carolina at Chapel Hill and North Carolina State University, United States

This works aims at guiding systematic experimental characterization for the design of 3D printed scaffolds for bone tissue applications, focusing on direct ink writing with a biocomposite of polycaprolactone (PCL), poly (ethylene oxide) (PEO) and hydroxyapatite (HA). Firstly, the effect of the material composition (HA concentration in the range from 55 to 85% w/w) on the PCL/PEO/HA ink rheology properties we studied. Secondly, the impact of the ink compositions on the 3D printed scaffold mechanical properties were systematically investigated. Thirdly, different concentrations of vancomycin drug (5%, 10%, and 15% w/w) have been successfully loaded on the PCL/PEO/HA scaffold, and drug release profile was investigated. Work is continuing to characterize the PCL/PEO/HA scaffolds in anti-microbial properties and tissue regeneration in biological models to develop a 3D multifunctional composite scaffolds by changing scaffold material, structures, and mechanical properties. The biocomposite scaffold fabricated in this study has the potential for the application of tissue replacement.

SB04.08.16
Additive Manufacturing of Bovine Serum Albumin-Based Hydrogels and Bioplastics Patrick Smith, Benjaporn Narupai, Jonathan Tsui, Sayami C. Millik, Ryan Shafranek, Deok-Ho Kim and Alshakim Nelson; University of Washington, United States

Bio-sourced and biodegradable polymers for additive manufacturing could enable the rapid fabrication of parts for a broad spectrum of applications ranging from healthcare to aerospace. However, a limited number of these materials are suitable for vat photopolymerization processes. Herein, we report a two-step additive manufacturing process to fabricate robust protein-based constructs using a commercially available laser-based SLA printer. Methacrylated bovine serum albumin (MA-BSA) was synthesized and formulated into aqueous resins that were used to print complex 3D objects with a resolution comparable to a commercially available resin. The MA-BSA resins were characterized by rheometry to determine the viscosity and the cure rate, as both of these parameters can ultimately be used to predict the printability of the resin. In the first step of patterning these materials, the MA-BSA resin was 3D printed, and in the second step, the printed construct was thermally cured to denature the globular protein and increase the intermolecular noncovalent interactions. Thus, the final 3D printed part was comprised of both chemical and physical cross-links. Compression studies of hydrated and dehydrated constructs demonstrated a broad range of compressive strengths and Young’s moduli that could be further modulated by adjusting the type and amount of co-monomer. The printed hydrogel constructs demonstrated good cell viability (> 95%) after a 21-day culture period.
These MA-BSA resins are expected to be compatible with other vat photopolymerization techniques including digital light projection (DLP) and continuous liquid interface production (CLIP).

SB04.08.17
Cucurbit[8]uril-Mediated Supramolecular Graphene Hydrogel Vijay K. Rana and Oren A. Scherman; University of Cambridge, United Kingdom

Once graphene (GR) is incorporated into polymer matrices, the resultant composites show enhanced mechanical, thermal, electrical and biological properties. However, the scalable production of uniformly distributed graphene-based composite materials remains a sizable challenge. While GR-polymer nanocomposites can be manufactured at large scale, processing limitations result in poor control over the homogeneity of hydrophobic GR sheets in the matrices. Such processes often result in difficulties controlling stability and avoiding aggregation, therefore eliminating benefits that might have otherwise arisen from the nanoscopic dimensions of GR.

Here, we report an exfoliated and stabilized GR dispersion in water. Bicationic viologen derivative was used to exfoliate and stabilize partially reduced/defected/oxidized graphene sheets in water. Finally, cucurbit[8]uril (CB[8])-mediated host-guest chemistry was used to obtain supramolecular hybrid hydrogels consisting of uniformly distributed, low amounts of graphene with guest-functionalized macromolecules. The obtained GR-hydrogels show superior bioelectrical properties over identical systems produced without CB[8]. Utilizing such supramolecular interactions with biologically-derived macromolecules is a promising approach to stabilize graphene in water and avoid oxidative chemistry.

SB04.08.18
Optimizing Thermal and Mechanical Properties of Poly(Lactic Acid) / Polypropylene / Graphene Nanocomposite Polymer Blends in Fused Deposition Modeling Systems Yu-Chung Lin1, Larry J. Huang2, Richard Li3, Addison Liu4, Nikita Salunke5, Yuval Shmueli1, Miriam Rafailovich1 and Steve Nitodas1; 1Stony Brook University, The State University of New York, United States; 2Wilton High School, United States; 3Conestoga High School, United States; 4Unionville High School, United States; 5Evergreen Valley High School, United States

The Fused deposition modeling (FDM) process is highly non-equilibrated and often has inadequate thermal retention, posing problems which can be addressed via binary blending. This work explores a binary polymer blend of polylactic acid (PLA) and isotactic polypropylene (iPP) with added graphene nanoplatelets (GNPs). Mechanical testing revealed that in comparison to a control sample of pure PLA, the addition of only 1% iPP resulted in a 66% increase in toughness, and a further increase to 2.5% resulted in an increase of only 16%. Further increase above 5% decreased the toughness by 45%. These results correlated with SEM and HD optical microscopy where the filament/filament interfaces were still visible in the pure PLA sample, while they appeared completely fused in the sample with 1% iPP. Water contact angle goniometry showed an increase from 66 degrees on the pure PLA sample to 88 degrees, the value of pure iPP, on the samples containing only 1% iPP. These results indicate that an iPP shell had formed at the filament surface, which is consistent with the segregation of iPP whose surface tension is significantly lower than that of PLA. The glass transition of iPP, also being lower than that of PLA, enables interdiffusion between filaments, leading to complete obliteration of the interface and enhanced mechanical properties. Blends of iPP/PLA containing 5% GNP were also produced and drawn into filaments. While SEM imaging indicated nearly complete alignment of the GNPs along the extrusion direction, partial sequestration of the particles in the iPP shell and internal phase segregated regions were also evident. Infrared imaging (FLIR A300) of samples in contact with a well-defined heat flux indicated an increase of 159% over the pure PLA control sample with the addition of 5% GNP. Addition of 5% GNP, with 2.5% and 5% iPP yielded an increase of 272% and 245% respectively, indicating greater thermal conduction efficiency when graphene platelets are confined in the iPP domains.

SB04.08.19
Thermoresponsive Triblock Copolymers for 3D Printing of Hydrogels Kusuma Betha Cahaya Imani and Jinhwan Yoon; Pusan National University, Korea (the Republic of)

Pluronic is a highly biocompatible and thermoresponsive triblock copolymer consists of hydrophobic poly(propylene oxide) (PPO) as the center block and hydrophilic poly(ethylene oxide) (PEO) as the side blocks. Because of its amphiphilic nature, pluronic possess the ability to form spherical micelles within aqueous solution above its critical micelle temperature (CMT). This phenomenon is driven by the decrease of PPO block’s solubility,
forming a core for the micelles. This reverse thermoresponsive characteristic allows pluronic to have shear thinning property, which can be utilized as an ink for extrusion 3D printing. The quick shear thinning behavior is useful to prevent the ink from flowing upon its deposition on a substrate and retain the desired shape. In this study, we combined pluronic F127 ((PEO)_{99}-(PPO)_{65}-(PEO)_{99}) with methacrylate groups into pluronic F-dimethacrylate (FDMA) as an ink to prepare hydrogels with extrusion-based 3D printing. The methacrylate groups are added to maintain the 3D printed structure after immersion in water by photopolymerization, forming crosslinking that prevent pluronic from dissolving out. In addition, we also manipulated the hydrogels toughness and conductivity by incorporation of ionic bonding and conductive materials. The synthesis of FDMA is simple and it has the prospect for further studies in various fields such as soft robotics and tissue engineering as artificial human organs.

SB04.08.20
Toughening of Polysaccharide Hydrogels for Biomedical Applications Muhammad R. Hossen and Michael Mason; University of Maine, United States

Polysaccharide hydrogels are excellent candidates for biomedical applications such as drug delivery, wound dressing and tissue engineering. For each of these applications, mechanical robustness of the gels, specifically in an aqueous environment, is crucial. Polysaccharide gels are commonly formed by fiber entanglement and hydrogen bonding. Water molecules can disrupt the hydrogen bonding and causes disentanglement of the fibers. Therefore, these gels lose their stiffness and structural integrity in water. Here we describe a new approach for generating wet stable and mechanically stiff semi-interpenetrating (IPN) composite hydrogels through the addition and photo-crosslinking of methacrylate functionalized carboxymethyl cellulose (MetCMC) in the polysaccharide matrices. Physical and mechanical properties such as wet stability, swelling, shrinkage, and stiffness of the gels were studied to test their suitability towards biomedical applications. Data supporting the superior mechanical properties and biocompatibility of the chemically cross-linked wet stable polysaccharide hydrogels will be presented.

SB04.08.21
Poly(ethylene glycol) diacrylate (PEGDA) Degradation Studies for Tissue Engineering Applications Ozlem Yasar and Deldrys Gomez Reynoso; City University of New York, United States

Tissue engineering targets to study the organ regeneration as an alternative approach to the organ transportation. Organ regeneration can only be done successfully, if cells are seeded on the building blocks that are known as scaffolds. Scaffolds help cells to grow in 3-D, as cells migrate within the scaffolds. In this research, Poly(ethylene glycol) diacrylate (PEGDA) was chosen to fabricate the engineered scaffolds. PEGDA is a photo-curable solution and it can be mixed with different chemical solutions to work with the different percentages of PEGDA. In this research, degradation rate of PEGDA was studied. First of all, three sets of cylindrical PEGDA samples with the height of 14 mm and diameter of 14 mm were fabricated by using the 20%, 40%, 60%, 80% and 100% of PEGDA. All of the cylindrical samples were weighted before the degradation tests. Then, first PEGDA sets were immersed into the limonene solution for four hours and they were weighted in every hour. Their dimensions were also measured in every hour. After that, the second set of PEGDA samples were immersed into the water and both weight and dimension measurements were also done in every hour for four hours. At the end, the third PEGDA samples were immersed into the 99% ethyl alcohol and their weight and dimensions were measured in every hour. Our results indicate that, as the PEGDA percentage increases, its degradation rate decreases. Also, PEGDA degrades away the most in the 99% ethyl alcohol more than limonene and water. Our research to study the degradation rate of PEGDA will extend to the use of hot-stir plate to study investigate the temperature affect.

SB04.08.22
Designing of Three-Dimensional Hybrid Scaffolds for Tissue Regeneration Olga Urbanek-Swiderska and Dorota Kolbuk; Institute of Fundamental Technological Research PAS, Poland

Application of electrospun nonwovens is limited due to its two-dimensional (2D) architecture. Hybrid scaffolds consisting of electrospun fibres and other 3D techniques are formed to overcome this problem. Those scaffolds are able to combine advantages of both materials’ forms [1]. Electrospun nanofibers mimic the biopolymer network of native tissue very well and provide significant surface area for attaching bioactive components for local stimulation of cellular activity. On the other hand, hydrogels and its freeze-dried forms provide 3D architecture. An example of 3D tissue are bones cavities, occurring in the result of disease or injuries. For this purpose fibres may be coated with
hydroxyapatite, in order to stimulate osteoblasts proliferation and activity [2]. The aim of this research was to develop 3D hybrid scaffold from the electrospun fibres and hydrogel. Poly(lactic-co-glicolide)(PLGA) fibres were formed via electrospinning technique and subjected to ultrasounds in order to increase the nonwoven dimensions. Additionally, this procedure was used to cover one group of the nonwovens with hydroxyapatite (nHAp). Finally, fibres were immersed in gelatine solution, crosslinked and subjected to both, materials characteristic and \textit{in vitro} biological tests.

The contribution of fibres to hydrogel mass after lyophilisation was 50/50 w/w. SEM imaging confirmed presence and homogeneously distributed PLGA and PLGA-nHAp coated fibres in the pore walls. FTIR, EDS analysis as well as WAXS measurement confirmed presence of nHAp crystal in the scaffolds, its distribution and structure. DSC analysis revealed no significant changes in glass transition temperature nor melting temperature of PLGA. The weight loss of 3D scaffolds was conducted per one month. During the first week of incubation the weight loss was ca. 5%. Moreover, the mechanical tests and \textit{in vitro} tests were conducted. The biological tests confirmed constant proliferation of cells in the analysed time points, as well as proper cell morphology and spreading on the scaffold surface.

Summarizing, presented technique is an effective method of 3D hybrid scaffolds preparation, based on ECM mimicking electrospun fibres.

\textbf{Acknowledgments:} This work was supported by the National Centre of Research and Development within the grant No. 388/L-6/2014.

Ankarao Kalluri1, Bilal Cakir2,2, Prabir Patra3,3, In-Hyun Park2 and Challa V. Kumar1,1; 1University of Connecticut, United States; 2Yale University, United States; 3University of Bridgeport, United States

A new facile synthesis of white light-emitting, multifunctional, water-soluble, metal-free, non-toxic, highly photostable, bio-active Protein Quantum Dot (ProQDot) hydrogels is reported here. These advanced functional nanoparticles consist of cross-linked bovine serum albumin (BSA) and graphene quantum dots (GQDs). The ProQDots contain blue, green and red dye conjugated GQDs, which are intern crosslinked with BSA to form white emitting hydrogels. These are bio-degradable and highly photostable when compared to organic and inorganic dyes. This bio-hydrogels are further characterized by XRD, CD, FT-IR, DLS, Raman, UV-Visible, TEM, SEM, confocal laser microscopy, photoluminescence spectroscopy, and gel electrophoresis techniques. This robust ProQDots with a variety of surface-functionalities with unique optical properties has led to promising applications in bioimaging, cellular biology, and drug delivery studies. Furthermore, as prepared ProQDot hydrogels can be used to study neuronal intracellular processes for in vivo observation of cell trafficking, tumor targeting, bio-sensing, CRISPR-Cas, and immunohistochemistry (IHC) applications.

SB04.08.26
Biorprinting Autologous Dermal Equivalent Organotypics Juyi Li1, Michael Cottone1, Philip Cottone1, Olias Christie1, Vivian Su1, Zahin Huq1, Michael Gozelski1, Sampson Berlinski1, Kimberly Lu1, Adeel Azim1, Christopher Chan2, Teresa Duong1, Saba Gulzar4, Clara Doyung Lee3, Stella Lessler4, Somya Mehta2, Katherine Tian2, Marcia Simon1 and Miriam Rafailovich1; 1Stony Brook University, The State University of New York, United States; 2Hicksville High School, United States; 3St. Anthony’s High School, United States; 4New Hyde Park Memorial High School, United States; 5Daegu International School, Korea (the Republic of); 6Yeshivah of Flatbush Joel Braverman High School, United States; 7Ward Melville High School, United States

Rheinwald and Green were pioneers in the development of cell culture methods later incorporated into the protocol for production of organotypic cultures. The technique, as described by [1], dermal fibroblasts are first spread as sheets encapsulated in a collagen matrix, then keratinocytes, expanded using immortalized 3T3 cells are spread on top at a high density. This technique proved very successful since it used autologous cells to minimize rejection, and the use of 3T3 cells allowed for rapid expansion of epithelial cells. In order to further increase the utility of these dermal equivalents, inclusion of vascularization is desirable. Production of the organotypics via bioprinting would greatly facilitate attainment of this goal, since the flat sheets could be replaced by patterned layers where vascularization could be initiated through insertion of angiogenic hydrogel segments. Here we first report on the production of the autologous organotypic following the protocol of Carlson [1] adapted for printing with a Cell Ink bioprinter. The first layer of fibroblasts embedded in collagen and second layer of keratinocytes were either printed with a 0.2mm nozzle or simply poured to make four different conditions of skin equivalents. The organotypics were evaluated by H&E staining and compared with those produced by the standard sheet deposition method. The results indicated that even though the structures had high integrity and good interlayer adhesion, the keratinocytes layer was significantly thinner in the printed samples. Ancillary experiments to determine the effect of nozzle shear showed no influence on the ability of fibroblasts to contract collagen, but a small yet significant reduction in colony formation by the keratinocytes was observed. Further testing will be performed to determine if this is a consequence of the larger keratinocyte cell printing density or the lower viscosity of printing solution. Overlaying the secondary pattern structures for vascular initiation may induce further shear, and the impact on the skin structures will be presented.

SB04.08.27
In Situ Simultaneous Time Resolved X-Ray Scattering and Thermal Imaging and of Isotactic Polypropylene Homopolymer and Graphene Nanocomposites During Fused Filament Deposition Printing Miriam H. Rafailovich1, Yuval Shmueli1, Yu-Chung Lin1, Sungsk Lee2, Mikhail Zherenkov3, Rina Tannenbaum1, Dilip Gersappe1 and Gad Marom4; 1Stony Brook University, The State University of New York, United States; 2Argonne National Laboratory, United States; 3Brookhaven National Laboratory, United States; 4The Hebrew University of Jerusalem, Israel

Fused filament deposition (FDM) is a common 3D printing technique, in which a thermoplastic polymer is melted and extruded in specific forms according to the user input file. In contrast to bulk fabrication methods, the FDM printing occurs under conditions which are far from equilibrium, and produce rapidly fluctuating thermal and
mechanical gradients, which have temporal as well as spatial variations that can impact crystallization and ultimately filament fusion and sample integrity. In order to image these gradients directly, and understand the structure property relationships during the FDM process, we have designed an apparatus which can be placed directly in an X-ray scattering beamline to simultaneously profile, with micron spatial resolution, temperature, and SAXS, MAXS and WAXS spectra. Here we describe results obtained with isotactic polypropylene (iPP) and iPP/graphene nanocomposite filaments. The homopolymer filaments were amorphous when they emerged from the nozzle, but crystallization, of a shish-kebab structure occurred within 12 seconds initially at the outer edge of the filament (shell) and propagating in time towards the center. When the second filament was printed, the core continued to crystalize, but crystallinity in the shell disappeared, which was attributed to chain relaxation to relieve stress across the interfacial region. Three-point-bending measurements of the flexural modulii showed no significant difference between molded and printed samples, consistent with SEM images which showed complete internal fusion of the filaments. The shish kebab structures were not present when more than 1% GNPs were included. Orientation of the graphene along the flow direction as well as redistribution of the platelets towards the center of the filament was observed, which correlated with large directional enhancement of the thermal and electrical conductivities of the printed samples. The depletion of GNP from the shell region correlated with SEM images of cryo-fractured segments. The enhanced thermal retention in this region enabled chain diffusion across the filament interfaces, consistent with the good mechanical performance of the composites.

**SB04.08.28**

**Enhancing the Flame Retardancy of Biodegradable Poly(vinyl alcohol) Hydrogels with Resorcinol Bis(diphenyl phosphate) Coated Starch**

Yuan Xue1, Jalaj Mehta2, Lauren Stiefel3 and Miriam Rafailovich1; 1Stony Brook University, United States; 2Hauppauge High School, United States; 3Yeshiva University High School for Girls, United States

Flame retardant components are necessities to a firefighter’s protective gear, such that more eco-friendly advancements in this technology have become more pertinent in an effort to better ensure the safety of both firefighters and victims in fire. Conventionally, flame retardants have been created from only slightly biodegradable superabsorbent polymers with extremely high water content. Generally these superabsorbent polymers are derived from acrylic acid and acrylamide and unless these are oligomers it is likely that they are not biodegradable. In lieu of these facts the primary goal of this research was to synthesize a biodegradable hydrogel flame retardant that is as efficient as its less environmentally friendly equivalents.

To create the hydrogel samples we used a cyclic freezing and defrosting procedure consisting of 24 hours in a -20 degree Celsius freezer and then 1 hour of defrosting at room temperature 3 times for each set of samples. We derived from the FTIR results that hydrogen bonds were present in the PVA and RDP-PVA, and learned that the gels were mainly shear-thinning through the rheological studies. Overall samples with PVA as the hydrogel base with RDP-coated starch performed the best in terms of the completeness of the char layer formed. The temperature of the skin sample under the hydrogel were kept being below 65°C during burning test. Additionally the flame retardant hydrogel displayed clear shear-thinning. Thermal protective performance (TPP) tests were performed to evaluate heat transmission through the FR hydrogel when exposed to a continuous heat source, and result compared to the Stoll Curve which represent the heat level for causing second-degree burn. The TPP test result showed that the poly(vinyl alcohol) flame retardant hydrogel provided a prolonged protection time.
Biofabrication is a specific area within the field of tissue engineering which takes advantage of rapid manufacturing (RM) techniques to generate 3D structures which mimic the natural extracellular matrix (ECM). A popular material in this respect is gelatin, as it is a cost-effective collagen derivative, which is the major constituent of the natural ECM. The material is characterized by an upper critical solution temperature making the material soluble at physiological conditions. To tackle this problem, the present work focusses on different gelatin functionalization strategies which enable covalent stabilization of 3D gelatin structures [1, 2].

In a second part, synthetic (multifunctional) acrylate-endcapped, urethane-based precursors will be discussed with exceptional solid state crosslinking behaviour compared to conventional hydrogels [3].

Several polymer processing techniques will be covered including conventional 3D printing using the Bioscaffolder 3.1, two-photon polymerization (see Fig.) and electrospinning starting from crosslinkable hydrogels. A number of biomedical applications will be tackled including adipose tissue engineering [4], vascularization [5], ocular applications [6], etc. The results show that chemistry is a valuable tool to tailor the properties of hydrogels towards processing while preserving the material biocompatibility.

Adaptable Hydrogels as Custom Bioinks Sarah C. Heilshorn; Stanford University, United States

Despite the rise of 3D printing of thermoplastics both in industry and the general public, a key limitation preventing the widespread use of cell-based 3D printing is the lack of suitable bioinks that are cell-compatible and have the required properties for printing. Current commonly used biomaterials have distinct limitations when used as a bioink including difficulty maintaining a homogeneous cell suspension, avoiding cell damage during extrusion, customizing the printed matrix properties to facilitate cell-matrix interactions, and printing within a bath to prevent cell dehydration while preserving high print resolution. We have designed a new family of tunable biomaterials specifically designed for cell-based 3D printing. These hydrogel-based bioinks are produced from blends of engineered recombinant proteins and peptide-modified, naturally occurring biopolymers such as alginate and hyaluronic acid. These materials undergo two-stages of crosslinking: (i) weak, peptide-based, self-assembly to homogeneously encapsulate cells in a shear-thinning hydrogel within the ink cartridge and (ii) stimuli-responsive crosslinking post-printing to rapidly stabilize the construct. Benefits of this two-stage crosslinking strategy include the prevention of cell sedimentation within the ink cartridge, mechanical shielding of the cell membrane from damaging extrusion forces during printing, rapid post-print self-assembly within an aqueous bath that prevents cell dehydration, and fine-tuning of the printed scaffold mechanical properties for optimal cell-matrix interactions.

Laser Direct Writing of Multi-Metal Microstructures in Hydrogel—From Core-Shell Nanoparticle Formation to Spatially-Selective Plasmon Absorption Manan Machida1, Takuro Niidome2, Hiroaki Onoe1, Alexander Heisterkamp1,3,4 and Mitsuhiro Terakawa1; 1Keio University, Japan; 2Kumamoto University, Japan; 3Gottfried Wilhelm Leibniz University Hannover, Germany; 4Laser Zentrum Hannover, Germany

For development of hydrogels to novel biomedical devices such as wearable or implantable devices, it has been desired to provide hydrogels with specific optical, electrical, or mechanical properties. Since metallic micro- and nanostructures exhibit unique properties depending on the size, shape, and material of the structures, further high-functional flexible devices can be realized if the metal structures are able to be fabricated spatial selectively inside a hydrogel. We demonstrated spatially-targeted fabrication of metal microstructures in poly(ethylene glycol) diacrylate (PEGDA) hydrogel by using femtosecond laser, in which multi-photon photoreduction of metal ions occurs in the tightly focused space of the laser pulses. The metal microstructures were fabricated along a predefined trajectory by using computer-aided laser scanning. We fabricated gold, silver, and gold/silver bimetallic structures coexisting in the same hydrogel in a stepwise manner by taking advantage of the hydrogel’s ionic permeability. Red
and yellow colors were observed for the fabricated gold and silver microstructures, respectively, which are attributed to the plasmonic resonances of the respective metal nanoparticles. Moreover, the absorbance peak of the fabricated bimetallic structures shifted from those of the single metal structures. EDX analysis revealed that the fabricated bimetallic structures consist of core-shell nanoparticles. Our technique allows to create arbitrary three-dimensional (3D) dissimilar metal microstructures, which provides the site-selective optical properties within the same supporting hydrogel that can be applied for various applications including optically-driven actuators and sensing applications.

Visualizing Morphogenesis through Instability Formation in 4D Printing Dong Wu, Jiaqi Song and Mutian Hua; University of California, Los Angeles, United States

Heterogeneous growth in a myriad of biological systems can lead to the formation of distinct morphologies during the species’ maturation processes. We demonstrate that the distinct longitudinal buckling observed in pumpkins can be reproduced using 4D printing of stimuli responsive materials, taking advantage of digital light processing (DLP) 3D printing and stimulus-responsive materials. The mechanical mismatch between the different printed regions results in buckling instability on the surface. The initiation and formation of buckles are governed by the ratio of core/shell radius and the difference in swelling ratio and stiffness of the core and shell. For a thin shell, the buckles are more likely to occur, which is corresponding to the phenomenon that buckling initiates at the top few layers. The number of buckling increases from 4 to 44 as the swelling ratio of the shell decreases. Furthermore, the rigid core not only acts as a source of confinement laterally, but it also sets a boundary at its ends, exerting compressive stress and inducing buckling formation along the shell layer. This heterogeneous structure with controllable buckling geometrically and structurally behaves much like the plant’s fruits.

3D Bioprinting Vascularized Hydrogel Constructs for Cancer Models Murat Guvendiren and Chya-Yan Liaw; New Jersey Institute of Technology, United States

3D bioprinting is an emerging manufacturing approach to fabricate (cell-laden) hydrogel constructs with embedded microchannels, which are potentially useful for fundamental studies to understand vascularization and angiogenesis, and for developing organ-on-a-chip devices for disease modeling. In this work, we developed a novel bioprinting approach to print a sacrificial ink within photocurable matrix hydrogels. Micro-channels are formed when sacrificial hydrogel is dissolved post-printing. Our approach differs from commonly utilized extrusion-based free-from printing approaches, as it doesn't require a support bath or a shear thinning behavior for the matrix hydrogel to enable needle motion. To achieve this, a photocurable hydrogel is printed layer-by-layer as usual, but each layer is exposed to light briefly (seconds) to create partially crosslinked, self-supporting layer. At a desired thickness, immediately after the layer is printed, prior to partial crosslinking step, sacrificial hydrogel is directly printed within this viscous uncrosslinked layer. The layer is then exposed to light to confine and support the sacrificial hydrogel. After fully crosslinking the system, sacrificial hydrogel is washed away, forming a channel. This approach allows bioprinting of cells with the matrix material and seeding of cells into channels after the sacrificial ink is removed. To further utilize our approach, we developed a photocurable bioink formulation enabling cell-mediated degradation, allowing cells to remodel their surrounding microenvironment. We fabricated a perfusable hydrogel device using these bioinks to investigate the behavior of cancer cells within vascularized 3D hydrogel microenvironment.

3D Printed Hydrogel-Based Electrical Impedance Tomography Sensor for In Situ Monitoring of Deformation Zhijie Zhu, Hyun Soo Park and Michael C. McAlpine; University of Minnesota Twin Cities, United States

The ability to directly print soft, compliant biomedical devices and sensors on the skin and inside the body could enable revolutionary advances in portable healing, wound monitoring, and traumatic shock reduction. Previously, we have shown the ability to directly 3D print functional materials on moving freeform surfaces, in which the rigid-body motion of the target surface can be tracked via a closed-loop feedback control system. Specifically, we were able to directly 3D print a functional electronic circuit directly on a moving hand, using the printer nozzle to “tattoo” electronics. Here, the capability of this adaptive 3D printing system is expanded for the first time to track the deformation of target surfaces, such as expansion and contraction of soft tissues. We demonstrate that the motions and time-variant geometries of the target surface can be estimated on-the-fly and in a closed loop fashion via
machine learning from a data set of 3D scans and a real-time visual tracking system. Using this approach, a unique and conformal ionic hydrogel sensor was directly printed on a ‘breathing’ swine lung in vitro under respiration-induced deformation. The ionic hydrogel sensor is compliant to the soft tissue surface and can monitor the tissue deformation utilizing electrical impedance tomography, which provides a spatial mapping of the deformation. This adaptive 3D printing method for the direct fabrication of soft, stretchable sensors on deforming surfaces may enhance robot-assisted medical treatments and minimally-invasive procedures with additive manufacturing capabilities, enabling autonomous, direct printing of wearable electronics and biological materials on and inside the human body.

Ultrashort Self-Assembling Peptides for Robotic 3D Cell Bioprinting under Physiological Conditions
Hepi Hari Susapto, Kowther Kahin, Zainab Khan, Salwa Alshehri, Sherin Abdelrahman, Jordy Homing Lam, Xin Gao and Charlotte Hauser; King Abdullah University of Science and Technology, Saudi Arabia

3D bioprinters have received considerable attention in latest studies, primarily owing to their customization and flexibility that provide an advantage over traditional lab-grown organ development. By printing with a bioink, productivity and efficacy are enhanced while accelerating medical procedures like organ transplantation. Many different natural bioinks have also been studied for their potential application in 3D bioprinting, such as matrigel, collagen, and alginate, all of which are obtained from non-human sources. Because of their complex and variable composition, these natural bioinks are not suitable for controlled modifications. Complications in controlling these materials’ physiological variables (e.g. pH and salt concentration) also pose challenges in mimicking the extracellular matrix (ECM). Their batch-to-batch fluctuations can also have a significant impact on the sustainability and immunogenicity of the bioprinted 3D structures, which are among the drawbacks of using these bioinks for tissue/organ growth or downstream clinical applications. In addition, 3D molds based on polymers are a prerequisite for the manufacturing of 3D structures using natural bioinks. This introduces more difficulties for complex molds as they are not easily constructed. The issues associated with natural bioinks can be solved by harnessing a synthetic peptide material that can self-assemble to form 3D nanofibrous scaffolds, in addition to other benefits, such as control over composition and ease of chemical modifications. In this study, we have developed an in situ bioprinting technique that enables the printing of cells under true physiological conditions using ultrashort self-assembling peptides as bioinks. Previously, we designed a set of ultrashort peptide bioinks that demonstrated adequate mechanical strength, rigidity, and shape fidelity on glass substrates. To understand more about the self-assembly process of these peptides, the morphology, secondary structure and viscoelastic property of self-assembled peptide nanostructures were further characterized, in addition to molecular dynamics simulations of these peptides in water to study fiber formation at the atomic scale. The 3D structure of these assembled peptides were then determined using NMR spectroscopy to support the simulation result. An extruder was engineered to be compatible with the peptide-based hydrogel and installed for improved printing by a 3D bioprinting robotic arm. We believe that as we print under truly physiological conditions, our unique in situ 3D bioprinting technique offers benefits over current bioprinting methods. The bioprinting methods that makes use of UV-treatment, chemical crosslinking, and viscous bioinks that result in stress to the cells can also be avoided with our method. Furthermore, the self-assembled peptide bioinks prove to be durable, readily printable, and offer great biocompatibility with tested cell lines including human dermal fibroblast cells and human mesenchymal stem cells. From the results, the cell proliferation in printed peptide hydrogels after 14 days and 21 days of culture was higher than that of alginate gelatin. RNA sequencing was also conducted to compare the difference in gene expression patterns in HDFn cells cultured in 2D, 3D bioprinted in IVZK and alginate-gelatin (AG) bioinks. We further demonstrate that various nanomaterials can easily be synthesized or incorporated into the 3D bioprinted peptide scaffolds that create a new opportunity for functionalized 3D scaffolds for a wide range of applications, including tissue engineering and regenerative medicine.

Biodegradable Thermoplastic Elastomers as 3D-Printed Nerve Guidance Channels for Peripheral Nerve Repair
Yang Hu1, Robert Newman1 and Adam K. Ekenseair1,2,3; 1Northeastern University, United States; 2The University of Texas at Austin, United States; 3University of Arkansas–Fayetteville, United States

The peripheral nervous system (PNS) is a complicated and extensive network of nerves that are the means by which
the brain and spinal cord control the rest of the body. The PNS is fragile and can be easily damaged by injuries or trauma. Surgical treatment is the only remedy currently available, with the gold standard for defects greater than 8 mm being autologous nerve grafts; however, only around 40% of the 1.8 million US PNS patients each year regain normal function. In addition, nerve grafts have been particularly ineffective at repairing critical-size nerve defects (>3 cm). Scaffold-based strategies where a tubular nerve guidance channel (NGC) is used to bridge the nerve defect have been promoted as a potential alternative that could avoid the additional surgeries and associated donor site morbidity involved in the harvest of nerve grafts. Clinicians have thus increased the use of NGCs combined with current surgical therapeutics. However, current NGCs lack patient-specific tunability and are only approved for small-gap (<3 cm) injuries by the U.S. Food and Drug Administration (FDA). Current research efforts are focused on creating more complex NGCs that can support the regeneration of critical-size defects.

In this context, our research seeks to use additive manufacturing technologies to create bioactive and cellular NGCs on demand for the repair of critical-size nerve defects. Recently, 3D printing has been increasingly used in research and medical therapeutics for rational, computer-aided design of biomaterial-based scaffolds with complex architecture. Furthermore, printing with co-axial extruders can enable the direct printing of layered tubular structures for use as NGCs. The NGCs should contain an outer flexible shell that seeks to mimic the mechanical properties of the surrounding biological tissue and enable diffusion of nutrients to support encapsulated cells. The use of biodegradable block copolymers with both hydrophilic and relative hydrophobic functions can provide a flexible, partially-hydrated, biocompatible and bioresorbable NGC shell.

In this study, A-B-A type triblock copolymers of PLLA-PEG-PLLA were synthesized using varied ratios of PEG and PLLA. The resulting block copolymers were characterized with gel permeation chromatography (GPC), differential scanning calorimetry (DSC), and nuclear magnetic resonance (NMR) to determine molecular weight, polymer structure, and thermal behavior. In addition, equilibrium water content, degradation rates, mechanical properties, and cell response were all evaluated and correlated to the polymer structure.

11:00 AM SB04.09.09
3D-Bioprinting of Spatially Organized Bacterial Microcosmoi Using Chaotic Flows Carlos F. Ceballos-González1, Edna J. Bolivar-Monsalve1, Carolina Chávez-Madero1,2, Everardo González-González1, Juan Yee-de León3, Christian C. Mendoza-Buenrostro1, Yu S. Zhang1,2, Mario M. Alvarez1,1 and Grissel Trujillo-deSantiago1,1; 1Tecnológico de Monterrey, Mexico; 2Harvard Medical School, United States; 3Delee Corp., United States

Cells do not work alone but as collaborative micro-societies. Cells in human tissues are spatially organized, and these deposition patterns may have significant effects on their functionality. In the case of bacteria, spatial distribution (micro-biogeography) has also been suggested as a determinant of their behavior. Unfortunately, current microbiological techniques, which are more focused on the culture of single bacterial strains or well-mixed bacterial communities, fail to reproduce the micro-geography of polybacterial societies. Moreover, printing spatially-controlled scaffolds at high resolution is currently challenging.

We developed a simple 3D-printing technique (chaotic bioprinting) that produces alginate-based and agar-based fibers at rates of ~1.0 m min⁻¹ and exhibiting finely-ordered internal lamellar microstructures with resolutions of ~4 μm. This straightforward approach allows us to place various bacterial strains in these constructs to analyze how their spatial distribution may affect their social behavior and/or survival abilities. We illustrate the use of chaotic bioprinting protocols to create fine-scale bacterial microcosmoi. For instance, we fabricated lamellar arrays of two different bacterial types (i.e., two *Escherichia coli* strains, each one producing a different fluorescent protein or containing different antibiotic resistance plasmids). We demonstrate that these biological microsystems can exhibit a competitive dominance or cooperation as a function of culture time, the development of hypoxic regions, and the degree of interface shared between the microcolonies.

Chaotic bioprinting enables the printing of cell-laden constructs with fine-scale deposition patterns. We envision that this technique will contribute to the development of more complex poly-bacterial microcosmoi, such as gut-microbiota models.

A 3D Bioprinted Brain-Like Co-Culture Network towards Modeling Neural Cell Interactions Yasamin
Reproducing the remarkable features of the multi-cellular three-dimensional (3D) environment of the brain in vitro, such as 3D cell-cell interactions, is considered a crucial step in creating reliable drug testing platforms for a variety of brain diseases. More specifically, the intercellular interactions between neural cells is a key factor to regulate brain functions and ensure health homeostasis. Recent advances in microfabrication and biomanufacturing techniques such as 3D bioprinting has opened new doors to create microscale 3D platforms to study 3D cell-cell interactions and mimic the structural and functional behavior of tissues in vitro. Here, a 3D brain-like co-culture construct is developed using multi-material embedded 3D bioprinting technology to study the neuron-glial interactions. Specifically, free-standing neuron-laden 3D structures are fabricated in a self-healing glia-laden support bath, resembling a brain-like tissue with neural fibers and glia-neuron interactions. The biomaterials were engineered to provide tunable soft tissue stiffness while allowing the creation of 3D geometries and complex networks. Moreover, the biomaterials showed excellent support for neural stem cell differentiation and glial cell spreading. Additionally, the differentiated neurons in the printed fibers exhibited glutamate synthesis capabilities, proving that the engineered brain-like tissue constructs can recapitulate neurotransmitter interactions, namely the glutamate-glutamine cycle. Eventually, the engineered brain-like co-culture constructs can prove useful for studying the levels of glutamate in the diseased brain and provide a reliable and highly reproducible in vitro platform for neurological drug screening and brain disease modeling.
employed the unusual multi-stimuli responsiveness of RMPs to create patterned surfaces,\textsuperscript{9} responsive interfaces\textsuperscript{10} and tunable co-assembled hydrogels.\textsuperscript{11} We have developed a directed self-assembly approach for colloidal synthesis of RMP-mediated size-controlled metallic nano-particles, nano-clusters\textsuperscript{12,13} and colloidal catalyst ink based electrocatalyst layer\textsuperscript{14} in aqueous medium under mild condition. Overall, the research has revealed the potential of the IDPs to pave the way for the design of novel biomaterials and nano-bio conjugates.

Architectured Conductive Hydrogel Sensors with High Sensitivity Jun Fu; Chinese Academy of Sciences, China

Ultrastretchable conductive materials are promising for electronic skin, human-machine interfaces, human activity monitors, and wearable devices. Currently, most strain sensors are comprised of elastomer matrix with metal particles/liquid, carbon materials, or conductive polymers. Conductive polymer hydrogels have recently been recognized promising for applications in pressure and strain sensors. The high stretchability and toughness are advantageous over those based on elastomers. Either electro-conductivity or ion conductivity could be achieved by appropriate design and synthesis of the network structures. So far, most conductive hydrogels are based on composites with a large amount of conductors, which is unfavorable for the linearity. Moreover, besides the high conductivity of the hydrogels, the sensitivity and performance of hydrogel sensors rely on the structural design of the sensors.

This talk introduces, ultrastretchable and tough hydrogels with electronic or ionic conductivities. Ionically conductive hydrogels comprised of zwitterionic chains interpenetrating freeze-thawed PVA network show adhesiveness to many substrates including glass, steel, polymer, and skin. The zwitterionic moieties in the network not only provide ion conductivity, but also serve as electrostatic crosslinks to toughen the hydrogels. Moreover, the strong electrostatic dipoles in the zwitterionic units enables robust adhesion to a variety of substrates from skin to polymer, glass and metals, which is beneficial for wearable devices. The hydrogels show outstanding strain and pressure sensing performance.

Electronic conductive hydrogels comprised of interpenetrating network of polyaniline (PANi) and poly(acrylamide-co-2-hydroxyethylene methacrylate) hydrogel show very high stretchability and toughness. The hydrogels show a very low threshold PANi content (0.5wt/vol%) to reach a plateau conductivity. A conductive network percolation is assumed in the hydrogel. At the percolation point, the hydrogels show a linear dependence on and high sensitivity to subtle tensile strains. The ultrastretchable and conductive hydrogels have been used to monitor subtle movements of joints and wrist pulse, which suggest important applications in implantable and wearable devices.

To prepare hydrogel sensors with very high sensitivity, conductive hydrogel arrays with well designed architectures have been fabricated by using 3D printing of hydrogel precursors followed by polymerization. The shape of each hydrogel unit can be well defined. Theoretical calculations and experimental results show that the sensitivity is highly related to the geometry of the hydrogels. Array sensors have been fabricated to detect pressures and pulse of 10 Pa and below.

Such hydrogel sensors and arrays are promising for wearable devices and implantable sensors.

Programmed Deformations of Composite Hydrogels into Multi-Stable Configurations Chen Yu Li, Zhi Jian Wang and Ziliang Wu; Zhejiang University, China

It is well-known that nature utilizes controlled deformation strategies to produce complex three-dimensional (3D) shapes of plant organs. Inspired by the natural activated systems, the realization of 3D shapes of artificial materials by programmed deformations has recently attracted great interest as a delightful concept and a practical technology with promising applications in biomedical devices, soft robotics, and flexible electronics. One fundamental task is to exploit new deformation modes and reveal the deformation mechanism. Shape transformations of intelligent materials are realized by switching the environmental conditions. However, it's challenging to form multi-stable morphing structures under the same condition. We present here a photolithographic method to pattern one responsive polymer in a non-responsive hydrogel sheet with well-designed gradient structures. Under external stimuli, the swelling mismatch results in the built-up of internal stress and thus programmed deformations of the composite hydrogel. Owing to the bi-stable nature of buckling deformation, i.e. the hydrogel sheet with in-plane gradient buckles upward or downward with almost equal possibility, the integrated composite hydrogel with multiple units of in-plane gradient structure has multiple distinct configurations. We will report both experimental and simulation results to demonstrate that various stable configurations can be obtained in one composite hydrogel under the same condition by controlling the buckling direction of each unit by a selective pre-swelling step. This concept and strategy should be applicable for other intelligent materials and merit their applications in diverse areas.

3:30 PM SB04.10.04
Expanding Gelation Conditions in Metal-Coordinated Hydrogels Seth A. Cazzell and Niels Holten-Andersen; Massachusetts Institute of Technology, United States

Polymer networks with dynamic physical crosslinks have generate widespread interest as tunable and responsive viscoelastic materials. A subclass of these materials containing multi-component, or complimentary, crosslinks, such as host-guest interactions and metal-coordination, are limited by their ability to percolate under stoichiometric imbalances of their crosslink components. Here we present a method to relax this stoichiometric requirement through the use of a third component, a dynamic, free competitor. This approach to expand the conditions that result in gelation is demonstrated experimentally with metal-coordinated hydrogels, and simulations are used to show the thermodynamic criteria that are necessary to expand the previously understood tight stoichiometric tolerance for gelation. This work can then be generally applied to advance engineering of the broadening class of polymer materials with dynamic crosslinks.

3:45 PM SB04.10.05
Molecular Understanding of Bond Dissociation Kinetics in Metal-Coordination Transient Hydrogels Using Simulation and Experiment Eesha Khare, Markus J. Buehler and Niels Holten-Andersen; Massachusetts Institute of Technology, United States

Metal-coordination hydrogels represent a new class of advanced materials for biomedical, composites, and structural applications. The dynamic properties enabled by this bonding are useful for the development of hydrogels in drug delivery, tissue scaffolds, and wound-healing, where tunable viscoelastic properties are critical in determining biological response. Metal-coordination bonds are reversible and tunable, unlike more static ionic or covalent chemical crosslinks commonly employed in hydrogels that permanently break upon fracture. As they have the capacity to break and reform after rupture, metal-coordination bonds can act as sacrificial bonds that help increase the fracture toughness of a material. Such sacrificial bonds are also important molecular motifs in biological systems where metal-mediated bonds play significant roles in protein folding and unfolding, rupture, and shock absorbance in many biological tissues such as mussel threads and other marine organisms. In fact, incorporating sacrificial metal bonding in hydrogels enables us to achieve transient mechanical properties which can be dynamically tuned over several time scales. Despite the emergence of new, dynamic properties enabled by metal-coordination chemistry, a fundamental understanding of the relationship between the chemistry, effective bond properties, and overarching macroscale mechanical properties of such systems is yet to be developed.

The development of histidine-divalent metal-coordination hydrogels presents a good model system with which to
study the role of metal coordination in the mechanics of hydrogels (Grindy et al., 2015). In this system, 4-arm polyethylene glycol (PEG) is end-functionalized with histidine derivatives that can coordinate with divalent metal cations (Zn²⁺, Ni²⁺, Cu²⁺) to form transient crosslinked gels. The kinetics of metal-coordination bonding to produce dynamic viscoelastic properties can be tuned through simple levers such as pH, temperature, and chemistry. This study couples multiscale computational modeling with experiment to characterize the molecular bonding landscape and kinetics of histidine functionalized PEG hydrogels. Density functional theory (DFT) and molecular dynamics (MD) are used to characterize the equilibrium bonding configuration and optical properties of the metal cations with the histidine ligand. The energy landscape of this bond is probed through metadynamics calculations and MD. Simulation results are compared with rheological and spectroscopic experimental characterizations of the hydrogels. Based on insights gained into the role of ligand-metal binding, coordination of surrounding ligands, and polymer physics from these calculations and experiments, this work proposes key design criteria for how this new class of metal-coordination chemistry hydrogels can be advanced for biological and environmental applications with dynamic, self-healing properties.

Bottom-Up Assembled Hierarchical Bacterial Network of Chronical Stability Pu Deng, Andrew Y. Xu and Xiaocheng Jiang; Tufts University, United States

Bioprinting is a method to create ex-vivo replicates of biosystems through precise three-dimensional (3-D) assembly of basic biocomponents into hierarchical structures with rationally designed functionalities. In the context of energy and environmental science, bacteria are widely exploited as self-sustainable biocatalysts to build systems that are capable of processing complex biochemical reactions and bioenergy transduction with superb efficiency and specificity at low-cost, mild reaction conditions. Ion crosslinked alginate is a popular supporting material for bacteria printing due to its fast and reliable gelation, structural similarities to the polysaccharide in native biofilms, and sufficient porosity for effective nutrients/metabolites transport. The lifetime of alginate supported bioprints, however, is quite limited, as a result from weak and reversible ion-alginate bonds, which initiate the leakage of encapsulated bacteria and eventually leads to the complete failure of the printed structures. To ultimately overcome this challenge, in this work, we modulated the alginate structure to strengthen the intermolecular interactions and improve the structural integrities of the bio-printed bacteria networks. Additionally, reduced graphene oxide (rGO) was introduced into this bacteria-alginate matrix, which further enhances the long-term stabilities through strong rGO-alginate interactions. These approaches result in the significant increase in the lifetime of bio-printed bacteria networks as the concentrations of the escaped/floating bacteria were reduced by 400% after 24 hours of culture. Based on this platform, we designed and constructed a 3-D living filter for toxic ions remediation using *S. loihica* encapsulated alginate microfibers as one-dimensional building blocks. Additionally, by tuning the composition and microstructure from bottom up, the degradability, bacteria loading density, and mass transport efficiency can be customized to meet the requirements of various wastewater conditions. The current work provides important insight about the fundamentals of bio-printing design and process and could open up new opportunities toward the creation of chronically stable biosystems with predictable and versatile functions encoded.

Anisotropic Hydrogels by Magnetically-Oriented Nanoclay Suspensions SungHo Yook and Mukerrem Cakmak; Purdue University, United States

With the presence of nanoparticles in a 3D hydrogel network, nanocomposite polymer hydrogels can exhibit additional functional properties in mechanical strength, swelling kinetics, and transparency. The nanostructure of nanocomposite hydrogels is generally isotropic because the nanoparticles entrapped within the 3D hydrogel network are randomly dispersed. However, the anisotropic features in hydrogels are often necessary to mimic anisotropic hierarchical structures in nature organism or to develop soft materials with directional mechanical/optical/thermal properties. In this study, anisotropic nanocomposite hydrogels were achieved by orienting nanoclay in a hydrogel network. The aqueous suspension of nontronite nanoclays, which are sensitive to magnetic fields due to high contents of ferric ions (Fe³⁺), were oriented in various strength of the magnetic field and then the final morphology was fixed by the synthesis of the hydrogel. The nanostructure of the anisotropic hydrogels was characterized by measuring birefringence, 2D Small Angle X-ray Scattering (SAXS), and transmission. The magnetic field-induced birefringence of anisotropic hydrogels increased with the applied magnetic field strength in a range between 0 to 9 Telsa in all different concentrations (0.05 wt%, 0.1 wt%, 0.2 wt%, and 0.4 wt%) as the orientation degree of nanoclay particles increased. The birefringence was also proportionally increased with nanoclay concentrations from
0.05 wt% to 0.2 wt%, but it significantly decreased at 0.4 wt% concentration. Furthermore, 2D SAXS revealed that the long axis of nontronite platelets was oriented parallel to the applied magnetic field direction. With 2D SAXS patterns, the orientation order parameter was calculated at different magnetic field strength and concentrations. At 0.1 wt% nanoclay concentration, the orientation order parameter increased up to 0.67 as applied magnetic field strength increased. The samples prepared in 9 Tesla showed high orientation order parameter in all different concentrations. The field-induced birefringence and orientation order parameter showed a linear correlation over the magnetic field strength range from 0 Tesla to 9 Tesla. The anisotropic hydrogels also showed the 7% and 8% increase in optical transmission to applied magnetic field direction at 0.1 wt% and 0.2 wt% concentrations.

**Printable Ag-Based Conductive Composites** Yunsik Ohm, Chengfeng Pan, Michael Ford, Xiaonan Huang and Carmel Majidi; Carnegie Mellon University, United States

Conductive and stretchable materials are important components in soft electronics and sensors that are used for emerging applications in soft robotics and wearable physiological monitoring. Compared with other stretchable conductors composed of different types of polymers, conductive hydrogels are promising candidates for soft electrode materials due to their mechanical compliance, which is similar to biological tissues (0.5-500 kPa) such as human skin; compatibility with aqueous environment due to high water content; and inherent ability to adhere to other materials. However, most conducting polymer-based hydrogels are ionic conductors, so they are not able to deliver direct current (DC) but instead support alternating current (AC). Here, we introduce a novel and facile method for making a soft (<1 MPa), highly stretchable (>200% strain), and electrically conductive (>10$^3$ S/cm) hydrogel composite that can be functional in water and conductive enough to transmit digital signals. The composite is composed of micron-sized silver (Ag) flakes (2-5 micrometers) distributed over an alginate-acrylamide based hydrogel matrix. The mixture of silver flakes and alginate-acrylamide hydrogel is not electrically conductive immediately after curing; however, it can achieve electrical conductance while maintaining its soft and deformable nature by controlling the amount of water inside the composite through drying. During the drying process, evaporating water enables the formation of a percolating network of silver flakes within the hydrogel matrix, which makes the conductive gel electrically conductive (maximum initial conductivity ~90000 S/cm). Moreover, the inherent mechanical properties of the hydrogel are preserved (e.g. maximum strain limit ~250% while maintaining electrical conductivity). We demonstrate the utility of the conductive hydrogel ink by powering a soft swimming eel that can swim with the help of bi-stable SMA actuators. We will also present a stencil-printed stretchable circuit in which several surface mounted LEDs are continuously powered through use of the conductive hydrogel ink. The stretchable and conductive hydrogel ink that we present here represents a new route to controlling conductivity in conductive hydrogel.

**4:45 PM SB04.10.09**

**Mussel Inspired Tough Double Network Hydrogel as Shapeable Adhesive** Xiaohan Wang, Yisheng Xu and Xuhong Guo; East China University of Science and Technology, China

Hydrogels with excellent adhesive and mechanical properties have attracted extensive attractions due to its application prospects in various fields such as wound dressing, electronic skin and wearable devices. However, few has successfully prepared “tough and sticky” hydrogel with desirable and tunable performance. In this work, dopa modified hyaluronic acid (HA-dopa) was firstly introduced to the double network (DN) system, which greatly improved the mechanical and adhesive performance of the original HA-Acrylamide (AAm) DN hydrogel. By modulating external parameters such as pH and Fe$^{3+}$ concentration of the precursor solution, the overall property of the hydrogel could be well-tuned. Moreover, a non-monotonic dependence of the HA-dopa content on mechanical and adhesive enhancement could be clearly observed. Based on this phenomenon, we proposed a new mechanism that the catechol moiety within HA-dopa played a different role and served as chemical crosslinker to reinforce the hydrogel, leading to a more compact network and improved overall performance. Therefore, as an effective approach to enhance the adhesive and mechanical property of hydrogel, this mussel-inspired practice would provide valuable insight into designing functional hydrogel and elastomer for various applications.
Biomimetic Cartilage Model Exhibiting Matrix “Prestress”

Peter Basser; National Institutes of Health, United States

A critical feature of extracellular matrix (ECM), in general, and cartilage tissue, in particular, is the prestress that develops within the tissue matrix. Cartilage is a composite medium whose proteoglycan (PG) components imbibe water, while its confining collagen matrix resists PG swelling. This balance of forces results in a significant matrix prestress—on the order of four atmospheres—under no external load. Our group recently developed a composite polymeric medium consisting of poly-acrylic acid (PAA) microgel assemblies (mimicking the PG phase) dispersed within a PVA gel network (mimicking the collagen matrix). This hydrogel composite exhibits remarkable load bearing ability, and key quantitative and qualitative material behaviors observed in human cartilage specimen. The osmotic modulus of this aggregate gel system provides an eloquent measure of its load bearing ability.

Transport into Stiff Gel-Like Deformable Articular Cartilage for Drug Delivery

Alan Grodzinsky; Massachusetts Institute of Technology, United States

Traumatic joint injury in individuals at any age can initiate cartilage and subchondral bone degeneration in the presence of elevated levels of inflammatory cytokines, leading to post-traumatic osteoarthritis (PTOA). There are currently no disease modifying drugs for osteoarthritis or PTOA, and a major challenge is the ability to achieve sustained levels of potential therapeutics inside a target tissue such as cartilage, with no side effects, after intra-articular delivery. We use in vitro organ culture models to study the beneficial effects of combination therapeutics (e.g., glucocorticoids, growth factors) to inhibit matrix degradation and cell apoptosis in cartilage. These experiments are performed with isolated cartilage explants, intact osteochondral plugs or osteochondral plugs in the presence of synovium explants (the latter known to release inflammatory proteins). To simulate a traumatic joint injury, the cartilage is also subjected to an initial acute impact compressive load. Parallel in vitro and animal studies are aimed at approaches to targeted tissue drug delivery. In particular, charge based intra-cartilage delivery of glucocorticoids and/or growth factors has been enabled using cationic nanoparticles including Avidin and supercharged green fluorescent proteins. In studies of cartilage degradation and repair, it is important to assess the mechanical function of newly synthesized tissue and constituent matrix molecules at the molecular scale. We have therefore developed and used an AFM-based wide-bandwidth rheology system to measure the dynamic nanomechanical behavior of normal and degraded cartilage as well as end-grafted aggrecan brush layers over the frequency ranges relevant to impact injuries. The effects of mechanical loading on cartilage degradation and repair is also under study, as it is very important to clinical rehabilitation.

Direct Visualization of Functional Crosslinkers in Swollen PNiPAm Based Microgels

Apostolos Karanastasis¹, Gopal Kenath¹, Yongdeng Zhang², Mark D. Lessard², Joerg Bewersdorf² and Chaitanya Ullal¹; ¹Rensselaer Polytechnic Institute, United States; ²Yale, United States

The spatial distribution of cross-links in bulk gels and colloidal gel particles impacts their mechanical and transport properties. Here we report on the spatial distribution of dye tagged crosslinkers of colloidal PNIPAM microgels revealed by super-resolution microscopy at the level of individual particles as well as at the ensemble level. Using a W-4PiMSMN microscope we demonstrate the presence of higher crosslink nanodomains within the already dense cores of the microgels. Additionally, we show that the average probability density profile, extracted from super resolution, can be used to extract quantitative relative reaction rate constants. We prove this by coupling the localization probability density profile with the temporal volumetric evolution of the particles to accurately predict the consumption of the dye tagged species with time. These predicted consumption curves are fit to accepted kinetic models for precipitation polymerization of microgels to extract relative rate constants for the functional cross-linker to n-isopropylacrylamide and N,N’-methylene-bis-acrylamide.

Tailoring hydrogels and their properties for customized applications is a highly interesting task in tissue engineering to develop biomimetic materials for biomedical applications. Thereby, crosslinking processes are commonly used since the degree of crosslinking precisely determines the material properties. Among the diverse techniques of crosslinking, high-energy electron treatment is a highly advantageous method, which allows reagent-free tuning of structural and mechanical features of hydrogels while chemical structure and cytocompatibility are excellently maintained.[1]

Within this contribution, we will introduce electron beam treatment and we will show the high potential to tailor precisely biological hydrogel properties. In particular, we will show how electron beam treatment effectively tunes network structure and viscoelastic properties of biological hydrogels such as collagen. In addition, we will demonstrate their excellently maintained chemical structure and cytocompatibility. With this, our research describes a promising reagent-free method to tailor precisely hydrogel properties for prospective biomedical applications.

10:30 AM *SB04.11.05
Electrical “Suturing” of Polyelectrolyte Hydrogels to Reseal Cut or Damaged Tissues Srinivasa Raghavan; University of Maryland, United States

This talk will present studies from our lab on the electrically induced adhesion of hydrogels and beads made from polyelectrolytes. When a rectangular strip of a cationic gel (connected to an anode) is contacted for just a few seconds with a strip of anionic gel (connected to a cathode) under a voltage of ~ 10 V, the two gel strips form a strong adhesive bond. When the polarity of the electrodes is reversed, the phenomenon is reversed, i.e., the gels can be easily detached.

While the above phenomenon of ‘electro-adhesion’ has been reported before for hydrogels, we show that it is much more general and widespread. Specifically, we can substitute either of the above gels with a spherical bead made using charged biopolymers such as chitosan or alginate. The same electro-adhesion works to join beads to gels, or two beads to each other. In turn, electro-adhesion can be applied for the pick-up and drop-off of soft cargo, and for the sorting of beads. Most interestingly, the same phenomenon also works with certain animal tissues. That is, many tissues are anionic, and we show that cationic gels can be electro-adhered to them. We thereby demonstrate that cuts or tears in tissues can be electro-sealed using beads or gel strips. As an extreme case, two severed pieces of a tube can be stuck back together using a gel strip that spans both cut segments; this is thereby an example of a needleless suture using only hydrogels and an electric field.

11:00 AM *SB04.11.06
Gelation Control in Polysaccharides Juan D. Londono¹, Kyle Kim², Natnael Behabtu² and Laura Clinger¹; ¹DuPont, United States; ²DuPont Biomaterials, United States

Polysaccharides are derived from renewable resources, supporting trends to reduce the consumption of plastics made from petrochemicals. Polysaccharides consist of sugar units linked by glycosidic bonds. Seemingly small variations in the glycosidic bond often result in dramatic changes in properties [e.g. hydrophobic cellulose β-(1→4) vs hydrophilic starch α-(1→4)]. There is, in addition, the possibility of mixed linkages and complex architectures, from linear to highly branched. Finally, polysaccharides may be derivatized, with the potential of changing properties entirely. Polysaccharides therefore provide a wide platform from which polymers with diverse properties can be obtained. Due to their versatility, these polymers are ubiquitous in nature and industry. Industrial polysaccharides are widely used as viscosity modifiers, food texturants and in oil recovery applications. The major source of industrial polysaccharides is the natural world. For example, carrageenans are a family of sulphated polysaccharides that are widely used as gelling agents and stabilizers in dairy, beverages, confectionery and meat applications. Carrageenans show a thermo-reversible disorder-to-order transition that is key for its gelling
and stabilization. Although carrageenans have a long history of use, it remains unclear which physical states different carrageenans have and which intrinsic and extrinsic factors influence their physical state. Polysaccharide viscosity depends on a structural hierarchy spanning a multitude of length scales, and a suite of analytical techniques are needed to understand the secondary, tertiary and quaternary structure of these materials. Characterization of this hierarchy from x-ray scattering, rheology, microscopy and size-exclusion chromatography are presented for carrageenan. Furthermore, polysaccharides harvested from the natural world entail issues of variability, heterogeneity, purity, and reliability. There is therefore the need for structural control at the molecular, nano and mesoscales, to improve industrial use of these polymers.

Another polysaccharide, α-(1→3)-D-Glucan (glucan), is mainly found in the cell wall of micro-organisms. A linear form of glucan can be obtained from fungi and yeasts while some bacteria produce branched glucan chains in human saliva where a connection to dental caries has been suggested. Several patents [1] and recent literature [2] have shown that the glucan polymer can be synthesized enzymatically with good yield. There are strong parallels between the glucan colloidal material as obtained from enzymatic polymerization and the hierarchical structures found in other conventional materials like fumed silica and carbon black. Indeed, both glucan and carrageenan hold promise for viscosity modification applications such as 3D printing with the added benefit that natural polysaccharides are both renewable and biodegradable. In addition, glucan is consistent in purity and quality since it is enzymatically derived.

11:30 AM SB04.11.07
A Simple Way to Synthesize a Protective ‘Skin’ around a Hydrogel Sai Nikhil Subraveti and Srinivasa Raghavan; University of Maryland, College Park, United States

In nature, various structures such as fruits and vegetables have a water-rich core that is covered by a hydrophobic layer, i.e., the skin. The skin creates a barrier for chemicals from the external environment to enter the core; at the same time, the skin also ensures that the water in the core is preserved and not lost by evaporation. Currently, for many applications involving hydrogels, especially in areas such as soft-robotics or bio-electronic interfaces, it would be advantageous if a hydrogel could be encased in a skin-like material. However, forming such a skin is challenging because it would need to be a hydrophobic material with a distinct chemistry from the hydrophilic gel core. Here, we present a simple solution to this problem, which allows any hydrogel of arbitrary composition and geometry to be encased in a hydrophobic ‘skin’. Our synthesis technique involves an inside-out polymerization, where one component of the polymerization (such as an initiator) is present only in the hydrogel core while other components (such as monomers) are present only in the external medium. Accordingly, a skin, i.e., a thin polymeric layer, grows outward from the core, and the entire process can be completed in a few minutes. We show that the presence of the skin prevents the hydrogel from swelling in water and also from drying in air. Likewise, hydrophilic solutes in the hydrogel core are prevented by the skin from leaking out into the external solution. The properties of the skin are all tunable, including its thickness, its mechanical properties, and its permeability. The ability to grow such a skin readily around any given hydrogel is likely to prove useful in numerous applications.

Tearing a Hydrogel of Complex Rheology Ruobing Bai1, Baohong Chen2, Jiawei Yang2 and Zhigang Suo2; 1California Institute of Technology, United States; 2Harvard University, United States

Tough hydrogels of many chemical compositions are being discovered, and are opening new applications in medicine and engineering. To aid this rapid and worldwide development, it is urgent to study these hydrogels at the interface between mechanics and chemistry. A tough hydrogel often deforms inelastically over a large volume of the sample used in a fracture experiment. The rheology of the hydrogel depends on chemistry, and is usually complex, which complicates the crack behavior. In this talk, we study a hydrogel that has two interpenetrating networks: a polyacrylamide network of covalent crosslinks, and an alginate network of ionic (calcium) crosslinks. When the hydrogel is stretched, the polyacrylamide network remains intact, but the alginate network partially unzips. We tear a thin layer of the hydrogel at speed $v$ and measure the energy release rate $G$. The $v$-$G$ curve depends on the thickness of the hydrogel for thin hydrogels, and is independent of the thickness of the hydrogel for thick hydrogels. The energy release rate approaches a threshold, below which the tear speed vanishes. The threshold depends on the concentration of calcium. The threshold may also depend on the thickness when the thickness is comparable to the
size of inelastic zone. The threshold determined by slow tear differs from the threshold determined by cyclic fatigue. We discuss these experimental findings in terms of the mechanics of tear and the chemistry of the hydrogel.

SESSION SB04.12: 3D and 4D Printing II

Spatially Patterned Magnetic Hydrogels for Responsive Cell Culture Applications Dermot Brougham\(^1\), Patricia Monks\(^2\), Jacek Wychowaniec\(^1\), Shane Clerkin\(^3\), John Crean\(^3\), Kevin McCarthy\(^3\), Andreas Heise\(^2\) and Brian Rodriguez\(^3\); \(^1\)School of Chemistry, University College Dublin, Ireland; \(^2\)Royal College of Surgeons in Ireland, Ireland; \(^3\)University College Dublin, Ireland

Responsive functional soft nanocomposite materials remain a significant focus of scientific effort worldwide due in part to their applications in biomedicine ranging from cancer treatment to biomolecule/drug delivery\(^4\) through to cell supports. Their responses to electric and/or magnetic fields, temperature, salts, pH, and light can be engineered through precise physicochemical modifications across multiple length scales and also by spatial patterning using 3D printing technologies\(^2\). Magnetic nanoparticles (MNPs) and also their clusters are used in the biomedical field in a wide range of applications from cancer treatment to MRI imaging\(^3\). The combination of MNPs and established 3D printable polymeric hydrogel formulations can provide multifunctional and stimuli-sensitive nanocomposite delivery systems with spatial-, temporal- and dosage-controlled release properties. We are interested in exploring these possibilities for tissue engineering applications.

A multi-head 3D printer was successfully built and modified to allow extrusion of Pluronic F127 hydrogels and composite gels including F127 and PEG-diacrylate with parameters of moderate temperature and pressure that would support cell viability. Magnetic nanoparticles were synthesised, stabilized and incorporated homogenously; oscillatory rheology measurements confirmed the viscoelastic properties with storage modulus values in the \(\sim 20 \text{ kPa}\) range providing ideal materials for 3D printing well-defined architectures with high fidelity for both magnetic and non-magnetic streams. The hybrid inks showed complete shear- and temperature-recoverability/reversibility to their initial state, confirming that at particle concentrations that enable magnetic responses the necessary printability is not lost. Various complex structures were printed with high resolution (~100 micron) with independent magnetic and non-magnetic patterned components and these were shown to be reproducible and robust and they could be cured in situ at magnetically responsive particle concentrations to retain the fidelity of printed features. Biocompatibility of the printed hybrid hydrogels for various cell lines including stem cells was demonstrated.

For AC-magnetic field responsiveness, high resolution IR thermography confirmed that incorporated magnetic nanoparticles retain sufficient magnetic response to provide spatial temperature gradients for cell stimulus and for stimulus-responsive release. The advantages of spatial patterning of thermally active components will be described. Applications of DC-magnetic fields to physical stimulation of patterned magnetic gels will also be presented.

ACKNOWLEDGMENTS

Living organisms use spatially controlled expansion and contraction of soft tissues to achieve complex three-dimensional (3D) morphologies and movements and thereby functions. However, replicating such features in man-made materials remains a challenge. Here we present a method named digital light 4D printing (DL4P) that encodes 2D hydrogels with spatially and temporally controlled growth (expansion and contraction) to create 3D structures with programmed morphologies and motions. This approach uses temperature-responsive hydrogels with locally programmable degrees and rates of swelling and shrinking. This method simultaneously prints multiple 3D structures with custom design from a single precursor in a one-step process within 60 s and is thus highly scalable. We suggest simple yet versatile design rules and the concept of modularity for creating complex 3D structures and a theoretical model for predicting their motions. We reveal that the spatially nonuniform rates of swelling and shrinking of growth-induced 3D structures determine their dynamic shape changes. We demonstrate shape-morphing 3D structures with diverse morphologies, including bioinspired structures with programmed sequential motions. This approach could potentially transform the way we design and fabricate soft engineering systems, such as soft robots, soft actuators, and 3D tissue structures.

Stem cell therapies have emerged as a promising method for treating injuries and diseases in regenerative medicine, but delivering stem cells often requires invasive techniques and results in heterogeneous injections and poor cell retention at the injection site. Traditional cell delivery methods using liquid injections or surgical implants have limited the efficacy of these treatments. We have designed a novel injectable polymer-nanoparticle based hydrogel for effective delivery of human mesenchymal stem cells. This supramolecular hydrogel supported by dynamic hydrophobic interactions is capable of longterm 3D cell maintenance and retains injected cells for up to 10 days, twice as long as traditional delivery with liquid PBS injections. We uncover the fundamental hydrogel mechanical properties that enhance the entire cell delivery process. Through both in vitro and in vivo experiments, we demonstrate a scalable, synthetic, and biodegradable hydrogel with tunable mechanical properties that enables effective cell delivery. This shear-thinning and self-healing polymer-nanoparticle hydrogel also presents valuable opportunities in designing novel inks for applications in 3D bioprinting.

Shape-morphing structured materials have the ability to transform a range of applications, from deployable systems and dynamic optics to soft robotics and frequency shifting antennae. Despite numerous advances, the integrated design and fabrication of shape-shifting structures that morph into complex three-dimensional (3D) shapes remains a challenge, owing to the difficulty of controlling the underlying metric tensor in space and time. Here, we exploited a combination of multiple materials, geometry, and 4D printing to create structured lattices that overcome this problem. We first produced printable inks composed of elastomeric matrices with tunable cross-link density and anisotropic fillers to control the material elastic modulus ($E$) and actuation capability via coefficient of thermal expansion ($\alpha$). We then printed curved bilayer ribs in the form of lattice structures, in which the geometry of each rib is individually programmed to achieve local control over the metric tensor. Using multiplexed bilayer ribs composed of four materials, we can independently control extrinsic curvature and thereby encode a wide range of three-dimensional shape changes in response to temperature. As exemplars, we designed and printed flat lattices that morph into frequency-shifting antennae and a human face that demonstrate functionality and geometric complexity, respectively. Our inverse design and multi-material 4D printing method can be readily extended to other stimuli-responsive materials and different 2D and 3D cell designs to create scalable, reversible, shape-shifting structures with unprecedented complexity.
Peptide/Graphene Hybrid Hydrogels as Potential 3D Injectable Cell Delivery Vehicle for Intervertebral Disc Repair
Cosimo Ligorio, Jacek Wychowaniec, Aravind Vijayaraghavan, Judith Hoyland and Alberto Saiani;
University of Manchester, United Kingdom

Cell-based therapies in particular have shown significant promise in tissue engineering with one key challenge being the delivery and retention of cells. As a result, significant efforts have been made in the past decade to design injectable biomaterials to host and deliver cells at injury sites. A recent strategy that has emerged for the design of increasingly functional hydrogels is the incorporation of nanofillers in order to exploit their specific properties to either modify the performance of the hydrogel or add functionality. The emergence of carbon nanomaterials in particular has provided great opportunity for the use of graphene derivatives (GDs) in biomedical applications. The key challenge when designing hybrid materials is the understanding of the molecular interactions between the matrix (peptide nanofibers) and the nanofiller (here GDs) and how these affect the final properties of the bulk material. For the purpose of this work, three gelling β-sheet-forming, self-assembling peptides with varying physiochemical properties and five GDs with varying surface chemistries were chosen to formulate novel hybrid hydrogels. First the peptide hydrogels and the GDs were characterized; subsequently, the molecular interaction between peptides nanofibers and GDs were probed before formulating and mechanically characterizing the hybrid hydrogels. We show how the interplay between electrostatic interactions, which can be attractive or repulsive, and hydrophobic (and π−π in the case of peptide containing phenylalanine) interactions, which are always attractive, play a key role on the final properties of the hybrid hydrogels. The shear modulus of the hybrid hydrogels is shown to be related to the strength of fiber adhesion to the flakes, the overall hydrophobicity of the peptides, as well as the type of fibrillar network formed. This work clearly shows how interactions between peptides and GDs can be used to tailor the mechanical properties of the resulting hydrogels, allowing the incorporation of GD nanofillers in a controlled way and opening the possibility to exploit their intrinsic properties to design novel hybrid peptide hydrogels for biomedical applications. [J. Wychowaniec et al. Biomacromolecules 2018, 19, 2731−2741]

Intervertebral disc (IVD) degeneration, a major cause of back pain, is a particularly relevant example where a minimally-invasive cellular therapy (injectable hydrogel) could bring significant benefits specifically at the early stages of the disease, when a cell-driven process starts in the gelatinous core of the IVD, the nucleus pulposus (NP). Based the knowledge gained above we explored the use of graphene oxide (GO) as nano-filler for the reinforcement of FEFKFEFK (β-sheet forming self-assembling peptide) hydrogels. We confirmed the presence of strong interactions between FEFKFEFK and GO flakes with the peptide coating and forming short thin fibrils on the surface of the flakes. These strong interactions were found to affect the bulk properties of hybrid hydrogels. At pH 4 electrostatic interactions between the peptide fibres and the peptide-coated GO flakes are thought to govern the final bulk properties of the hydrogels while at pH 7, after conditioning with cell culture media, electrostatic interactions are removed leaving the hydrophobic interactions to govern hydrogel final properties. The GO-F820 hybrid hydrogel, with mechanical properties similar to the NP, was shown to promote high cell viability and retained cell metabolic activity in 3D over the 7 days of culture and therefore shown to harbour significant potential as an injectable hydrogel scaffold for the in-vivo delivery of NP cells. Exploring the Future of Hydrogel Systems in Preserving 3D Mechanical Integrity of Cell-Extra Cellular Matrix(ECM) Mixtures within Biofabricated Assemblies
Raymond Oliver and Chawisa Deesomboon;
Northumbria University, United Kingdom

In the UK, 1 in 111 people have a disfigurement of the face. Each year, 1 in 44 people require surgical reconstruction due to facial deformity from congenital disease, cancer resection, burns, paralysis or inflammatory skin diseases. Current surgical reconstruction involves restoring facial defects including bone, cartilage, muscle and skin with the patients own tissue from elsewhere in the body where possible. Often tissue is limited to restore the defect and there are drawbacks including donor site morbidity, long term pain and surgical risks. Thus, there is a compelling and urgent need to find a new solution to restoring facial tissues for example, which transends the current surgical approach.

As we advance our knowledge of biocompatible and responsive material systems and beneficial cell biology, we
have an opportunity to accelerate viable outcomes in regenerative medicine for human repair. It is generally accepted that in designing an appropriate and proper scaffold biomaterial, one must try to translate the mechanical characteristic features of the target tissue into the mechanical features of the desired fabricated construct. For example, hard tissue regeneration requires strengths of $O[10-1500 \text{ MPa}]$, while soft tissue strengths are typically located between $O[0.4 – 300 \text{ MPa}]$.

As part of the overall solution, we are investigating how best to preserve the mechanical integrity of the scaffold which contributes significantly to the overall success of the intervention. Using 3,4D additive biofabrication through precision extrusion, we have observed that mechanical integrity can be enhanced as indicated through evidence based characterisation and measurement and that the important role that hydrogels can play not only in control of the mechanical properties but also over biological and sensory effects. Our paper will discuss some of the results of our studies using both polysaccharide and alginate based hydrogel systems can enhance cell – ECM viability for human repair.

3:30 PM SB04.12.07
Electrochemical 4D Printing of Bimetallic Objects Xiaolong Chen; University of Cambridge, United Kingdom

3D printing (additive manufacturing) is drawing more attention as a flexible manufacturing technology. In particular, Selective Laser Sintering (SLS) is a metal-based additive manufacturing technique that has been widely applied in medical, aerospace and motorsport applications. However, the essential parts of SLS system, such as high-power laser nozzle and metals powders, have high capital cost associated with the safety risks, which limit its wider application. In addition, most of the existing metal 3D printing systems can only print in a single material, which lack design flexibility. Concurrently, interest in 4D printed structures, which can react to environmental stimuli such as temperature, light, electrical and strain, is also growing due to the potential of creating objects with passive mechanisms and self-morphing characters. However, most 4D printed structures currently use polymer-based or hydrogel-based materials, which limits their mechanical strength and operating temperature.

Here, I present a novel multi-metal electrochemical 3D printer that can fabricate copper-nickel bimetallic with different architectures. Due to the mismatch in the thermal expansion coefficients, the mechanical deformation of printed bimetallic structures was programmed at temperatures up to 300 °C enabling tailored high-temperature responsive behaviour. Using a combination of scanning electron microscopy, optical microscopy, energy dispersive X-ray spectroscopy, X-ray computed tomography and electrical measurements, the morphologies of the printed structures were investigated. Moreover, electrochemical deposition of these metals create polycrystalline structures, achieving electrical conductivities that lie between that of nanocrystalline copper ($5.41 \times 10^6 \text{ S/m}$) and nickel ($8.2 \times 10^6 \text{ S/m}$). A tightly formed metal-metal boundary can be achieved, reducing delamination problems observed in other multi-material printing approaches. However, non-uniform convex cross-sections are created due to current density vibration. The work also explores different bimetallic structural designs and how modifications of this can generate different programmable structures with examples being a self-assembled “ICL”.

The author believes that this technique has broad and high impact applications due to the ability to process a range of materials and alloys, which can produce high temperature 4D structure and more importantly opens possibility for creating more intelligent structures and sensors at low cost and high safety. Other advantages include the fact that this process can be both additive and subtractive through reversal of potential, allowing for recycling of components through electrochemical dissolution.

3:45 PM SB04.12.08
Patterned Hygroscopic Control of Four-Dimensional Prints of Silk Fibroin Protein Xuan Mu and David L. Kaplan; Tufts University, United States

Four-dimensional (4D) printing of shape-morphing hydrogels is generally realized through patterning composite materials with contrasting properties (e.g., rigid vs. soft, responsive vs. non-responsive) or through control of crosslink density within photo-curable polymers. Here, we demonstrate a new strategy to print shape-morphing monolithic structures of silk fibroin protein by exploiting molecular assembly to pattern hygroscopicity. Hygroscopicity results in materials that expand and shrink upon absorption and removal of water, respectively, which has been found in natural and synthetic materials including paper, polycarbonate, wood, nylon as well as silk. Macroscopic deformation results from changes of hydrogen bonds between/within molecular chains and the transport of water molecules through nano- and micro-scale porous morphology. We used well-dispersed silk fibroin solution (~30 wt%) regenerated from B. mori. cocoons as the printing ink, which was then printed in layer-by-layer fashion on plain glass slides immersed in an aqueous inorganic salt bath. The bath was rationally designed to direct
the assembly of silk fibroin molecules into hierarchical structures from beta-sheet crystals to nano-fibrils, to micro-filaments and then to 3D macro-prints. The phase transition of the protein ink from liquid to water-insoluble solid was accompanied by the removal of water into the salt bath; while water removal at the bottom/first layer (adjacent to the water-impermeable glass slide) was more difficult than later layers that are fully exposed to the aqueous bath. The residual water influenced the crystallinity and porous morphology of the assembled structures. FTIR and SEM identified the bottom layer with ~48% beta-sheet and micro-pores (~10 micrometer diameter) in contrast to 41% and nano-pores (~10 nm) for the later layers. There is a significant difference in the magnitude of hygroscopic strain of the filaments from the different layers. We employed the mismatch of the strain to transform a planar print into a range of Gaussian curvatures including positive (cone), zero (cylinder) and negative (saddle). Furthermore, full control over the transformation of planar two-layer rectangles into 3D helices was demonstrated, where the pitch and radius of the helix was dictated by filament interval and angle. In order to predict the transformations of the printed structures, a finite element analysis model was developed to simulate large hygroscopic strains under humidity changes using experimentally obtained hygroscopic coefficients and hyperelastic properties of silk fibroin. The numerical simulations were in good agreement with the experimental results, supporting the proposed mechanism of patterned hygroscopic control. The versatile and programmable transformations, as well as the simulations, should enable a range of biomedical applications and provide key insights into 4D printing of other hygroscopic materials.

Non-Genetic Projection-Specific Modulation of Neuronal Activity Huiliang Wang, Lief Fenno, Yun-Sheng Chen, Christina Kim, Charu Ramakrishnan, Masatoshi Inoue, Sam Gambhir and Karl Deisseroth; Stanford University, United States

Developments in optogenetics and virology have demonstrated that modulating the neural activity of specific projections in the brain is capable of rescuing behavioral deficits, including those relevant to depression, autism and anxiety. This approach requires genetic modification of neurons via viral transduction of transducers of visible light, and thus light penetration depth is limited by the scattering of visible light (although fiberoptic interfaces can overcome this challenge). Additional channels for modulating neural activity would be valuable, ideally minimally-invasive. Here, we developed a non-genetic, nanoparticle-based approach to achieve projection-specific modulation of neural activity in freely behaving mice. First, we observed that gold nanorods were rapidly endocytosed into cultured neurons after just a few minutes of incubation. Transmission electron microscopy images illustrate that gold...
nanorods are located both inside and outside the endosome. Second, we showed that the endocytosed gold nanorods were transported retrogradely and anterogradely along axons, with average speed of 0.2 μm/s (1.7 cm/day). Third, we demonstrated the effectiveness of photothermal inhibition of neural activity with axon-transported gold nanorods, illustrating the concept of projection-specific modulation of neural activity in vitro, and also demonstrated biocompatibility of gold nanorods in neurons after one-week incubation and photothermal neural modulation. Finally, we observed the neural uptake and axonal transport of gold nanorods in vivo, as well as the effectiveness of neural modulation in mouse behavior. Overall, this nanoparticle-based methodology demonstrates a promising approach to non-genetic, projection-specific modulation of neural activity.

8:15 AM SB05.01.02
Luciferase-Chlorin e6 Conjugates for Bioluminescent Photodynamic Therapy Sarah Forward1, Hao Yan2, Kwon-Hyeon Kim2, Anokhi Kashiparekh1, Sheldon J. Kwok3,1 and Seok-Hyun Yun1,2,3; 1Massachusetts General Hospital, United States; 2Harvard Medical School, United States; 3Massachusetts Institute of Technology, United States

Bioluminescence (BL) has the potential to serve as a new “light” source to activate photosensitizers. Since excitation energy is delivered chemically, this approach can overcome the light-penetration problems of conventional photodynamic therapy (PDT) in deep tissue. We have developed novel RLuc8-Ce6 conjugates, which generate bioluminescence resonance energy transfer (BRET) from RLuc8, a Renilla luciferase mutant, to Chlorin e6 (Ce6), a photosensitizer, upon binding with methoxy-e-coelenterazine (meCTZ) substrates. A high BRET efficiency was achieved by optimizing the molecular ratio and spacing, as well as the spectral overlap. We also developed a protocol based on membrane fusion liposomes to deliver the protein constructs effectively into cells and obtained promising therapeutic effects of BL-PDT in a mouse model of metastatic, triple-negative breast cancer.

8:30 AM *SB05.01.03
Optical Stimulation of Excitable Tissues by Optocapacitance Francisco Bezanilla1,2 and Joao Carvalho-de-Souza3; 1The University of Chicago, United States; 2Universidad de Valparaíso, Chile; 3University of Arizona, United States

The technique of optocapacitance is a non-genetic way used to initiate action potentials in excitable tissues with light. The principle is simple: the current $I_c$ flowing to the cell membrane capacitance $C$ is given by $I_c = \frac{C}{dV/dt} + \frac{(V-V_s)dC/dt}{dV/dt}$, where $V$ is the membrane potential and $V_s$ is the net surface potential. Membrane capacitance increases with an increase in temperature, therefore a fast increase in temperature will induce a term that, under conditions of current clamp, it depolarizes the membrane which opens sodium channels thus initiating an action potential. The energy required to excite a neuron decreases as the pulse is made shorter. This is because the induced current depends on the rate of change of the temperature and not the temperature change. Therefore a long pulse does not contribute to the capacitive current thus becoming wasted energy. Experimentally, maximum efficiency is obtained with microsecond pulse durations (1). There are several ways to achieve this fast increase in temperature. An infrared pulse will increase the membrane temperature but the disadvantages are poor tissue penetration and increase of the tissue temperature (2). A more localized approach is to use light-to-heat energy transducers located in close proximity to the cell membrane. Gold nanoparticles, that have the advantage of surface plasmon resonance absorption, have been successfully used as such transducers to deliver just enough heat energy to quickly change membrane temperature of the neuronal membrane for the initiation of an action potential (3). In addition, gold nanoparticles can also be functionalized to get bound to a particular cell using antibodies (3) or specifically to the cell membrane using cholesterol (4). Other materials such as graphite particles, carbon nanotubes and mesoporous silicon (5) are also very good light-to-heat transducers that we have used to excite neurons. The technique has been applied to cultured dorsal root ganglion cells or to tissues such as brain slices (3) or isolated retina.

9:00 AM SB05.01.04
Functional Interaction between Light-sensitive Conjugated Polymer and Cytochrome C for Active Control of Intracellular Signalling Ilaria Abdel Aziz1,2, Francesco Roggiani3, Marco Malferrari1, Gabriele Tullii3, Stefania Rapino3 and Maria Rosa Antognazza1; 1Istituto Italiano di Tecnologia, Italy; 2Politecnico di Milano, Italy; 3Università di Bologna, Italy; 4National Research Council, Italy

Light modulation of cell activity is an active field of research: the possibility of coupling low invasiveness and high resolution assisted the transition from a passive, diagnostic element to an active modulator of cellular physiology. The lack of natural absorbers led to the development of tools able to transduce the optical signal into a biologically readable one, typically through a combination of photo-thermal, photo-electrochemical and photo-capacitive effects. In this framework, organic materials, and in particular poly-thiophene based materials, demonstrated to be reliable for both \textit{in vitro} and \textit{in vivo} use [Feyen et al, 2016, Lodola et al, 2017, Zucchetti et al, 2016, Bossio et al, 2018].

In this work, we prove the behaviour of Poly-3-hexyl thiophene (P3HT) as active modulator of redox metabolic signalling. We first demonstrate that the photocatalytic activity of P3HT in aqueous environment is spatially and temporally confined to the illuminated area by means of Scanning ElectroChemical Microscopy (SECM). To study the possible interactions with the photoexcited polymer, in view of \textit{in vitro} application, we focus our attention on two possible acceptor moieties present in the cell cytosol, namely cytochrome C and oxygen, being their energetic levels well aligned with those of P3HT. The former is a transmembrane protein located across the mitochondrial membrane, being one of the components of the cellular respiration cycle. Its biological relevance is thus associated with the metabolic functions of the cell. By coupling electrochemical and spectro-electrochemical methods, we demonstrate for the first time that a direct, photoinduced electron transfer does occur between P3HT and cytochrome C in extracellular, aqueous environment.

Our results shed light on a technique for active redox modulation of cell metabolism, through on demand, light-activated smart organic interfaces.

9:15 AM SB05.01.05
Controlling Capacitive and Faradaic Charge Transport Processes in Organic Photoelectrodes for Optoelectronic Biointerfaces Tobias Cramer1, Eric D. Glowacki2, Beatrice Fraboni1 and Vedran Derek2; 1University of Bologna, Italy; 2Linköping University, Sweden

Optoelectronic wireless stimulation of cells and tissue is evolving as an inherently less invasive alternative to wired microelectrodes. Wireless stimulation is enabled by photoelectrodes that harvest the light excitation in a semiconducting layer and transduce it to a stimulating ionic current sufficiently strong to depolarize attached neurons thus allowing for optical triggering of action potentials. Organic semiconductors offer a range of important advantages for photoelectrodes such as biocompatibility and the possibility to process them on flexible plastic substrates.\textsuperscript{1} In addition organic semiconductors can show an exceptional electrochemical stability in water and do not require a dielectric to separate the cell-containing electrolyte. As a result a high capacitive coupling is achieved between the semiconductor and the electrolyte. It is exploited in organic photocapacitors to stimulate efficiently retinal cells.\textsuperscript{2} However, the absence of a dielectric can allow for direct charge transfer into the liquid causing faradaic currents and potentially cytotoxic reactive electrochemical species. Therefore the optimization of organic semiconductor based photoelectrodes requests the detailed understanding of the materials and device properties that impact on these different routes of ionic current generation.

Here we address the problem in organic photoelectrodes based on a planar p/n junction containing phthalocyanine (H2PC) and N,N’-dimethyl perylenetetracarboxylic diimide (PTCDI).\textsuperscript{2} We combine the detailed characterization of photoelectrochemical currents with spectroscopic measurements and impedance spectroscopy. The data allows to establish a model that predicts quantitatively faradaic or capacitive current transients based on material properties and layer thicknesses. We find that most crucial to avoid faradaic processes are the semiconductor energy levels as well a precise tuning of electric fields present at the semiconductor liquid interface.

10:30 AM *SB05.01.06
Nanowire Templated Three-Dimensional Fuzzy Graphene for Remote Photothermal Stimulation of Cells
Tzahi Cohen-Karni; Carnegie Mellon University, United States

Electrical stimulation of tissue and ultimately individual cells has not only played an essential role in our understanding of the structure and function of excitable tissue but continues to serve as the basis for a variety of therapeutic interventions for the treatment of disorders ranging from cardiac arrhythmias to Parkinson’s disease. Advances in technology have attempted to overcome barriers associated with the spatial resolution (i.e., who and where to stimulate) and the invasiveness of the process. Optogenetics has revolutionized the way we can record and affect the electrophysiology of cells and tissue, using light as the input/output (I/O) interface. Though optogenetics has developed at a great pace and is making profound scientific contributions, the core of the technique requires genetic modifications of the cells or organism. This presents challenges both in terms of achieving targeted gene expression and the potential deleterious consequences of the expression of foreign proteins, which have implications on clinical translation to humans and regulatory approval. We report our developed breakthrough hybrid-nanomaterial synthesis process to enable minimally invasive, remote and non-genetic light-induced control of targeted cell activity with high spatial-temporal resolution. We combine one-dimensional (1D) nanowires (NWs) and two-dimensional (2D) graphene flakes grown out-of-plane with tailor-made physical properties for highly controlled photostimulation. Our non-genetic NW templated 3D fuzzy graphene (NT-3DFG) platform adds a powerful toolset to the basic scientists studying cell signaling within and between tissues, obviating the need for slow and expensive breeding protocols and/or the screening of viral serotypes to enable the use of light to control cell activity. As we continue to struggle to understand the cells and circuits involved in health and disease, our approach to controlling cell excitability has the potential to accelerate knowledge generation as well as the identification of novel therapeutic targets. Last, this platform can be adapted to address challenges in tissue engineering, i.e. the much-needed non-genetic stimulation control of engineered tissues. By controlled delivery of the NT-3DFG we will be able to locally and selectively control cellular activity with high spatial and temporal resolution of 3D tissues.

Photonic Upconversion in Organic Nanoparticles via Cooperative Energy Pooling Sean E. Shaheen1, Cody W. Sharp1 and Garry Rumbles2,1; 1University of Colorado-Boulder, United States; 2National Renewable Energy Laboratory, United States

Organic nanoparticles provide a platform for two-photon microscopy and theranostics that has highly tunable spectroscopic properties and versatile biocompatibility pathways. Here we demonstrate two-photon absorption and subsequent photon upconversion in organic nanoparticles that utilize a three-body resonant energy transfer known as cooperative energy pooling (CEP). CEP is based on the sensitization of two-photon absorbing chromophores with low-energy antennae molecules in the surrounding environment. It relies on the simultaneous transfer of two singlet excitons, initially generated on the sensitizers, to a single high-energy exciton state on an acceptor. This provides for a vast increase in the effective two-photon absorption cross-section of the acceptor by placing real, as opposed to virtual, states at the low-energy resonance. It relaxes the requirement of coincident photons normally needed for two-photon absorption by temporarily storing the energy of one photon in a singlet exciton state. It also circumvents the need for intersystem-crossing events that occur in triplet-triplet annihilation (TTA) upconversion and therefore allows for the possibility of high energetic efficiency and short, nanosecond timescales for the upconversion process. Here we synthesize organic nanoparticles of sensitizer-acceptor mixtures with diameters on the order of 100 nm and with zeta potentials of approximately -50 mV. These carry out photon upconversion from red to blue light with energetic efficiencies of ~77% and on timescales of a few nanoseconds. We discuss the photophysical process, its efficiency, and its intensity dependence, and we suggest strategies for utilizing the concept in biological applications.

The Photosynthetic Reaction Center Encapsulated in Micro and Nano Containers Based Upon Melalin-like
Polymers Massimo Trotta1, Danilo Vona2, Gabriella Buscemi2,1, Stefania Cicco1, Roberta Ragni2, Angela Agostiano2,1, Francesco Milano1, Marco Lo Presti2 and Gianluca M. Farinola2; 1Consiglio Nazionale delle Ricerche, Italy; 2Università degli Studi di Bari Aldo Moro, Italy

The photosynthetic enzyme reaction center (RC) is the photochemical core of the photosynthetic bacterium *Rhodobacter sphaeroides*, a bacterium able to grow using light as sole energy source. The RC is a transmembrane protein composed by three subunits and nine cofactors involved in a cascade of electron transfer reactions that, upon the absorption of a photon, produce a hole-electron couple. The electrical charges generated within the enzyme are roughly 3 nanometers apart from each other and have a lifetime that can last from tenths to few seconds. The generation of such nanocapacitor has a conversion photons to electrons efficiency close to unity, making this biological transduction appealing in principle for bioelectronics applications. [1] This biological macromolecule are also amenable for the assembly of organic-biological hybrids with improved enzymatic photoconversion ability. [2-4]

Such photoconverters, either bare or as biohybrids, require an optimised interface with electrode surfaces for their applications [5]. Recently polydopamine (PDA), a self-assembling melanin-like bioinspired polymer, has been exploited to attach and protect enzyme into metal-organic frameworks (MOF) [4] and graphene nanosheets [5] on devices substantially maintaining their activities.

We present here PDA nanoparticles containing the photosynthetic RC able to confine the photoenzyme that retains unaltered the photoactivity, i.e. the capability to generate nanocondensers. The RC has been encased into PDA particles of different size from the micrometer to the nanometer, the smaller being characterised by a bright yellow luminescence. These PDA nanocontainers have an intrinsic n type semiconductive [6] making these organic RC containing nanocapsules highly interesting for bioelectronics purpose.

This work was funded by European Commission through the EU project 800926 - HyPhOE (Hybrid Electronics based on Photosynthetic Organisms)

Photoactivated Bismuth Vanadate for Light-Induced Disassembly of Alzheimer's β-amylloid Aggregates

Kayoung Kim, Saehg Ha Lee, Da Som Choi and Chan Beum Park; KAIST, Korea (the Republic of)

Bismuth vanadate (BiVO₄) is a promising n-type semiconductor due to its superior photoelectrocatalytic performance, chemical stability, cost-effectiveness. Despite its beneficial advantages along with non-toxicity and biocompatibility, there are few studies for a biomedical application of BiVO₄. Here, we report a BiVO₄’s newly discovered capability to dissociate the β-amylloid (Aβ) aggregates associated with Alzheimer’s disease (AD) under illumination. An accumulation of β-sheet-rich amyloid aggregates in the brain is a major pathological hallmark of AD. The extremely high stability of amyloid structures makes it challenging to disassemble Aβ aggregates, which sparks the need for the development of new agents for breaking the pre-existing amyloid aggregates and alleviating Aβ-induced toxicity. The use of photoactive materials in medical application is an attractive strategy because of the temporal, spatial controllability, reduced side effects. The development of optogenetic technologies has opened up a new possibility of light-assisted treatment of AD by delivering light energy directly into the brain, which motivated us to develop a new photo-active anti-Aβ neurotoxin agent for localized therapy of AD. In this study, we have verified that nanoporous BiVO₄ photoelectrode can effectively break long Aβ aggregates into non-toxic, small-sized,
and soluble Aβ species under the illumination of a white light-emitting diode and applied bias. According to our photochemical and microscopic analyses, photoexcited BiVO₄ photoelectrode under anodic bias generates oxidative stress, such as superoxide ions and hydrogen peroxide, which play a significant role of oxidizing Aβ peptides and irreversible disassembling the Aβ aggregates. The efficacy of photoelectrocatalytic disaggregation against Aβ assemblies was enhanced by doping Mo ions into BiVO₄ photoelectrode by improving electron-transport properties of BiVO₄. Furthermore, we have demonstrated that both pristine and Mo-doped BiVO₄ photoelectrodes are biocompatible and effective in reducing Aβ-induced cytotoxicity. Our work shows the potential of the visible light-active, nanoporous BiVO₄ photoelectrode-based platforms for dissociating the neurotoxic, highly stable self-assembled ß-sheet-rich aggregates using light energy.

11:30 AM *SB05.01.10
Photonic Structures with Diatoms Microalgae and Molecular Fluorophores Gianluca M. Farinola; University degli Studi-Bari Aldo Moro, Italy

Diatoms are a large and prolific class of single cell photosynthetic microalgae, whose mesoporous biomineralized silica shells (frustules) encase the organic protoplasm [1]. Frustules exhibit interesting properties such as high surface area, mechanical resistance and mesoporosity, which make them appealing materials for applications in photonics, sensing, optoelectronics and biomedicine [2]. In particular, due to their quasi-periodic 3D hierarchical patterns of pores on both the nano- and microscale, frustules can act as natural photonic crystals.

We have demonstrated that in vivo incorporation of organic molecular emitters into frustules through diatoms’ silica biomineralization represents an efficient biotechnological route to new photonic materials whose properties result from the combination of the frustule hierarchical nanostructure with the luminescence of incorporated emitting molecules [3]. The in vivo incorporation approach has been also exploited by our group to generate porous biosilica nanostructures doped with organometallic iridium emitters [4]. More recently, we have also demonstrated that the in vivo incorporation of tailored light harvesting organic antennas into diatom cells can be a suitable method to enhance the algal photosynthesis, leading to increased diatoms growth rate and biomass production. In particular, our study points out that the combination of tailored photoactive molecules with diatoms microalgae can either represent a profitable strategy to get novel biohybrid photonic materials or be a straightforward non-genetic approach to enhance algal growth and biomass production.

Living Electronic Biocomposites Guillermo Bazan, Samantha McCuskey and Yude Su; University of California, Santa Barbara, United States

Composites, in which two or more material elements are brought together to provide properties unattainable by single component alternatives, have a long historical record dating back to ancient times. Few of them have included a living microbial community as a key design element. Here, we describe the use of a self-doped conjugated polyelectrolyte, namely CPE-K, in combination with Shewanella oneidensis to generate gels that can produce biologically-derived currents. CPE-K is a key ingredient due to its ability to dope via protonation reactions and the stability of the resulting polarons under biologically relevant conditions, i.e. buffered aqueous media. Moreover, CPE-K forms gels that exhibit both ionic and electrical conductivity and permit the diffusion of nutrients/waste to/from microorganisms entrapped within the gel network. One finds that the biocomposite gels can generate more than two orders of magnitude greater biocurrent density, when compared to a standard Shewanella oneidensis biofilm formed atop gold electrodes. Such an increase reflects the increase in dimensionality of the biotic/abiotic interface from two to three. We will also provide characterization of the device characteristics and will discuss the vitality of the microbial community within the gels.

3D Human Eye Model Using Soft and Rigid Materials Simon Regal, Roger Delattre, Thierry Djenizian and Marc Ramuz; Ecole des Mines de Saint-Etienne, France

We present here the development of a physical human eye model – based on hybrid soft/rigid materials - in order to create a test bench reproducing the optical eye properties.

We have developed phantom eye tissues in order to mimic the different parts like the sclera or the ciliary body as finely as possible regarding the optical properties. As a matter of fact, these parts are crucial in order to mimic human eye but often neglected in the literature. For the development of these models, we used the optical parameters (absorption and scattering coefficients; and refractive index) extracted from an experimental study carried out on porcine eyes – which are close to human one. Moreover, we present a soft actuated model of the iris where the aperture ranges from 1 mm to 8 mm. Finally, all the different parts are put together to obtain a device mimicking exactly the optical properties of an eye. Our work encompasses eye optical simulation, soft material for fabrication and characterization of the eye phantom model.

Light stimuli are used in the medical field to treat diseases as glaucoma based on infrared light or used blue light to treat circadian sleep disorders. The models developed in this study allow us a better understanding of the amount of light that propagates inside the eye.

Wireless Organic Electronic Ion Pumps Driven by Photovoltaics Marie Jakesova, Theresia Arbring Sjöström, Vedran Derek, David J. Poxson, Magnus Berggren, Eric D. Glowacki and Daniel T. Simon; LiU, Sweden

Organic electronic ion pumps (OEIP) are an emerging bioelectronic medicine technology for on-demand delivery of pharmacologically-active species. While electrical control is advantageous for providing precise spatial, temporal, and quantitative delivery, it necessitates wiring, which complicates implantation. Herein we demonstrate integration on a flexible carrier of an OEIP with a photovoltaic driver which can be addressed by red light within the tissue transparency window. Organic thin-film bilayer photovoltaic pixels are arranged in series and tandem to provide the 2-5 V necessary for operating the high-resistance electrophoretic ion pumps. We demonstrate light-stimulated transport of protons as well as acetylcholine. The end result of our work is a thin and flexible integrated wireless device platform for targeted drug delivery.

3:00 PM BREAK

3:30 PM *SB05.02.05
Soft Electronic Devices for High Resolution Neuro-Technology Yael Hanein; Tel Aviv University, Israel
Stimulating and recording the electrical activity of neurons and muscles is a major scientific and technological challenge. Although this field dates back centuries, it still remains at the forefront of contemporary investigations, in particular owing to the exploding interest in brain machine interfaces and electronics skin technology. Our investigations in recent years focus on developing and characterizing highly efficient nanomaterial based platforms for superior electronic interfacing with the human body. In particular, we focus on artificial vision and skin electronics for recording emotions. Artificial vision in particular is a very active field with many researchers and companies are trying to restore vision to blind patients through specially designed electronic devices. We recently implemented and validated ex-vivo, two novel systems: The first consists of photosensitive pixels made of a three-dimensional matrix of carbon nanotubes (CNTs) decorated very densely with quantum dots (QDs) or nano rods (NRs) (referred to also as quantum rods (QRs)). Light is absorbed and converted into a transient electrical dipole by the QRs/CNTs system. The use of a three-dimensional matrix as well as an optimized selection of QRs, their surface coating, and conjugation procedure contributes to the superior properties of our films. The second system consists of organic pigments. These materials offer superior photo response and most importantly can be readily implemented on flexible materials. Compared with other photo-sensitive artificial retinal platforms the two systems we have developed so far are marked by several clear advantages. Foremost is low stimulation threshold. Second is their biocompatibility, chemical stability and mechanical flexibility rendering the devices improved stability in the tissue. Implementing some insights gained in our artificial retina project into the realm of skin electronics, we developed a new skin electromyography system to open entirely new and exciting opportunities in recording facial emotions, in neuro-modulation application and in bio-feedback based on EMG.

4:00 PM *SB05.02.06
Charge Accumulation Spectroscopy of Solid-Liquid Interfaces in Organic Bioelectronic Devices Yu Zhang¹, Jonathan Rivnay² and Ni Zhao¹; ¹Chinese University of Hong Kong, Hong Kong; ²Northwestern University, United States

Organic electronics has recently emerged as a powerful technology platform for bio-sensing applications. In many applications, the organic devices are operated in direct contact with an aqueous environment, thus resulting in strong coupling between charge transport in the organic solid and water dipoles, ions and cells in the liquid. These interactions, although dictate the sensing performance, are not well understood. In particular, how these interactions are influenced by the structural and morphological properties of the organic materials remains unknown. In terms of sensing mechanisms, many devices make use of only the electrical responses of organic semiconductors, while the optical signatures of these materials, which are very sensitive to their surroundings, have not been utilized.

In this talk, I will introduce how charge accumulation spectroscopy (CAS) can be applied with other characterization techniques to study the structure-charge transport property relations at the water-solid interfaces. In the first example, we exploit water-gated organic field-effect transistor as the testing platform to investigate the structure-dependent localization of polaronic charge carriers at the organic semiconductor-liquid interface. Our results reveal that the degree of charge delocalization is reduced drastically when the charge carriers are moved from the bulk semiconductor to the semiconductor-water interface, suggesting the existence of a highly disordered surface layer in contact with water. It is also found that the charge delocalization could be further reduced by intercalation of chloride ions (from saline solution) in the semiconductor surface layer. This study suggests that the spectroscopic signatures of polaronic charge carriers could be a sensitive probe to detect the structure-dependent charge localization at organic solid-liquid interfaces. In the second example we combine electrochemical quartz crystal microbalance (EQCM) with CAS to study the ion-to-electron conversion efficiency and water uptake properties of the active layer of organic electrochemical transistors (OECTs). Two material systems, namely PEDOT:PSS (representing depletion-mode OECT) and p(g2T-TT)(representing accumulation-mode OECT), are investigated. We found that the ion-to-electron conversion efficiency of both p(g2T-TT) and cross-linked PEDOT:PSS is close to one at low voltage, indicating highly efficient doping and de-doping processes; while the coupling tends to be weaker at higher voltages, suggesting reduction in the doping efficacy at high ion concentrations. The study also reveal that the PEDOT:PSS layer with low or no cross-linkers exhibits low ion-to-electron conversion efficiency, which is likely associated with the high density of trap states for cations. By simultaneously measuring the mechanical, electrical and optical properties of the polymeric active layer, we are also able to estimate the water hydration numbers of the injected ions. The result suggests that due to the hydrosopic nature of the PSS phase, the PEDOT:PSS film becomes increasingly viscous and hydrated upon ion injection at high operation voltages.

4:30 PM SB05.02.07
NIR Responsive Composite Materials for Stem Cell Behaviors Study Yixiao Zhang, Sy-Tsong D. Chueng,
Photo-crosslinking hydrogels have been vastly utilized as scaffolds for tissue engineering and regenerative medicine. Albeit, ultraviolet and visible light, which has been shown strongly intervene with biological systems, are currently utilized as major excitation sources for hydrogel photo-crosslinking methods. Moreover, these excitation wavelengths are highly limited for in vivo applications because of the compromised spatial resolution and penetration depth. Alternatively, near-infrared (NIR) lights with minimal cellular and tissue interactions become a better candidate. Given the significance of NIR light in next-generation photo-crosslinking hydrogel for regenerative medicine and tissue engineering, a NIR-mediated photo-crosslinking and post-gelation modification method is on demand. Recently, with the swift development of upconversion nanoparticle (UCNP), emerging efforts have been made to drive various photoreactions with NIR light, for instance photo-cleavage, photo-isomerizations, photo-click reaction, and photo-polymerization. In terms of hydrogel crosslinking, the incorporation of NIR light as external stimulus is limited to photothermal crosslinking. The photothermally induced crosslinking mechanism requires high intensity NIR light for generating chemical reactions, where significant heating effect is inevitable. In theory, a NIR photo-crosslinking mechanism without utilizing heat as energy source will be more desirable for biomedical applications. Interestingly, photochemically activated initiator is rarely explored for NIR based hydrogel crosslinking systems.

This study demonstrates NIR-mediated photo-crosslinking (NmPC) of functionalized 4-arm-PEG with small molecule cross-linker, in which the interaction between NIR (980nm) excitation and UCNPs activate a photo initiator, resulting in stimulated photo-click reaction to form hydrogel. In order to utilize NIR excitation more efficiently, multi-shelled UCNPs were synthesized according to a reported procedure. As the efficient NIR (980nm) to visible (520nm-540nm) converter, the multi-shelled size increase was confirmed with TEM (30-60nm) and a 19 times luminescence enhancement was confirmed with luminescence spectroscopy. From rheometry characterization, the NIR mediated hydrogel cross-over point ($G'' = G'$) was found to be 43 seconds under 15 W/cm² 980nm laser intensity and Young’s moduli was found to be 1.9 kPa. Typical porous hydrogel structures were confirmed with SEM and HIM. Adipose-derived Mesenchymal Stem Cells (ADMSCs) were seeded on NmPC hydrogel with different surface binding ligand (RGD) density, showing great cellular viability and different spreading behaviors. Based on the hydrogel mechanical property, different chondrogenic behaviors were observed depending on different surface RGD functionalization, where low density (2mM) shows better chondrogenic markers expression comparing to high density (10mM) and conventional tissue culture polystyrene (TCPS). Interestingly, a proof-of-concept demonstration of NIR-mediated hydrogel printing was succeeded using same hydrogel precursor composition and focused 980nm laser beam.

By utilizing the upconversion effect of UCNPs to convert NIR light into visible emission, 4-arm-PEG chains could be crosslinked through photo-click reaction mediated by the photo initiator. To generate a 2D culture environment for ADMSCs differentiation, various concentrations of RGD ligands were functionalized on the hydrogel surface using NIR light. Low density RGD surface functionalization showed better chondrogenic differentiation comparing to high density and TCPS. With further improvement on the efficiency of upconversion process and better photo-initiator for the photo-click reaction, this hydrogel system can be a powerful approach for in vivo hydrogel property manipulation, cell/protein delivery, and tissue engineering applications.

4:45 PM SB05.02.08
Synthesizing Tunable Artificial Color—A Combined Approach Sunanda Sharma, Bianca C. Datta, Christoph Bader, Sara L. Wilson and Neri Oxman; Massachusetts Institute of Technology, United States

In living systems, color is generated in three main ways - through bioluminescence, as seen in dinoflagellates; through pigments that absorb and reflect light, such as in human skin; or through specific structures that combine light interference and diffraction, such as in peacock feathers. The latter two phenomena do not involve light emission, but rather interact with light to yield an impressive range of colors. Many structural colors also involve the use of pigments, including melanins, that are patterned to geometrically interact with light and thereby enhance the phenomenon. Melanins are a group of organic pigments widely found across the kingdoms of life and are best known for their protective qualities against ultraviolet radiation. Eumelanin, responsible for light brown to black coloration, forms melanosomes in several types of bird feathers, which consequently organize to form structural color with and without iridescence, while simultaneously protecting from UV light, dissipating heat, and minimizing misdirected scattering.

This useful combination of protective and tunable characteristics has long been pursued across the fields of biochemistry and materials science. There has been great interest in controlled synthesis of color using pigment-
related structural color, as the applications of such biocompatible and visually dramatic materials in products such as passive displays, inks, or cosmetics, become more evident. Only a handful of methods have thus far been published, the most prominent of which involve the use of high refractive index melanin or melanin-like materials as the shell layers or core of silica or polystyrene particles. Other methods include incorporation of polydopamine or synthetic melanin into photonic crystals, or thin films. In all of these approaches, the focus has largely been on incorporating eumelanin or a similar synthetic analog such as polydopamine. However, there are other types of pigments, such as pheomelanin or carotenoids, that may also be involved in structural color in Nature. In contrast to eumelanin, these pigments absorb at different spectra and thus may expand the toolbox of synthetic, protective, and biocompatible structural colors. Furthermore, combinations of pigments within multi-layer structures that utilize materials with both high and low refractive indices can create additional complexity with regard to light interaction, pointing towards optical assemblies that yield greater precision, efficiency, reflectance, and finer tunability.

Here we explore the incorporation of mixtures of synthetic eumelanin, pheomelanin, and carotenoids in multiple layers of synthesized particles to yield combination pigment-structural colors. We will examine criteria such as multi-layer shell coating, stacking of close-packed layers of pigment-incorporated particles, shell thickness, and shell composition, and heterogeneity of structures. Properties such as reflectance, absorption, packing, layer interfaces, and global architectures will be studied using a variety of methods, including spectrophotometry, scanning and transmission electron microscopy, light microscopy, and angular spectroscopy. In doing so, we hope to provide a path towards the utilization of the impressive protective properties and functions of natural pigments and their synthetic analogs in the study of structural color, resulting in multi-functional, biocompatible, and scalable coloration.

High Sensitivity, High Multiplexity Biosensor Based on Graphene-Enhanced Raman Spectroscopy
Shengxi Huang, Alexander Silver and Dongqiang Han; The Pennsylvania State University, United States

Graphene is a two-dimensional (2D) material consisting of a single sheet of sp2 hybridized carbon atoms laced in a hexagonal lattice, with potentially wide usage as a Raman enhancement substrate, also termed graphene-enhanced Raman scattering (GERS), making it ideal for sensing applications. GERS improves upon traditional surface-enhanced Raman scattering (SERS), combining its high sensitivity and spectral fingerprinting of molecules, and the unique advantages of graphene including simple processing, superior uniformity and low cost. This enables fast and highly sensitive detection of a wide variety of analytes. Accordingly, GERS has been investigated for a wide variety of molecule sensing applications. In the field of molecule sensing, biomolecule detection is an important branch and plays significant roles in biomedical research and medical diagnosis. While GERS have witnessed great success in the sensing of small organic molecules, its potential in biomolecule sensing is yet to be discovered. In this work, we report our pioneer investigations in using GERS for biomolecule detection, including various types of proteins. The unique molecular selection rules in GERS of small molecules still apply for proteins. In addition, we revealed several structures in proteins that enable strong GERS signals. Furthermore, the application of GERS for tissue imaging show unprecedentedly high signal-to-noise ratio, high spatial resolution, rapid measurement and multiplexed data obtained. We further demonstrate the effectiveness of GERS-based hyperspectral imaging as a novel tool for disease diagnosis. Our work unveiled the tremendous potential of GERS in biomedical studies and opened a new path of biosensing using GERS,

Mechanism of Plasmonically Enhanced Selective Virus Inactivation
Ramprasath Rajagopal, Mina Nazari, Min Xi, Netania Marc, Suryaram Gummuluru, Mi Hong, Björn M. Reinhard, Lawrence Ziegler and Shyamsunder Erramilli; Boston University, United States

Efficient Plasmon enhanced photonic pan-microbial pathogen inactivation was demonstrated under conditions that
allow for shockwave generation and E-field mediated cavitation. We report ultra-fast transient absorption of gold nanoparticles to explore the microscopic mechanism of shockwave generation. We use 800nm, 100fs pulses with a repetition rate of 1KHz generated with chirped pulse amplification as the pump beam and a white light continuum derived from the pump beam incident on a sapphire plate as the probe beam. Transient absorption spectra were obtained by chopping the pump beam at 500Hz with lock-in detection. Systematic studies of probe wavelength, intensity, and nanoparticle morphology to test the proposed mechanism of inactivation. Our work demonstrates the potential of plasmonic nanomaterials for pan-pathogen inactivation without targeting.

SB05.03.03

Hybrid Donor Acceptor Polymer Particles (HDAPPs) Comprised of Oligomer and High Molecular Weight PCPDTBSe for Near-Infrared Fluorescence Imaging and Photothermal Ablation of Cancer

Santu Sarkar, Elizabeth G. Graham, Christopher M. MacNeill, Bryce D. McCarthy, Aron M. Mohs, Sneha Kelkar and Nicole Levi-Polyachenko; Wake Forest University of School of Medi, United States

Near infra-red (NIR) light mediated photothermal therapy (PTT) has emerged as an excellent therapeutic method to ablate cancer due to its outstanding benefits of noninvasiveness, high specificity and high tissue transparency. Along with therapeutic treatment, diagnosis of tumors is equally vital for the visualization of the tumor and approaching therapeutic activity of remotely activated nanoparticles. Among several imaging modalities, NIR fluorescence imaging is an excellent technique due to its high sensitivity, low scattering, portability and safety. Recently, conjugated polymer nanoparticles have successfully employed as biological imaging agents and more recently evolved for photothermal therapy.

Our lab has recently demonstrated that the donor acceptor based conjugated polymer poly[4,4-bis(2-ethylhexyl)-cyclopenta[2,1-b;3,4-b']dithiophene-2,6-diy-alt-2,1,3-benzoselenadiazole-4,7-diy] (PCPDTBSe) is an excellent photothermal therapy agent but the oligomer of PCPDTBSe as fluorescent material has not yet been explored. Oligo PCPDTBSe showed emission in the NIR region (800 nm) upon excitation at 550 nm. The NIR fluorescence of the oligomer was explored for cellular imaging along with photothermal therapy when combined with the high molecular weight (hMW) segment of PCPDTBSe in 2:1 (oligo: hMW) ratio to form hybrid donor acceptor polymer particles (HDAPPs). Oligo NPs and hMW NPs were also prepared from oligomer and hMW of PCPDTBSe respectively by similar method for comparison. HDAPPs showed absorption maxima at 550 nm and 760 nm in UV-visible spectroscopy due to the presence of oligomer and hMW PCPDTBSe respectively, along with a new peak at 650 nm because of combined absorption. HDAPPs displayed a huge stokes shift of 264 nm with emission maxima at 810 nm upon excitation at 550 nm, producing 0.077 quantum yield. The hydrodynamic diameter of HDAPPs was found 65 nm, whereas oligo NPs and hMW showed 107 nm and 94 nm respectively. Upon 808 nm laser (3W) irradiation, 100 µg/ml hMW NPs produced temperature increase to 45°C, whereas equal concentration of HDAPPs produced temperature increment to 40°C; which is an unexpected phenomenon as HDAPPs contain only 1/3 of the heat generating hMW PCPDTBSe. HDAPPs were photostable with minimal decrease in fluorescence intensity through consecutive heating cycles. No significant decrease in heat generation capacity or fluorescence ability of HDAPPs was found despite of autoclaving for sterilization. HDAPPs incubated with non-tumorigenic MCF10A breast cells and triple negative MDA-MB-231 breast cancer cells displayed no cytotoxicity up to 100 µg/ml in the absence of NIR exposure. HDAPPs were clearly visible in the cytoplasm around the perinuclear region of MDA-MB-231 cell lines in Fluorescence microscopy. Upon 808 nm laser (3W) irradiation, MDA-MB-231 cells incubated with 40 µg/ml HDAPPs produced 35% cell viability whereas 100% cell killing was observed with 100 µg/ml HDAPPs. These results demonstrate that HDAPPs are a novel theranostic photothermal agent composed of two different molecular weights of PCPDTBSe for imaging as well as ablation of cancer cells.

SB05.03.04

Refractive Index Determination of Fabricated Squid Chromatophore Pigment Thin Films via Ellipsometry

Sean R. Dinneen1, Camille A. Martin2, Amrita Kumar2, Yassine Ait-El-Aoud1, Michael Okamoto1, Leila Deravi2 and Richard M. Osgood1; 1Combat Capabilities Development Command - Soldier Center, United States; 2Northeastern University, United States

We further our understanding of the optical properties of squid chromatophore pigment in order to interrogate its utility as a functional optical coating. Cephalopods (which include octopuses, cuttlefish, and squid) have evolved to create one of the most complex photonic systems. Using hierarchical layers of optical organs, these animals can change the color patterns of their skin within milliseconds. A majority of their bulk coloration is facilitated by pigmentary organs known as chromatophores, which can expand many times their size in surface area. The pigment
responsible for this color has been identified as a mixture of xanthommatin and decarboxylated xanthommatin in previous studies, and its refractive index has been measured in both the solution phase and aerosol phase. The indices of refraction of the pigments are needed for essential analysis and modeling of the chromatophore organs in order to understand how the cephalopod accomplishes its unique color and pattern changes for camouflage. To examine these optical properties in the solid state, we fabricated thin films using extracted squid chromatophore pigment mixed with polyvinyl alcohol (PVA) in a 50/50 mixture by weight. The pigment/polymer solution was spin-coated onto silicon substrates achieving a range of thicknesses (200 – 700 nm) by controlling the spin speed. The polymer aids in the homogenous distribution of pigment throughout the film by eliminating aggregation and crystallization. This method has resulted in improved ellipsometry measurements, which require very smooth films, and thus can model the pigment’s refractive index from visible wavelengths up to 3 microns. Using the procedures in this study, we demonstrate increased control of thin-film fabrication methods of extracted pigments, and a greater understanding of their optical utility within the animal, for photonic devices, or coatings.

**Membrane Environment Enables Ultrafast Isomerisation of Amphiphilic Azobenzene**

Giuseppe M. Paternò¹, Vito Vurro¹, Francesco Lodola¹², E. Colombo¹, Simone Cimò¹, Matteo Bramini¹², D. Fazzi², Cosimo D’Andrea¹, F. Benfenati¹², C. Bertarelli³ and Guglielmo Lanzani¹³; ¹Istituto Italiano di Tecnologia, Italy; ²IRCCS Ospedale Policlinico San Martino, Italy; ³Politecnico di Milano, Italy; ⁴University of Cologne, Germany

Optogenetics and covalent approaches to bio conjugation allow to achieve large and effective cell photo-stimulation, yet these are invasive methods that might encounter severe limitations on the way towards clinical applications in photopharmacology. The non-covalent affinity of photoresponsive molecules to biotargets represents an attractive alternative. Here, we show that an amphiphilic azobenzene photochromic molecule, fully locked in water, recovers its photo switching dynamics once screened by the plasma phospholipid system. According to our steady state and time resolved spectroscopic investigations the photophysical scenario in different media is dramatically different. In molecular aggregates formed in water the isomerization reaction is hindered while the radiative deactivation is enhanced by an excimer type transition. Once protected by a lipid bilayer, either in artificial micelles or in the cell membrane, the photochromic molecules reacquire their photoisomerisation capacity. Together with the natural affinity for the plasma membrane, this suggests a potential in cell opto-stimulation. We demonstrate in vitro the reversible modulation of the membrane potential via illumination with visible light. These data represent a new rationale for designing photoresponsive systems that operate via simple non-covalent affinity to biotargets and can be of importance for future applications in photopharmacology.

**SB05.03.06**

**A Soft, Conformable, Free-Form OLED for Skin-Attachable Phototherapeutics**

Yongmin Jeon¹, Hye-Ryung Choi², Seungyeop Choi¹, Kyoung-Chan Park² and Kyung Cheol Choi¹; ¹Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); ²Seoul National University Bundang Hospital (SNUBH), Korea (the Republic of)

Realizing soft, conformable, free-form opto-bioelectronic devices is of great interest in the wearable and bio-compatible medical device industries [1-2]. To achieve superior wearable and bio-compatible photomedical devices, high-performance and highly reliable free-form optoelectronic devices should be manufactured to accommodate a wide range of soft materials and shapes. In addition, a conformable surface light source should be directly attached to the skin to achieve a high-performance therapeutic effect. However, most studies have reported limited opto-bioelectronic devices that can only be fabricated on specific materials and shapes, or have relatively low performance and reliability. Even wearable photomedical device studies are mostly non-contact approaches based on point light sources, which are not flexible. Few studies on skin-attachable phototherapeutics based on ultimately soft, conformable, free-form optoelectronic devices have been reported.

In this study, we report soft, conformable, free-form OLEDs that can be attached to the skin for effective phototherapeutics. Ultra-thin free-form OLEDs (10 μm) are sandwiched by an attachable barrier and can be transferred to any soft, conformable material, including the skin. The attachable barrier is made of a nano-laminate film composed of three dyads of ZnO, Al₂O₃, and SiO₂ polymer to have high barrier performance (1.2 x 10⁻⁸ g/m²/day) and reliability to prevent a phase transition to boehmite even in moisture such as sweat [3]. Therefore, free-form OLEDs transferred to any soft material such as the skin and textiles showed high performance (>20mW/cm², 80 cd/A), low voltage (<10V), folding reliability, long operation reliability (>100h), and washing
reliability. When these free-form OLEDs were applied to real human skin keratinocytes and fibroblasts, cell proliferation was stimulated (>25%) and cell migration was effectively enhanced (>30%). Also, when the free-form OLED was attached to the rats' skin wound, the skin area was increased (>10%) and re-epithelialization was improved (>20%). In conclusion, it is expected to be applicable to various skin-attachable phototherapeutics based on high-performance, high-reliability, bio-compatible free-form OLEDs.

Graphene Based Health Monitoring Dmitry Kireev and Deji Akinwande; The University of Texas at Austin, United States

The modern healthcare and biomedical systems show a clear trend towards personalized, predictive, and preventive medicine. Development of the concept, commonly known as mobile health (mHealth), means that a huge shift in the paradigms of medical device architectures is to be expected in the near future thanks to the increased portability of medical devices as well as increase in number of specific mobile-based apps. An ideal wearable device should possess a set of important requirements, such as (i) low cost of fabrication, (ii) being conformable and compatible with human skin, and (iii) multifunctionality. The latter is of special importance if the goal is to build not just a single specific device, but to rather develop a technology and basis for scalable fabrication of devices that are capable to detect a plurality of vital signals (HR, EEG, ECG, hydration, galvanic response, etc.).

In order to develop the universal technology that meets all three requirements mentioned above, we propose to utilize graphene in combination with epidermal technology. The conventional epidermal biosensors are based on metal and silicon based thin films that are patterned into special structures for softness and stretchability and embedded into soft biocompatible polymers. The choice of two-dimensional materials is the most natural due to their ultra-thinness, allowing extreme flexibility, transparency, and conformability to almost any rough surface, including skin [1]. Graphene based passive electrodes have been successfully used to epidermal sensing of electrocardiograms (ECG), electromyogram (EOG), electroencephalogram (EEG), skin temperature, and skin hydration [1], [2]. It is important to emphasize that the research work is based on large-area CVD-grown graphene, allowing us to develop low-cost, wearable, and fully conformable to skin devices. Furthermore, large area fabrication gives an ultimate promise for future devices fully based on 2D materials to be available on market. In terms of possible applications, the proposed technology can be easily expanded towards other fields of healthcare biosensing, such as in vivo electrophysiology, UV exposure sensing, pressure sensing, or even towards building electronic skin, and prosthetics.

Multifunctional Fiber Based Neural Probes with Integrated Neurotransmitter Detection Atharva Sahasrabudhe1,4, Tural Khudiyev1, Tomo Tanaka2, Kyoungsuk Jin1, Marc-Joseph Antonini1,3, Andres Canales1, Yoel Fink1,3, Kartish Manthiram1 and Polina Anikeeva1,3; 1Massachusetts Institute of Technology, United States; 2NEC Corporation, Japan; 3Harvard-MIT Division of Health Science and Technology, United States
One of the major challenges in deciphering the fundamental principles of cognition is the lack of appropriate tools for seamless interfacing with neurons across all their signaling modalities. Gaining holistic understanding of neural circuits and their control of behavior requires invention of neural probes that can simultaneously record and modulate electro-chemical activity of neurons while evoking minimal inflammatory response for periods ranging from minutes to years. Multifunctional fibers have recently emerged as a promising platform for integrating multiple functional elements to probe and control neural activity that also minimizes the foreign body response.

In my presentation, I will describe our efforts in further expanding the multifunctionality of polymer-based fiber probes by incorporating an electrochemical sensor that enables real-time tracking of neurotransmitter dynamics in behaving animals. This is achieved by introducing a carbon nanotube (CNT) based electrocatalytic electrode within the multifunctional fiber-based probes during their fabrication via thermal drawing process. The resulting devices can be implanted chronically and perform electrical recording and stimulation of neurons, light delivery through waveguides for optogenetics, drug and gene delivery via microfluidic channels, and voltammetry via the CNT electrodes for dynamic detection of dopamine. We envision that these multimodal, miniature, and mechanically compliant probes will facilitate understanding of the neurophysiological underpinnings of dopamine-dependent behaviors including reward, addiction, and motor control.

Chronic Recordings from Behaving Animals Using Microwire-CMOS Technology Nicholas Melosh; Stanford University, United States

Mammalian brains consist of billions of neurons operating at millisecond time scales, which current recording techniques only capture a tiny fraction. Recent advances in CMOS device design have led to high-recording quality planar probes, with diminishing sizes to ameliorate the extent of tissue damage. Matching these powerful silicon electronics to the inherently three dimensional architecture of the brain has remained challenging however, as devices are constrained to the planar two dimensional surfaces required for silicon processing. Here we describe a chronic interface using arrays of microwires read out by CMOS-based devices with a low-tissue damage, and controllable, three dimensional distribution of recording sites. The core concept is using a bundle of insulated microwires mated to a large-scale CMOS microelectrode array, such as found in modern camera chips or displays. We show recent results on the mechanics and tissue damage from microwire insertion scales strongly with wire diameter. Microwires with <25µm diameters are shown to have minimal to no vascular disruption or bleeding, as opposed to more conventional 75 to 100 µm devices. These microwires are then arranged into bundles to control the spatial arrangement and three dimensional structure of the distal (neuronal) end, while providing a robust parallel contact plane on the proximal side which is interfaced to a planar pixel array. The modular nature of the design enables a wide array of microwire types and size to be mated to a variety of different CMOS chips, making the same fundamental platform scalable from a few hundred electrodes to tens of thousands. We thus link the rapid progress and power of commercial multiplexing, digitisation and data acquisition hardware together with a bio-compatible, flexible and sensitive neural interface array. We present recent massively parallel recording using mouse and rat models, showing both spiking activity from single neurons and local field potentials within both chronic and acute settings.

Membrane Curvature at the Interface between the Cell Membrane and Nanoscale Electrodes Bianxiao Cui; Stanford University, United States

The interaction between the cell membrane and the measuring electrode is crucial for crucial for sensitive measurement of cell electric activities. We are interested in exploring nanotechnology and novel materials to improve the membrane-electrode coupling efficiency. Recently, we and other groups show that vertical nanopillars protruding from a flat surface support cell survival and can be used as subcellular sensors to probe biological processes in live cells. The nanopillar electrodes deform plasma membrane inwards and induce membrane curvature when the cell engulfs them, leading to a reduction of the membrane-electrode gap distance and a higher sealing resistance. As an electrode sensor, nanoelectrodes offer several advantages such as high sensitivity, subcellular
spatial resolution, and precise control of the sensor geometry. Furthermore, we found that the high membrane curvature induced by nanoscale electrodes significantly affects the distribution of curvature-sensitive proteins and stimulates several cellular processes in live cells. Our studies show a strong interplay between biological cells and nanoscale topography, which is an essential consideration for future development of interfacing devices.

Engineering Skin-Like Soft Electrical Interface with Biological Systems Zhenan Bao; Stanford University, United States

In this talk, I will discuss several projects related to engineering conductive materials and developing fabrication methods to allow electronics with effective electrical interfaces with biological systems, through tuning their electrical as well as mechanical properties. The end result is a soft electrical interface that has both low interfacial impedance as well as match mechanical properties with biological tissue. Several applications of such electronics will be presented.

11:00 AM *SB05.04.07/SB02.04.07/SB07.03.07
Soft Materials in Wireless Closed-Loop Neuromodulation Systems for Treating Organ Dysfunction John A. Rogers; Northwestern University, United States

Bioelectronic medicines targeted at the peripheral nervous system have the potential to address a wide variety of diseases, from diabetes to bladder dysfunction. The foundational concepts have existed for decades but implementation has been limited and fraught with persistent challenges, including lack in target specificity, nerve interface biofouling, and inability to acquire real time physiologic signals for conditional delivery of corrective stimuli, leading to excess and unnecessary stimulation. Here we present a set of materials, a treatment strategy and supporting technology platform that address many of these challenges, using bladder control as model system. Specifically, we report capabilities for continuous monitoring of bladder function using an ultralow modulus, stretchable strain gauge to measure dimensional changes, real-time data analytics to identify pathological behavior based on the resulting data, and automated, closed-loop optogenetic neuromodulation of bladder sensory afferents to normalize bladder function in the context of acute cystitis, with generic applicability to many other organ systems and conditions.

11:30 AM *SB05.04.08/SB02.04.08/SB07.03.08
Miniature, Wireless Bioelectronics by Harvesting Energy from Magnetic Fields Jacob T. Robinson; Rice University, United States

Miniature, wireless bioelectronic devices enable less invasive surgical implantation and the ability to target tiny nerves or brain areas. However, as these neural stimulators become smaller, we must engineer new ways to deliver power. Conventional power deliver relies on long wires to deliver power from an implanted battery or subcutaneous antenna. These leads can limit device placement and cause device failure due to lead breakage or infection. Conventional wireless power delivery through biological tissue is difficult when devices are miniaturized and placed deep in the body. Here we show that magnetic materials can effectively harvest energy from magnetic fields and power millimeter-sized bioelectronics. These materials show excellent power densities even as the devices are made small allowing them to be fully implanted and wirelessly powered. We demonstrate that these mm-sized wireless devices can be used to power different types of conventional stimulation electrodes when implanted in rabbits, pigs, and freely moving rats. Furthermore, these miniature electrical stimulators can be adapted to power many individually addressable stimulation channels while still maintaining a small overall device footprint.
A fundamental goal of Neuroscience is to understand how the activity of specific neuronal circuits mediates behavior. Determining which aspects of neural activity are used by downstream circuits to guide behavior requires to manipulate activity while simultaneously monitoring behavioral readout. Holographic optical stimulation is an emerging toolbox for distributed control of spatiotemporal neuronal activity, which could shed new light on its direct link to behavior, by precisely manipulating the neural code while monitoring behavioral readout and neural responses.

I will describe new models, tools and experiments that together lead to recent advances in several fundamental technical aspects of optical neural interfacing and applications of such systems towards producing behaviorally relevant neural activity. First, I will focus on surprising new insights at the level of membrane biophysics that enable predictive modeling of both photo-thermal and optogenetic light-tissue effects. I will then describe our efforts to precisely probe neural circuits using rapid two-photon optogenetic stimulation and imaging with cellular resolution and ms-timescale temporal precision. Using high-energy lasers and rapid spatial light modulation we stimulate dozens of neurons deep (>250 µm) in brain tissue at a high rate. Our new system allows to generate and precisely manipulate artificial sensory responses. This approach has a broad range of potential applications in dissecting the activity codes that guide behavior across different modalities.

Recently, there is a growing interest in techniques for regulating the activity of nerve cells using light. The optical stimulation method has a higher spatiotemporal resolution than the electrical stimulation, and it is easy to implement multiple stimuli using multiple wavelengths. Although optogenetics, which is based on light-sensitive ion channels and pumps, has been widely used as an experimental tool owing to high cell specificity, the necessity of carrying out genetic manipulation is a limitation in terms of translation to clinical situation. To overcome this, nongenetic optical stimulation has been actively studied, and photothermal stimulation is one of them.

Photothermal stimulation is a method of modulating neuronal activity by applying heat to nerve cells via a substance that converts light into heat. Plasmmonic nanomaterials were used as transducers to induce photothermal effects. Among those nanomaterials, gold nanorods (GNRs) have been studied extensively in the field of nanomedicine on photothermal therapy because GNRs selectively absorb near infrared (NIR) rays and are highly efficient in converting light energy into thermal energy. Our group has been developing NIR sensitive GNR platform to suppress the neuronal activity, and investigated the inhibitory effect of photothermal stimulation on neuronal activity on in vitro neural activity.

In this presentation, I will present a GNR-based platform for locally applying photothermal stimulation to specific areas or cells of the network on a planar microelectrode array chip. In order to create a local heating pattern in tens of micrometer scale, two approaches were taken: patterning GNR particles onto the chip surface, or patterning the light. We applied inkjet printing technique to make high-quality GNR patterns in large area, and optimized the surface interaction with GNR ink droplets using a layer-by-layer technique. In order to pattern NIR light to the micrometer level, optical system was designed to achieve sufficient optical power density at a single cell size. We grew in vitro neural networks on microelectrode arrays to investigate the effect of local photothermal stimulation by multichannel spike recordings. When local photothermal stimulation was applied to a part of the network, the synchronized activity of the network was reduced and the degree of connectivity was changed. In the case of single cell-level photothermal stimulation, inhibition and rebound of action potential were observed. Comparing the optical power required for electrical activity inhibition, the action potential was instantaneously suppressed by using a very small level of optical power for single cell stimulation.

This study was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (NRF-2018R1A2A1A05022604).
Microalgae are extremely important photosynthetic organisms for both their environmental functions (e.g. CO$_2$ fixation and O$_2$ production) and industrial applications (e.g. food, drugs and bio-fuel production). In order to increase biomass production it is, indeed, of fundamental importance to increase the efficiency of microalgae photosynthesis. This approach fits perfectly into a circular economy scheme, in fact many waste products from industrial processes (e.g. CO$_2$, wastewater, sludge and agro-waste) can be used to feed photosynthetic processes to produce biomass. Among microalgae, diatoms constitute a major group that have found many industrial applications from biomedicine to photonics and they are particularly interesting for their hierarchically organized porous biosilica shells.

One possible strategy to enhance photosynthesis consists of filling the spectral gap in the light absorption of microalgae pigments (e.g. chlorophylls and carotenoids). The basic idea of this approach consists in introducing photoactive components which absorb light in the uncovered solar spectral regions and they transfer the collected energy to the photosynthetic units of the microalgae. Genetically engineered approaches can be exploited but, unfortunately, these tools in microalgae are still limited to few species.

In this work we demonstrate a new non-genetic approach to artificially increase the photosynthetic efficiency of *Thalassiosira weissflogii* diatoms by adding exogenous antennae cyanine molecules (Cy5) as a staining dye. In particular we observe that Cy5 is rapidly incorporated into the chloroplast of the microalgae without being toxic, increasing diatoms cell growth and photosynthetic oxygen production upon illumination. Cy5 dye was chosen as a possible FRET donor for chlorophyll a (acceptor) because of the following characteristics: (i) low toxicity, (ii) absorption/emission features and (iii) molecular structure.

By means of confocal microscopy we observe that Cy5 is localized in the shell and chloroplasts of the diatoms, where they can be still detected after 8 days. The incorporation of the dye is likely favored by the charged functional groups on the cyanine molecule which causes the electrostatic interaction between cyanine and cell membrane. Time-resolved fluorescence spectroscopy shows a decrease in the Cy5 excited state lifetime which is consistent with a resonant energy transfer (FRET) process between Cy5 (donor) and Chl a (acceptor). The quenching effect, and hence energy transfer, reaches a maximum after about 24 hours and, then, it gradually decreases never reaching the initial value after 6 days. In order to confirm the role of Cy5 as an enhancer of photosynthesis, photosynthetic activity was measured in the presence and absence of Cy5. The presence of Cy5 increases Pmax (maximum photosynthetic activity) by 49% compared to the control. In order to exclude that the increased productivity could be ascribed to any sort of Cy5 metabolism independent from light we repeated the measurement in the dark, observing no significant difference in cell density. This proves that only the simultaneous presence of Cy5 and light causes the diatoms growth increase. Finally it is worth stressing that the algae population is healthy for the whole experiment, and no toxic reactions or adverse effects in general have been observed.

In conclusion, in this work we demonstrated a novel method to increase *in vivo* photosynthetic activity in diatoms by...
adding Cy5 as exogenous antennae molecules. This route represents a convenient alternative to genetic modifications. This approach may be in principle extended to other photosynthetic organisms and it lays the foundations for the bio-photonic engineering of algal production by using photoactive molecules and it can impact on algae production technology, for instance extending the active volume of bioreactors and thus enhancing the yield.

Design Nanophotonics Interface for Photoacoustic Brain Stimulation Chen Yang; Boston University, United States

Implantable nanophotonics devices and injectable nanomaterials with new functions interfacing with neural systems enables new techniques to fire neurons. High spatial resolution and deep penetration in brain provided by NIR light opens up potential to overcome fundamental limitation of other photo or magnetic driven neural modulation techniques. Specifically, we will report our recent progresses on photoacoustic devices and nanotransducers for successful in vitro and in vivo neuro stimulation. In the first application, we designed and developed a miniaturized fiber with the fiber tip with two layer coating: a diffusion layer and an expansion layer with nanocomposites to produce high intensity and controlled frequency of localized ultrasound when excited with nanosecond laser light. In vitro and in vivo neuron stimulation was successfully achieved with a laser duration of 20 millisecond. Neural stimulation in motor cortex of intact awaken mouse brains confirmed the photoacoustic stimulation was localized with a high spatial resolution of 500 microns and not through indirect auditory stimulation. Additionally, to enable non-invasive and MRI compatible neurostimulation, we developed a semiconducting polymer based nanotransducer, which generate ultrasound upon excitation of NIR II nanosecond laser light and perform stimulation when binding to neuron membrane. In vitro photoacoustic neuron stimulation with a successful rate of 80% is achieved with a laser duration of 3 millisecond. Different neuron response were demonstrated through controlling the binding between nanotransducers and neuron membrane.

Light-Sensitive Conjugated Polymers Optically Control the Fate of Endothelial Progenitor Cells Francesco Lodola¹, Vittorio Rosti², Gabriele Tullii³, Andrea Desii³, Laura Tapella³, Paolo Catarsi³, Dmitry Lim³, Francesco Moccia⁴ and Maria Rosa Antognazza³; ¹Istituto Italiano di Tecnologia, Italy; ²IRCCS Policlinico San Matteo Foundation, Italy; ³Università del Piemonte Orientale "Amedeo Avogadro", Italy; ⁴University of Pavia, Italy

Direct control of cells homing to damaged myocardium after an ischemic insult is an overarching goal in the cardiac repair field because this will allow to prime the re-activation of the injured myocardium and vasculature. Here we propose a novel strategy to gain optical control of Endothelial Progenitor Cell (EPC) fate, avoiding the drawbacks associated with current approaches, mainly based on cell therapy and electro-mechanical stimulation. Our strategy is based on the combination of light sensitive conjugated polymers (CPs), used as photo-actuators, with the advantages offered by optical stimulation. At variance with cell therapy and electro-mechanical stimulation, light modulation offers unprecedented spatial and temporal resolution, permitting lower invasiveness and higher selectivity, and it allows to provide either excitation/inhibition of the cell activity. We focus on Endothelial Colony
Forming Cells (ECFCs), which represent the only known EPCs subset truly belonging to the endothelial lineage showing robust in vitro proliferation and overwhelming vessel formation in vivo. We demonstrate that polymer-mediated optical excitation is able to induce a robust enhancement of cells proliferation and lumen formation in vitro. Moreover, we identify the pathways leading to this effective enhancement in ECFCs network formation, as due to light induced activation of transient receptor potential vanilloid channels. Altogether our results represent a novel effective application of semiconducting polymer-based optical modulation to induce angiogenesis in vitro. More in general, this work represents, to the best of our knowledge, the first report on use of CP for optical modulation of the cell fate, with important perspectives in cell-based therapy and regenerative medicine.

4:45 PM SB05.05.08
Nanowire Arrays for Artificial Retina Jing Tang; Stanford University, United States

The restoration of light response with complex spatiotemporal features in retinal degenerative diseases towards retinal prosthesis has proven to be a considerable challenge over the past decades. Herein, inspired by the structure and function of photoreceptors in retinas, we develop artificial photoreceptors based on gold nanoparticle-decorated titania nanowire arrays, for restoration of visual responses in the blind mice with degenerated photoreceptors. Green, blue and near UV light responses in the retinal ganglion cells (RGCs) are restored with a spatial resolution better than 100 µm. ON responses in RGCs are blocked by glutamatergic antagonists, suggesting functional preservation of the remaining retinal circuits. Moreover, neurons in the primary visual cortex respond to light after subretinal implant of nanowire arrays. Improvement in pupillary light reflex suggests the behavioral recovery of light sensitivity. Our study will shed light on the development of a new generation of optoelectronic toolkits for subretinal prosthetic devices.

Engineering and Characterization of Polymer Colloidal Nanoparticles for Retinal Prosthesis Jonathan Barsotti, Guglielmo Lanzani and Giovanni Manfredi; Istituto Italiano di Tecnologia, Italy

Hybrid interfaces composed by organic semiconductors in contact with living tissues are appealing for the controlled photo-stimulation of tissue cells in both in-vivo and in-vitro applications. Organic optoelectronic materials, such as light sensitive and conjugated polymers, provide an easy processable, biocompatible and tunable tool for the development of bio-devices and prosthesis able to restore vision. Planar organic prosthesis based on a thin film of poly(3-hexylthiophene) (P3HT) have been proven to be successful in inducing vision recovery in rat model affected by retinitis pigmentosa.

Considering such a promising result, we decided to investigate P3HT nanoparticles (NPs). According to preliminary results, P3HT NPs succeeded in restoring vision acuity in blind rats. However, despite the encouraging results, the mechanisms at the basis of the retinal organic prosthesis functioning is still not well understood.

In this work, we investigate the photophysical properties of light sensitive core-shell nanoparticle in which one component is P3HT. Different core materials were selected (among which: ITO, TiO2 and Au) in order to have core-shell systems with different optoelectronic properties, permitting to investigate the cores effect on the organic NPs prosthesis.

Core-shell NPs provides a ground for investigating the photoexcitation mechanism and eventually controlling it by engineering ad hoc interfaces where energy level alignment can be predicted. NPs are a versatile system able to be widespread in the whole treated tissue. Moreover, NPS properties, such as tissue selectivity, light sensitivity, elasticity, etc. can be tuned, providing a versatile tool for the comprehension and improvement of the interaction between the prosthesis and the biological tissue.

8:30 AM *SB05.06.02
**Laser Particles as Novel Bioimaging Agents** Nicola Martino\textsuperscript{1,2}; \textsuperscript{1}Massachusetts General Hospital, United States; \textsuperscript{2}Harvard Medical School, United States

The emerging understanding of cellular heterogeneity in complex biological systems has necessitated new tools for large-scale, single-cell analysis. Single-cell molecular analyses have led to identification of new cell types and discovery of novel targets for diagnosis and therapy. Despite these advances, a major challenge is the ability to tag and discriminate individual cells, and track them over time or over the course of different measurements. Current fluorescence-based approaches are fundamentally limited in multiplexing ability due to typical fluorophores emission linewidths, between 30-100 nm.

We have recently developed a novel class of imaging probes, called \textit{laser particles} (LPs), with massive multiplexing capability and optimized properties for cell tagging applications. Our LPs are made of silica-coated semiconductor optical microcavities in a microdisk geometry, with ~2 μm diameter and 400 nm thickness. Upon optical pumping with a 1064 laser, the LPs generate single narrowband emission peaks (<0.5 nm) ranging from 1170 to 1580 nm, enabling massive spectral multiplexing. The LPs are readily internalized into cells to act as unique optical barcodes, where they occupy only ~0.1% of the cell volume.

In this contribution, I will present our results regarding the fabrication and characterization of these LPs, their stability and biocompatibility in biological environments and the use of these probes for wavelength-multiplexed cell tagging and imaging. I will demonstrate real-time tracking of thousands of individual cells in a 3D tumor spheroid invasion assay over several days showing different behavioral phenotypes.

**9:00 AM SB05.06.03**

**Optomechanical Microdisks for Biological Sensing** Eduardo Gil Santos\textsuperscript{1}, Jose Jaime Ruz\textsuperscript{1}, Oscar Malvar\textsuperscript{1}, Daniel Ramos\textsuperscript{1}, Sergio García-López\textsuperscript{1}, Priscila Kosaka\textsuperscript{1}, Aristide Lenaître\textsuperscript{2}, Ivan Favero\textsuperscript{3}, Montserrat Calleja\textsuperscript{1} and Javier Tamayo\textsuperscript{1}; \textsuperscript{1}Instituto de Micro y Nanotecnología (IMN-CNM, CSIC), Spain; \textsuperscript{2}Laboratoire de Photonique et Nanostructures, France; \textsuperscript{3}Université Paris Diderot, France

The field of Optomechanics has made impressive advances in the last decades, covering a broad range of applications going from ultrasensitive sensing to fundamental quantum studies. The use of optomechanical devices for biosensing has acquired crescent interest in the last years, being semiconductor microdisks one of the most promising platform on this field. Semiconductor microdisks support both, optical and mechanical modes, which possess extraordinary properties. Optically, semiconductor microdisks support the so called whispery gallery modes (WGMs), where the light circulates around the disk periphery. WGMs combine submycron optical mode volume and low optical dissipation, reaching optical quality factor above $10^5$. From the mechanical point of view, they support a family of modes, the radial breathing modes (RBM), which present extremely high mechanical frequencies (> GHz) and low energy losses in liquids. These assets, together with their remarkably low masses (in the pg range), provide them with extremely low mass sensitivities and high speed, notably, while immersed in liquid [1]. Moreover, semiconductor microdisks can be integrated in collective configurations, thus, improving their sensing efficiency while keeping their individual capabilities [2].

Optomechanical microdisks allows to simultaneously monitor optical and mechanical modes, which provides them with access to the optical and mechanical properties of the given analyte. This dual sensing approach is fully innovative and significantly improves the sensor reliability and robustness. We have first applied this novel method on the detection of environmental changes, particularly temperature and humidity. We demonstrated that the method allows to decoupled humidity and temperature effects with extraordinary precision, which place them as excellent sensors for this purpose. Notably, in this work we show the first application of optomechanical devices as biological sensors. We have developed a novel deposition method which allow us to precisely locate individual, alive and intact bacteria in our sensors. By simultaneous detecting changes in their mechanical and optical modes, we probe that microdisks allows to determine the mechanical properties (rigidity, viscosity and mass) and the optical properties (index of refraction, optical absorption coefficient and size) of \textit{Staphylococcus Epidermidis} bacteria. Importantly, besides their capabilities to sense the analyte optical and mechanical properties, we also proven that optomechanical microdisks can detect the intrinsic mechanical resonances of the bacteria. This concept has been never realized even proposed before. By coupling the mechanical modes of the sensor with the ones of the analyte, the coupled system supports detectable collective mechanical modes, which provide precise information about the analyte modes. Importantly, coupling between the sensor and the analyte modes require having close resonance frequencies. It is important to note that the detection of analyte mechanical modes provides extremely high sensitivity on the determination of the morphology and mechanical properties of the analytes. In addition, the
method allows to track in real-time the mechanical resonance frequency of the bacterium, which significantly increases the responsivity of the system to analyte changes. The proposed method radically departs from the classical paradigm for sensing the mass and stiffness of analytes with micromechanical resonators. This novel concept opens the door for studying biological interactions at the most fundamental level.

Trans-Membrane Fluorescence Enhancement by Carbon Dots—Ionic Interactions and Energy Transfer
Stefanie D. Pritzl1, Fernando Pschunder2, Florian Ehrat1, Santanu Bhattacharyya1, Theobald Lohmüller1, Maria A. Huergo2 and Jochen Feldmann1; 1Ludwig-Maximilians-Universität (LMU), Germany; 2Universidad Nacional de La Plata - CONICET, Argentina

We present how trans-membrane energy transfer and ionic interactions can be controlled across the bilayer membrane of large unilamellar vesicles. A system has been designed, where hydrophobic carbon dots (CDs) are embedded in the lipophilic part of lipid bilayers, while fluorescein molecules are covalently bound to the hydrophilic lipid heads [1]. The CDs are built of polycyclic aromatic hydrocarbon domains [2] that form biocompatible nanoparticles (~1.0 - 1.5 nm) with high photochemical stability. The spectral overlap between the CD emission and the fluorescein absorption spectra allows to establish trans-membrane Förster resonance energy transfer (FRET). We observe energy transfer efficiencies of 51% for a separation distance of ~4 nm between the donor CDs and the acceptor dyes, which is in good agreement with the bilayer geometry. Furthermore, we find that ionic interactions between the positively charged CDs and the anionic fluorescein let them conjoin within the vesicle membrane. This co-localization of both components does not only facilitate energy transfer, but also results in photoluminescence enhancement of the membrane bound dyes, which is beneficial for imaging applications and microscopy studies of membrane systems. Overall, this capability of balancing energy transfer and ionic interactions within a model membrane represents a general strategy to investigate trans-membrane related processes such as ion transport and changes of the membrane potential with high spatiotemporal control and resolution.

3D Nanostructures for Biosensing in Living Cells Francesco de Angelis; Istituto Italiano di Tecnologia, Italy

The ability to interact with neuronal cells and to monitor their status plays a pivotal role in neuroscience, pharmacology and cell biology. In the last years, we deeply investigated both theoretically and experimentally the interactions of 3D nanostructured surface sensors with living cells such human neurons and cardiomyocytes [1]-[2]. The aim is to make an effective interface between the intracellular compartment and different class of nano-sensors including optical sensors, electrodes and nano-needles for intracellular delivery or sampling [3]. We developed a method based on plasmonic generation of nano-shockwaves [4] for opening transient nanopores into the cell membrane that is in close proximity with the plasmonic nanosensor. After the membrane poration the tip of the sensor is in direct contact with the intracellular compartment thus enabling intracellular investigations which include Raman traces of biomolecules [5]-[6], electrical recording of action potentials [7], and controlled delivery of single nanoparticles into selected cells [8]. However, for these applications have a real impact in the fields of Biology and Medicine it is necessary to make them available on the market, i.e. in the hands of biologist and researchers working in those fields. To this aim, we introduced the concept of planar meta-electrodes [9], namely a nanostructured surface that can work as electrode, a broad band plasmonic antenna, and optimal cellular interface. We show that meta-electrodes combined with commercial CMOS technology enable high quality intracellular electrical signals on the large network scale of human neuron and cardiomyocytes. Due to its robustness and easiness of use, we expect
the method will be rapidly adopted by the scientific community and by pharmaceutical companies. In fact, the field suffers the lack of reliable approaches for pharmacological screening of drugs devoted to the central nervous system. Also, we will take this opportunity to give a short overview of different types of optical and plasmonic biosensors we are currently developing. The latter includes single molecule Raman Sensors, DNA detection, and Protein sequencing.

10:30 AM *SB05.06.06
Biological Imaging of Chemical Bonds—Next Frontier of Light Microscopy Wei Min and Yuan Yang; Columbia University, United States

Innovations in light microscopy have revolutionized the way researchers study biological systems. Although fluorescence microscopy is currently the method of choice for cellular imaging, it faces several fundamental limitations such as the rather bulky fluorescent tags, color barrier for multiplex imaging, and limited ability for probing in vivo metabolism. To address these challenges, I will present three coherent Raman imaging strategies, respectively. First, we devised a Bioorthogonal Chemical Imaging platform suited for probing small bio-molecules. This scheme couples the emerging stimulated Raman scattering (SRS) microscopy with tiny vibrational probes. Exciting biomedical applications such as imaging fatty acid metabolism, glucose uptake and metabolism, drug trafficking, protein synthesis, DNA replication, and tumor metabolism will be presented. Second, we invented a super-multiplex optical imaging technique. We developed electronic pre-resonance SRS microscopy with high sensitivity. Chemically, we created vibrational palettes consisting of novel dyes. This super-multiplex optical imaging approach promises to facilitate untangling intricate interactions in complex biological systems, and can also find broad applications in photonics and biotechnology. Third, we introduced a platform that combines deuterium oxide (D2O) probing with SRS microscopy (DO-SRS) to image in situ metabolic activities in animals. Enzymatic incorporation of D2O-derived deuterium into macromolecules generates carbon-deuterium (C-D) bonds, which track biosynthesis in tissues in situ. Within the broad vibrational spectra of C-D bonds, we discovered lipid-, protein-, and DNA-specific Raman shifts with macromolecular selectivity. DO-SRS, being noninvasive and universally applicable, can be adapted to a broad range of biological systems to study development, tissue homeostasis, aging, and tumor heterogeneity.

11:00 AM SB05.06.07
Oxygen Monitor to Study Vascularization of Medical Devices Avid Najdahmadi¹, Rachel Gurlin¹, Mellonie Zhang,² John Weidling,¹ Sean White¹, Bhupinder Shergill², Jonathan Lakey¹ and Elliot Botvinick¹; ¹University of California Irvine, United States; ²University of California, Davis, United States

Subcutaneous medical devices designed for cell therapy can be advanced by a prevascularization phase that
proceeds the transplantation of tissue into the device. This approach holds promise to replace whole organ transplantation with thin vascularized devices hosting only the necessary supporting cells. We have developed a noninvasive optical technology to study the vascularization into such medical devices. In our technique, oxygen partial pressure within a device is monitored by Oxygen Sensitive Tubes (OSTs), comprising oxygen permeable silicone tubes coated on their inner surface with a porphyrin oxygen-sensitive dye. OSTs were placed within a PDMS device and transplanted into athymic nude mice. An optical probe placed on the skin excites the OSTs with a pulse of light and detects the luminescent lifetime of emitted light. The lifetime is uniquely related to oxygen partial pressure. Further, we developed a Dynamic Inhalation Gas Test (DIGT) to determine the oxygen transport rate between the microvasculature and the device. DIGT works by monitoring oxygen partial pressure during a step change in the inhaled gas oxygen content. We report changing DIGT oxygen dynamics from a series of experiments spanning eight weeks. Our study shows DIGT dynamics are unique to each implant, suggesting the important role of the host tissue response in the availability of oxygen over time.

11:15 AM SB05.06.08
Wavelength Modulation of Fluorescent Nanosensors for High SNR Operation in Thick Tissue Volodymyr Koman, Naveed Bakh, Freddy Nguyen, Daichi Kozawa, Michael A. Lee and Michael Strano; Massachusetts Institute of Technology, United States

Fluorescent sensors directly probe chemical kinetics in remote locations, transmitting the signal wirelessly to the observer. However, many biological organisms suffer from the limited penetration depth of light, obstructing the sensor use. Here, we present wavelength modulation spectroscopy (WMS) that improves the signal to noise ratio (SNR) in thick tissues by 100x. This allows the detection of near-infrared signals from sensors implanted at depths of up to 4.5 cm in chicken breast tissues. Additionally, WMS can eliminate the need of reference measurements, as it self-corrects for mechanical artefacts caused by tissue movements. WMS is enabled by the modulating the excitation wavelength across 50 nm in 0.2 s and measuring the changes in emission, which allows us to separate autofluorescent and fluorescent components of the response based on the period of modulation. We demonstrate the application of WMS on common near-infrared sensors, such as carbon nanotubes and ICG. We applied WMS to improve the SNR in sensing H2O2, riboflavin, and ascorbic acid in vivo. This technique may find a variety of uses in diagnostics, real-time therapeutics, and biochemical studies.

11:30 AM SB05.06.09
Towards Rapid, All-Optical Pathogen Identification Using Raman Spectroscopy and Machine-Learning Amr A. Saleh, Chi-Sing Ho, Neal Jean, Loza Tadesse, Niaz Banaei, Stefano Ermon and Jennifer A. Dionne; Stanford University, United States

Rapid, accurate identification of pathogens and their antibiotic susceptibility/resistance are essential to improve patient prognosis, slow the spread of infectious diseases, contain epidemics, and mitigate the misuse of antibiotics. Unfortunately, the gold standard for bacterial identification and antibiotic susceptibility testing (AST) still rely on century-old culturing methods that typically takes few weeks to run. In this work, we introduce a novel platform that combines Raman scattering spectroscopy with machine-learning to enable the identification of individual pathogens solely through their Raman signatures. Notably, cellular membranes have a unique molecular composition that give rise to a characteristic Raman signature that can be used for cellular identification. However, practical implementation of Raman-based identification has been hindered by the reproducibility of Raman measurements at the single cell level. To overcome this challenge and allow for accurate single-cell classification using Raman spectroscopy, we developed a machine-learning classification algorithm. Particularly, we developed a convolutional neural network (CNN) trained on Raman spectra from individual pathogens. Our CNN architecture consists of 25 one-dimensional (1D) convolutional layers and residual connections - instead of two-dimensional images, it takes one-dimensional spectra as input. Our training dataset consists of 60,000 single-cell spectra from 30 bacterial and yeast isolates representing over 94% of all bacterial infections treated at Stanford Hospital. The training data we used was acquired at a rate of 1 s per individual cell, corresponding to a signal-to-noise ratio (SNR) of 4.1 - roughly an order of magnitude lower than typical reported bacterial spectra. Using this dataset, we show that the average pathogen strain-level classification accuracy achieved is 93.8%. When these strains are grouped based on their empiric antibiotic treatment, the classification accuracy increases to more than 99% for the treatment group classification. To further enable studying the changes in the Raman signatures of pathogens upon exposure to external stimuli such as antibiotics while improving the signal-to-noise ratio, we implemented a liquid chamber
where mixtures of pathogens and gold nanorods were prepared. Using a palette of gold nanorods with resonances ranging from 650nm to 920nm and a 785nm excitation laser, we show that significant enhancement in the Raman signatures of both E. Coli (Gram-negative) and Staphylococcus (Gram-positive) can be achieved. Interestingly, the obtained enhancements are achieved using two different nanorod sizes for the two tested species; while nanorods with shorter resonant wavelengths result in a more pronounced enhancement for Gram-negative E. Coli, longer-wavelength resonant nanorods produce the largest enhancement for the Gram-positive Staphylococcus. This is due to the tendency of nanorod aggregation with the Gram-negative E. Coli, due to the bacterial and nanorod surface charge interaction, causing the nanorod frequencies to red-shift. Our results lay the foundation for a fast, all-optical pathogen identification and antibiotic susceptibility classification beyond the conventional slow culture methods.

11:45 AM SB05.06.10
Hybrid Plasmonic/Photonic Crystals for Optical Detection of Bacterial Contaminants Giuseppe M. Paternò¹, Liliana Moscardi¹,², Stefano Donini¹, Davide Ariodanti², Ilka Kriegel³, Emilio Parisini¹, Guglielmo Lanzani¹,² and Francesco Scotognella¹,²; ¹Istituto Italiano di Tecnologia, Italy; ²Politecnico di Milano, Italy; ³Materiali e Ingegneria Chimica "Giulio Natta", Italy; ⁴Istituto Italiano di Tecnologia (IIT), Italy

Photonic crystals (PhCs) have been largely employed as detection/sensing devices in recent years, since the photonic stop-band can be tuned by applying a number of external stimuli, such as chemical¹, thermal² and mechanical triggers³. In this context, we have recently proposed porous 1D photonic structures exhibiting electro-optical tunability, due to the incorporation of optoelectronically-active plasmonic nanoparticles in the photonic structures.⁴–⁶ Here, we show that a hybrid plasmonic/photonic crystal consisting of a thin layer of bioactive plasmonic material (i.e. silver) deposited on top a 1D PhC can detect one of the most common bacterial contaminant, namely Escherichia coli. We speculate that the change in the plasmon charge density brought about by metal/bacterium interaction results in a variation of the plasmon resonance which, in turns, translates in a shift of the photonic structural color.

References
As a result, there is still a need to develop methods capable of monitoring ENM-cell interactions in a quantitative fashion, independent of specific surface modifications. Addressing these concerns, here we show how scatter enhanced phase contrast (SEPC) microscopy, a dual light source microscopy technique, can serve as a generalized label-free approach for monitoring nanoparticle uptake and transport dynamics. By avoiding fluorescent labels, SEPC allows for a rational exploration of the surface properties of nanomaterials in their native state. We demonstrate this experimentally, showing that SEPC works for a variety of metal and metal oxides, including Au, Ag, TiO2, CeO2, Al2O3, and Fe2O3 nanoparticles. Additionally, we show that when combined with microcontact printing, a technique which can be used to control cell morphology, we are able to normalize dynamics across multiple cells, enabling a quantitative study of ensemble nanoparticle uptake (n= ~480 particle trajectories). Using this approach, we observed that particles began as evenly distributed across the cell surface but became clustered in the perinuclear region after a short duration, indicating the bulk of ENM transport occurs within the first 30 minutes of exposure. These studies also suggested further spatial heterogeneities in ENM dynamics, revealing three distinct regions of particle transport across the cell, with particles moving faster near the edge of the cell and slowing down as they approach the nucleus. Overall, this indicated that membrane dynamics play an important role in regulating initial particle flow, while intracellular vesicular transport dictates intermediate dynamics. Collectively, this ensemble approach to studying transport dynamics has important implications for designing next-generation ENM-based drug delivery systems and in better understanding the uptake of existing materials.

SB05.07.02
Three-Dimensional Quantitative Characterization of Migrating Cells Revealed by Optical Diffraction Tomography Yongkeun Park, Ariel J. Lee, Herve Hugonnet and Wei Sun Park; KAIST, Korea (the Republic of)

The wound-healing assay is one of the most useful methods for the study of collective cell migration and cell-to-cell interaction. Furthermore, it provides an inexpensive and easy tool for therapeutics, by observing the effect of various chemical treatments on wound healing speed. Numerous studies have observed some novel mechanical and molecular interactions between the cells during the healing process using this assay. Nonetheless, most are remaining at the stage of two-dimensional analysis such as gap closure rate, direct counting of cells or individual cell tracking, although it clearly involves a complex three-dimensional (3D) process. There are limitations when viewing the healing mechanism in 2-dimension. People do not have a full understanding of collective cell migration yet. The 3-dimensional (3D) properties of cells like thickness or velocity vector during the process present a new perspective to understand how cells near and away from the boundary migrate and interact with the neighboring cells. Here, we utilized non-labeling 3D long-term imaging and developed analysis tools for the wound healing assay.

Optical diffraction tomography (ODT) is an effective tool for imaging low-scattering samples like cells by utilizing intrinsic physical information in the sample without labeling. Based on laser interferometry, it reconstructs a three-dimensional refractive index tomogram of live cells or tissue, from multiple 2D measurements of optical field images of the sample illuminated from various angles. ODT provides label-free and quantitative phase imaging capability. Especially in terms of the experimental complexity or availability, its label-free imaging ability without difficulties such as photobleaching has an incomparable strength in monitoring the healing process for an extended period of time. A wide enough field of view for analysis can be covered by using a stitching algorithm. Thus, ODT with the aid of the stitching algorithm is an excellent fit for imaging the expanded area of wound healing model for an extended period of time in 3D.

To investigate dynamic 3D motions of cells in a wound-healing assay, we have systematically controlled the ODT imaging system and a motorized sample stage in a synchronized manner. We have measured a large area of a sample (up to 1 mm x 1 mm) with a high resolution (down to 110 nm and 360 nm in the lateral and axial spatial resolution, respectively) at a high frame rate (up to 3-5 tomograms per second for a specific field of view 81 μm x 81 μm). We studied both the overall shape and the subcellular structures of individual cells in a time-lapse manner. Several quantifiable 3D properties such as the thickness of cells or condensation level of the nuclei chromatin in groups of cells with different chemical treatments are explored by employing the system. Especially, an examination of RI distribution in the nucleus of cells revealed different chromatin condensation level near the boundary and the inner regions of cells. This provides a new tool to study and monitor the wound healing mechanism and how the chemical treatments affect cells.

Our 3D non-labeling imaging and analyzing techniques of wound healing will deliver a significant impact on the pharmaceutical industry. Quantitative 3D analysis for migrating cells’ behavior during the wound healing allows a unique chance to study and analyze with precision the wound healing mechanisms. Studying more complex 3D wound healing models utilizing this technique will be the subsequent step which may give us a fundamental
understanding of the in-vivo wound healing process.

SYMPOSIUM SB06

TUTORIAL: Molecules and Materials in Mechanobiology
December 1 - December 1, 2019

TUTORIAL
Molecules and Materials in Mechanobiology

Sunday Afternoon, December 1, 2019
Hynes, Level 2, Room 201

This tutorial aims at reviewing the fundamentals and applications of mechanobiology in the context of materials science. A comprehensive overview from the cellular principles to biomaterials will be given.

Recent developments in Materials Science and Biology have made it possible to investigate cell-matrix interactions in relation to mechanics. Therefore, the tutorial "Materials in Mechanobiology" presents the principles of mechanobiology in relation to materials science. The course includes an introduction into mechanobiology (1:30-3:00 pm), followed by a discussion of biofunctionalized materials that are relevant for controlling cells by environmental cues (3:30-5:00 pm).

The objective of the tutorial is to introduce materials scientists into this highly interdisciplinary, lively field of research.

1:30 PM
Molecules of Mechanotransduction Medha M. Pathak, University of California Irvine

The 1st half of the tutorial will review the most recent progress on mechanobiology. A particular focus will be on mechanotransduction, the process by which mechanical cues from the extracellular environment are transduced into biochemical signals, which in turn control physiological processes. The methods that allow cells to actively probe their environment, i.e. intracellular forces, will also be explained. Central to mechanisms of force sensing and transduction are mechanically-activated ion channels. The tutorial will provide an in-depth introduction to these molecules and their interaction with the cytoskeleton. Overall, this part of the tutorial will give a comprehensive introduction into the biological background that needs to be considered when designing materials for mechanobiology.

3:00 PM BREAK

3:30 PM
Strategies to Control Cellular Environmental Cues One at a Time or Combined Together Virgile Viasnoff, National University of Singapore and Centre National de la Recherche Scientifique
The 2nd half of the tutorial will cover biofunctionalized materials for investigating how cells respond to environmental cues. Such materials can have different features, ranging from specific matrix materials, specific geometry, to topography. These materials have high potential for controlling cells in a variety of applications, including tissue engineering. Therefore this tutorial will discuss methods to generate biofunctionalized materials that have well-defined ligand patterns, specific rheological properties, and well-controlled topography at the micro- and nanoscale. A highly timely aspect will be the presentation of methods to dynamically control such material properties over space and time.

Sensing Local Strains in the Cytoskeleton via LIM Domains Patrick Oakes; Loyola University Chicago Stritch School of Medicine, United States

The actin cytoskeleton plays a fundamental role in giving cells their shape and mediating interactions between the cell and the extracellular environment. Specifically, actin filaments transmit the forces generated in the cytoskeleton by myosin motors to the extracellular matrix. It has been shown previously that proteins that contain multiple LIM domains (e.g. zyxin, paxillin, etc…) specifically recognize sites of strain in the cytoskeleton and localize to stress fiber tears. Using these proteins as markers in conjunction with an optogenetic approach to induce local contractions in the cytoskeleton, we have recently shown that strain in actin filaments is distributed non-uniformly. We find that in addition to random failures in the network, strain in the actin cytoskeleton preferentially concentrates at the interface between focal adhesions and stress fibers. We also surprisingly find that these proteins localize to sites of potential compression. Here we use the LIM family protein testin to explore these mechanisms of mechanosensing behavior. Using a combination of laser ablations and optogenetics, we find that full length testin localizes to the cytosol and is not mechanosensitive. Truncations of the protein that include just its three LIM domains (LIM1-3), however, localize to focal adhesions and sites of strain. Stress fibers that are fully severed show no recruitment of the LIM1-3 construct, suggesting that LIM domain proteins recognize a change in the conformation of actin, and not just free barbed ends. Further truncation constructs reveal that the first LIM domain is required for mechanosensitivity. Finally, using various phosphomutants, we find that we can drive testin to localize at adhesions, but that only a subset of them retain their mechanosensitivity. Together these results indicate a potential role for
phosphorylation in regulating the conformation of testin, thereby controlling its mechanosensitivity and its ability to recognize local strain in actin filaments.

Mechanical Manipulation of Tandem Repeats of Biological Motifs—One Molecule at a Time Jaba Mitra1,2 and Taekjip Ha2; 1University of Illinois at Urbana-Champaign, United States; 2Johns Hopkins University, United States

Tandem repeat motifs are ubiquitous across the central dogma of biology and regulate a variety of physiological processes including gene regulation, membrane functionalization etc. For example, in eukaryotic cells, the ends of linear chromosomes are capped by 50-200 nt long telomeric DNA, consisting of tandem hexanucleotide guanine (G)-rich repeats. Four of such telomeric, G-rich motifs can spontaneously associate and fold into thermodynamically stable structures, known as G-Quadruplexes (GQs). Interplay between mechanical forces and structural transformations is fundamental to several biological processes, such as, transcription, replication, cellular locomotion etc. We integrated the unique abilities of single molecule fluorescence and optical traps to demonstrate unprecedented heterogeneity in GQs, with at least six interconvertible species which differ in mechanical responses, but are largely resistant to unfolding by cellular motor proteins associated with transcription, replication etc. Additionally, our studies revealed direct mechanical regulation of a GQ-core in presence of unassociated G-rich motifs. The extreme conformational and mechanical diversity of GQs may induce differential protein binding in cells and serve as cornerstones for engineering novel anti-cancer therapeutics. The conformational versatility of G repeats have been harnessed for development of molecular tools called “light-up” aptamers used for visualization and localization of RNA in cells. We evaluated the mechanical stabilities of two classes of such RNA aptamers, known as Mango and Spinach. Our results illustrated that despite a common GQ core, the aptamers have characteristic mechanical signature and in general, with respect to Mango, Spinach is mechanically weaker and susceptible to unraveling via helicases and polymerases. Thus, the RNA aptamers can be leveraged as molecular platforms for simultaneous visualization and prediction of forces involved in transcription. We next extended our assay to demonstrate linear spring-like mechanical response of a malarial circumsporozoite protein (CSP). CSP being a surface protein, this facilitates gliding motility of the sporozoites in the host. Moreover, the repeat peptides can be used for engineering cellular tension sensors which are sensitive to forces between 1 and > 30 pN.

9:15 AM SB06.01.03
Biologically Inspired, Cell–Selective Release of Aptamer–Trapped Growth Factors by Traction Forces Benjamin Almquist; Imperial College London, United States

Biomaterial scaffolds that are designed to incorporate dynamic, spatiotemporal information have the potential to interface with cells and tissues to direct behavior. Here, I will describe a bioinspired, programmable nanotechnology–based platform that harnesses cellular traction forces to activate growth factors, eliminating the need for exogenous triggers (e.g., light), spatially diffuse triggers (e.g., enzymes, pH changes), or passive activation (e.g., hydrolysis)1. Flexible aptamer technology is used to create modular, synthetic mimics of the Large Latent Complex that restrains transforming growth factor–β1 (TGF–β1). I will show that this nanotechnology–based approach works with multiple growth factors, integrates with both 2D and 3D substrates and scaffolds, and enables fundamentally new capabilities such as selective activation of growth factors by differing cell types (e.g., activation by smooth muscle cells but not fibroblasts).

9:30 AM *SB06.01.04
Watching Cellular Mechanotransduction—Piezo1 Activation by Cellular Traction Forces Kyle L. Ellefsen1, Jesse R. Holt2, Alice C. Chang1, Jamison L. Nourse2, Janahan Arulmoli2, Armen Mekhdjian1, Hamid Abuwarda2, Francesco Tombola1, Lisa A. Flanagan2, Alexander Dunn2, Ian Parker1 and Medha M. Pathak2; 1University of California, United States; 2University of California, Irvine, United States; 3Stanford University, United States

A major unanswered question in biology is how mechanical forces are generated, detected and transduced by cells to impact biochemical and genetic programs. Our work is aimed at uncovering the mechanical principles at play in cells and tissues using novel molecular, imaging and bioengineering tools. Here we present insights gleaned from
non-invasive approaches to measure and manipulate mechanical cues in native cellular conditions. We find that the mechanically-activated ion channel Piezo1 transduces cell-generated traction forces to regulate lineage choice of neural stem cells. We show that actomyosin-based cellular traction forces generate spatially-restricted Piezo1 Ca2+ flickers in the absence of externally-applied mechanical forces. Although Piezo1 channels diffuse readily in the plasma membrane and are widely distributed across the cell, their Ca2+ flicker activity is enriched in regions proximal to force-producing adhesions. The mechanical force that activates Piezo1 arises from Myosin II phosphorylation by Myosin Light Chain Kinase. We propose that Piezo1 Ca2+ flickers allow spatial segregation of mechanotransduction events, and that mobility allows channel molecules to efficiently respond to local mechanical stimuli.

From Microdishes to Microniches—Controlling Single Cell Apico-Basal Polarity and Lumenogenesis Virgile Viasnoff1,2, Yue Zhang1, Richard deMets1 and Celine Stoecklin1; 1National University of Singapore, Singapore; 2Centre National de la Recherche Scientifique, France

The key influence of the microenvironment on cell behavior and fate is increasingly recognized. It follows that new techniques to control the 3D environment around cells are essential to understand the processes by which cells probe and respond to the cues received by their microniches. Here, we present an approach that allows transforming microwells into artificial microniches where the chemical coating, the rheological properties and the topographical properties can be differentially controlled on the top, sides and bottom of the wells and assembled in a combinatorial way. This technique is also compatible with high and super resolution imaging that allows probing the dynamics of cell cytoskeleton and regulatory proteins with unprecedented resolution down to the single molecule level in 3D. We exemplify how these bone fide artificial microniches can be used to induce full apico-basal polarization of single epithelial cells as well as to control intercellular stresses driving the anisotropic growth of intercellular lumens. We will detail our recent studies on the role of mechanical forces in the development of bile canaliculi in liver and explain our minimal organ approach.

11:00 AM *SB06.01.06
Mechanism in Collective Organizations of Living Cells Joachim P. Spatz and Oskar Staufer; Max Planck Institute for Medical Research, Germany

Regulating the emergence of leading individuals is a central problem to collectively migrating biological entities. For example, leaders in the mobile animal groups arise through collective decision making of the followers. However, the fundamental control of leader selection remains unclear in the physiologically relevant collective migration of epithelial cells. Here we present that the selective emergence of leader cells at the epithelial wound-margin depends on the dynamics of the follower cells and is spatially limited by the length-scale of collective force transduction. Owing to the dynamic heterogeneity of the monolayer, cells behind the prospective leaders manifest locally increased traction and monolayer stresses much before these leaders display any phenotypic traits. Once formed, the territory of a leader can extend only to the length up-to which cells can pull on their neighbors. These findings provide a novel mechanobiological-insight into the hierarchy in cell collectives during epithelial wound healing.

Soft Tissue Mechanics Result from Fibrous Networks Confined by Close-Packed Cells Anne van Oosten1,2, Xingyu Chen1, Vivek Shenoy1,1 and Paul A. Janmey1; 1University of Pennsylvania, United States; 2Leiden University, Netherlands

Crosslinked semi-flexible polymer networks are ubiquitous to both the internal cytoskeleton and the extracellular
matrix. The viscoelasticity of these networks is therefore presumed to dominate tissue mechanics. However, the responses of soft tissues and semiflexible polymer gels to uniaxial loading differ from each other in many respects. Tissues stiffen in compression but not in extension, whereas semiflexible polymer networks soften in compression and stiffen in extension. In shear deformation, semiflexible polymer gels stiffen with increasing strain, but tissues do not. Tissue rheology emerges from an interplay between strain-stiffening polymer networks and volume-conserving cells within them. Polymer networks that soften in compression but stiffen in extension, can be converted to materials that stiffen in compression, but not in extension, by including within the network either cells or inert particles to restrict the relaxation modes of the fibrous networks that surround them.

SESSION SB06.02: Cell Adhesion and Mechanics

1:30 PM SB06.02.01
Single-Molecule Measurements of Force Transmission by Integrin Heterodimers in Living Cells Alexander Dunn; Stanford University, United States

Integrins are heterodimeric transmembrane adhesion proteins that link the cytoskeleton to the extracellular matrix (ECM), and hence play a central role in the construction of complex, multicellular tissues. Although integrins are required for both cellular traction generation and for sensing mechanical cues such as substrate rigidity, the magnitude of the forces born by integrin heterodimers was unclear. We used FRET-based molecular tension sensors to determine the magnitude and origins of the forces experienced by individual integrins in living cells. We found that this distribution was highly skewed, with the majority of integrins bearing loads of ~2 pN, while a small subpopulation experienced forces >11 pN. Further experiments revealed that this distribution was controlled in a modular manner: integrin heterodimer usage controlled the number and stability of cellular connections to the ECM, while the proteins that link integrins to the cytoskeleton regulated the distribution of loads borne by individual integrin complexes. These and other observations support a general model for how cells create the regulated and dynamic adhesion complexes that are a defining feature of multicellular life.

2:00 PM SB06.02.02
Multiscale Modeling of the Facet Capsule Ligament—Size Effects and Problem Size Reduction through Generalized Boundary Conditions Jacob Merson and Catalin Picu; Rensselaer Polytechnic Institute, United States

A Multiscale approach (similar to the FE2 method) is developed to investigate the mechanics of the facet capsule ligament (FCL). The multiscale analysis technique allows for discrete micromechanical representations of the collagen tissue, coupled to a macroscale model which can use geometries obtained from segmented image stacks of biologically relevant domains. These complex biological geometries are coupled with other data sets, such as initial network orientation fields, to obtain models which can output biologically relevant mechanics information such as network orientation trajectories and local stresses not accessible by direct measurement. One of the challenges with the multiscale analysis is choosing an adequate sized representative volume element (RVE) at the microscale. This talk will discuss size effects on the RVE fiber network, and tools which can be used to ameliorate the large RVE sizes which are needed.

2:15 PM SB06.02.03
Towards Non-Optical, Label-Free Measurements of Particle and Cell Stiffness in Flow Charles Dhong1 and Darren J. Lipomi2; 1University of Delaware, United States; 2University of California, San Diego, United States

The mechanical properties of cells, such as cell stiffness, are important biomarkers in both clinical applications (e.g. detecting circulating tumor cells) and fundamental biological studies. Despite the importance of cell stiffness in mechanobiology, there are relatively few facile techniques that have the temporal resolution for basic research, or
the throughput required for clinical applications. Limitations of current technologies is that they rely on optical equipment, which can be bulky and expensive, or indirect measurements of force, such as calcium labeling. Here, we describe a new technique for monitoring the properties of particles and cells within an elastic, microfluidic channel. As a particle flows inside the channel, it deforms the walls in a characteristic manner. This fluid-induced deformation (i.e., elastohydrodynamics) is measured by using ultra-sensitive piezoresistive strain sensors. By transducing the wall deformation into voltage, we are able to monitor analytes within the channel without the use of any optical equipment. We discuss our validation of using elastohydrodynamic phenomena to monitor analytes and the future directions for the platform.

2:30 PM *SB06.02.04
Local Catalytic Effects in Adherent Membranes Ana-Sucana Smith; FAU Erlangen-Nürnberg, Germany

A number of cell functions rely on the formation of macromolecular platforms in the plasma membrane. While the functional role of these assemblies has been intensively investigated over the years, little is known about the mechanisms underlying their formation. In this presentation, several possible pathways will be discussed, including the role of the membrane elasticity, composition fluctuations, and the interactions with the cytoskeleton. Furthermore, cooperative attachments of proteins with different length, flexibility and affinities will be explored, allowing the development of a hypothesis regarding the simultaneous repellent and catalytic roles of the glycocalyx in the formation of membrane-associated macromolecular assemblies.

Synthetic Extracellular Matrices to Study Mechanotransduction in 3D Britta Trappmann; Max Planck Institute for Molecular Biomedicine, Germany

Cell fate decisions are influenced by many cues, which together constitute the cell microenvironment. One critical regulator is the extracellular matrix (ECM), which varies not only in composition, but also in physical properties such as stiffness. The impact of matrix stiffness on cell spreading and differentiation has been studied intensively on 2D surfaces using synthetic hydrogels, but very little is known about stiffness sensing within more complex 3D matrices. Here, a major hurdle is to isolate the role of ECM stiffness from other matrix properties, in particular degradability. If cells are fully encapsulated, changes in bulk stiffness also influence the amount of matrix crosslinks that a cell has to cleave in order to spread and interact with its surroundings, impacting cell shape and function. Here, we have developed a sugar-based hydrogel system that offers independent control over mechanical properties, adhesive ligand density and matrix degradation rates. The material can be processed under physiologic conditions rendering it suitable for cell encapsulation. Matrix metalloproteinase (MMP) cleavable peptides as crosslinking units enable cellular matrix remodeling and variation of their sequence gives access to a range of degradation rates. Using this system, we study the impact of matrix stiffness and degradability on cell spreading, mesenchymal stem cell differentiation and angiogenic sprouting. In particular, we demonstrate that matrix degradability, mechanics and adhesivity jointly control the multicellularity of 3D endothelial cell invasion.

4:00 PM SB06.03.02
A Sensitive Tool for Probing Cellular Mechanics—Tracking Longitudinal Rotation with a Kinked-Silicon Nanowire Youjin Lee, David Wu, Yuxing Peng and Bozhi Tian; The University of Chicago, United States

A technique for tracking the longitudinal rotation of nanoscale objects has the potential to serve as a powerful
experimental tool to researchers across a variety of fields. Longitudinal rotation (i.e. rolling about a long axis) is a subtle movement that requires less free space than other types of movements such as translation and lateral rotation. Therefore, longitudinal rotation is particularly sensitive to small forces and does not significantly alter the local environment. This is especially true for long cylindrical objects since they require no additional space to rotate along their long axis. As such, tracking the longitudinal rotation of nanowires can serve as a sensitive and minimally perturbing method to probe forces in nanoscale environments. In this work, we present a simple and versatile method of tracking longitudinal rotation using a kinked silicon nanowire. By imaging the changes in the length of the kinked nanowire’s arm projected on the detection plane, we can measure the nanowire’s longitudinal rotation. To precisely measure the projected length of the nanowire’s arm, we developed a sub-pixel particle detection algorithm. To improve efficiency in the data processing pipeline, we incorporated a statistical procedure (principal component analysis) to automate the detection process. We applied this method to study the longitudinal rotation of nanowires in the presence and absence of endothelial cells. We found that nanowire rotational dynamics were significantly affected by the nanowire’s environment. While the free-floating nanowires underwent consistent and fast sub-diffusive rotation, the cell-interacting nanowires exhibited a greater variety of behaviors, including slow sub-diffusive random rotation and super-diffusive unidirectional rotation. The nanowires underwent this type of unidirectional rotation when the cell actively extended its boundary to cover the nanowire or when the cell contracted significantly. Our ability to detect cellular behavior via conspicuous changes in the nanowire’s longitudinal rotation showcases the sensitivity of this technique. Furthermore, the detection algorithm and the statistical method developed for this work can be applied to tracking the movements of other nanoscale objects with various geometries.

NIR-Actuated Composites to Perturb and Profile Mechano-Chemical Cell Signaling Nicholas Vishnosky and Rachel Steinhardt; Syracuse University, United States

Mechanical and chemical signals from the extracellular milieu are crucial to cell differentiation, morphology, and function. New materials are needed that can send precise, multivariate cues on cellular length- and timescales. For this purpose we are synthesizing novel near-IR actuators and incorporating them in new composite materials. The resultant biocompatible structures can change modulus and 3D morphology in response to tissue-penetrating wavelengths of light on multiple length scales, and we are now incorporating protein and drug functionalities onto the materials' surface. We are currently tailoring these composite materials for use as venous stents and stem cell differentiation scaffolds.

A Materials Approach to Studying Forces, Form and Function in Cells and Tissues Christopher Chen1,2; 1Boston University, United States; 2Harvard University, United States

A long recognized tenet of biological systems is that structure gives rise to function. Mechanical force in contrast has emerged only recently as a critical dimension that links form and function, providing the central effector to sculpt the body plan during morphogenesis, as well as a mechanism for cells to sense and respond to local changes in tissue structure and mechanics. Despite the realization that forces, form, and function permeate all living systems, we as a research community sorely lack methods to control the mechanics of the environment, the spatial organization of cells, or the architecture of cell-matrix and cell-cell interfaces, which collectively define the boundary conditions for how forces are transmitted into cells. Here, I will describe our efforts to design and build physical microenvironments that explicitly manipulate and monitor the physical (structural and mechanical) interactions between cells and their surroundings. Using these approaches, we demonstrate that mechanical forces generated either internally by the cytoskeleton or externally regulate cell, matrix, and tissue structure, signaling, and function, and begun to use these insights to build in vitro organotypic models of the cardiovascular system that mimic native tissue functions. I will use our studies to illustrate how deeper insights into the structure-function links are critical to our ability to engineer stem cells to recapitulate differentiated function, and how engineered systems ultimately could have a major impact on biomedical research.

Towards the Development of a Macroscopic, Biohybrid, Hydrogel-Based Actuator Christine Arndt, Mohammadreza Taale, Florian Ceynowa, Fabian Schuett, Rainer Adelung and Christine Selhuber-Unkel; Kiel University, Germany

Biohybrid soft robotics is an emerging field of research that offers new concepts for the current challenges of soft robotics. This includes the ability to self-heal, soft touches and miniaturization possibilities, as well as situational and autonomous adaptations. Here, living beings have an unprecedented variety of possibilities to manipulate and interact with objects and the combination of elements from soft robotics with living cells opens up new opportunities. As an example, skeletal muscle cells can be used to actuate biohybrid, hydrogel-based actuators but they require electrical stimulation in order to contract. However, most currently used biomaterials, e.g. in cardiac tissue engineering, lack electrical conductivity and appropriate mechanical properties. Both parameters are important for regulating skeletal muscle cell behavior. In this work, we present conductive and structured hydrogel scaffolds where the conductivity is achieved by incorporating reduced graphene oxide or carbon nanotubes in the material. Further, the stiffness of the scaffolds can be tailored to match the stiffness of native muscle tissue. MTT-assays have shown that the scaffolds have no negative impact on the cell viability. Apart from this, the samples are biofunctionalized with collagen to enhance cell adhesion. The presented work illustrates the potential of conductive and structured hydrogels as a first step towards the development of a biohybrid, hydrogel-based actuator.

SB06.04.02
Detachment of the Biomolecule Bindings between the Microtubules and Kinesins Kenta Hatazawa1, Ryuzo Kawamura2, Masahiro Nakamura1 and Takayuki Hoshino1; 1Hirosaki University, Japan; 2Saitama University, Japan

Microtubule (MT)-kinesin gliding systems are known as the biomolecules to cause cell motility cytokinesis and cellular transport [1]. Previously, we reported the local detaching control of a living cell from the SiN membrane and investigated spatio-temporal distributions of intracellular elastic strain as mechanical strain microscopy by using a fine virtual cathode (VC) on the VC display [2]. In addition, to examine the biomolecules control using the VC display [3], we reported the pause of the target gliding MTs [4]. In the same way as the former report, we considered that the pause mechanics of the gliding MTs are caused by detachments between the biomolecules (= MTs and kinesins) bindings. In this report, we examined to cause the detachments between the target MT and kinesins on the VC. As the results, some target MTs were confirmed to move to the directions different from the each MTs axial direction by applying the VC. These results showed that the MTs detached from the kinesins and showed the detach between the biomolecules can be controlled on the VC. In summary, the detachments of the biomolecules binding forces include the mechanical function could provide the novel tool to molecule mechanobiology.

Behavior and Phenotype of Cancer Cells in Response to Varied Mechanical Environment in 3D Hydrogel Models Cultured In Vitro Tayler Laycox, Riley Aspinwall, Ian Schmidt and Jason W. Nichol; Endicott College, United States

Cells of all types react in response to changes in their mechanical environment typically to return their surroundings to homeostatic conditions. In cancer cells this response is varied in ways which also vary based on the cancer type or even the phenotype within one type of cancer. These are some of the reasons why mechanical stiffness and the extracellular matrix (ECM) play key roles in tumor formation/progression and cancer cell phenotype. Cancer cells originating from different tissues, possessing different stiffnesses, will respond to their environment differently,
which could yield important information in better understanding cancer cell physiology. Gelatin methacrylate (GelMA) is a UV-crosslinkable hydrogel that has been shown to be effective in the 2D and 3D culturing of cells in a wide variety of applications including cancer models. Cells can easily bind to GelMA 2D surfaces and within 3D structures, and can proliferate, elongate, and remodel their surroundings due to the presence of natural binding and enzymatic degradation sites in the gelatin backbone. GelMA is a highly elastic material with tunable mechanical stiffness through variation of gel concentration and degree of methacrylation. It has been established that normal breast tissue has a compressive modulus of roughly 200 Pa, whereas precancerous regions have a modulus of roughly 600 Pa and cancerous regions can be as high as 1-2 kPa. Analogous studies are underway to create similar stiffness ranges for other cancer types such as prostate, as well as to control stem cell differentiation via similar principles. The major aims in these studies were to create robust GelMA hydrogels in the 3 mechanical ranges (normal, precancerous, tumor) for breast and other tissues, and once validated to investigate the differences in behavior, morphology and gene expression of cancer cells encapsulated in these hydrogels. Validation studies with NIH 3T3 cells determined the parameters and conditions (exposure time, lamp power, photoinitiator concentration) where cells could be 3D encapsulated with a high degree of early viability that was maintained for 1-2+ weeks. Preliminary results suggest evidence that different cancer cell types react differently to varied levels of mechanical stiffness. Further experiments will aim to further elucidate these effects and the factors driving these phenomena through RNA isolation and analysis using NextGen sequencing.

SB06.04.04
The Signaling Response of Artificial Neurons Made from Chemical Oscillators James Sheehy and Seth Fraden; Brandeis University, United States

Rhythmic movements in biology are abundant, across a number of length scales from the beating of a heart to digestion, locomotion, and breathing. These simple yet vital functions are controlled by patterns of signals created by a series of neurons, known as central pattern generators. Neurons within these central pattern generators are capable of robustly maintaining these complex oscillations without the benefit of inputs from higher brain functions, yet they are also able to modify their oscillatory behavior in response to stimuli. The Belousov-Zhabotinsky reaction is a fluid which acts as a chemical oscillator, which obeys reaction-diffusion dynamics. This chemical oscillator periodically oxidizes and reduces, causing a periodically spike in voltage. Using microfluidic techniques, we can embed pockets of this chemical oscillator within a gel network which allows us to control the connections between these pockets. It has been shown that using this technique, we can create artificial central pattern generators. In this work, we will investigate how individual artificial neurons respond to changes in local environment in order to examine how these artificial neurons change their behavior in response to changes in stimuli. Additionally, we will examine the communication between pairs of these artificial neurons in order to understand how the interactions give rise to robust complex patterns.

*We acknowledge financial support from the U. S. Army Research Laboratory and the U. S. Army Research Office under contract/ grant number W911NF-16-1-0094, and the microfluidics facility of the NSF MRSEC DMR-1420382.

SB06.04.05
Characterizing Hetero-Oligomers from Amyloid-Beta and Alpha-Synuclein with AFM Eun Ji Shin and Joon Won Park; Pohang University of Science and Technology, Korea (the Republic of)

A large proportion of patients with Alzheimer's disease or Parkinson's disease may have symptoms of both diseases at the same time. Such diseases overlapping Alzheimer’s disease and Parkinson’s disease have been attempted to explain with the hetero-oligomer hypothesis associated with Amyloid-beta (Aβ) peptides and Alpha-synuclein (α-syn) peptides. However, neither presence nor structure of the hetero-oligomers have not been clarified. Herein, we have investigated surface structure of protein oligomers at the single peptide level. We employed Atomic Force Microscopy (AFM) with a liquid cell to characterize the hetero-oligomers generated in vitro. In particular, a probe tethering an antibody recognizing the N-terminal of Aβ and another probe tethering N-terminal of α-syn were prepared, and one-to-one interaction was realized through utilizing dendron coating of the probes before the conjugation with the antibodies. High resolution force maps of the oligomers were obtained with thus-prepared AFM probes. It revealed that specific unbinding events with respect to two different antibodies were observed within an oligomer,
and such coexistence of specific pixels was persistent for all sizes under investigation. Because homo-oligomers were not observed at all, it can be said that formation of the hetero-oligomers is strongly favored. It is intriguing to note that the percentage of positive pixels for the hetero-oligomer is higher than that for the homo-oligomer, suggesting a different mode of aggregation for the hetero-peptide oligomerization. We suggest that this approach is useful for understanding the overlap of neurodegenerative brain disorders.

Designed Liquid Crystalline Polypeptide Fibres
James MacDonald1, Hannah Leese2,1, Karan Bali1, Paul Freemont1 and Milo Shaffer1,1; 1Imperial College London, United Kingdom; 2University of Bath, United Kingdom

Significant progress has been made in the de novo design of protein-based biomaterials at the atomic-level.1 But, to date, there has not been a significant advance in the de novo design of macroscopic biomaterials that match the extraordinary mechanical properties of some natural materials such as silk. Self-organising materials are commonly observed in biological systems and the ability to control this self-organising behaviour in optimally designed systems opens up new approaches for the creation of advanced materials. Synthetic biology provides the tool to build artificial proteins that can be ideal precursors for such advanced materials as their structure can be controlled at the atomic level and synthesised with monodispersed precision. In this work, we show that de novo synthetic proteins spontaneously display liquid crystalline behaviour at critical concentrations. These liquid crystalline synthetic proteins were successfully wet-spun into aligned tough continuous fibres without disruption of the protein back-bone.

SB06.04.07
Cortex Dominates Bacillus subtilis Spore’s Water-Responsive Behaviors
Zhi-Lun Liu, Haozhen Wang and Xi Chen; The City University of New York, United States

Water-responsive (WR) materials that swell and shrink in response to changes in relative humidity (RH) show a great potential as building blocks for developing better actuators and artificial muscles. Bacillus (B.) subtilis spore has demonstrated a WR energy density of ~10 MJ m⁻³ that is significantly higher than that of reported actuator materials. However, the origin of such a powerful actuation of spores remains unclear. Here, we present that cortex layers within spore exhibit dramatic water-responsiveness that could dominate spores’ WR actuation. We isolated cortex from B. subtilis spores and found that its WR strain and stiffness reach ~38.7 % and 1 GPa, respectively, which suggests a WR energy density of 74.9 MJ m⁻³. To correlate WR properties of cortex to that of spores, we characterized the distribution of cortex within spores by 3D reconstructing serial cross-sectional images of spores obtained from an FIB-SEM. We have analyzed 85 spore samples and found cortex’s average thickness and volume ratio to be 122.4 nm and 52.4 %, respectively. These results, together with the measured WR strain and energy density, suggest that spores’ water-responsiveness is largely contributed by its cortex layer rather than other components. Our finding of the extreme water-responsiveness of spores’ cortex also provides insight to its important functions in spores’ biological processes.

SB06.04.08
Understanding the Molecular Mechanism of Cartilage Degradation and Cation Channel Activity
Deng Li,
Biomechanical forces play a critical role in our body. Collagenous tissues such as cartilage and bone are smart materials that can adapt their properties in response to mechanical forces through altering their structures from the molecular level up. They are able to convert mechanical forces into biochemical signals that control many biological and pathological processes such as wound healing and tissue remodeling. However, how collagenous tissues convert the biomechanical forces into signaling that regulates the cells during tissue development and remodeling remains unclear.

Here we employed a bottom-up computational approach to investigate the joint mechanobiology from two aspects: the molecular mechanisms of the extracellular matrix degradation and the molecular mechanisms of how point mutations affect the constitutive activity of transmembrane cation channel. We find that specific residues in the vicinity of the catalytic site play crucial roles in forming a stable binding pose in cartilage, which is vital for cartilage degradation. Our results also show that point mutations alter the molecular structure of the transmembrane protein and thus affect the channel size, which is one of the essential factors that alter the constitutive activity of the channel. Understanding the molecular mechanisms from the molecular level is crucial for the development of novel skeletal regenerative medicine or preventative strategies for related diseases.

SB06.04.09
Nanofibrils as Basic Building Blocks of Natural Spider Silk Qijue Wang, Chloe Walsh, Dinidu Perera and Hannes C. Schniepp; College of William and Mary, United States

As one of the most exciting biomaterials nature has to offer, spider silk has long fascinated researchers in various disciplines because of its both superior mechanical properties and biocompatibility. In order to replicate these properties in synthetic materials, an accurate and detailed structural description of silk is necessary. Though protein nanofibrils have been proposed to be the key structural element in natural silk fibers, experimental evidence about their existence, dimension, and structure is insufficient. Many important details of these nanofibrils, including their formation and spatial organization within a silk thread, are still missing.

Recently, we showed that the ribbon-like silk of the brown recluse spider is entirely composed of 20-nm thin nanofibrils using atomic force microscopy (AFM) and scanning electron microscopy (SEM). This is the first time that the fibrillar percentage and the complete structure down to the nanofibril level can be determined experimentally for any spider silk. First-ever evidence of individual isolated spider silk nanofibrils was also obtained. We also studied fibers from other spider species and observed nanofibrils with similar morphologies. Hence, we suggest that nanofibrils are the dominating structural element in all silk fibers. Consequently, the formation of nanofibrils will also be important in novel synthetic materials inspired by spider silk. For the first time, we achieved in-vitro self-assembly of nanofibrils from the native silk dope of the golden silk orb-weaver spider (*Nephila clavipes*), one of the most studied species. In the presence of shear, silk protein molecules form individual 20-nm thin nanofibrils longer than 1 mm, similar with what we have observed in natural silk fibers. This unprecedented observation suggests an intrinsic tendency to form a linear fibrillar structure for the silk molecules. Furthermore, based on our spectroscopy study about the protein secondary structures within spider silk, and with the help of force modulation microscopy (FMM), we can characterize the mechanical behaviors of these nanofibrils at the molecular level.

Thus, our exhaustive investigation of silk nanofibrils from multiple angles points to nanofibrils as the basic and necessary building blocks of all silk fibers. This puts a complete structural description for natural silk materials within reach, and benefits efforts to develop protein- and polymer-based high-performance materials and biocompatible medical devices.

SB06.04.10
Influence of Different Mechanical Conditions on Cell Behavior Sandra Sindt, Yasmeen El-Rayyes, Galen Ream and Christine Selhuber-Unkel; Kiel University, Germany

In nature, cells are exposed to various environmental conditions that can influence their behavior. How chemical cues influence cell behavior has been studied for decades, whereas the sensing and reaction of cells to external mechanical stimuli still contains a vast number of open questions.

A very well-known aspect, however, is that integrin-based adhesion clusters can grow upon externally applied shear forces. Furthermore, many cell types respond to the stiffness of their underlying substrate, and it has even been
shown that cells can feel a stiff substrate underneath a soft material layer if the soft layer is thin. For example, mesenchymal stem cells sense an underlying hard substrate if the thickness of the soft layer is below 5 µm. This ability of cells to feel through soft material layers is essential in the design and application of implants, particularly in soft environments like the brain. Hence, the understanding of the underlying principles of these mechanosensory cell mechanisms is vital for biomedical research. In addition, the manipulation of cells with mechanical stimuli has great potential for biomedical applications.

However, external mechanical cues might affect single cells and cells in ensembles in different ways as cells in collective ensembles have the ability to distribute the applied stress over several cells via, for example, rearrangement processes. Consequently, they can bear mechanical stress better than single cells. To investigate how single cells and collective cell ensembles react to external stress, we built a setup to induce different mechanical stimuli. We will here present results on how such induced mechanical stimuli influence the cell behavior of cell ensembles and furthermore show how the thickness of soft layers affects the adhesion of single cells.

SB06.04.11
Rapid Magnetic Printing of 3D Cell Structures Sarah Mishriki1, Abdel Rahman Abdel Fattah1,2, Tobias Kammann1,2, Srivatsa Aithal1, Rakesh Sahu1, Fei Geng1 and Ishwar K. Puri1,1; 1McMaster University, Canada; 2KU Leuven, Belgium; 3Friedrich-Schiller-University, Germany

The demand for tissues and organs is unmet by the current supply. Engineering solutions are desired to create 3D cell structures to help fulfill this need. Using a unique bottom-up approach, we can rapidly form 3D cell assemblies by exploiting the diamagnetic property of cells. Most mammalian cells are weakly attracted to a magnet. This is also true of their culture medium, which is an aqueous solution of proteins, sugars, and nutrients to maintain their growth. The addition of a paramagnetic salt hydrate, such as gadopentetic acid (Gd-DTPA), transforms the culture medium to become paramagnetic. This establishes a difference between the magnetic susceptibility of cells and their liquid counterpart. The presence of a magnetic field gradient displaces the suspended cells towards regions of relatively lower magnetic field in the direction of where H is the magnetic field. This movement of cells followed by the movement of the culture medium seeds the formation of 3D cell cluster in a contactless, label-free manner within hours. Using this method, 3D cell structures can be formed on an ultra-low attachment surface, and 2.5D cell structures on a tissue-culture treated surface. The presence of a co-culture introduces new printing abilities and cell morphologies. This engineering solution has the potential to overcome limitations in bioprinting to expedite efforts in drug discovery, tissue engineering and regenerative medicine.

SB06.04.12
Design of Novel Scaffolds for Effective Healing of Bone Fractures Using Topology Optimization Based on Mechano-Biological Model, Angiogenesis and Scaffold Degradation Mervenaz Sahin1, Mehmet Serhat Aydin1 and Gullu Kiziltas Sendur1,2; 1Sabanci University, Turkey; 2Sabanci University Nanotechnology Research and Application Center, Turkey

Bone repair is known to be a complex process affected by many parameters such as fracture size. 3D composite porous tissue scaffolds loaded with bioactive molecules and cells are being developed to offer a better solution for bone fracture healing. Accordingly, an ideal bone tissue scaffold should provide the following functions: a. mechanical support for the growth and functioning of new tissue, b. adequate porosity and permeability for nutrients and oxygen supply, waste removal and growth factors release, c. suitable surface for cell attachment, differentiation and growth, and d. controlled degradation. Therefore, an optimal bone tissue scaffold should have a multi-functional structure with desired mechanical, biological and chemical properties. However, it is still unclear what kind of properties optional bone scaffolds should provide leading to effective tissue repair. Thus, there is a critical need to find methods suitable for designing novel bone scaffolds and the investigation of structure-function relationships for optimal tissue regeneration. Existing experimental studies are usually very time and cost ineffective.

Most of the computational design studies in literature that target ideal scaffold geometries with desired functional properties do not account for dynamic effects within the scaffold-tissue-cell environment. Among these, topology optimization based studies offer promise to design novel architectures of bone tissue scaffolds1 but mostly have neglected the dynamic mechano-biological nature of regenerative healing2. Unlike topology optimization, scaffold design studies based on parametric size optimization3 and mechano-biological regeneration models offer limited design freedom, hence resulting designs are not necessarily the best candidates to ensure effective healing.
Moreover, angiogenesis - a critical part of the regeneration process- and scaffold degradation are not considered in any of these studies together despite their known coupled effect in healing. To address these limitations, we propose, for the first time, a computational framework to design the optimal microstructure of scaffolds that maximize bone formation considering mechano-biology, angiogenesis and scaffold degradation simultaneously. Thus, our model includes the following 4 parts in an integrated fashion: 1. Mechano-biological model describing tissue differentiation, 2. Angiogenesis, 3. Topology optimization targeting maximum bone formation, and 4. Time dependent degradation of the bone scaffold.

The proposed computational design framework is developed in a MATLAB GUI as an integration of above computational modules with a FEA software, namely COMSOL Multiphysics, a SIMP based topology optimization method and a random walk approach for angiogenesis modeling. The computationally designed scaffolds are compared with existing designs and fabricated based on a recently introduced phase separation technique. Morphological and mechanical characterization techniques will be performed to validate bone regeneration performance of designed bone tissue scaffolds. Integration of the proposed computational framework to existing experimental studies should pave the way for more efficient and low-cost solutions in bone tissue engineering.

**Keywords:** Tissue engineering, bone tissue scaffold, topology optimization, mechano-biology, angiogenesis, scaffold degradation.

**Modulation of Chemical Reactivity by Strong Coupling to Molecular Vibrations**

Wonmi Ahn, Igor Vurgaftman, Adam Dunkelberger, Jeffrey Owrsutsky and Blake S. Simpkins; 1Excet Inc., United States; 2U.S. Naval Research Laboratory, United States

Quantum emitters placed in resonant optical cavities have shown modified spontaneous emission rates and frequency when they are coupled in the weak coupling regime. In the so-called strong coupling regime, however, the coupled oscillators, i.e., emitters and optical modes, exchange energies inextricably, creating new hybrid states called polaritons. Recently, this half-light half-matter quasi-state has been demonstrated in a system where molecular vibrations are coherently coupled to optical cavity modes. In this talk, we will demonstrate our recent results on the vibrational strong coupling, with a particular focus on its ability to modify chemical reactivity. We monitor transmission spectra of the Fabry-Pérot microcavity filled with species that cause a simple addition reaction. Both reactants and products have strong molecular vibrations that couple to the optical cavity modes, resulting in quantifiable vacuum Rabi splittings. We examine the reaction rates in and out of the cavity to elucidate the influence of vibrational strong coupling on the chemical reactivity. Our results will extend the potential of cavity-modified material properties, which will have important implications for controlling chemical reactivity and biological activity by light.
Cells sense their environment by transducing mechanical stimuli into biochemical signals. Commonly used tools to study cell mechanosensing provide limited spatial and force resolution. To overcome this limitation, we recently reported a novel platform for monitoring cell forces, which was based on nanowires functionalized with ligands for cell immunoreceptors, and used this platform to explore mechanosensitivity of Natural Killer (NK) cells [1]. We found that nanowires stimulate cell contraction, and, by assessing the nanowire deflection, detected forces of down to 10 pN applied by cells. Furthermore, we found that the combination of (i) nanowire topography and (ii) activating produced enhanced activation of NK cells. Thus, we proposed a mechanosensing mechanism of NK cells, by which they integrate biochemical and mechanical stimuli into a decision-making machinery analogous to AND logic gate, whose output is the immune activation. This mechanosensing platform allowed unprecedented integration of biochemical and mechanical cues at the nanometric length-scale. Still, this platform lacked the ability to control another important signaling aspect – the spatial distribution and clustering of extracellular ligands. Indeed, in the physiological immune synapse, ligand-receptor pairs form highly regulated nanometric clusters, whose exact role is still obscure. On the contrary, in our reported nanowire-platforms the activating ligands were immobilized all over the nanowires surface, providing continuous medium for biochemical stimulation of NK cells.

Motivated to investigate the role spatial ligand clustering in cell mechanosensation, we engineered a new nanowire-based platform for mechanical stimulation of NK cells, in which extracellular ligands are spatially confined within specific regions on nanowires. To that end, we grew Si nanowires from Au catalytic nanoparticles, and selectively functionalized the Au nanowire tips, whose size was about 30-50 nm, with biotinylated thiols, to which we conjugated biotinylated anti-NKP30 (activating ligands for NK cells) via neutravidin bridge. We verified that the functionalization is specific to the nanowire tips using fluorescent imaging of the attached avidin. We then stimulated primary NK cells onto the functionalized nanowires, which we grew either as a continuous array, or as ordered separated clusters with a diameter of 5 microns. Interestingly, we detected two sub-populations within the cells stimulated on the clustered nanowires. The first sub-population consisted of cells on the surface among the nanowire clusters. These cells had elongated shape, and expressed very low degree of activation, as assessed by the expression of degranulation marker CD107a. The second sub-population consisted of cells laying on the top of the nanowire clusters. These cells showed high circularity, low spreading area, and enhanced degree of activation, most probably due to the combination of (i) the high compliance of nanowires to the mechanical forces applied by the cells and (ii) the contact formed by the cell with the antigen-functionalized nanowire tips. These newly results confirmed the importance the integration of the mechanical and chemical cues in the immune signaling.

Furthermore, the demonstrated nanowire platform for the cell stimulation presented two new, unprecedented features. On the molecular level, it allows and exquisite control over spatial positioning and clustering of extracellular ligands on the nanowires. On the cell level, it allows three-dimensional spatio-mechano-chemical guidance of the cell motility and immune activity, and paves the way to numerous studies aimed at understanding the integration of mechanical and biochemical signals in cells.

altering actomyosin contractility. Altogether, these findings demonstrate a key role for matrix plasticity in MSC biology and spreading, and we anticipate this will have ramifications in the design of biomaterials to control cell function and fate and in numerous biological contexts where matrix properties are altered.

Photoresponsive Materials for Resolving Mechanobiology in Collective Cell Migration Jun Nakanishi; National Institute for Materials Science, Japan

Collective cell migration is the migration of cells in a group rather than individually. It plays a pivotal role not only in physiological processes, including morphogenesis, wound healing, and immune responses, but also in pathological ones, such as cancer invasion, metastasis, and tissue fibrosis. In addition to such involvements in various biological reactions, collective migration draws interests of researchers as it includes emergent collective characteristics that cannot be expected from simple summation of multiple single cells. For example, at the leading edges of migrating epithelial cell sheets, boundary cells are divided into actively migrating “leader cells” with frequent extension of lamellipodia and “follower cells” following the leaders. Also, some of cell collective exhibit autonomous group rotation with preferential asymmetry (left or right). All of these phenomena indicate that surrounding cells are not mere physical hindrance, rather those cells chemically and mechanically communicate with each other and against their extracellular matrices (ECMs) to function as an active soft matter. To decipher such complex regulation mechanisms of collective phenotypes from the reductionism viewpoint, our group is developing photoactivatable substrates based on photocleavable poly(ethylene glycol), where collective migration can be analyzed spatiotemporally under controlled chemical, mechanical, and geometrical cues (1-3). In this presentation, I will represent some of our recent progresses in the development and applications of the photoactivatable substrates, with special focus on the impact of chemical and mechanical cues on leader cell formation. I will also represent our new photoresponsive materials that can be used for analyzing collective behaviors on dissipative matrices.

Dynamic, Reversible Control of Biomaterial Properties Using DNA Nicholas Stephanopoulos; Arizona State University, United States

The ability to dynamically control the mechanical properties of biomaterials is critical for regenerative medicine applications. For example, matrix stiffness controls the differentiation of stem cells, or the metastasis of cancer cells. However, most methods for tuning the mechanical properties of 3D hydrogels are not reversible, or involve potentially harmful stimuli like UV light. Here we use DNA as a programmable crosslinker to reversibly change the stiffness of gelatin hydrogels. We modified DNA with a methacrylate moiety, allowing it to be crosslinked along with methacrylated gelatin (GelMA). By tuning the amount of pre-formed DNA crosslinks relative to GelMA, we were able to tune the stiffness of the hydrogels obtained from 0.5 – 2 kPa, as measured by an AFM-based method. The crosslinkers contained single-stranded toehold sequences, allowing them to be broken by adding fully complementary displacement strands. The stiffness of the formed hydrogels could be tuned through the amount of
displacement strand added, and the process was reversible: adding more crosslinker restored the stiffness to the original value. We explored various crosslinker lengths, designs, and geometries (including branched and more rigid multi-helical DNA tiles), demonstrating the straightforward tunability of DNA. The use of GelMA allows for photopatterning of hydrogels into micron-sized patterns, and cells could be incorporated into the materials and responded to the reversible changes in stiffness. DNA-based crosslinking also enables spatial patterning of stiffness, and will allow for incorporation of multiple ligands in a programmable manner to impart the gels with bioactivity. We will also outline chemical strategies for incorporating DNA into other biomaterial scaffolds, such as hyaluronic acid or PEG, demonstrating the versatility of our approach. We envision that DNA-based control of stiffness will allow for programmable and reversible control of hydrogel properties, and lead to advanced biomaterials for regenerative medicine, tissue engineering, and fundamental biological studies.

Design and Development of Mechanobiological Gels That Can Control Mechanical Property Takeshi Ueki¹, Ryota Tamate¹, Aya Akimoto², Ryo Yoshida² and Jun Nakanishi¹; ¹National Institute for Materials Science, Japan; ²The University of Tokyo, Japan

Mechanical environment around cells, not only physiological chemistry surrounding cells, strongly affects cell behaviors such as spreading, proliferation, and differentiation. Here, we describe a novel platform of cell culture scaffold that possesses tunable mechanical property. The design strategy for the materials includes self-assembly of block copolymers, photo-responsiveness, and solvent engineering of polymer gels. We show a 3D cell scaffold gel as one example that can change stress relaxation surrounding cells on demand. The gel is made by self-assembly of a well-defined coumarin containing ABA triblock copolymer. We demonstrated that the cell spreading embedded the 3D scaffold dynamically changes corresponding stress relaxation of gels.

Building with Cells—Exploiting Mechanobiology to Use Living Cells as an Engineering Material Kevin Kit Parker; Harvard University, United States

Some engineers build with steel, copper, polymer composites, and wood. Bioengineers build with cells and because these cells are alive, they have a vote in our successes or failures. Our team has spent the last 15 years understanding how cells build themselves, how tissues assemble themselves, and the emergence of structure-function relationships in organs. These hierarchal organizations span from nanometer to meter length scale and have provided insight, and useful tools for drug discovery, toxicology, food, and regenerative medicine. This presentation will discuss how we have tried to understand the architecture and function of biological pumps, both in marine lifeforms and human organs, to understand the fundamental design principles that allow cells to serve as engineering materials.

Bioinspired Materials for Deconstructing Matrix Structure-Cell Function Relationships Kristopher Kilian; University of New South Wales, Australia

The extracellular matrix surrounding cells in tissue is a dynamic composite material, where the presentation of biophysical and biochemical information directs functional bioactivities. We are interested in how the properties of the extracellular matrix guides tissue form and function and have developed a suite of engineered extracellular matrices to probe matrix structure-cell function relationships. Microengineered hydrogels that control tissue geometry, mechanics and composition have served to model how the microenvironment may exert an influence on
The Adaptive Behavior of Cells as Archetype for Novel Strain-Stiffening Structures

Cells have developed several mechanisms to protect themselves from physical damage. One of these mechanisms is the cell's ability to form stress-fibers as a response to mechanical deformation. This can for example be observed in epithelial cells that form stress-fibers to withstand the cyclic deformation of a blood vessel. Stress-fibers are cross-linked bundles of actin-filaments that show a higher stiffness than the underlying unlinked filaments. This ability to actively increase the stiffness as a response to deformation was the archetype for the development of our innovative strain-stiffening structures. A material behaves strain-stiffening if its stiffness is increased with increasing deformation. This behavior is desired for engineering applications like damping systems or shock absorbers where all requirements are met with already available materials. But these materials have disadvantages that make them unsuitable for special applications like novel orthotic devices or artificial blood vessels. The stiffening is either not reversible, highly dependent on the rate of deformation, can only be achieved with special materials or only occurs when the material is compressed. By taking advantage of the strain-stiffening mechanism we observed in cells, we were able to come up with structures that do not show any of these disadvantages. Our structures contain parallel slats, as a resemblance of cytoskeletal fibers, that touch each other upon deformation. This mimics the cross-linking of cytoskeletal fibers. The touching of the slats also leads to a change of mechanical properties of the entire material and its stiffness is increased. This effect is completely reversible, does not depend on the rate of deformation and every elastic material can be brought into the developed geometry. By variations of the geometry and the underlying material we are able to finely tune the mechanical properties of the structure and define, if the stiffening occurs upon compression or elongation. The influence of several geometrical factors on the strain-stiffening behavior was determined via finite element simulations and tensile tests. With the help of our novel strain-stiffening structures more comfortable orthotic devices and more compliant artificial blood vessels are now in development.

Stiff and Responsive Hybrid Bacterial Assemblies through Covalent Crosslinking of Nanoparticles to Engineered Bacterial S-Layer Proteins

Engineered Living Materials (ELMs) that incorporate genetically modified cells to actively adjust the expression and organization of biomacromolecules are excellent candidates for applications in bioelectronics, biosensing, enzyme biocatalysis, and smart materials. Here we report a new strategy to create an ELM using *Caulobacter crescentus*. The surface layer (S-layer) protein of *C. crescentus* has been engineered to display a 2D array of functional peptide, *i.e.* SpyTag, over the entire cell body. A layer of closely packed nanoparticles is attached to the recombinant protein lattice through formation of SpyCatcher-SpyTag iso-peptide bond. The functionalized bacterial cells are further crosslinked into hierarchically ordered 3D assemblies. Stiffness of the self-assembled bacterial assemblies increases more than 30 times compared to non-crosslinked case. Cleavage of a disulfide bond inserted between SpyCatcher and the nanoparticles results melting of the bacterial assemblies, indicating the specific covalent linkage between S-layer proteins and nanoparticles is responsible for the enhanced mechanical properties. In the presence of excess nanoparticles, the crosslinked bacterial assemblies can autonomically self-regenerate after being damaged due to the continuous growth of *C. crescentus* cells and the expression of new S-layer proteins. Furthermore, the bacterial that coated with magnetic nanoparticles can form cohesive assemblies guided by external magnetic field, and the shape of the assemblies maintains when the magnetic field is removed due to the crosslinking. The ubiquity of S-layers in almost all archaea and many bacteria indicates the current crosslinking method could be applied to other microbe systems to create new ELMs with tunable mechanical properties.
Lipid vesicles are aqueous volumes surrounded by a bilayer of lipid molecules, which are amphiphilic molecules with their head groups facing water and tail groups facing oil. These vesicles are simple models that mimic cell membranes and can be used for drug delivery. Similarly, block copolymers are amphiphilic molecules that form vesicles by themselves or when mixed with lipids. Like lipid vesicles, polymer vesicles can also be used for cell membrane mimicry and drug delivery. One interesting type of lipid/polymer vesicle is the asymmetric vesicle, in which its bilayer is composed of two dissimilar lipid monolayers or a lipid monolayer and a polymer monolayer. Importantly, all eukaryotic cell membranes exhibit this type of asymmetry and asymmetry is also proposed to enhance mechanical properties of the membrane. Here, we use microfluidics to fabricate mono disperse and highly controllable asymmetric vesicles, which unlike the conventional methods that often end up with highly poly disperse samples. To achieve this, asymmetric vesicles are produced using water/oil1/oil2/water emulsions in a glass capillary device, with different lipids/polymers immersed in two different volatile oil phases. Using the asymmetric vesicles, we are trying to measure how mechanical properties are affected by this asymmetry and also how to improve the degree of asymmetry in our vesicles even more. In future, we envision asymmetric lipid/polymer vesicles could open a new door in the field of drug delivery.

Mechanophores are force sensitive molecules that undergo productive chemical transformations under a mechanical force including color change, small molecule release, and cross-linking. Mechanophore reactivity depends on the intrinsic molecular structure as well as the extrinsic environment of the mechanophore. This presentation summarizes the extrinsic, force-focusing effects of mechanochemical activation at an interface. New methodologies are developed to characterize interfacial mechanochemical transformations for two different color-changing mechanophores. Maleimide–anthracene (MA) mechanophores covalently anchored at a fused silica–polymer interface are activated using laser-induced stress waves. In contrast to activation in solution or bulk polymers, whereby a proportional increase in mechanophore activity is observed with applied stress, interfacial activation occurs collectively with spallation of the polymer film. MA mechanophores located at the interface between poly-(glycidyl methacrylate) (PGMA) polymer brushes and Si wafer surfaces were also activated locally using atomic force microscopy (AFM) probes. In a separate set of experiments, the reaction of spiropyran (SP) mechanophores is demonstrated at nanoparticle/polymer interfaces. A new SP mechanophore containing a pentene and alkyl bromide group at each pulling point was designed and synthesized for functionalization of silica nanoparticles. The mechanical activity of the SP functionalized at the interface between silica particles and a polymer matrix is compared with that of SP linked directly into bulk polymers. As anticipated, the interfacial mechanophores exhibit more efficient mechanical activation under tensile loading.

Nature has effectively revised engineering designs of elastomeric biopolymers through years of evolutionary history. In this work, we examine the molecular and multiscale mechanisms of elasticity of biopolymers exhibiting...
exceptional elasticity in vivo to deduce design principles and mechanisms that can be used to develop novel elastic biopolymers for medical and engineering applications. We consider two examples from nature: resilin, a biopolymer found in insect cuticles and elastin, a key component within the extracellular matrix of elastic tissues in mammals. We use molecular models to compare effects of sequence and structural hierarchy, hydration, librational effects and temperature on elasticity. Through this comparison, we identify unifying principles that can be used for rational design of elastomeric biopolymers.

Morphogenic Patterning in Synthetic Polymers Evan M. Lloyd1,2, Adam Feinberg1,2, Philippe Geubelle1,2, Nancy R. Sottos1,2 and Jeffrey Moore1,2; 1University of Illinois at Urbana-Champaign, United States; 2Beckman Institute for Advanced Science and Technology, United States

Complexity in biological systems spontaneously emerges from an initial state of symmetry through coupled reaction and diffusion, a process known as morphogenesis. In this work, we explore the coupled reaction and thermal diffusion inherent to frontal ring-opening metathesis polymerization (FROMP) of dicyclopentadiene (DCPD) as a synthetic mimic to biological morphogenesis. Propagation instabilities arise from an initial state of symmetry and generate patterns of thermal fluctuations on multiple length scales. Incorporation of thermo-active small molecules enables spontaneous patterning of the optical, chemical, and mechanical properties of structural thermosets. Material stiffness and glass transition temperatures were found to vary by up to two-fold and 30 °C, respectively. Control over patterns by tuning reaction and diffusion rates will also be discussed.

Embodied Intelligence and Energy in Autonomous Matter Rob Shepherd; Cornell University, United States

Embodied Intelligence is the principle that describes autonomous mechanical responses to external environmental inputs (e.g., stress causes strain). This concept has been explored in depth previously and has resulted in a variety of compliant mechanisms and smart materials that combine, for example, the functions of structure and actuation. Energy (e.g., Chemical, Mechanical, Electrical, Optical) sources can also be put to multifunctional use; for example, a lead-acid battery being used a counterweight in a forklift. A more principled approach to Embodied Energy, however, does not presently exist. This talk will, for the first time, introduce this concept and focus on specific examples of forming these energy sources at a finer scale, into structural and other functional components and composite materials that provide benefits in the form of reduced SWaP tradeoffs. Examples of how these energetic composites and their chemo-electro-opto-mechanical responses can be tuned to perform work autonomously or in cooperation with higher level sensing and control for augmenting, supplementing, or replacing some robotic systems, including morphing structures, will be presented, and identification of gaps and future needs will also be discussed.

Cells, Gels and Shear—Designing Soft Materials for Biomedicine Angela Pitenis; University of California, Santa Barbara, United States

Epithelial cells are the body’s front-line defenders against foreign objects and environmental challenges and could be considered the biological equivalent of surface engineers. These cells continuously secrete high water content mucin gels to protect approximately 400 square meters of underlying cells, tissues, and organs from damage. Surfaces involving intentional and frequent sliding contact – such as the cornea, the digestive and reproductive...
tracts, and many distal interfaces for organs and tissues – adopt a stratified epithelial tissue approach. Epithelial cells are sophisticated sensors of mechanical stresses; friction and the resulting direct contact shear stresses have been shown to increase gene expression of pro-inflammatory cytokines and pro-apoptotic markers in vitro. In this work, a suite of experiments was performed under acute and chronic conditions to explore the onset and progression of apoptosis in corneal epithelial cell monolayers using in situ fluorescence microscopy and a custom-built microtribometer with aqueous gel probes. Recent results suggest that the onset of apoptosis occurs near physiological shear stresses (<100 Pa), although direct contact pressures in the absence of sliding did not initiate apoptosis, even at contact pressures approaching 3,000 Pa. These findings may help inform future designs of soft implants to mitigate friction-induced inflammation.

Mechanically Tunable Structured Hydrogels and Their Impact on Cells Katharina Siemsen¹, Chanh Hu Trinh¹, Florian Ceynowa¹, Rainer Adelung¹, Jan Lammerding² and Christine Selhuber-Unkel³; ¹Kiel University, Germany; ²Cornell University, United States

The mechanical properties of different mammal tissues vary within the body. Starting with the structural components of the body like bones with a Young’s modulus of several hundreds of kPa down to soft tissue like the brain with a Young’s modulus of 1 kPa and below.¹ This knowledge is important for the development of synthetic material for biomedical applications. It is assumed, that a mismatch between implant material and tissue can lead to scar tissue formation and tissue remodeling. Consequently, the understanding and investigation of the link between the mechanical properties and the structure of an implant material and the tissue response are essential. Another critical point is that cells in the body are often situated in a 3D structured and porous environment. Therefore, it is important to mimic such environments in implant materials to investigate questions such as how single cells migrate through different 3D constrictions and the consequences on the cells.

A step towards studying these questions is the use of a synthetic and 3D structured material, which closely mimics the natural tissue and its environment with similar hydration and mechanical properties. We developed a 3D environment consisting of a polyacrylamide hydrogel with interconnected and hollow microchannels.² It enables to vary the Young’s modulus by changing the chemical composition of the crosslinker to match elasticity values within a certain (soft) tissue regime up to 120 kPa.

Using such materials, we are investigating different hydrogel stiffness (1 kPa – 50 kPa) and the consequences of compliant and incompliant material mechanics towards cell behavior in 3D environments. With the possibility of using different adhesion ligands for the biofunctionalization such as collagen or fibronectin, we are able to specifically induce cell adhesion of different cell types. These cell types include pathogenic species, such as Acanthamoebae castellanii, for which we can use the hydrogel microchannels as biomedical capture device. Another possibility is the usage of cells with a preference to soft tissue surroundings such as fibrosarcoma cells, which act as an excellent robust role model for cells of the soft tissue region.

In conclusion, we show an artificial 3D interconnected environment with designed Young’s moduli and our investigation towards the influences on the cellular behavior of fibrosarcoma cells such as adhesion and migration on and within interconnected microchannels.

Hyper-Activation of Cellular Rigidity Sensing Pathways by the Surface Tension of Biomedical Silicones Zhu Cheng, Carolyn Shurer, Samuel Schmidt, Vivek Gupta, Grace Chuang, Jin Su, Amanda Watkins, Jason Spector, Chung-Yuen Hui, Heidi Reesink and Matthew Paszek; Cornell University, United States

Silicone gels are commonly used for the encapsulation and construction of implantable medical devices. Viscous silicone “oils” are also commonly used for lubrication of current-generation pre-fillable syringes, which are known to expel silicone oil droplets into patients during administration of aqueous drug formulations. While silicones are generally viewed as relatively inert to the cellular milieu, they can mediate a variety of inflammatory responses and other deleterious effects, but the mechanisms underlying the bioactivity of silicones remain unresolved. Cells physically interrogate their extracellular environment to make decisions related to cell proliferation, migration
and other critical processes. In addition to biochemical signals, physical properties of the extracellular matrix, including its stiffness, are key regulators for cell behaviors. Typically, on stiff substrates, cells display large spreading areas, assemble robust integrin-based adhesion complexes, whereas on soft substrates these functions are suppressed. However, cell behaviors that defy expectations based on substrate rigidity alone have been observed.

Here, we report that silicone liquids and gels have high surface stresses that can strongly resist deformation at cellular length scales. We demonstrate that cells interacting with soft materials with high surface tension primarily sense and respond to surface tension and not the bulk elastic moduli of the materials. Our results are consistent with theory that predicts that solid surface tension can dominate over elasticity at cellular length scales. On silicone materials with appreciable surface tension, cells assemble robust adhesion complexes and cytoskeleton stress fibers, spread over large areas, upregulate canonical integrin-based signal transduction, proliferate and migrate efficiently. Grown directly on the interior materials of silicone breast implants, cells are well spread and show nuclear localization of gene transcriptional factor YAP. In 3D culture models, liquid silicone droplets support robust cellular adhesion and the formation of multinucleated monocyte derived cell masses that recapitulate phenotypic aspects of granuloma formation in the foreign body response.

Together, our results indicate that material surface tension is a cellular stimulant that should be considered in application of silicones for biomedical purposes.

4:30 PM *SB06.09.04
Mechanobiology in the Hematopoietic Stem Cell Niche Cornelia Lee-Thedieck; Leibniz University Hannover, Germany

The hematopoietic stem cell (HSC) niche in the bone marrow is a unique microenvironment, which controls HSC maintenance and differentiation throughout the entire lifespan. HSCs are the source of all blood cells that are produced in billions on a daily basis. The niche is the only place, where HSCs can expand while keeping their stem cell properties. Thus, recreating the HSC niche in the lab for producing HSCs for clinical applications is an intriguing research objective that is pursued since the 1960s, when HSC transplantation became a life-saving treatment option for patients with hematological diseases. In this endeavor, researchers have concentrated for a long time on the influence of biological and chemical factors that are naturally found in the niche on HSCs. Only during the last decade, the importance of physical parameters – including 3D architecture, nanostructure and mechanical stimuli – became evident. We and others could show in vitro that human hematopoietic stem and progenitor cells are mechanosensitive and we proposed a model, how mechanical properties in the HSC niche might change and thus influence HSC behavior under different physiological conditions. Nevertheless, most in vitro experiments to test the mechanosensitive responses of cells still rely on hydrogels, in which the crosslinking degree is modulated to tune the mechanical properties of the resulting polymer network. Changing the crosslinking degree, however, does not only change the E modulus of hydrogels, but also their porosity, hydrophilicity or other parameters at the same time, which makes it impossible to conclude on the influence of one particular parameter from these experiments. To overcome this challenge, we developed a new platform-technology allowing to investigate mechanotransduction in a hydrogel-independent way. In a proof-of-principle study we could show that this platform allows to decouple mechanical from biochemical properties of biomolecules and thus to investigate the influence of both parameters on cells independently from each other. The results of these studies will help us to gain a fundamental understanding of the role of mechanobiology in the HSC niche, which might be an important step towards the goal of an artificial niche for HSC production for clinical applications.
Cell invasion into the surrounding matrix from non-vascularized primary tumors is the main mechanism by which cancer cells migrate to nearby blood vessels and metastasize to eventually form secondary tumors. This process is mediated by an intricate coupling between intracellular and extracellular forces that depend on the stiffness of the surrounding stroma and the alignment of matrix fibers. A multiscale model is used to elucidate the two-way feedback loop between stress-dependent cell contractility and matrix fiber realignment and strain stiffening, which enables the cells to polarize and enhance their contractility to break free from the tumor and invade into the matrix. Importantly, our model can be used to explain how morphological and structural changes in the tumor microenvironment, such as elevated rigidity and fiber alignment prior to cell invasion, are prognostic of the malignant phenotype. The model also predicts how the alignment of matrix fibers can recruit macrophages, which are among the first responders of the innate immune system following organ injury and are crucial for repair, resolution, and re-establishing homeostasis of damaged tissue. I will discuss how the deformation of the nucleus during migration can lead to changes in the spatial organization of chromosomes and their intermingling which can result in genetic mutations and genomic instability. I will also discuss how targeting extracellular matrix mechanics, by preventing or reversing tissue stiffening or interrupting the cellular response in cancer and fibrosis, is a therapeutic approach with clinical potential.

**BIO:** Vivek Shenoy is the Eduardo D. Glandt President’s Distinguished Professor in the School of Engineering and Applied Sciences at the University of Pennsylvania. Dr. Shenoy’s research focuses on developing theoretical concepts and numerical methods to understand the basic principles that control the behavior of both engineering and biological systems. He has used rigorous analytical methods and multiscale modeling techniques, ranging from atomistic density functional theory to continuum methods, to gain physical insight into a myriad of problems in materials science and biomechanics. Dr. Shenoy's honors include a National Science Foundation CAREER Award (2000), the Richard and Edna Solomon Assistant Professorship (2002-2005) and the Rosenbaum Visiting Fellowship from the Isaac Newton Institute of Mathematical Science, University of Cambridge and the Heilmeier award for excellence in faculty research (2019). He is the principal investigator and director of the NSF-funded Science and Technology Center for Engineering Mechanobiology established in 2016. He also serves the editor of the Biophysical Journal and is a fellow of the American Institute for Medical and Biological Engineering.

**Biomechanical Imaging of Cancer Cells and Tumor Development in 3D**

*Ming Guo; Massachusetts Institute of Technology, United States*

Sculpting of structure and function of three-dimensional multicellular tissues depend critically on the spatial and temporal coordination of cellular physical properties. Yet the organizational principles that govern these events, and their disruption in disease, remain poorly understood. Here, I will introduce our recent progress performing biomechanical imaging to quantify cell and extracellular matrix (ECM) mechanics, as well as their mechanical interaction. By integrating confocal microscopy with optical tweezers, we have developed a platform to map in three dimensions the spatial and temporal evolution of positions, motions, and physical characteristics of individual cells throughout a growing mammary cancer organoid model. Compared with cells in the organoid core, cells at the organoid periphery and the invasive front are found to be systematically softer, larger and more dynamic. These mechanical changes are shown to arise from supracellular fluid flow through gap junctions, suppression of which delays transition to an invasive phenotype. Together, these findings highlight the role of spatiotemporal coordination of cellular physical properties in tissue organization and disease progression.

**3D Traction Force Microscopy of Multicellular Invasion in Biomimetic Silk-Collagen Hydrogels**

*Susan E. Leggett¹, Mohak Patel¹, Thomas M. Valentin¹, Christian Franck² and Ian Y. Wong¹; ¹Brown University, United States; ²University of Wisconsin–Madison, United States*

Epithelial tumors exhibit dysregulated cell-cell and cell-matrix adhesions as they invade into the surrounding extracellular matrix. In particular, the epithelial-mesenchymal transition (EMT) is associated with weakened cell-cell adhesions and strengthened cell-matrix adhesions, resulting in multicellular dissemination. Traction force microscopy enables new insights into the cell-generated forces that mediate these behaviors, but has primarily been
applied to individual cells in 3D. Here, we elucidate the collective tractions of multicellular clusters in 3D matrix after induction of the EMT master regulator Snail. We find that multicellular clusters exhibit characteristic spatial signatures that can be used for mechanophenotypic profiling. In particular, EMT results in highly localized “hotspots” of strong cell-matrix adhesion, associated with high contractility and front / back polarization. We further show that chemotherapeutics and targeted inhibitors can perturb clusters towards more epithelial or mesenchymal-like mechanophenotype. We envision that this 3D culture assay will enable high content preclinical screening of targeted anticancer compounds as well as to predict the clinical response of human patient samples.

9:45 AM SB06.10.04/SB09.08.04
Unjamming and Collective Migration in MCF10A Series of Breast Cancer Cell Lines Jae Hun Kim and Jeffrey Fredberg; Harvard University, United States

Carcinoma cells tend to migrate in collective strands, ducts, sheets or clusters (Friedl, & Gilmour, Nat. Rev. Mol. Cell. Bio. 2009). To migrate collectively, the epithelial collective has been argued to overcome geometric constraints attributable to cell jamming (Atia et al., Nat. Phys. 2018). If so, then the greater is the degree of cellular jamming, then the more would be the extent to which each individual cell becomes caged by its neighbors, and therefore, the less rapidly it would be able to migrate (Park et al., Nat Mat. 2015). The jamming hypothesis, however, has never been tested in the context of cancer cell invasiveness. Using classical in vitro cultures of six breast cancer models, here we investigate structural signatures of jamming, dynamical signatures of jamming, and the relationship between them. In order of increasing invasiveness, the cell lines examined included MCF10A, MCF10A.vector; MCF10A.14-3-3z; MCF10.Erb2, MCF10AT; and MCF10CA1a. Across all models tested, cell shape and shape variability from cell-to-cell conformed well to structural signatures of cell layer jamming. In all cases but one, migratory dynamics changed roughly in concert with expectations based on structural signatures –as the strength of structural signatures of unjamming increased, the rapidity of migratory dynamics tended to progressively increased. The exception was the case of MCF10CA1a, wherein structure signified a moderately jammed state whereas migratory dynamics were excessively rapid and therefore discordant with structure. Closer examination of migratory dynamics of MCF10CA1a showed anomalously large migratory persistence, but the mechanism of discordance in this case remains unclear. A hallmark of cancer is multiple dimension of heterogeneity. Nevertheless, each of the diverse cases examined here reveals that cell jamming imposes an overriding geometric constraint.

Mechanical Forces, the Microenvironment and Metastasis of 3D Microtumors Joe Tien¹, Celeste Nelson² and Bryan A. Nerger²; ¹Boston University, United States; ²Princeton University, United States

Progression to metastatic breast cancer requires cancer cells to invade from a solid tumor into the surrounding stroma and escape into a lymphatic or blood vessel. To understand the biophysical and biochemical parameters that define the kinetics of invasion and escape, we engineered a three-dimensional model of human breast microtumors embedded within native extracellular matrix. We previously found that interstitial fluid pressure (IFP) determines the invasive response of human breast microtumors: specifically, interstitial hypertension (i.e., elevated IFP) prevents invasion, whereas interstitial hypotension (i.e., lowered IFP) promotes invasion. We have now used this system to examine the effects of matrix density, proteolysis, proliferation, and IFP on the kinetics of tumor cell escape into an empty cavity. Our data suggest that the physical microenvironment of a tumor dictates the rates of two early steps in the metastatic cascade, namely, invasion of the surrounding interstitium and escape into an open space. These physical features dictate whether escape results from a ballistic or diffusive invasion process. Furthermore, acute changes in interstitial pressure can suppress tumor cell escape after invasion has already occurred. Our results point to the possibility of using physical therapies to delay or prevent metastatic progression in breast cancer.

11:00 AM *SB06.10.06/SB09.08.06
Engineered Microfluidic Environments to Study the Role of Nuclear Mechanobiology in Cancer Progression Jan Lammerding; Cornell University, United States
Cancer metastasis, i.e., the spreading of cells from the primary tumor to distant organs, is responsible for more than 80% of all cancer deaths. During cancer cell invasion and metastasis, tumor cells migrate through interstitial spaces and transendothelial openings substantially smaller than the diameter of the cell. Recent research has made it apparent that cells migrating in such confined three-dimensional (3D) environments face substantially physical challenges. In particular, the cell nucleus is the largest and stiffest organelle, making nuclear deformation a rate-limiting factor in the passage of cells through confined 3D environments. We have used micro- and nano-fabrication approaches to generate microfluidic devices that closely mimic the physical constraints of physiological interstitial environments, while providing precise control over the constriction geometry and enabling live-cell imaging at high spatial and temporal resolution. Using these devices, we demonstrated the importance of available pore size and nuclear deformability on the ability of cells to move through 3D environments. We combined these devices with fluorescent reporters for nuclear envelope rupture and DNA damage to assess the functional consequences of the physical forces exerted on the nucleus during confined migration. In addition, we developed a microfluidic micropipette aspiration device to rapidly measure nuclear stiffness in large numbers of cells. We found that highly metastatic breast cancer cells had decreased levels of the nuclear envelope proteins lamin A/C, which determine nuclear deformability, compared to less aggressive tumor cells, and that the increased nuclear deformability promoted migration through tight spaces. Increasing expression of lamin A in breast cancer cells with normally low levels of lamin A/C significantly impaired their invasive properties, while depletion of lamin A/C increased invasive potential through micron-scale microfluidic constrictions and dense collagen matrices. Importantly, analysis of human breast tumor tissue microarrays showed that low levels of lamin A/C correlated with reduced disease-free survival, demonstrating the clinical relevance of our findings. Taken together, these studies indicate that downregulation of lamin A/C could promote both cancer cell invasion and metastasis in breast cancer while highlighting the appeal of engineered materials and microenvironments to study tumor cell mechanobiology. Insights gained from this work could improve prognostic approaches; ultimately, targeting regulator pathways associated with altered lamin expression may offer novel therapeutic avenues to control metastatic disease in breast cancer.

The National Cancer Institute’s Support for the Interface of Bio/Nano Materials with Cancer Research Nas Zahir; National Cancer Institute, United States

The U.S. National Cancer Institute (NCI) leads, conducts, and supports cancer research across the nation to advance scientific knowledge and help people live longer, healthier lives. Many advancements in cancer research in areas of progression, metastasis, and treatment response have been enabled by the development of innovative technologies, including novel biomaterials, microfluidics, and biomimetic engineered technologies. Several programs at the NCI have helped foster cancer technology development in these areas as well as the overall convergence of approaches and perspectives from the physical sciences and engineering into cancer research. Over the past decade, the NCI has supported the NCI Physical Sciences – Oncology Network (PS-ON), which is comprised of nearly 30 transdisciplinary teams that integrate physical sciences perspectives with cancer research to complement and expand on our current understanding of cancer across many biological length- and time-scales. Thematic areas under investigation in the PS-ON include transcriptional dynamics and genomic architecture, modeling evolutionary dynamics of treatment response, cancer mechanobiology and the physical microenvironment, and multi-scale computational modeling approaches to integrate data across length scales. PS-ON investigators and those in the affiliated Cancer Tissue Engineering Collaborative (TEC) research program are utilizing biomaterials and biofabrication for experimental model systems of cancer that recapitulate the tumor microenvironment and tumor-stromal interactions. There is also sophisticated incorporation of bioreactors and microfluidic culture to mimic perfusion, lymphatics, interstitial pressure, and molecular gradients. Other research initiatives supported by the NCI to promote convergent, cross-disciplinary research that include projects incorporating novel biomaterials are the Cancer Systems Biology Consortium (CSBC) and the Innovative Molecular Analysis Technologies (IMAT). The NCI demonstrates its interest in supporting materials science and engineering in cancer research by investment in these areas through investigator-initiated research and the targeted programs. The continued investigation of the physical dynamics of cancer and incorporation of novel biomaterials and biomimetic engineered technologies will be important, focusing on understanding the complex and dynamic multiscale interactions of the tumor, host, and immune system. Innovative technology development will continue to be critical for unprecedented measurements and discoveries in cancer research.

The Dynamic and Reciprocal Relationship between Tissue Tension and Pro Tumor Immunity Valerie Weaver; University of California, San Francisco, United States

Tumors show increased tissue level forces and a present with a chronically stiffened extracellular matrix (ECM), and transformed cells exhibit a perturbed oncogene-stimulated and ECM-tuned mechanophenotype. We have been studying how these aberrant cell and tissue level forces promote malignant transformation and drive tumor metastasis, and how they modulate tumor recurrence and treatment resistance in breast and pancreatic cancer and glioblastoma. We use two and three dimensional culture models with tuned extracellular matrix stiffness, as well as transgenic and syngeneic mouse models, human PDX models and human biospecimens, in which ECM crosslinking and stiffness and integrin mechanosignaling can be quantified and modified. Our studies have thus far revealed that the ECM in all tumors is progressively remodeled and stiffened by stromal fibroblasts and that this occurs prior to malignant transformation. We determined that ECM remodeling and stiffening is mediated very early during malignancy by stromal fibroblasts that are activated by factors including TGFb that are secreted by infiltrating pro-inflammatory macrophages. The stromal-fibroblast stiffened ECM disrupts tissue organization, promotes cell growth and survival and drives cell invasion. A chronically stiffened tissue stroma drives angiogenesis, and activates STAT3 to induce key cytokines and chemokines that promote pro-tumor immunity to foster tumor growth and dissemination and impede tumor treatment. The stiffened ECM also drives an epithelial to mesenchymal transition and primes the metastatic niche to foster metastasis. I will discuss the dynamic and reciprocal interplay between tissue tension and innate and acquired immunity and how this can not only force tumor aggression and metastasis but may also initiate tumor progression.
Hydrogels, highly hydrated cross-linked polymer networks, have emerged as powerful synthetic analogs of extracellular matrices for basic cell studies as well as promising biomaterials for regenerative medicine applications. A critical advantage of these synthetic matrices over natural networks is that the biophysical and biochemical properties of the material can be tuned with high control and precision. For example, bioactive functionalities, such as cell adhesive sequences and growth factors, can be incorporated in precise densities. We have engineered poly(ethylene glycol) [PEG]-maleimide hydrogels that support improved pancreatic islet engraftment, vascularization and function in diabetic models. Two biomaterial strategies will be discussed. We have developed proteolytically degradable synthetic hydrogels, functionalized with vasculogenic factors, engineered to deliver islet grafts to extrahepatic transplant sites via in situ gelation. These hydrogels induce differences in vascularization and innate immune responses among subcutaneous, small bowel mesentery, and epididymal fat pad transplant sites with improved vascularization and reduced inflammation at the epididymal fat pad site. This biomaterial-based strategy improves the survival, engraftment, and function of a single pancreatic donor islet mass graft compared to the current clinical intraportal delivery technique. In a second application, we have developed a localized immunomodulation strategy using hydrogels presenting an apoptotic form of Fas ligand (SA-FasL) that results in prolonged survival of allogeneic islet grafts in diabetic mice. A short course of rapamycin treatment boosts the immunomodulatory efficacy of SA-FasL-hydrogels, resulting in acceptance and function of allografts over 200 days. Survivors generate normal systemic responses to donor antigens, implying immune privilege of the graft, and have increased T-regulatory cells in the graft. Current studies focus on evaluating this immunomodulatory strategy in a large animal model of type 1 diabetes. This localized immunomodulatory biomaterial-enabled approach may provide an alternative to chronic immunosuppression for clinical islet transplantation.

Viscoelasticity and Cancer

It has long been recognized that tissue mechanical properties are altered in cancer, and this can serve as the basis for early diagnosis. While the impact of changes in tissue stiffness has been the focus of research to date, the role of tissue viscoelasticity has not been widely explored. We have developed hydrogels which allow for independent control over elastic moduli and stress relaxation/creep, and can mimic the fibrillar architecture of native collagenous matrices. These material systems are being utilized in 3D cell culture models of cancer and immunotherapy, and demonstrate that the gene expression of various cell types present in tumors, including cancer cells, mesenchymal cells, and immune cells is profoundly impacted by the viscoelastic properties of their matrix.

Integrin-Specific Hydrogels Direct Mesenchymal Stem Cell Immunomodulation and Bone Regeneration

Mesenchymal stem cells (MSCs) are a promising cell source for regenerative medicine applications due to their ability to self-renew, capacity for multipotent differentiation and secretion of a diverse array of cytokines and growth factors (the MSC secretome). These cells are frequently utilized in conjunction with biomaterial scaffolds designed to encourage cellular retention and direct the cells’ regenerative properties. However, hydrogel carriers have not yet yielded significant results in the clinic in part due to a lack of understanding of how hydrogel biophysical and biochemical properties impact cellular function. Although many synthetic hydrogels incorporate short peptides (e.g. RGD) to support integrin-mediated cell adhesion, the impact of hydrogel adhesive properties on transplanted cell function remains unknown.

We engineered integrin-specific hydrogels for the delivery of MSCs by tethering either the ubiquitous RGD cell adhesion motif or the type-1 collagen derived GFOGER adhesion motif into synthetic poly(ethylene) glycol (PEG)-
based hydrogels. Integrin-specificity was confirmed using blocking antibodies and a custom spinning disk platform in which cells attached to hydrogel disks are exposed to well-defined hydrodynamic shear forces allowing for sensitive measurements of the force required to detach the cell from the substrate. The effects of integrin-specific adhesive peptide presentation on MSC secretome and MSC-macrophage interactions were evaluated in vitro using Luminex multiplex technology. Finally, integrin-specific hydrogel directed MSC bone tissue regeneration was assessed over the course of 8 weeks in a critical size radial bone defect in an NSG mouse model.

Spinning disk analysis shows that cell adhesion to hydrogels presenting the adhesive peptides RGD and GFOGER are specific to αvβ3/β1 and α2 integrins respectively. Luminex data shows that the secretome of MSCs encapsulated in integrin-specific hydrogels cluster distinctly based on peptide and secretion of IL-6, IL-8, and VEGF is increased in GFOGER functionalized gels compared to RGD and non-adhesive controls. Further, in a co-culture assay, we show that macrophage cytokine secretion is differentially modulated by MSCs encapsulated in integrin-specific hydrogels, including an increase in IL-10 secretion by macrophages interacting with GFOGER encapsulated MSCs. Finally, MSCs delivered in GFOGER functionalized hydrogels significantly enhance repair of critical size bone defects in vivo compared to RGD and non-adhesive controls. Taken together, our results demonstrate that integrin specificity can be engineered into synthetic hydrogel systems resulting in modulation of the MSC secretome, differential MSC-macrophage interactions and improved tissue healing.

SESSION SB06.12: Poster Session II: Bringing Mechanobiology to Materials—From Molecular Understanding to Biological Design II

Elucidating the Effects of Direct Physical Contact between Dental Pulp Stem Cells Cultivated on Polybutadiene with Different Stiffness on Proliferation and Differentiation Behaviors
Yihan Shen1, Zijian Ma2, Ya-Chen Chuang3,4, Jessica Hofflich3, Miriam Rafailovich3 and Marcia Simon3; 1St. Andrew's School, United States; 2Tianjin Nankai High School, China; 3Stony Brook University, United States; 4ThINC Facility, Advanced Energy Center, United States

Dental Pulp Stem Cells (DPSCs) have demonstrated immense potential for therapeutic purposes due to their easy accessibility as well as their capacity for self-renewal. Nonetheless, despite the increasing body of knowledge of stem cell transplantation, achieving specificity in cell responses remains challenging. In our previous study, we have shown that monodispersed Polybutadiene (PB) forms a convenient biocompatible scaffold to which cells can adhere without additional coatings. DPSCs plated on these PB substrates were able to adjust their moduli in response to the film thickness. However, a threshold at 2.3 MPa was observed after 28 days such that large amounts of biomineralized deposits would be produced if the substrate moduli were higher than this value. In this work we investigated how direct cell-cell contact of DPSCs cultured on PB substrates with different thicknesses (20nm and 200nm), representing hard and soft substrate mechanics effects, respectively, impacts differentiation pathways. The substrates were designated into 3 groups: contact group, non-contact group, and control group. Cell moduli and morphology were investigated by Atomic Force Microscopy and Confocal Laser Scanning Microscopy, respectively, after the first week of culture. Reverse Transcriptase Polymerase Chain Reaction was performed for selected gene markers: Alkaline Phosphatase (ALP), Runx-related transcription factor (Runx), and late markers, Dentin Sialophosphoprotein (DSP) and Osteocalcin (OCN). The latter served as indicators of odontogenic and osteogenic differentiation. In addition, microarray was conducted to explore whether genetic expressions were affected by cell contacts. Finally, biomineralization images were captured on day 28 using Scanning Electron Microscopy. Our experimental results signify that DPSCs on substrates with different mechanics can alter their behaviors through direct cell-cell contact. No biomineralization was found on either hard or soft substrates when cells physically contact; however, differentiated and non-differentiated cells were
capable of coexisting within a single culture when they did not contact across different substrates, where the phenotype was governed by the substrate mechanics. This study explored the influence of purely mechanical heterogeneity and the significance of cell communication, which are important for applying printed scaffolds as dentin/tooth regenerative biomaterials and promoting stem cell-based treatments.

SB06.12.02
Bio-Inspired and Bio-Mimetic Self-Assembled Materials Sharon Gilead and Ehud Gaizt; Tel Aviv University, Israel

Bio-inspired nanotechnology aspires to harness natural compounds, their chemical derivatives and formed supramolecular structures for various technological applications. In recent years, a key direction in the electronics and electro-optics technologies involves the transition from inorganic to organic components, including organic light emitting diodes (OLED), thus paving the way towards flexible and wearable electronic and light emitting devices. Bio-inspired organic materials may be the next-generation of organic optoelectronic devices based on self-organization principles, which allow facile synthesis, eco-friendliness, resistance to oxidation and no need for heavy metal doping.

We and others, have taken a reductionist approach to form new materials based on self-assembled peptide structures. We were the first to demonstrate that ultrashort peptides can form well-ordered nanostructures such as nanotubes and nanospheres. Specifically, the diphenylalanine peptide (FF) self-assemblies have been shown to display intriguing features, including mechanical, optical, semiconductive and piezoelectric properties. We thoroughly characterized mechanisms that facilitate peptide self- and co-assembly and the structural basis for the resulting physical properties. Several studies have explored the piezoelectric properties of the FF peptide. In the presence of an external electric field, vertically aligned FF microrod arrays can be organized on a substrate, resulting in enhanced piezoelectric response.

Here we show the ability of FF and other similar peptide assemblies to be used in various electronics and optics application as new bioorganic materials. FF assemblies and derivatives can act as an active optical waveguiding material, allowing locally excited states to propagate along the axis of the assemblies. In addition, Fmoc capped building blocks exhibit remarkable optical properties, such as quantum confinement and fluorescence. In addition, We based on our reductionist approach, to expand our search for minimal building blocks towards single amino acids as well as other metabolites such as nucleobases, demonstrating their self-assembly into various ordered structures. Doing this we are enlarging our library of biological building blocks which bear the potential to be novel bio-inspired supramolecular materials for optics and electronic applications.

SB06.12.03
Investigating Substrate Mechanics Effects in Combination with TiO2 Thin Layer Coated by Atomic Layer Deposition (ALD) for Dental Pulp Stem Cell Proliferation and Differentiation Megha Gopal1, Jessica Hofflich2, Ya-Chen Chuang2,2 and Miriam Rafailovich2; 1New Hyde Park Memorial High School, United States; 2Stony Brook University, The State University of New York, United States

Dental Pulp Stem Cells (DPSC) provide a valuable and enticing avenue for the field of regenerative medicine. Previously, we determined that DPSC cultured on monodispersed polybutadiene (PB), a biologically compatible substrate without additional coating, induced high levels of biomineralization in surfaces with a modulus over 2.3 MPa. [1] Similarly, titanium surfaces have been noticed to support osseointegration in dental implants. [2] In this study, we introduce a new method to deposit a 2–3 nm layer of titanium dioxide by Atomic Layer Deposition (ALD) on PB substrates to investigate DPSC behavior and differentiation lineages in an environment where surface chemistry has changed but substrate modulus remains the same.

ALD was employed to deposit TiO2 on thin (20 nm) and thick (200 nm) PB substrates, which respectively formed hard and soft substrate mechanics effects. All substrates were cultured with human DPSC, with data samples taken weekly. At first week, population doubling time determined that ALD had no major effect on cell proliferation while confocal images showed similar actin density and length of DPSC on all hard and soft PB substrates, suggesting that the TiO2 nanolayer has minimal effect on cell behaviors in the initial period. At the later stage of differentiation, biomineralization was characterized by SEM/EDS and Ramen spectroscopy, with templated, mineralized deposits observed only on ALD coated both hard and soft PB substrates. Osteocalcin (OCN) antibody staining observed by confocal also showed that ALD coating substrates favored OCN protein, suggesting that TiO2 ALD coating promotes differentiation and biomineralization on soft PB substrates where no mineralized deposits and upregulation of OCN was found. On the other hand, on hard PB substrates, even though biomineralization and differentiation
were found on both with and without ALD coating substrates, templated mineralized deposits and more evenly spread OCN protein were observed on ALD coating hard substrates, while particle-like deposits without fibers templated were presented on hard PB substrates without coating, suggesting that surface chemistry of TiO₂ coating by ALD may alter DPSC behaviors and differentiation pathway. This ALD method provides a potential application to coat a nanolayer on titanium on any biomaterial to further promote stem cells differentiation and proliferation.

We acknowledge support from the Louis Morin Charitable Trust and the NYS Department of Economic Development.

SB06.12.04
Shape Memory Cell Culture Platform for Mechanobiology Koichiro Uto and Mitsuhiro Ebara; National Institute for Materials Science, Japan

It is well-known that biomimetic microenvironments play an important role in governing cell function and fate. Conventionally, researchers utilize tissue culture plastic for cell culture; however, there are large and obvious differences in the biochemical and mechano-structural properties of cellular surroundings in vitro (plastic dish) and in our body. In addition, the native cellular environment incorporates several dynamic cell stimulatory factors beyond static biochemical and mechano-structural cues. To understand and bridge these gaps between in vitro and in vivo cell culture, a new research field known as ‘mechanobiology’ has emerged. Though today we have a greater understanding of the mechanobiological cellular phenomena in static systems, we have yet to fully explore the effects of ‘dynamic stimulation’ on cell behavior.

To recapitulate the complex microenvironment inside the body, spatio-temporal biomaterials have emerged as powerful tools to probe and direct active changes in cell function. In this presentation, I will briefly introduce our established dynamic cell culture platforms with ‘shape memory’ abilities. In order to evaluate the potential for cultured cells to respond to dynamic changes in their in vitro microenvironment as they do in vivo, we studied the effects of controllable anisotropic topographies on cell function. Given the importance of dynamic cues in regulating cell behaviors, investigation of such dynamic topography may have important implications to advance cellular manipulation and performance in vitro, as well as improving our understanding of cellular development in response to dynamic biophysical cues.

SB06.12.05
Engineering Tubular Structured Epithelial Organoids by Directed Tissue Assembly Yan Yan Shery Huang, Ye Liu, Joo-Hyeon Lee, Catherine Dabrowska and Iek Man Lei; University of Cambridge, United Kingdom

Epithelial organoids cultured in appropriate 3D conditions typically develop a microscopic, cystic structure lined with a polarized epithelium. Despite their great potential in research and therapy, epithelial organoids grow in heterogeneous sizes, and are too small to display physiologically relevant performance and applications. Here, we show directed assembly of mouse tracheal basal stem cell organoids towards geometrically-defined, lumenized constructs. We demonstrate perfusion of the macroscopic organoid construct; and the transplantation of the construct devoid of a carrier matrix, in a de-epithelialized explant model. Drawing parallel to liquid droplet interaction, we provide hypothesis on how epithelial organoid assembling can be achieved in a more efficient and predictable manner, of which principles could be extended to other organoid types developed form epithelial stem cells. The guided self-assembly system presented here opens up the possibility for engineering size-relevant, geometrically defined epithelial structures towards broad applications in biomimetic organoid-devices and tissue engineering.

**Non-Dissolvable Silk—From Hydrated Films to Bionic Links**  
Anoop Patil1,1 and Nitish Thakor1,1,2;  
1National University of Singapore, Singapore;  
2Johns Hopkins University, United States

**SUMMARY AND MOTIVATION** - This paper presents non-dissolvable silk fibroin in the form of highly-bendable and flexible films, housing ultrathin electrodes and conductive traces to enable soft bionic links. These links are wrapped around challenging nerve geometries and laminated onto planar cortical surfaces, assisting in the electrical recording of neural activity from the target tissue surfaces. Various materials tests and functional demonstrations in an anesthetized animal model illustrate the suitability of non-dissolvable silk as a candidate material for use in water-stable electrical sensing devices for *in vivo* applications.

**ADVANCES OVER PREVIOUS WORKS** - Silk, due to its excellent biocompatibility, has largely facilitated the development of resorbable devices meant to function *in vivo* for a limited amount of time. Even though there have been research studies on the sustainability of pristine silk in an animal model, use of non-dissolvable silk films in the design of fully functional bionic links has not been reported.

**METHODS** - A silk substrate housing the gold electrode sites was integrated with a patterned silk film to yield a silk link. EIS measurement was carried out in an electrochemical workstation. The functional validation of the silk link was carried out in a rat model. The silk links were deployed on the sciatic nerve and the cortex *in vivo* using a medical grade adhesive. *In vitro* material tests were carried out in a saline medium using an accelerated soak model.

**RESULTS** –
1. **Impedance:** The electrode sites of the nerve links provided an impedance of ~2.1 kΩ (1 kHz), and ~22 kΩ (at 1 kHz) in case of cortical links. The impedance values were found to be consistent across different samples ($Z=1.9±0.2$ kΩ at 1 kHz; n=6 sites, nerve link; $21 ± 1.21$ kΩ at 1 kHz, n=12 sites, cortical link).
2. **Flexibility:** The silk links could be bent around a silicone tube (~600 µm Ø) without inducing any cracks or delamination. Impedance measurements prior to and post wrapping showed negligible differences.
3. **In vitro recording:** The silk links could record minute sinusoidal signals (0.5-7 kHz), fed into the saline medium from a signal source.
4. **Young’s modulus:** The Young’s modulus of hydrated non-dissolvable silk films used as substrates and insulation layers was ~6-8 MPa; n=3.
5. **Affinity to wet surface:** The hydrated silk films used in the bionic links showed affinity to the wet surfaces and conformed well with the slimy surfaces of the sciatic nerve and the cortex *in vivo*.
6. **Biocompatibility Test:** Silk films did not exhibit any toxicity to neuronal cells including rat primary Schwann cells, DRG neurons, and hNSC. The films showed excellent cell-material interactions and good bioactivity with
7. *In vivo recording:* The sciatic nerve was electrically stimulated, and the corresponding evoked action potentials recorded by the distally placed silk links measured ~320 µV (E#1) and ~170 µV (E#2) in an experiment trial (60 µs pulse, 600 µA). The electrocorticogram (ECoG) recording capability of the silk link was demonstrated using a rat transient ischemia (TIA) model. ECoG recordings (evoked through forepaw stimulation) prior to induction of stroke served as the baseline and recordings post induction provided functional validation of the silk link. Suppression of the ECoG activity observed post induction of stroke was captured cleanly by the silk link.

**CONCLUDING OPINION** - The materials and methods described here provide the basis for excellently biocompatible sensor links on ultrathin non-dissolvable silk that offers robust conformal lamination onto tissue surfaces *in vivo*. Upcoming research studies will focus on building a well-tested and validated soft neurotechnology toolbox that can offer a library of materials to design tissue-compliant interfaces that are well-accepted by the biological milieu. Non-dissolvable silk, given its excellent biocompatibility, transparency, flexibility, and robustness is a value-add to such a toolbox.

**Transparent Single Layer Graphene Electrodes for Electroretinogram Recordings** Jose de la Cruz¹, Diep Nguyen², Serge Picaud², Clement Hebert¹ and Jose Antonio Garrido¹,²; ¹Catalan Institute of Nanoscience and Nanotechnology, Spain; ²Institut de la Vision, France; ³ICREA, Spain

Graphene has proved to be an outstanding material for the fabrication of biocompatible electrodes and microelectrode arrays (MEA). Motivated by their high sensitivity, low noise, scalability and stability in aqueous electrolyte, graphene-based MEA have been used for the detection of relevant molecules and biomolecules as well as electrical cell signals, either in vivo or in vitro. Using these new technology developments we are now able to shed new light onto several diseases and pathologies. One particular field in which this technology can be useful is electroretinography (ERG). This technique involves placing an electrode on the cornea, flashing the eye with light and recording the electrical signal produced by the retina. Usually, a metal electrode bended in a loop or a contact lens with attached wires are used. These types of electrodes mainly present two problems: discomfort produced by the used rigid materials and the difficulty to measure signals from the whole cornea, since their opacity would block the light meant to stimulate the retina. Therefore, electrodes combining flexibility and transparency could provide a solution for ERG measurements. In this work we present the fabrication and characterization of such devices based on single layer graphene technology, as well as their use on two different applications.

On the one hand we use single layer graphene electrodes to diagnose retinitis pigmentosa on a P23H rat model. Retinitis pigmentosa is a degenerative disease that causes the loss of photoreceptor cells on the retina producing night blindness and a progressive loss of the visual field. The graphene electrode, despite its small size, performs very well, enabling the diagnosis of the disease as good as its bulkier, more uncomfortable gold counterpart. Furthermore, the graphene device shows better resolution when dealing with the high frequency components of the ERG signals.

On the other hand, we use this technology to gain insight on the spatial distribution of electrical signals across the retina. With a flexible and transparent graphene MEA we can measure individual signals on different locations of the cornea without blocking the light used to elicit the retinal response. These measurements can shed new light on how the electrical signals are produced and propagated inside the eye. Using these devices, we have detected differences on the signal recorded on the centre of the cornea compared to that coming from the edges. Altogether, SLG electrodes provide an outstanding solution to perform ERG. Graphene transparency, flexibility and biocompatibility allow us to fabricate devices that can compete with the current state of the art ERG electrodes.

**Biocompatible Nanomesh Electronics for Wearables and *In Vitro* Characterizations** Takao Someya¹,²,
Stretchable thin-film electronics are expected to open up a new class of applications ranging from wearable electronics for health-monitoring and human-machine interfaces, implantable electronics, and in vitro characterization. In this talk, we will review recent progress and outlook of hypoallergenic electronic sensor that can be worn on the skin continuously for a week without discomfort. The elastic electrode constructed of breathable nanoscale meshes holds promise for the development of noninvasive on-skin devices that can monitor a person's health such as electrocardiogram and skin moisture levels continuously over a long period. Then, similar nanomesh sensors is applied to in vitro characterization. These can monitor the field potential of cardiomyocytes on gel, while enabling them to move dynamically without interference.

9:00 AM SB07.01.04
Porous and Elastomeric Resistive Pressure Sensors for Wearable Devices Dan Li, Sophie Shi, Hyun-Joong Chung and Anastasia L. Elias; University of Alberta, Canada

Human skin is excellent at detecting pressures over a wide range of values, from the light movement of air against its surface (< 1 kPa) to the load of heavy weights (> 10 kPa). An electronic analog to skin (e-skin) is highly desirable, both to provide closed-loop (tactile) feedback for robotic limbs and to enable wearable devices for human health monitoring (e.g. detecting pulse). Towards the development of e-skin, numerous thin film-based pressure sensors have been demonstrated in the literature; these devices are typically designed to undergo changes in either resistance or capacitance in response to pressure, transducing a mechanical force into an electrical signal. In such devices, different microstructures or porous structures may be leveraged to control the physical deformation of the sensing material that occurs in response to the applied force.

Here, we demonstrate a simple, non-lithographic method for fabricating resistive pressure sensors with a broad range of working pressures (up to 40 kPa) and a low limit of detection. The device is soft, compact and conformable, with a thickness of around 300 microns. One advantage of this device design is that all electrical contact is made at the interface between the two layers; therefore very small changes in pressure can be measured, resulting in a low limit of detection (20 Pa). As the applied pressure increases, the pores themselves can deform drastically and form new contacts between the layers. This sensor has a sandwich structure comprised of metallized top and bottom sheets of porous polydimethylsiloxane (PDMS), fabricated using a simple templating method. In this method, a spin-coated layer of PDMS is pressed onto a layer of powder. The PDMS is then cured and the template is subsequently dissolved. To metallize the structures, the inner faces of each of these porous layers are coated with a layer of conductive silver nanowires, which coats the surface of the pores. The Ag nanowires layers are initially in light contact, and the device undergoes a change in resistance when pressure is applied perpendicular to the plane of the sheets.

In this work, we investigate how the properties of the porous layers affect both the mechanical properties and the response of the device by varying both pore size and elastomer stiffness. The stiffness of the elastomer was tuned by varying the ratio of base to crosslinker in the material (5:1, 10:1, and 15:1); as the fraction of crosslinker in elastomer increased, the response time of the sensor was found to decrease. To vary pore size, three different powder templates were utilized: KCl, NaCl, and sugar, with typical diameters of 60-80 µm, 150-200 µm, and 400-550 µm, respectively. The sensor fabricated with a KCl template (which had the smallest pores) and 10:1 PDMS demonstrated the best performance, with a sensitivity of 14.1 kPa⁻¹ (up to 3.5 kPa), 4.8 kPa⁻¹ (up to 10 kPa), 1.84 kPa⁻¹ (up to 40 kPa) and no performance degradation over 1000 loading and unloading cycles.

Wearable electronic applications of these devices, including pulse measurement, facial movements, and sound tracking, are demonstrated in this work. Overall the combination of non-lithographically-defined pores and solution-processed Ag nanowires yields a simple to fabricate device which exhibits high sensitivity and a low limit of detection. In addition to providing tactile feedback to robotic limbs, such devices may have applications in intrinsically stretchable bioelectronics.

9:15 AM SB07.01.05
Fully Printed Silver Nanowire-Based Biosensor for Point-of-Care Measurement of Prothrombin Time Brittani
Heart failure is a critical public health issue affecting tens of millions of people each year. One paradigm that has revolutionized treatment plans is the continuous flow Ventricular Assist Device (VAD). However, due to the thrombogenic nature of the VAD, complications associated with bleeding events and thrombosis require the patients to take blood thinners, which limit the overall quality-of-life and survival of implanted patients. When on a continuous regiment of blood thinners, VAD patients require frequent monitoring to ensure that prothrombin time (and the corresponding international normalized ratio, INR) is within a clinically acceptable range. Currently, the standard of care requires outpatient testing of prothrombin time (PT) every 1–4 weeks. This is time-consuming and burdensome to patients and healthcare systems, and furthermore recent studies indicate that patients may benefit from more frequent testing intervals. An affordable, point-of-care test (POCT) coagulometer for home monitoring of PT would fill these needs.

In this work, a fully printed point-of-care test (POCT) for the measurement of PT using electrical transduction is demonstrated. In order to create a low-cost device, an inexpensive testing platform was designed, which consists of a printed silver nanowire thin-film resistor to provide high electrode surface area and to set the baseline impedance signal. The nanowires had diameters of 30-50 nm and lengths of 2-6 µm and were synthesized using the polyol method. After all rinsing steps, the silver nanowire concentration was measured using atomic absorption spectroscopy (AAS) and then concentrated in water at 10 mg mL⁻¹. The resultant Ag nanowire inks were printed using an aerosol jet printer under ultrasonic atomization, forming thin films with a resistance in the range of 50–200 Ω. Interrogation of whole blood modulates the impedance of the Ag nanowire film, with the impedance maximum corresponding to the PT. Measured using electrochemical impedance spectroscopy (EIS), the operating frequency was found to be optimal at 15kHz, at which a stable and reproducible clotting time response was obtained. The functionality of the device was demonstrated in whole blood derived from both animal and human subjects. Devices were printed on both glass and polyimide, establishing the ability to measure identical clotting times even on a flexible substrate under strain / bending. These results lay the groundwork for fully printed impedimetric coagulometers that could address the unmet need for a low-cost, robust POCT to improve outcomes for VAD patients by straightforward monitoring of PT/INR.

9:30 AM *SB07.01.06
Reflectance Oximetry Enabled by Flexible Organic Array of Printed Devices
Yasser Khan, Donggeon Han, Adrien Pierre, Jonathan Ting, Ana Claudia Arias and Anju Toor; University of California, Berkeley, United States

The optical method to determine oxygen saturation in blood is limited to only tissues that can be transilluminated. The status quo provides a single-point measurement and lacks 2D oxygenation mapping capability. We have demonstrated a flexible and printed sensor array composed of organic light-emitting diodes and organic photodiodes, which senses reflected light from tissue to determine the oxygen saturation. We use the reflectance oximeter array beyond the conventional sensing locations. The sensor is implemented to measure oxygen saturation on the forehead with 1.1% mean error and to create 2D oxygenation maps of adult forearms under pressure-cuff–induced ischemia. In addition, we present mathematical models to determine oxygenation in the presence and absence of a pulsatile arterial blood signal. The mechanical flexibility, 2D oxygenation mapping capability, and the ability to place the sensor in various locations make the reflectance oximeter array promising for medical sensing applications such as monitoring of real-time chronic medical conditions as well as postsurgery recovery management of tissues, organs, and wounds.

10:30 AM *SB07.01.07
Wireless E-Tattoos Chargeable On-the-Go
Nanshu Lu; The University of Texas at Austin, United States

Soft, noninvasive and multifunctional epidermal electronics (a.k.a. e-tattoos) have demonstrated many exciting applications in mobile health, human-machine interface (HMI) and so on. However, e-tattoos are only practically useful when they are low cost and wireless. Previously, our group has invented a dry and digital manufacturing approach named the “cut-and-paste” method for the rapid prototyping of e-tattoos using a paper/vinyl cutter plotter [1]. This method has been demonstrated to work for thin film metals [1, 2], various polymer sheets [1, 3], ceramics
As the quality of life increases, people’s interest in better healthcare grows, and their demand for customized healthcare devices for individuals increases. Accordingly, there is an increasing interest in wearable devices that can be worn on the body and detect biological signals in real time. Thus, many researchers have intensively studied to develop skin-attachable electronics without any physical inconvenience in daily life. These wearable electronics vitally need not only bio-signal sensing devices but also data storage components to manage a user’s health condition in real time. Therefore, nonvolatile memory is a key part of these customized healthcare wearable devices. Among various nonvolatile memories, a resistive random-access memory (RRAM) is attracting attention as a next-generation nonvolatile memory device because of its advantages of high-speed switching, low power consumption, low manufacturing cost, etc. However, in order to apply RRAMs to skin-attachable wearable devices, problems such as ultra-lightweight, unbreakable, and free-form design must be resolved. To overcome these problems, organic-based RRAMs can be an attractive candidate with advantages such as flexibility, simple process, and so on. However, these organic-based RRAMs are difficult to apply to skin-attachable devices due to their sensitivity to the external environmental factors. In particular, moisture could cause degradation of an organic thin film and fatally affect the memory operations of organic-based RRAMs. Therefore, resolving issues such as degradation of the electrical performance of organic-based RRAMs due to external moisture before implementing...
for skin-attachable wearable devices become an important factor. In this study, we demonstrate a novel organic material, nitrocellulose (NC), as a switching layer of RRAM for the first time that meets the requirements of the skin-attachable wearable devices. NC is obtained by nitriding cellulose and can be formed at low temperature through a simple solution process. To fabricate NC based RRAMs, we deposited NC by solution process on the p+Si wafer, and top electrode, Al/Au, was deposited by the thermal evaporator. Fabricated NC based RRAMs shows bipolar switching behavior for current-voltage (I-V) characteristic. The 'Set' voltage, which is converted from a high resistance state (HRS) to a low resistance state (LRS), is about 2.5 V, and the 'Reset' voltage, which is converted from LRS to HRS, is -1.5 V. NC based RRAM shows a resistance switching window of 10² and maintains switching operations after 100 cycles of consecutive endurance tests. Data retention results show reliable data storage performance of up to 10⁴ seconds under constant voltage stress of 0.3 V. As one of the previous researches of organic-based RRAMs proposes, the switching operation in organic-based RRAMs using the easily oxidizable metal electrode is attributed to the formed native oxide layer between the organic layer and the metal electrode. Likewise, as Al is one of the easily oxidized metals when it is used as a top electrode of NC based RRAMs, it is easily oxidized by the oxygen functional groups present in NC. Thus, We can deduce that NC based RRAMs show the switching operation by the formed native Al oxide. We found a new layer was formed between Al and NC by high-resolution transmission electron microscopy (HR-TEM) images. In addition, an energy dispersive X-ray spectrometer (EDS) mapping and an X-ray depth photoelectron spectroscopy (XPS depth) analysis confirmed that the newly formed layer is Al oxide. Additionally, NC based RRAMs show robust memory operations even after dipping in deionized water (DI water) for 24 hours due to the high moisture stability of the nitrocellulose. Finally, this RRAM is fabricated on polyimide (PI) to demonstrate the applicability of flexible memory suitable for skin-attachable wearable devices.

11:15 AM *SB07.01.10
Bouncing Balls and Inflating Balloons—Exploiting Rubbers Nature Ingrid M. Graz; Johannes Kepler Universität Linz, Austria

Rubber’s inherently dissipative nature and its extreme elastic properties make it the material of choice for children’s toys such as bouncing balls and air-filled balloons. This talk takes inspiration from these toys to understand materials properties and design soft actuators: Bouncing balls help exploring the dissipative properties for damping structures inspired by fruit while balloon shaped actuators inspired by plants enable fast and strong actuators. Potential applications include design guidelines for protective structures in two and three dimensions such as cushioning e-skin complete with stretchable sensors and soft actuators for exoskeletons.

SESSION SB07.02: Materials for Bioelectronics

Fabrication of Ready-to-Wear Resistive Strain Sensors by Electroless-Nickel Immersion Gold Deposition on Nitrile Butadiene Gloves for Hand Gesture Mapping Sara Mechael, Yunyun Wu, Yiting Chen and Tricia B. Carmichael; University of Windsor, Canada

Wearable electronics enable an intimate experience between users and their devices. In contrast to conventional large, rigid-body electronics, wearables conform to the human body even during routine motion. Wearable electronics can be applied to strain sensing, contributing to fields such as physiotherapy, virtual reality gaming, and robotics. Current efforts to prototype soft strain sensors often disregard the integration of the sensor onto a wearable platform, instead using temporary mounting techniques such as taping or gluing onto skin or articles of clothing. While these methods enable characterization of the strain sensors, they are not suitable for practical wearability. Here, we present an alternative method for the fabrication of wearable strain sensors by creating ready-to-wear prototypes by fabricating stretchable metal strain sensors on the surfaces of commercially available wearable nitrile butadiene rubber (NBR) gloves. In this presentation, we discuss the fabrication method, which uses a stencil mask to pattern a spray-coated latex resist, followed by electroless-nickel immersion-gold deposition selectively within the
regions unprotected by the resist. We discuss the surface morphology, resolution of the patterning technique, electrical performance, and durability of these strain sensors. We also demonstrate the versatility of this ready-to-wear strain sensor as a low-cost, lightweight, fitted glove sensor in relation to gesture monitoring in an American Sign Language translator and remote control of a soft robotic hand that mirrors the gestures made by the glove user.

1:45 PM SB07.02.02
Organic Electronics for Self-Powered ECG Signal Acquisition Patches Georgios Spyropoulos, Zifang Zhao, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

In the near future, wearable electronics that can serve as devices for point of care diagnostics, brain machine interfaces, and therapeutic responsive stimulation may not only facilitate health monitoring and disease diagnosis, but on-the-spot treatment and intervention. Low cost energy storage, flexibility, and capacity for internal functionality are ideal characteristics that those devices should exhibit.

In this project, we demonstrate a thin, flexible self-powered epidermal electronic device that provides an efficient interface for high quality electrophysiological signal acquisition. This medical patch-like device is built on a micrometer thick parylene substrate with microfabricated gold interconnects and consists of three main parts; i) a biological interface, ii) a microcontroller/bluetooth module, and iii) a flexible battery. Because of its conformability, it can be attached as a patch on different human body areas. To determine the configuration and material composition for optimal signal acquisition, we microfabricated various designs with gold interconnects that lead to several biological interfaces. Gold electrode contacts coated with conductive poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) enriched with D-sorbitol or PEDOT:PSS based anisotropic layers enable low impedance, adhesive interfaces with high spatial resolution. Additionally, internal ion gated organic electrochemical transistor (IGT)-based interfaces were tested to acquire locally amplified physiological signals. The signals are sent to a microcontroller with high speed data acquisition for processing and storage. The heart of the device is a battery based on an electrolyte sandwiched between a composite film of highly conductive PEDOT:PSS and an aluminum electrode, serving as cathode and anode respectively. The battery shows an average cell discharge voltage of 0.5V and can provide specific energy of at least ~15 Whkg⁻¹, which can operate our system continuously for at least 40 hours.

The resulting optimal patch was attached on human subjects to obtain high quality electrocardiogram (ECG). Detection algorithms run by our devices can locate ST segment abnormalities that indicate coronary ischemia. Our findings communicate concrete steps towards subtle wearable bioelectronics systems and medical care devices that can record and potentially intervene with the electrophysiological signal of human body.

2:00 PM *SB07.02.03
Development of Semiconducting Polymers for Electrochemical Transistors for Organic Bioelectronic Applications Iain McCulloch; King Abdullah University of Science and Technology, Saudi Arabia

Organic electrochemical transistors (OECTs) have been shown to be promising devices for amplification of electrical signals and selective sensing of ions and biologically important molecules in an aqueous environment, and thus have potential to be utilised in bioelectronic applications. The sensitivity, selectivity and intensity of the response of this device is determined by the organic semiconducting polymer employed as the active layer. Until now, most OECTs have been fabricated with commercially available conducting poly(3,4-ethylenedioxythiophene) (PEDOT:PSS) as the active layer, and therefore operated in depletion mode with limited modulation. This work presents the design of new organic semiconducting materials which demonstrate significant improvements in OECT performance, through operation in accumulation mode, with high transconductance and low operating voltage, combined with good operational stability.

We discuss here the design, synthesis and performance of novel intrinsic semiconducting polymers for efficient accumulation mode OECT devices. Key aspects such as ion and charge transport in the bulk semiconductor and operational voltage and stability of the devices are addressed in order to elucidate important structure-property relationships. A range of new semiconducting polymers, designed to exhibit facile electrochemical doping of either holes or electrons, facilitate ion penetration and migration, as well as have aqueous compatibility are reported. Electrochemical stability will also be discussed. Optimisation of a series of polymer parameters including electrochemical doping, charge carrier mobility and capacitance are discussed. This approach leads to the design of polymers that can outperform state-of-the-art PEDOT:PSS based depletion mode devices with peak
transconductances above 20 mS, peak currents in the mA regime, on/off ratios above 105 and excellent switching times below 1 ms. In addition, we demonstrate that polymers with sufficiently high electron affinities and low ionisation potentials can achieve charge carrier ambipolarity, with both p and n-type device operation.

2:30 PM SB07.02.04
Fully Rubbery Electronics and Biointegrated Devices Cunjiang Yu; University of Houston, United States

While human organs and tissues are mostly soft; conventional electronics are hard. Seamlessly merging electronics with human is of imminent importance in addressing grand societal challenges in health and joy of living. However, the main challenge lies in the huge mechanical mismatch between the current form of rigid electronics and the soft curvy nature of biology. Here, I will present a new form of electronics, namely “rubbery electronics and bioelectronics”, with skin-like softness and stretchability, which is constructed all based upon elastic rubbery electronic materials. These rubbery electronic materials are structured in the format of composites, which can be scalably manufactured from common and commercial available materials without dedicated and complicated synthesis. Specifically, we build nanofibril organic semiconductor and metallic nanowires percolated in the elastomeric polymer matrix in a composite format for the rubbery semiconductors and conductors, respectively. Employing these rubbery electronic materials, we have achieved fully rubber format devices, including transistors and sensors, logic gates, active matrices, elastic sensory skin systems, and biointegrated devices, etc. I will showcase a few examples including artificial skins, biomedical implants, and wearable applications.

2:45 PM SB07.02.05
Reversible Electronic Solid-Gel Switching of a Conjugated Polymer, from Electroactive Filters to Drug Delivery Devices Johannes Gladisch¹, Sarbani Ghosh¹, Alexander Giovannitti², Maximilian Moser², Igor Zozoulenko³, Iain McCulloch³, Magnus Berggren¹ and Eleni Stavrinidou¹; ¹Linköping University, Sweden; ²Imperial College London, United Kingdom; ³King Abdullah University of Science and Technology, Saudi Arabia

Conjugated polymer films can transform electrical energy into volume changes when included in electrochemical devices via the exchange of ions and solvent. So far, this volumetric change has been limited to 40% and 100% for reversible and irreversible systems, respectively, thus restricting potential applications of this technology. We report a thiophene based conjugated polymer that reversibly expands by about 300% upon addressing, relative to its previous contracted state, while the first irreversible actuation can achieve values ranging from 1000-10000%, depending on the voltage applied. From experimental and theoretical studies, we find that this large and reversible volumetric switching is due to reorganization of the polymer during swelling as it transforms between a solid-state phase and a gel, still maintaining percolation for conductivity. The polymer was utilized as an electroactive cladding to reduce the void sizes of a porous carbon filter electrode by 85% and for controlled delivery of large biomolecules.

3:30 PM SB07.02.06
Perovskite Nickelates as Biological and Brain Interfaces Hai-Tian Zhang, Yifei Sun and Shriram Ramanathan; Purdue University, United States

Bioelectrical interfaces between biological systems and electronic devices are crucial in understanding physiological pathways, monitoring onset of diseases at early stages, and transferring information across brain-machine interfaces. Simultaneous transduction of ionic-electronic signals would be of particular interest in this context since ionic transmitters are the means of information transfer in biological media while traditional electronics utilize electrons or holes. In this presentation, we propose strongly correlated oxides (mainly focused on perovskite nickelate) as a potential candidate for this purpose.¹,² We show that perovskite nickelates can be doped with small ions such as H⁺ and Na⁺ and show large amplified response in their electrical resistance through the Mott metal-insulator transition. The capability of reversibly accepting small ions and converting ionic signal to electrical signals renders perovskite nickelate a strong candidate for bioelectrical and haptic interface applications. We will present case studies of mouse brain interfacing with nickelate devices to record neurotransmitter release. We will also discuss the structural as well as electronic mechanisms leading to experimental observations based on X-ray absorption techniques and first-principle calculation studies. Collaborative contributions will be pointed out in the presentation.
New Semiconducting Materials for Organic Bioelectronic Application Christian Nielsen; Queen Mary University, United Kingdom

The emerging research field of organic bioelectronics has developed rapidly over the last few years and elegant examples of biomedically important applications including for example in-vivo drug delivery and neural interfacing have been demonstrated.

The organic electrochemical transistor (OECT), capable of transducing small ionic fluxes into electronic signals in an aqueous environment, is an ideal device to utilise in bioelectronic applications. To date, nearly all OECTs have been fabricated with commercially available PEDOT:PSS, heavily limiting the variability in performance. We have previously shown that tailor-made semiconducting polymers are fully capable of matching the performance of PEDOT:PSS. To capitalise on this discovery and the versatility of the organic chemistry toolbox, further materials development is needed. In my talk I will discuss our recent work in this area covering examples of both molecular and polymeric semiconducting materials and their performance in bioelectronic devices.

Designing Polymer Mixed Conductors for Applications in Bioelectronics Jonathan Rivnay; Northwestern University, United States

Direct measurement and stimulation of ionic, biomolecular, cellular, and tissue-scale activity is a staple of bioelectronic diagnosis and/or therapy. Such bi-directional interfacing can be enhanced by a unique set of properties imparted by organic electronic materials. These materials, based on conjugated polymers, can be adapted for use in biological settings and show significant molecular-level interaction with their local environment, readily swell, and provide soft, seamless mechanical matching with tissue. At the same time, their swelling and mixed conduction allows for enhanced ionic-electronic coupling for transduction of biosignals. These properties serve to enable new capabilities in bioelectronics. In the first part of my talk I will focus on the design of polymer bioelectronic materials for enhanced electrophysiological sensors based on electrochemical transistors. Synthetic design and processing can yield stable and high performance mixed conductors with high volumetric capacity, high transconductance, and steep subthreshold switching characteristics for low power sensing. Rising areas in stability and circuit integration are highlighted. I will then discuss the unique form factors enabled by polymer electronics, and their applications in regenerative engineering, including the development of thermo-responsive conductive hydrogel composites with osteoinductive characteristics. New materials design will continue to fill critical need gaps for challenging problems in bio-electronic interfacing.

Role of the Cation in Electrochemical Doping of p-Type, Accumulation Mode Polymers for Bioelectronics Lucas Flagg, Jonathan W. Onorato, Christine Luscombe and David S. Ginger; University of Washington, United States

Mixed ionic/electronic conductors have demonstrated importance for a number of applications including bioelectronics, neuromorphic computing, and energy storage. Of particular interest are organic electrochemical transistors (OECTs), which have multiple uses for biosensing, but also provide a valuable platform for studying the fundamental properties of mixed conducting materials. The current understanding of the doping mechanism for p-type, accumulation mode OECTs is that the application of a negative gate bias causes the injection of anions into the polymer film along with a corresponding accumulation of holes. However, the highest performing materials demonstrate extensive swelling in the presence of electrolyte, suggesting that there is some intrinsic cation uptake prior to electrochemical biasing. Here we carefully examine the role of the cation on the doping mechanism of poly(3-[(2-(2-methoxyethoxy)ethoxy)methyl]thiophene-2,5-diyli) (P3MEEMT), a high performing OECT active layer material with glycolated side chains. We study the mass of the polymer film at different doping levels using
Electrochemical Quartz Crystal Microbalance (EQCM) and find significant mass loss during the initial stages of doping for smaller cations. We confirm the initial presence and the subsequent expulsion of cations from the polymer film by Glow Discharge Optical Emission Spectroscopy (GDOES). From these measurements we propose the following doping mechanism for this polymer: 1) initial diffusion of electrolyte (cation and anions) into the film, 2) cation expulsion and hole accumulation upon applying a gate bias, 3) anion insertion and further hole accumulation. Lastly, we show that the cation expulsion step does not exist when very large cations are used, presumably because large cations cannot diffusively enter the film initially. These findings help clarify the doping mechanism in the highest performing mixed ionic/electronic conductors and demonstrate that OECT operation depends not only on the anion, but also the cation, paving the way to further improvements.

4:45 PM SB07.02.10
Energetic Control of Redox–Active Polymers towards Safe Organic Bioelectronic Materials
Alexander Giovannitti1,2, Reem Rashid3, Bryan Paulsen3, Jenny Nelson1, Alberto Salleo2, Iain McCulloch1 and Jonathan Rivnay2; 1Imperial College London, United Kingdom; 2Stanford University, United States; 3Northwestern University, United States

In this study, we draw attention to electrochemical side–reactions of redox–active polymers for organic electrochemical transistors (OECTs)1. We find that electron–rich polymers such as PEDOT:PSS1 or pg2T-TT2 can undergo oxygen reduction reactions (ORRs) and form hydrogen peroxide (H2O2) as a side product. H2O2 is an oxidant that can cause harm to biological systems and devices. Hydrogen peroxide production occurs through an electron transfer from the electron–rich conjugated polymer to molecular oxygen dissolved in the electrolyte, with the ionization potential (IP) of the redox-active polymer determining whether or not the reaction occurs spontaneously under ambient conditions.

To prevent this side–reaction from taking place during device operation, we designed a redox–active polymer with an IP > 4.9 eV. The polymer is a donor–acceptor type copolymer with polar side chains, specially designed to achieve a high redox-stability in aqueous electrolytes. OECTs were fabricated and tested where we observe a turn on voltage at –0.4 V (vs Ag/AgCl), a peak transconductance of 200 S/cm (at VG = –0.7 V), and good device stability with no sign of H2O2 formation during device operation. This study elucidates the interaction of redox-active conjugated polymers and molecular oxygen which has previously been overlooked with potentially critical issues for operating electrochemical devices in oxygen containing aqueous electrolytes (biological environments).

Graphene Based Health Monitoring
Dmitry Kireev and Deji Akinwande; The University of Texas at Austin, United States

The modern healthcare and biomedical systems show a clear trend towards personalized, predictive, and preventive medicine. Development of the concept, commonly known as mobile health (mHealth), means that a huge shift in the paradigms of medical device architectures is to be expected in the near future thanks to the increased portability of medical devices as well as increase in number of specific mobile-based apps. An ideal wearable device should possess a set of important requirements, such as (i) low cost of fabrication, (ii) being conformable and compatible with human skin, and (iii) multifunctionality. The latter is of special importance if the goal is to build not just a single specific device, but to rather develop a technology and basis for scalable fabrication of devices that are capable to detect a plurality of vital signals (HR, EEG, ECG, hydration, galvanic response, etc.). In order to develop the universal technology that meets all three requirements mentioned above, we propose to
utilize graphene in combination with epidermal technology. The conventional epidermal biosensors are based on metal and silicon based thin films that are patterned into special structures for softness and stretchability and embedded into soft biocompatible polymers. The choice of two-dimensional materials is the most natural due to their ultra-thinness, allowing extreme flexibility, transparency, and conformability to almost any rough surface, including skin [1]. Graphene based passive electrodes have been successfully used to epidermal sensing of electrocardiograms (ECG), electromyogram (EOG), electroencephalogram (EEG), skin temperature, and skin hydration [1], [2]. It is important to emphasize that the research work is based on large-area CVD-grown graphene, allowing us to develop low-cost, wearable, and fully conformable to skin devices. Furthermore, large area fabrication gives an ultimate promise for future devices fully based on 2D materials to be available on market. In terms of possible applications, the proposed technology can be easily expanded towards other fields of healthcare biosensing, such as in vivo electrophysiology, UV exposure sensing, pressure sensing, or even towards building electronic skin, and prosthetics.

8:15 AM SB07.03.02/SB02.04.02/SB05.04.02
Multifunctional Fiber Based Neural Probes with Integrated Neurotransmitter Detection Atharva Sahasrabudhe1,1, Tural Khudiyev1, Tomo Tanaka1,2, Kyoungsuk Jin1, Marc-Joseph Antonini1,1,3, Andres Canales1, Yoel Fink1,1, Karthish Manthiram1 and Polina Anikeeva1,1,1; 1Massachusetts Institute of Technology, United States; 2NEC Corporation, Japan; 3Harvard-MIT Division of Health Science and Technology, United States

One of the major challenges in deciphering the fundamental principles of cognition is the lack of appropriate tools for seamless interfacing with neurons across all their signaling modalities. Gaining holistic understanding of neural circuits and their control of behavior requires invention of neural probes that can simultaneously record and modulate electro-chemical activity of neurons while evoking minimal inflammatory response for periods ranging from minutes to years. Multifunctional fibers have recently emerged as a promising platform for integrating multiple functional elements to probe and control neural activity that also minimizes the foreign body response.

In my presentation, I will describe our efforts in further expanding the multifunctional activity of polymer-based fiber probes by incorporating an electrochemical sensor that enables real-time tracking of neurotransmitter dynamics in behaving animals. This is achieved by introducing a carbon nanotube (CNT) based electrocatalytic electrode within the multifunctional fiber-based probes during their fabrication via thermal drawing process. The resulting devices can be implanted chronically and perform electrical recording and stimulation of neurons, light delivery through waveguides for optogenetics, drug and gene delivery via microfluidic channels, and voltammetry via the CNT electrodes for dynamic detection of dopamine. We envision that these multimodal, miniature, and mechanically compliant probes will facilitate understanding of the neurophysiological underpinnings of dopamine-dependent behaviors including reward, addiction, and motor control.

Chronic Recordings from Behaving Animals Using Microwire-CMOS Technology Nicholas Melosh; Stanford University, United States

Mammalian brains consist of billions of neurons operating at millisecond time scales, which current recording techniques only capture a tiny fraction. Recent advances in CMOS device design have led to high-recording quality planar probes, with diminishing sizes to ameliorate the extent of tissue damage. Matching these powerful silicon electronics to the inherently three dimensional architecture of the brain has remained challenging however, as devices are constrained to the planar two dimensional surfaces required for silicon processing. Here we describe a chronic interface using arrays of microwires read out by CMOS-based devices with a low-tissue damage, and controllable, three dimensional distribution of recording sites. The core concept is using a bundle of insulated microwires mated to a large-scale CMOS microelectrode array, such as found in modern camera chips or displays.
We show recent results on the mechanics and tissue damage from microwire insertion scales strongly with wire diameter. Microwires with <25µm diameters are shown to have minimal to no vascular disruption or bleeding, as opposed to more conventional 75 to 100 µm devices. These microwires are then arranged into bundles to control the spatial arrangement and three dimensional structure of the distal (neuronal) end, while providing a robust parallel contact plane on the proximal side which is interfaced to a planar pixel array. The modular nature of the design enables a wide array of microwire types and size to be mated to a variety of different CMOS chips, making the same fundamental platform scalable from a few hundred electrodes to tens of thousands. We thus link the rapid progress and power of commercial multiplexing, digitisation and data acquisition hardware together with a bio-compatible, flexible and sensitive neural interface array. We present recent massively parallel recording using mouse and rat models, showing both spiking activity from single neurons and local field potentials within both chronic and acute settings.

9:30 AM *SB07.03.05/SB02.04.05/SB05.04.05
Membrane Curvature at the Interface between the Cell Membrane and Nanoscale Electrodes Bianxiao Cui; Stanford University, United States

The interaction between the cell membrane and the measuring electrode is crucial for sensitive measurement of cell electric activities. We are interested in exploring nanotechnology and novel materials to improve the membrane-electrode coupling efficiency. Recently, we and other groups show that vertical nanopillars protruding from a flat surface support cell survival and can be used as subcellular sensors to probe biological processes in live cells. The nanopillar electrodes deform plasma membrane inwards and induce membrane curvature when the cell engulfs them, leading to a reduction of the membrane-electrode gap distance and a higher sealing resistance. As an electrode sensor, nanoelectrodes offer several advantages such as high sensitivity, subcellular spatial resolution, and precise control of the sensor geometry. Furthermore, we found that the high membrane curvature induced by nanoscale electrodes significantly affects the distribution of curvature-sensitive proteins and stimulates several cellular processes in live cells. Our studies show a strong interplay between biological cells and nanoscale topography, which is an essential consideration for future development of interfacing devices.

10:00 AM BREAK

10:30 AM *SB07.03.06/SB02.04.06/SB05.04.06
Engineering Skin-Like Soft Electrical Interface with Biological Systems Zhenan Bao; Stanford University, United States

In this talk, I will discuss several projects related to engineering conductive materials and developing fabrication methods to allow electronics with effective electrical interfaces with biological systems, through tuning their electrical as well as mechanical properties. The end result is a soft electrical interface that has both low interfacial impedance as well as match mechanical properties with biological tissue. Several applications of such electronics will be presented.

11:00 AM *SB07.03.07/SB02.04.07/SB05.04.07
Soft Materials in Wireless Closed-Loop Neuromodulation Systems for Treating Organ Dysfunction John A. Rogers; Northwestern University, United States

Bioelectronic medicines targeted at the peripheral nervous system have the potential to address a wide variety of diseases, from diabetes to bladder dysfunction. The foundational concepts have existed for decades but implementation has been limited and fraught with persistent challenges, including lack in target specificity, nerve interface biofouling, and inability to acquire real time physiologic signals for conditional delivery of corrective stimuli, leading to excess and unnecessary stimulation. Here we present a set of materials, a treatment strategy and supporting technology platform that address many of these challenges, using bladder control as model system. Specifically, we report capabilities for continuous monitoring of bladder function using an ultralow modulus, stretchable strain gauge to measure dimensional changes, real-time data analytics to identify pathological behavior based on the resulting data, and automated, closed-loop optogenetic neuromodulation of bladder sensory afferents to normalize bladder function in the context of acute cystitis, with generic applicability to many other organ systems and conditions.
Miniature, wireless bioelectronic devices enable less invasive surgical implantation and the ability to target tiny nerves or brain areas. However, as these neural stimulators become smaller, we must engineer new ways to deliver power. Conventional power delivery relies on long wires to deliver power from an implanted battery or subcutaneous antenna. These leads can limit device placement and cause device failure due to lead breakage or infection. Conventional wireless power delivery through biological tissue is difficult when devices are miniaturized and placed deep in the body. Here we show that magnetic materials can effectively harvest energy from magnetic fields and power millimeter-sized bioelectronics. These materials show excellent power densities even as the devices are made small allowing them to be fully implanted and wirelessly powered. We demonstrate that these mm-sized wireless devices can be used to power different types of conventional stimulation electrodes when implanted in rabbits, pigs, and freely moving rats. Furthermore, these miniature electrical stimulators can be adapted to power many individually addressable stimulation channels while still maintaining a small overall device footprint.

1:30 PM *SB07.04.01
Optically-Triggered Dynamics at the Semiconductor-Cell Interfaces Bozhi Tian; University of Chicago, United States

Optically-controlled non-genetic biological modulation represents a promising approach for the fundamental study of biological circuits and the clinical treatment of disorders. Among existing material candidates that can transduce light energy into biologically-relevant cues, silicon and silicon carbide are particularly advantageous due to its highly tunable electrical and optical properties, ease of fabrication into multiple forms, and biocompatibility. In this talk, I will present some of the latest research in our lab, including the use of intracellular silicon for biophysical studies in cardiac system, and doped silicon carbide for several types of biological modulation. I will also present a few new directions where many other soft materials can be incorporated for bioelectronics studies.

2:00 PM *SB07.04.02
Organic Optoelectronic Biointerfaces—Photocapacitive and Photofaradaic Effects Marie Jakesova, Vedran Derek, Malin Silverà Ejneby, Ludovico Migliaccio, Maciej Gryszel and Eric D. Glowacki; Linkoping University, Sweden

We report on development of ultrathin optoelectronic devices for stimulating biophysical processes. All of these devices rely on near infrared irradiation in the tissue transparency window to actuate nanoscale organic semiconductor components. Our flagship technology is the photocapacitor – a device that mimics biphasic current-pulse neurostimulation and thus transduces an optical signal into directly-evoked action potentials in neurons. The devices operate in the tissue transparency window of the near-infrared, where light can penetrate deeply through skin and bone. The motivation is to provide a wireless and minimalistic implant which can perform the duty of standard implantable electrodes, but without the wiring. The devices we fabricate are not only wireless, but also 100-1000 times thinner than most existing technologies. Making implants have as small as possible mechanical footprint improves the efficacy of bioelectronic medical treatments by minimizing the risk for inflammation and making surgical implantation less invasive. On the other hand, the other block of our research efforts is directed at devices which, when stimulated with light, deliver controlled amounts of reactive oxygen species (mostly peroxide). We aim to study the effects of photoelectrochemically-generated peroxides on physiological processes, with the hope of developing novel therapeutic approaches to neurodegenerative diseases.
Bioresorbable Pressure Sensors Protected with Thermally Grown Silicon Dioxide for the Monitoring of Chronic Diseases and Healing Processes Jiho Shin; Massachusetts Institute of Technology, United States

Measurements of pressure in organ systems such as the brain, eyes, bladder and blood vessels form an essential diagnostic basis for the assessment of patient health and progression of diseases such as traumatic brain injury, hydrocephalus (intracranial pressure), glaucoma (intraocular pressure) and hypertension (blood pressure). Therefore, the capacity for precise, continuous monitoring of pressure can be critically important in defining treatment protocols that decrease the rate of morbidity and increase the pace of recovery. Conventional sensor technologies designed for this purpose are available in the form of accurate, implantable devices that must be surgically extracted following clinical use. These procedures are costly and they expose the patient to additional risks of complications. The devices can also serve as a nidus for infection and immune-mediated inflammatory responses. Emerging classes of bioresorbable electronic sensor systems have the potential to address these disadvantages. Here, all of the constituent materials dissolve in biofluids over well-defined periods of time, with biologically benign endproducts. Although recently reported bioresorbable pressure sensors have comparable sensitivity and accuracy to those of conventional, nonresorbable analogues, they offer stable operation over a period of only several days, which is insufficient for many applications. Extending this operational lifetime to several weeks demands solutions to daunting challenges in materials science and device design that follow directly from the requirement that the systems must ultimately dissolve completely, at a molecular level, without adverse effect. This difficulty is inherent to all classes of implantable, bioresorbable systems because immersion in biofluids immediately initiates processes of bioresorption. The most effective method to prolong their lifetimes relies on passive encapsulating layers that delay the time at which biofluids come into contact with the active materials. Bioresorbable polymers such as silk fibroin, poly(L-lactide) and poly(lactic-co-glycolic acid) (PLGA) are attractive for such purposes, but their hydrophilic nature leads to swelling and water permeation, thereby causing premature fracture, buckling and/or dissolution of the underlying materials. Inorganic alternatives such as silicon dioxide, silicon nitride and various metal oxides formed by chemical or physical vapour deposition offer exceptionally slow rates of dissolution, but the extreme difficulties in forming coatings without micro- or nanocracks, pinholes or other defects limit their practical utility.

Here, we demonstrate materials, device structures and fabrication methods for bioresorbable pressure sensors that rely on thermally grown layers of silicon dioxide on device-grade silicon wafers as biofluid barriers with defect-free, materials-level perfection over large areas. Overall fabrication involves bonding of a pair of silicon-on-insulator wafers using adhesion layers of amorphous silica formed by calcination of poly(dimethylsiloxane) (PDMS), followed by elimination of the handle wafers. Data on the biodistribution of dissolved silicon in mice at five weeks following implantation of intracranial sensors formed in this manner, together with assessments of the haematology (complete blood count), blood chemistry and MRI compatibility, confirm their biodegradability and clinical utility. Measurements of intracranial pressures in rats over 25 days illustrate high accuracy and low drift, with an overall performance that compares favourably to that of non-resorbable clinical standards. The results not only establish routes to bioresorbable pressure monitoring technologies that meet requirements for clinical use, but they also serve as a generalizable platform for broad classes of bioresorbable electronic devices that can offer stable operating characteristics over long periods of time.

2:45 PM SB07.04.04
Temporary Tattoo Electrodes in Magnetoencephalography Application Laura M. Ferrari1,2, Usein Ismailov3, Jean-Michel Badier4, Francesco Greco5 and Esma Ismailova3; 1Istituto Italiano di Tecnologia, Italy; 2Scuola Superiore Sant’Anna, Italy; 3École des Mines de Saint-Étienne, France; 4Aix-Marseille Université, France; 5Institute of Solid State Physics, Graz University of Technology, Austria

Recently, ultraconformable TTEs have been adopted in the recording of many electrophysiological signals (1,2). Medical standard wet electrodes are routinely used in electrophysiology thanks to their high signal quality. On the other hand, these electrodes exhibited many disadvantages which impose severe restrictions especially in electroencephalography applications. The major issues are related to their limited time stability, due to gel drying, and to their cumbersome nature. In order to provide an alternative technology in the broad field of brain recordings, we investigated the TTEs capabilities in electroencephalography (EEG) applications and their compatibility with the
magnetoencephalography (MEG). While EEG records the variations of the electrical field generated by cortical pyramidal neurons, the MEG senses modification in the magnetic field, induced by changes of the electric field generated by the same population of neurons. These two techniques are frequently used in combination, thanks to their high temporal resolution. The simultaneous EEG/MEG assessment is essential in the understanding of dynamic cognitive processes and in focal epilepsy diagnostics. The MEG instrumentation is very sensitive to electromagnetic variations. Besides the use of a proper shielded room, also dedicated electrodes are usually adopted to perform EEG/MEG recordings. As an example, ferromagnetic materials are forbidden in order to avoid the generation of magnetic artefacts. Furthermore the vertical profiles of the electrodes has to be minimized to allow an efficient coupling with the MEG sensor. In order to meet these requirements, we exploited TTEs as metal-free and ultra-thin sensors to efficiently combine EEG/MEG recordings. Indeed the fabrication method developed allows the production of sensors that are all made of polymers and with an overall thickness < 1-2 µm. We firstly validated TTEs in EEG application with the recording of alpha waves, the most known and studied brain rhythm. TTEs were also compared with Ag/AgCl electrodes, through Power Spectral Density (PSD) assessment, showing a good match over the whole signal spectrum. Then, the participant, with TTEs laminated on his head, was placed under the MEG apparatus. We were able to record neural activity at different frequencies without any high-density magnetic flux appearance in the electrode’s proximity. The EEG and MEG recordings were performed simultaneously showing well visible alpha waves. To the best of our knowledge, this is the first demonstration of dry organic electrodes performance in joint EEG/MEG assessment.

Wearable Organic Electrochemical Transistors for Biomarker Detections Feng Yan; Hong Kong Polytechnic University, China

Wearable biosensing technologies have emerged as an alternative tool for the personalized healthcare management. Compared to the conventional wearable biosensors, organic electrochemical transistor (OECT) -based biosensors can be more sensitive due to the merits of in-situ amplification and ion-to-electron conversion. OECTs have been successfully used in the following applications. (1) The glucose level in sweat can be real-time and wirelessly monitored and analyzed by OECT sensors remotely controlled by a mobile phone (2) Label-free RNA detection has been realized using flexible OECTs based on the interaction between RNA molecules and the organic semiconductor channels. The devices can selectively detect RNA cancer biomarkers down to the concentration of 1 pM. (3) Fabric OECTs are successfully prepared on Nylon fibers and integrated into wearable systems for monitoring glucose and uric acid levels with high sensitivity. All the results clearly indicate that OECT biosensors can be an excellent platform for wearable healthcare monitoring. The wearable biosensing technology has many advantages, such as simple apparatus, quick detection, short waiting time, and versatility for different wearable scenarios, which could revolutionize the current wearable technologies in individual disease diagnosis and health monitoring applications.

A Flexible Bioelectronic pH Sensor with Enhanced Sensitivity Based on an Organic ElectroChemical Transistor Erika Scavetta, Federica Mariani, Isacco Gualandi, Beatrice Fraboni and Marta Tessarolo; University of Bologna, Italy
Real-time, non-invasive pH monitoring of biofluids such as human sweat is currently attracting a great deal of interest for accessing information from our body. However, such emerging bioelectronic application poses several constraints to existing sensing technologies, as configurational versatility and ultra-sensitivity stand out as essential requirements. In this scenario, organic electrochemical transistors (OECTs) are promising electronic platforms that can interface the biological domain providing intrinsic signal amplification and they can be exploited as sensing devices without the need of a freestanding reference electrode.

In this contribution, we show the optimisation of pH responsive materials, able to successfully convert a pH chemical signal into an electrical one, which are exploited to modify the gate electrode of the OECT. The semiconducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) was electrochemically doped with pH dyes (Bromothymol Blue or Methyl Orange) and the PEDOT:dye composites were thoroughly investigated by electrochemical and spectroscopic analyses. It was demonstrated that the transduction mechanism of the proposed materials originates from the pH-dependent change of the dyes’ electronic charge. Due to its electrostatic interaction with the polymer backbone, this phenomenon affects the doping level of the semiconducting polymer. The PEDOT:dye composites were employed as sensing element in an OECT configuration to obtain a device that can reliably detect pH variations in the range 1-9 with super-Nernstian sensitivity, taking advantage on the amplification offered by the transistor. Finally, thanks to the OECT major advantages with respect to conventional electrochemical sensors, we assessed the sensor adaptability to a plastic substrate. With our flexible sensor, we were able to estimate the pH of an artificial sweat sample with a standard deviation equal to 0.06 pH units within a medically relevant range.[1] Moreover, the pH sensor was realized on sterile bandage and integrated into a smart patch. With the help of a simple, textile microfluidic system, we made our device compatible with wearable applications and continuum, small-volume sampling of biofluids.

Multifunctional Inkjet-Printed Cutaneous MXene Electrodes Abdulelah Saleh, Shofarul Wustoni, Eloise Bihar, Yizhou Zhang, Husam N. Alshareef and Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Skin electronics are rapidly advancing due to the increased interest in wearable electronics, which allows monitoring of various biosignals. Ti$_3$C$_2$ MXene is a promising 2D conducting material for applications in skin electronics. It is biocompatible, easily processable in many solvents, including water, and is highly conductive. Ti$_3$C$_2$ MXene also makes an excellent candidate ink for inkjet printing. However, Ti$_3$C$_2$ MXene has only been shown so far to be printed in organic solvents and alcohols. While these inks are easily processable, they are toxic and introduce difficulties when scaling up, which is the main advantage of printed electronics. Here we report the first inkjet printable aqueous Ti$_3$C$_2$ MXene ink. The films printed thereof that were conductive at even one layer and deposited on various substrates. Ti$_3$C$_2$ MXene films were printed on a conductive flexible substrate to develop a multifunctional sensor that can record ECG signals while detecting Na$^+$ ions and cytokine biomarkers.

4:15 PM SB07.05.04
Patterning Soft and Stretchable Liquid Metal Electrodes for Biological Interfaces Ishan D. Joshipura$^{1,2}$, Collin B. Eaker$^2$, Hudson Ayers$^2$ and Michael Dickey$^2$; $^1$Lawrence Livermore National Laboratory, United States; $^2$North Carolina State University, United States

This work presents approaches to pattern gallium (Ga)-based liquid metal alloys to form ‘softer than skin’ electrodes for biological interfaces. These soft and fluidic conductors exhibit low toxicity, maintain electrical performance under tension and torsion, and are self-healing. Thus, combining Ga alloys with soft materials can form robust biocompatible electrical interfaces. These metals can also integrate with microfluidic platforms for fundamental biological studies (i.e., organ-on-chip). This work reports methods to rapidly (~secs) form liquid metal electrodes onto or within a wide range of materials, including soft polymers, at ambient conditions (i.e., room temperature, atmospheric pressures), and outside clean-room settings. One approach utilizes the adhesion of the native surface oxide of Ga to simply ‘paint-on’ liquid metal electrodes. This oxide ‘skin’ (~3 nm) can serve as a stretchable and self-healing dielectric for capacitive sensing (~0.1 μF/cm$^2$) and ultra low-voltage electrowetting (0 to 2 V). Alternatively, injecting liquid metal into molds placed against rough surfaces enables patterning of liquid metals into arbitrary designs. Because the interface with the rough surface is non-wetting, the mold can peel off to form open-
to-air electrical contacts. As a result, this technique forms open surface patterns of conductive traces of liquid metal that can interface directly with biological tissues, be transferred onto other substrates, or encapsulated by other materials.

**Flexible and Transparent Reduced Graphene Oxide Strain Gauges with Extremely High Gauge Factor**

Joe Neilson and Brian Derby; University of Manchester, United Kingdom

Flexible and transparent strain gauges are of interest for applications such as: e-skins, wearable sensors, voice recognition, and haptic sensing. Development of sensors with high displacement sensitivity which are flexible and transparent remains a challenge. Here, we present the simple and efficient assembly of highly sensitive, flexible and transparent resistive strain sensors formed from sheets of reduced graphene oxide (RGO) assembled at the interface between immiscible solvents.

Previous work on graphene based strain sensors relied on the percolation of electrical current through a network of overlapping graphene flakes deposited on a flexible substrate. As the substrate is strained the stiffer graphene flakes slide past each other and change the resistivity of the network leading to stable and repeatable strain gauges with gauge factors (GF) in the range 100 – 300. [1,2] Thin film sensors with gauge factors around 1000 have been fabricated that exploit networks of cracks that form in thin conductive films, these have GF of around 1000 but the conductive films are opaque to light. [3,4]

In this work, nanoflakes of electrochemically exfoliated graphene oxide (EGO)[5] were assembled at the interface of immiscible solvents to generate an ultrathin film of EGO. By initiating gradients of interfacial tension at the liquid/liquid interface, the EGO film is placed in compression and this generates efficient packing and flake edge contact without significant flake overlap. The ultrathin film was transferred onto flexible and transparent substrates of polydimethyl siloxane and the resulting thin film is a monolayer of EGO flakes with minimal overlap and predominantly edge to edge contact between flakes. The packing density of the transferred films is high (92 %). After chemical reduction, the resulting RGO thin films were highly transparent (transmittance 88 % at 550 nm) and conductive (10000 S/m).

The thin films of RGO on flexible substrate were analysed for their mechanosensing capabilities. To our knowledge, the gauge factor of the strain gauges is the highest reported for graphene oxide based sensors (>2000 over 2% strain). The extremely high gauge factor is enabled by the formation of nanoscale cracks perpendicular to the direction of strain which cause disconnection and reconnection of the RGO film.

**Breathable, Single-Crystalline Electronic Skin**

Hanwool Yeon, Yeongin Kim, Jaekang Song, Wei Kong, Jiho Shin, Kuan Qiao, Sungkyu Kim, Jaeyong Lee, Sanghoon Bae, Peng Lin and Jeehwan Kim; Massachusetts Institute of Technology, United States

Electronic skin patch represents one of the mainstream innovations in human/Internet of Things (IoTs) interfaces technologies, enabling communication of bio-information obtained from the skin to computing machines. For the long-term communication without damping of the device performance during an extraction of the body information
as well as transmission of the data, an interface-stable, conformal contact of the electronic patch on the skin has been developed. Surprisingly, amid this sweeping trend, human skin has been treated mostly as a curvilinear surface for mounting electronic patches to monitor health of internal organs and neglects to recognize how these may affect the biological functions of the skin. Skin is the outmost and the largest organ covering the entire body surface, protecting inner organs from various external hazards and perspiration through the skin pores are essential for preserving the homeostasis of the human body via temperature regulation and water retention. However, non-breathable electronic skin induces degradation of physical properties of skin, more importantly, deterioration of barrier functionality against viruses will lead to secondary infections and complications with physiological problems. Therefore, the electronic skin patch should possess open-spaces that do not block sweat and maintain a perspiration for long-term health monitoring with securing homeostasis of the skin. Here we introduce a platform of breathable electronic skin that can permeable to sweat as well as vapors, showing ~100% breathability on the skin, via a sweat pore-inspired through-holes on thin-film electric modules and skin-like, soft patch. We have engineered through-hole structures by forming ‘dumbbell’ patterns that include kirigami patterns (auxetic fractal cuts) at the patches with drilling the circular holes at the sharp edges of fractal cuts. Such kirigami fractal cuts enhance conformability of the patches on the skin by increasing biaxial expandability while rounded hinges of the cuts prevent stress-localization-induced crack. Dumbbell patterns also drive skin-like elastic modulus of patches, resulting in an imperceptible lamination onto the skin. More importantly, dumbbell hole patterns form open-space onto sweat pore, enabling sweat penetration through the electronic skin in addition to the vapor, thereby long-term attachment without sweat trapping at skin/patch interface. Additionally, such dumbbell-patterned patch system exhibits excellent mechanical endurance (1,000,000 fatigue cycles with 5% strain cyclic loadings). With this precisely engineered skin patches and interconnects, we have developed the method to heterointegrate single-crystalline freestanding semiconductors on them to maximize the sensitivity of the electronic skin. As a sample case for an ultrasensitive sensor, we have integrated 200-nm-thick single-crystalline GaN freestanding membranes on our advanced skin patch. GaN has been selected as it is bio-compatible while its piezoelectric properties can be maximized when it is free from substrate clamping. Thus, high quality GaN epitaxial films are prepared by remote epitaxial growth on graphene-coated GaN wafers followed by mechanical exfoliation from graphene surface. GaN sensor arrays exhibit ultrahigh strain sensitivity with ~5000 of gauge factor (GF) and 0.001% of strain sensing limit without a signal amplifier. This enables monitoring a nanometer-scale mechanical deformation of stratum corneum that contains clinical information such as dehydration and skin complications, unravelling a kinetics of natural skin movement. Our breathable electronic skin system with freestanding single-crystalline sensors lay foundation for developing ultrasensitive electronic skins for monitoring various biomarkers from human body by applying variety of single-crystalline functional materials as active parts in the breathable electronic skins.

3D Graphene Integration with Skeletal Muscle Yongdeok Kim, Gelson Pagan-Diaz, Judy Suh and Rashid Bashir; University of Illinois, United States

Graphene has been spotlighted as a promising nanomaterials for biological applications such as bioelectronics, imaging, drug delivery, and tissue engineering because of its unique and outstanding optical, electrical, mechanical, and biological characteristics. Especially, regenerative properties of graphene and its derivatives let them broadly used for tissue engineering and regenerative medicine area. Among its tissue applications, it is very interesting for skeletal muscle with graphene because it can effect on the adhesion, proliferation, and myogenesis. Skeletal muscles, serving the primary actuator in animals, have been used for biohybrid actuators in the soft robotics field. Integration of a three dimensional (3D) engineered skeletal muscle embedded in extracellular matrix (ECM) with 3D printed hydrogel skeleton ranging from mm to cm scale enabled a locomotion from electrical or optical stimulation for walking or pumping functions. If the biohybrid machine can integrate with electronics, it can be very synergetic
for various functions with electrical applications such as electrical actuation control and sensing.

In this regard, the integration of the conductive graphene electrode with a 3D skeletal muscle tissue has a great potential for electrical applications of biological systems due to its biocompatibility and significant electrical properties. However, its applications for skeletal muscle have been limited on 2D cultured cellular system not for 3D due to the 2D nature of graphene. Although 3D structured graphene systems as a tissue scaffold have been reported using 3D printing or dry spinning with graphene derivatives such as reduced graphene oxide or graphene oxide, they have limited electrical conductivity due to the presence of insulating polymer. In addition, the reduced graphene oxide has a worse uniformity compared with chemical vapor deposition (CVD) synthesized graphene. Several previous work has been reported for the 3D integration using CVD grown graphene using a thin poly (methyl methacrylate) (PMMA) as a supportive layer. However, the PMMA based wet transfer is limited for the biological application due to its cytotoxicity. Although the PMMA layer was removed after graphene transfer, it is difficult to remove the layer perfectly and the remained residue can be problematic for biological applications.

Here, we report a novel 3D graphene transfer method using a poly (ethyelne glycol) diacrylate (PEGDA) supportive layer and its integration with 3D skeletal muscle ring. A softer PEGDA layer enabled the conformal integration of graphene with a millimeter scaled 3D printed PEGDA pillars. The softer PEGDA supportive layer which has a 10^5 times lower Young’s modulus compared with PMMA made a conformal integration with 3D printed pillars, followed by integrated with the muscle ring. Considering the PEG is an FDA approved biocompatible material, it can be a good candidate for 3D biological application with electronics. The 3D integrated graphene on the 3D printed pillars was characterized using Raman spectroscopy and electrical conductivity was measured. As an electrical application with 3D electrode integrated tissue system, the 3D muscle ring on the integrated structure was actuated by electrically with different voltages and frequencies through the transferred graphene which contacts to muscle ring. We believe that it can be a potential integration platform of electronics with 3D in-vitro tissue for electrical applications in the soft robotics or tissue-on-a-chip areas.

Biodegradable Polycarbonate IonGels for Electrophysiology Measurements Luca Porcarelli1, Alexander Y. Yuen1, Roberto H. Aguirresarobe1, Ana Sanchez-Sanchez2, Isabel Del Agua1, Usein Ismailov3, George G. Malliarias2, David Mecerreyes1, Esma Ismailova1 and Haritz Sardon1; 1University of the Basque Country, Spain; 2University of Cambridge, United Kingdom; 3Ecole Nationale Supérieure des Mines, France

In recent years, polymer matrices loaded with ionic liquids - namely iongels - have emerged as promising materials for long-term cutaneous electrophysiology. Iongels display high ionic conductivity, negligible vapor pressure and can be designed on demand. Despite the attractive properties, the availability of biocompatible and biodegradable iongels remains scarce. In this work, biodegradable polycarbonate-based iongels were prepared by organo-catalyzed ring-opening polymerization of N-substituted cyclic carbonate monomers in the presence of imidazolium lactate ionic liquid. Our iongels were able to incorporate up to 30 wt% of ionic liquid without compromising the mechanical properties. The ionic conductivity of these iongels increased with the amount of free ionic liquid, up to 5×10^-4 S cm^-1. Additionally, we showed that the polycarbonate matrix of the iongel can undergo hydrolytic bond cleavage, returning non-toxic degradation products. The iongels reduced the impedance of gold electrodes placed on the skin, and were used to record physiologic signals with accuracy levels similar to that of commercial Ag/AgCl electrodes. The low toxicity and biodegradability of polycarbonate-based iongels make these materials highly attractive for cutaneous electrophysiology applications.

SB07.06.03
Highly Flexible Multi-Modal Capacitive Pressure Sensors Responsive over Wide Pressure Range for Artificial Skin Haechang Lee1, Hanul Moon2 and Seunghyup Yoo1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2Stanford University, United States

Human skin recognizes the information of shape and texture of various objects by sensing tactile and pressure changes in space over a wide dynamic range. In order to mimic such functionalities, artificial skin should not only be sensitive in low pressure range (e.g. tactile stimulation and measure of artery pulse, etc.) but also should be able to detect mid-to-high pressure change. In addition, it is desired to be thin enough to be applicable to various objects. For this reason, film-type pressure sensors using a variety of materials and structures have been widely studied in recent years. However, it has been challenging to realize a wide pressure sensing range and high flexibility at the
same time, because there is a trade-off relationship between wide range and thickness of the pressure sensors. Furthermore, the problem becomes more severe when one tries to realize a multi-modal sensor having high sensitivity in low pressure region as well.

In this study, we propose a flexible capacitive pressure sensor based on topographically patterned arrays of concaved ionic gels as a dielectric layer whose capacitance is responsive to applied pressure, which are positioned in between two substrates having electrodes. The ionic gel film is electrically suitable for high sensitivity due to ultra-high capacitance based on electric double layers, and it is also promising in terms of mechanical properties as a pressure sensing material because it has low Young’s modulus similar to that of rubber. By structuring the surface of the ionic gel film with concave shape of several micro-meter scale to utilize compression of air confined between the structure and an electrode, linear response to large pressure range of over 100 kPa has been obtained. In addition, the complete pressure sensor can be highly flexible because the thickness of the ionic gel film can be reduced near or even below 10 μm. By using an appropriate surface structure of ionic gel film, the sensor shows distinctive responses to low and high pressure regions, respectively, thus demonstrating a multimodal sensing capability for both tactile and pressure signals.

With the overall thickness of the proposed pressure sensor being as low as ca. 15 μm, it exhibits a high degree of mechanical flexibility. Together with this, multi-modal sensing capability, the proposed pressure sensors are expected to be highly beneficial as a key element for artificial skin, which can be important in human-machine interfaces and healthcare products for disabled people.

**Spatial Modulation of Hydrogel Stiffness for Soft and Integrated Wearable Electronics** Hao Liu¹, Moxiao Li¹, Pengpeng Jia¹, Tian J. Lu², Fei Li¹ and Feng Xu¹; ¹Xi’an Jiaotong University, China; ²Nanjing University of Aeronautics and Astronautics, China

One major conundrum that impedes the development and application of the emerging soft and stretchable electronics lies in the integration of electronic components with soft substrates for rational combination of various device functionalities into a single wearable state, since the rigid, nondeformable electronics tend to detach from the deformable substrate under mechanical loadings like stretch. Modulating the stiffness of soft materials in a spatially controllable manner provides a promising solution to this rigid-soft coupling challenge, by shielding the local strain of rigid components while maintaining the stretchable property of soft substrates. Hydrogels with superb biocompatibility and skin-like mechanical features are ideal candidates to interface human body and electronic functionalities for the cutting-edge wearable uses, where there exists a major challenge of spatially modulating stiffness of hydrogel to meet the application demands.

In the present work, we develop a facile and straightforward scheme to spatially modulate hydrogel stiffness through local stiffening of the hydrogel. Locally stiffened patterns on hydrogel featuring highly increased stiffness compared to that of the raw hydrogel can be easily achieved via additional crosslinking the hydrogel. For example, the polyacrylamide-alginate (PAAm-alginate) hydrogel demonstrated here is locally stiffened through additional crosslinking with multi-valent ions in specifically designed areas. The local stiffness of hydrogel can be controllably adjusted by tuning ion concentration and the time of additional crosslinking, providing one order of magnitude enhancement of hydrogel stiffness. The locally stiffened hydrogel shows excellent strain shielding efficacy with only ~12% actual strain observed in the stiffened area, relative to a 100% strain applied to the whole hydrogel substrate. With this strategy, rigid electronic components can be directly mounted onto the locally stiffened sites on hydrogel to isolate strains as induced by substrate stretch. We further develop a hydrogel-based multifunctional integrated electronic device and its satisfactory performance in monitoring temperature, UV exposure and EMG signals unveils the brilliant prospect for advanced wearable healthcare applications.

**SB07.06.06**

**Ultra-Efficient and Highly Water-Insensitive Self-Healing Sensing Platforms** Muhammad Khatib; Technion-Israel Institute of Technology, Israel

Imparting self-healing capabilities into soft electronic devices and sensors has been of outmost importance for increasing long-term reliability and sustainability. Though some advances have been made in this endeavor, the use of self-healing electronics in environment of wet and/or (under)water has been most challenging. Herein, we report
on a new self-healing thermoplastic elastomer having high stretchability and mechanical strength that can reach 1000% and ~ 6 MPa, respectively. The elastomer exhibits high (>90%) self-healing efficiency in harsh humidity and/or (under)water conditions without the assistance of any external physical and/or chemical triggers. Flexible electronic devices, chemical and electrochemical sensing platforms were demonstrated to operate in extreme wet or underwater conditions (e.g., salty sea water). Moreover, the healing process eliminates significant electrical leakages that would have been caused by structural damages. The healing process can reach ~90% efficiency, in terms of mechanical strength, within ~ 24 hr even after multiple harsh mechanical scratches or cuts. These highly-efficient and self-healing properties would serve as a shuttling pad for extending the use of flexible electronics outside lab applications and for widening the spectrum into wide variety of wet (implants) and sub-marine applications.

**SB07.06.07**

**Conductive, Self-Healing Interfaces** Antonio Riu¹, Gabriel Gaal¹, Carlos Avila-Avendano², Anerise Barros², Mônica J. Andrade², Varlei Rodrigues¹, Manuel Quevedo-Lopez² and Ray Baughman²; ¹Universidade Estudal de Campinas, Brazil; ²The University of Texas at Dallas, United States

Soft and healable structures mimicking biological systems have received great attention due to their applications in flexible electronics, soft robotics and bioelectronics. The layer-by-layer technique is a simplified, elegant way to form nanostructures having molecular level thickness control, and homogeneous dispersions of materials for the formation of multifunctional nanocomposites. Thereafter, poly(ethyleneimine) (PEI) and poly(acrylic acid) (PAA) LbL matrices have been extensively explored in this task due to its intrinsic self-healing ability when in contact with water at ambient conditions. Here, we studied the incorporation of conductive materials (metallic nanoparticles, PEDOT:PSS and reduced graphene oxides) in the (PEI/PAA) LbL matrix in order to check a balance between healing and electrical properties. The main motivation has been the fact that the increase in the electrical conduction of the composites implies in a decrease in the healing ability. Electrical and mechanical characterizations were performed in distinct molecular architectures, with multiple healing cycles verified in one case that presented high electrical transport.

Acknowledgment: Capes, CNPq, INEO, Fapesp (2017/19862-3 and 2017/11277-4) and NanoTech Institute at the University of Texas in Dallas.

**Self-Healable Organic Electrochemical Transistor with High Transconductance, Fast Response and Long-Term Stability for Robust Bioelectronics** Wei Lin Leong, Jieun Ko, Xihu Wu and Abhijith Surendran; Nanyang Technological University, Singapore

Organic electrochemical transistors (OECTs) are highly attractive for applications ranging from circuit elements, neuromorphic devices to transducers for biological sensing and the archetypal channel material is poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate), PEDOT:PSS. The operation of OECTs involves the doping and dedoping of a conjugated polymer due to ion intercalation under the application of a gate voltage. The major challenges in developing self-healable conjugated polymers for organic electrochemical transistors (OECTs) lie in maintaining good mixed electronic/ionic transport and the need for fast restoration to the original electronic and structural properties after the self-healing process.

Herein, we demonstrate ionic liquid doped PEDOT:PSS that shows good mechanical properties, robust towards physical deformation and further capable of showing high transconductance, fast transient response and high device stability over 3600 switching cycles.[1] Next, we provide the first report of an all solid state OECT that is self-healable and possess good electrical performance, by utilizing a matrix of PEDOT:PSS and non-ionic surfactant as channel, and ion conducting poly(vinyl alcohol) hydrogel as a quasi-solid-state polymer electrolyte. The fabricated OECT exhibits high transconductance (maximum 54 mS), on/off current ratio of ~1.5×10³, fast response time of 6.8 ms and good operational stability after 68 days of storage. Simultaneously, the OECT showed remarkable self-healing and ion-sensing behaviors and recovered ~95% of its ion sensitivity after healing. These findings will contribute to the development of high performing and robust OECTs for wearable bioelectronic devices.

Sheet-Type Instrumentation Amplifier Integrated with Bio-Conformable Organic CMOS Circuit and Thin-Film Resistors
Masahiro Sugiyama1,2,3, Takafumi Uemura1,3, Masaya Kondo1,2,3, Mihoko Akiyama1, Naoko Namba3, Yumi Inoue1, Shusuke Yoshimoto1, Tepppei Araki1,2,3, Yuki Noda1 and Tsuyoshi Sekitani1,2,3; 1The Institute of Scientific and Industrial Research, Japan; 2Osaka University, Japan; 3Advanced Photonics and Biosensing Open Innovation Laboratory, National Institute of Advanced Industrial Science and Technology (AIST), Japan

In this study, we have developed a sheet-type biosignal voltage amplifier integrated with fully flexible electronic components. The biosignal amplifier comprises from thin-film resistors and CMOS circuits with organic thin-film transistors (OTFTs). All electronic components were integrated on a single 1-μm-thick polymeric foil, therefore showing high mechanical flexibility and conformability to attach on a soft human skin surface. The sheet-type amplifier shows high signal gain over 55 dB that can be tunable by the resistance control of feedback thin-film resistors. The use of such flexible voltage amplifier would play a significant role as an analog-front-end of wearable bioelectrical interfaces for processing human physiological activities.

Flexible and bio-conformable organic circuits are expected to build active electronic components of wearable medical and healthcare applications. In this sense, various kinds of fabrication processes and materials have been intensively studied to realize high performance OTFTs[1,2]. However, electronic circuits with OTFTs such as voltage amplifier are not still satisfactory to condition weak biological information with high signal integrity due to the substantial electrical variations in OTFTs and the lack of flexible passive components such as resistors and/or capacitors with high yield.

The developed circuit is based on an instrumentation amplifier with integration of organic CMOS operational amplifier circuits and film metal resistors. The organic operational amplifier comprises from p-type and n-type OTFTs, and exhibits the high amplification gain of 2,185 ± 272 with the low supply voltage below 3 V. Parylene dielectrics with the surface modification of thermally-evaporated triptycene layer were used for the gate dielectrics, enabling field-effect mobility of 0.68 cm²/Vs for p-type OTFTs and 0.12 cm²/Vs for n-type OTFTs. Thin-film resistors were realized by the 3-nm-thick and 14 μm-wide nichrome layers with the sheet resistance of 765 Ω/square. We also implemented compensation techniques on the organic circuit utilizing top-gate structures to reduce the electrical variations in the amplifier, enabling low input offset voltage ~ 0 V.

Printed, Ultrathin and Transparent Organic Electrochemical Transistors via Selective Wetting and Thermal Lamination for Soft Bioelectrical Interfaces
Ashuya Takemoto1,2,3, Teppei Araki1,2,3, Yuki Noda1, Takafumi Uemura1,3 and Tsuyoshi Sekitani1,2,3; 1ISIR, Osaka University, Japan; 2Graduate School of Engineering, Osaka University, Japan; 3Advanced Photonics and Biosensing Open Innovation Laboratory, National Institute of Advance Industrial Science and Technology (AIST), Japan

This work reports on ultrathin and transparent organic electrochemical transistors (OECTs) fabricated with printing technologies of selective wetting and thermal lamination. The printed OECTs exhibit high transconductance of gm = ~0.97 mS, high stability to diluted-water washing (~8.7% change in gm), and mechanical durability to crumpling. Furthermore, the biosignal amplification using the printed OECTs can be demonstrated. These features of printability, high gain, washability, and flexibility would be suitable for disposable and soft bioelectrical interfaces. OECTs are attracting interest as ideal bioelectrical interfaces because of many advantages such as low-voltage operation, high transconductance, and biocompatibility [1–3]. Recently, the OECTs have been constructed in ultrathin design with 2–4 µm thickness and used as soft bioelectrical interfaces to evaluate brain and heart activities [2, 3]. Until now, the ultrathin OECTs have required the complicated fabrication process such as photolithography, but they could be more cost-effective by manufacturing with low-cost and high-throughput printing technologies. However, the ultrathin OECTs are still limited to inert gold electrodes prepared with thermal vacuum evaporation, because O2 plasma process to prepare through holes in OECTs encapsulation layers can easily dysfunction most printable electrodes such as metal nanomaterials, nanocarbons, and conductive polymers.

Here, this work introduces the thermal lamination process for encapsulation of printed ultrathin OECTs. First in the fabrication, transparent silver-nanowires (AgNWs) electrodes and PEDOT:PSS active layers are printed by using a selective-wetting method with hydrophilic/hydrophobic surface patterns. Then, for the encapsulation, a parylene film with through holes is thermally laminated onto a base parylene film with AgNWs and PEDOT:PSS. This thermal lamination allows us for the low gate-leakage current, and for the narrow ion-electron interaction sites (=
channel areas with ~100 µm width) between PEDOT:PSS and electrolytes. The completed OECTs achieve stable low-voltage operation < 0.6 V with negligible changes in \( g_m \) after diluted-water washing (~8.7% change) and under white-light illumination (~0.35% change). Furthermore, the OECTs exhibit high transconductance of \( g_m = \sim 0.97 \) mS, comparable to OECTs fabricated with inert gold electrodes [2, 3], and mechanical durability to crumpling (~25% change) due to the ultrathin design with total 2 µm thick. This presentation will show the detailed information on the printing technologies, the OECTs properties, and biosignal (ie. EEG, ECG) amplification demonstration.

SB07.06.14
Building High-Performance FETs at DNA-CNT Interface Mengyu Zhao1, Kexin Wang1, Ming Zheng2 and Wei Sun1; 1Peking University, China; 2National Institute of Standards and Technology, United States

Building high-performance field-effect transistors (FETs) is the foundation towards using CNTs in future high-performance logic circuits, flexible sensors and diagnostic platforms. In particular, aligned CNT arrays with both parallel orientation and evenly small spacings promote on-state performance and accelerate on-off switching. Conventional thin-film approaches produce inter-CNT spacings down to 2 nm, on the cost of wide orientation and crossing CNT junctions, which lead to large subthreshold swing (slow on/off switching) around 500 mV/dec.

Self-assembled biomolecular templates, especially DNA, exhibit complex in silico designed morphologies and atomic-precise dimensions. Using biomolecule-templated fabrication, CNT FETs have been constructed with prescribed CNT orientations. However, surface charges and metal ions within biomolecular templates surround the assembled CNTs, which screen the gate modulation and increase the scattering of charge carriers. As results, the biomolecule-templated FETs typically exhibit one order of magnitude worse on-state performance and on/off switching compared to those fabricated from non-biomolecule approaches.

We here develop a general strategy in constructing high-performance FETs at biomolecule (DNA)-CNT interface. CNTs aligned onto self-assembled DNA templates exhibit uniform inter-CNT spacing down to 8 nm. Next, we explore the impact of DNA at the FET channel area. Within a top-gated PMOS FET, high-concentration DNAs negatively shift the threshold voltage, and increase the doping level at n-region. Furthermore, we invent a method that eliminate DNA templates without affecting the CNT alignment after DNA removal. Using this method, we finally construct multi-channel CNT FETs with record-high transport performance in biomolecule-templated FETs (10 folds better than previous records). Both high on-state conductance (exceeding 0.3 mS/um) and fast on/off switching (less than 150 mV/dec) have been simultaneously demonstrated within a same FET, which is still challenging via conventional thin-film-based approaches.

More generally, current strategy could be used to construct diverse devices at biology-electronics interface, including bio-compatible or bio-implantable optoelectronics and multiplexed sensors. It could also be used to construct 3D device architectures over wafer scale, thus building a bridge between precise biomolecular self-assembly and high-performance electronics.

SB07.06.15
Highly Stretchable Organic Electrochemical Transistors Yang Li1, Shiming Zhang2 and Fabio Cicoira1; 1Polytechnique Montréal, Canada; 2University of California, Los Angeles, United States

Organic electrochemical transistors (OECTs) become suitable candidates for biological interfacing and logic circuitry applications due to the synthetic tunability, facile fabrication, and bio-compatibility. Our group has demonstrated stretchable OECTs can be stretched up to 30% strain while maintaining identical transistor characteristics via optimizing the processing conditions during device fabrication. However, some circumstances, such as heart beating monitoring, require electronics to withstand larger strain comparing with wearable electronics on the skin (30% strain). In this talk, we show that the addition of polyethylene glycol (PEG) can greatly enhance the stretchability of conducting polymer films on the elastomer. With the formation of microcracks at a pre-set strain, the conducting polymer can maintain a stable current during high strain stretching cycles. As a result, the OECTs using highly stretchable conducting polymers as the channel material can keep the same performance during
stretching even at strain higher than 30%. This work paves the way for OECTs applications as conformable biosensors or bio-electronics which need to endure high strain, such as heartbeat monitoring.

Transfer-Printing PEDOT:PSS Films with Hydrogels Haonan Ling, Shiming Zhang, Ali Khademhosseini and Martin Hartel; University of California, Los Angeles, United States

The use of conducting polymer PEDOT:PSS for the development of flexible organic bioelectronic devices, such as organic electrochemical transistors (OECTs), is growing fast [1] [2]. However, direct manipulation of PEDOT:PSS thin films on flexible substrates remains challenging [1] [3]. Transfer printing films from glass to flexible substrates offers an alternative solution. In this communication, we report that PEDOT:PSS thin films on glass substrates, once mixed with surfactants such as dodecylbenzene sulfonic acid (DBSA), can be delaminated with hydrogels and thereafter transferred to flexible substrates without any further treatments. The proposed method allows easy, fast, and reliable transfer of patterned PEDOT:PSS thin films from glass substrates to various soft substrates, facilitating their application for soft organic bioelectronics. We take advantage of this method and demonstrate a skin-attachable OECT prototype, which is relevant for conformable, lightweight, and wearable biosensing.

Ultra-Low Fouling PCB Layer on PEDOT:PSS Based Organic Electrochemical Transistor for Sensitive Ion Detection in Human Serum Shin-Ya E. Chen, Erjin Zheng and Qiuming Yu; University of Washington, United States

Organic Electrochemical Transistor (OECT) is a voltage to current transducer with high transconductance (~1 mS) and low operating voltage (< 1 Volt). These features make OECT a good candidate as biosensor. Instead of typical solid dielectric material used in Organic Field Effect Transistor (OFET), electrolyte is used to couple gate and channel in OECT. In particular, ions which injected from electrolyte to channel will either dope or de-dope the channel conducting polymer (CP) and modulate the bulk conductivity of channel. The ion injection lies in the center of all OECT applications. If ions can’t diffuse into CP channel, the OECT will operate as an electrolyte-gated OFET with smaller transconductance. To date, the most common used CP material in OECT is Poly(3,4-ethylenedioxythiophene): Poly(styrenesulfonate) (PEDOT:PSS) due to its high conductivity and solution processability. PEDOT:PSS based OECT had been used for cation detection as well as detecting metabolites and protein biomarker concentration in Phosphate-buffered Saline (PBS) solution. However, when tackling with human serum or plasma, albumin and other proteins will non-specifically attach onto channel CP surface. This may hinder the ion injection and cause the false detection results for PEDOT:PSS based OECT biosensor.

In this work, we covalently link a roughly 30 nm thick copolymer with carboxybeteaine functional group on top of PEDOT:PSS based OECT device. We then investigate the device ion sensing ability after the surface is exposed to 5 Wt% Bovine Serum Albumin (BSA) solution or human serum. The copolymer used is PCB(30%), poly(Carboxybeteaine acrylamide (CBAA) -co- n-buty methacrylate (BMA) -co- N-(4-benzoylphenyl) acrylamide (BPAA)), with CBAA, BMA and BPAA at 7:2:1 ratio. While in contact with aqueous solution, the carboxybeteaine functional group will flip onto surface and prevent the non-specific adsorption. The BMA functional group helps the copolymer to attach onto the surface while the BPAA functional group reacts with alkyl backbone of CP after UV
Biocompatible microbatteries have a high potential as energy sources for a wide range of applications—electronic medical implants, health monitoring devices, and environmental sensors. One concrete example of the application of such microbatteries is in ingestible electronic devices. These devices can be employed for regular monitoring of vital body functions such as core body temperature, pH level, for controlled drug release, and for checking of medication adherence. Presently, ingestible electronic devices are usually powered by relatively large batteries that often contain toxic materials. As a consequence, the whole battery necessitates encapsulation to avoid any leakage of potentially harmful substances into the body, but this also makes the devices difficult to swallow and increases the risk of retention inside the body. Moreover, fabrication of the batteries is mainly based on conventional, macroscale techniques and therefore possesses only limited prospects for miniaturization and mass production. Previously, we developed a primary biocompatible microbattery that was entirely realized by conventional microfabrication techniques. However, the thin film electrodes (thickness about 2–3 µm) had only limited capacities of about 0.5–0.8 µA h, enabling operating times of about 10–25 minutes.

To overcome these limitations and to increase the capacities, we have developed microbatteries that can be realized by a combination of conventional microfabrication and direct printing of the active materials using functional inks. The device consists of two main parts: a Si microreservoir that is filled with the electrolyte (gastric acid) once the device is swallowed, and the microbattery itself. The Si microreservoir was fabricated by dry etching in Si, which was then bonded to a glass wafer that contained the microbattery. For the fabrication of the cathode and anode, Au thin films were first deposited as current collectors (nominal size 0.7 × 3.2 mm²), using standard photolithography followed by sputtering. The anode ink consisted of Zn powder that was mixed with ethyl cellulose as binder and acetylene black to increase the conductivity, while Ag/AgCl ink was used for the cathode. Both Ag/AgCl cathodes and Zn anodes were printed directly on the current collectors using a custom-made 3D printing system, allowing electrode thicknesses of the order of 100–150 µm. The performance of the microbatteries was assessed by galvanostatic testing in simulated gastric fluid (pH 1.2) at current levels ranging from 2 to 10 µA. Compared to the sputtered thin film electrodes, the printed electrodes enabled increasing the capacities to about 10 µA h. It is expected that by optimizing the ink composition, especially the content of the active materials, that the capacities can be increased further. The combination of established microfabrication techniques with direct printing is expected to enable more complex microbattery architectures, allowing customized and easier-to-integrate energy sources in future electronic devices aimed at medical and environmental sensing applications.

**Microbatteries for Ingestible Electronic Devices Realized by Combining Conventional Microfabrication with Direct Printing**  
Sven Stauss, Ryuichi Miyazaki, Yoshiyuki Gambe and Itaru Honma; Tohoku University, Japan

Biocompatible microbatteries have a high potential as energy sources for a wide range of applications—electronic medical implants, health monitoring devices, and environmental sensors. One concrete example of the application of such microbatteries is in ingestible electronic devices. These devices can be employed for regular monitoring of vital body functions such as core body temperature, pH level, for controlled drug release, and for checking of medication adherence. Presently, ingestible electronic devices are usually powered by relatively large batteries that often contain toxic materials. As a consequence, the whole battery necessitates encapsulation to avoid any leakage of potentially harmful substances into the body, but this also makes the devices difficult to swallow and increases the risk of retention inside the body. Moreover, fabrication of the batteries is mainly based on conventional, macroscale techniques and therefore possesses only limited prospects for miniaturization and mass production. Previously, we developed a primary biocompatible microbattery that was entirely realized by conventional microfabrication techniques. However, the thin film electrodes (thickness about 2–3 µm) had only limited capacities of about 0.5–0.8 µA h, enabling operating times of about 10–25 minutes.

To overcome these limitations and to increase the capacities, we have developed microbatteries that can be realized by a combination of conventional microfabrication and direct printing of the active materials using functional inks. The device consists of two main parts: a Si microreservoir that is filled with the electrolyte (gastric acid) once the device is swallowed, and the microbattery itself. The Si microreservoir was fabricated by dry etching in Si, which was then bonded to a glass wafer that contained the microbattery. For the fabrication of the cathode and anode, Au thin films were first deposited as current collectors (nominal size 0.7 × 3.2 mm²), using standard photolithography followed by sputtering. The anode ink consisted of Zn powder that was mixed with ethyl cellulose as binder and acetylene black to increase the conductivity, while Ag/AgCl ink was used for the cathode. Both Ag/AgCl cathodes and Zn anodes were printed directly on the current collectors using a custom-made 3D printing system, allowing electrode thicknesses of the order of 100–150 µm. The performance of the microbatteries was assessed by galvanostatic testing in simulated gastric fluid (pH 1.2) at current levels ranging from 2 to 10 µA. Compared to the sputtered thin film electrodes, the printed electrodes enabled increasing the capacities to about 10 µA h. It is expected that by optimizing the ink composition, especially the content of the active materials, that the capacities can be increased further. The combination of established microfabrication techniques with direct printing is expected to enable more complex microbattery architectures, allowing customized and easier-to-integrate energy sources in future electronic devices aimed at medical and environmental sensing applications.
Recent advances in soft electronics have enabled a class of bio-integrated sensors that combine advanced sensing functionality with skin-compliant form factors that reduces contact resistances and motion artifacts. Research efforts have yielded a range of biophysical and biochemical sensors for measurements of motion, electrophysiology, sweat biomarkers, temperature and several other clinically relevant quantities.

Here, we demonstrate the use of arrays of thermal sensors and actuators to map out heat transfer through soft tissue and extract properties such as thermal conductivity, thermal diffusivity and volumetric heat capacity. The low thermal masses and contact resistances of these sensors are uniquely suited to making these precise, quantitative thermal measurements to extract depth-dependent tissue properties as they correlate to vascular perfusion, skin hydration and overall activity level. We will discuss three broad areas where we have made significant recent progress:

1. **Measurements of skin thermal transport properties for a range of clinical conditions:** The thermal transport properties of skin are determined by its constituent materials, including vasculature and free and bound water molecules. These constituents change in response to activity levels and changes in ambient thermal conditions, a critical mechanism for thermoregulation. We present materials, mechanics and thermal transport considerations to map out heat transfer as a correlate for each of the above, with systematic validations in the form of benchtop studies, finite element analyses and on-body testing. These sensors can also be used to map directional, anisotropic thermal transfer in the presence of flow through large blood vessels or implanted catheters. We discuss the potential of these materials advances to in the creation of a class of wearable flow sensors to fundamentally improve the care and treatment of patients suffering from hydrocephalus, a neurological condition caused by the buildup of cerebrospinal fluid in the ventricles of the brain.

2. **Fully implantable flow sensors to map vascular changes through peripheral nerves:** The peripheral nervous system represents a large research area for materials scientists and neuroscientists alike, presenting challenges due the mechanical mismatch between soft, deformable nerves and traditional rigid, metallic recording electrodes. Here, we discuss our recent work in creating a class of soft, tissue-compliant nerve ‘cuffs’ formed via a novel buckling process of pre-strained elastomer bilayers, that are instrumented with the thermal characterization electronics discussed above. These sensors are capable of measuring blood perfusion through peripheral nerves in a manner that can be correlated with overall nerve health.

3. **Wireless powering and data transfer schemes:** Wireless power and data transfer are critical for the deployment of these sensors for continuous, real-time monitoring. We discuss two paradigms for wireless operation that offer the advantages of soft, tissue-compliant materials, while allowing for high-precision data transfer and completely wireless powering. The first involves the use of near-field communication (NFC) while the second involves Bluetooth-low energy (BLE) protocols. We demonstrate the utility of these materials integration schemes for measurements of skin hydration and flow.

**A Novel, Flexible and Ultra-Thin Pressure Sensor for Concentric Tube Manipulators in Intra-Ventricular Neurosurgery Robotic Tools** Tianhao Chen, Zia Saadatnia and Hani E. Naguib; University of Toronto, Canada

In minimally invasive endoscopic intraventricular surgeries, very small robotic surgical tools such as a grasper and cutter can be designed and miniaturized to a size of less than 2 mm while maintaining its dexterity and force required to resect brain tumors without open-skull surgery. However, due to remote control the robotic systems, there are very limited haptics namely tactile and kinesthetic information being received by the surgeons, leading to loss of control over tissue and causing unexpected slippage and trauma. This study presents the design of a small and highly sensitive smart material-based sensor being integrated to the tool shaft, known as the concentric tube manipulators, to provide instrument-tissue interaction force feedback for this tool. A 100 μm-ultrathin layer of micropatterned resistive carbon-filled polyvinylidene fluoride (PVDF) conductive polymer is wrapped spirally around the 2 mm-diameter concentric tube for static and quasi-static force sensing. A layer of interdigitated electrodes, connecting with a high-frequency, real time data acquisition (DAQ) system, is designed to achieve pressure readings with both directional and locational information. These pressure readings are visual pressure profile displays generated based on concentric tube-brain tissue contact mechanics with assumption of cylinder-sphere contact model. Optimizations are performed on the size, pitch and shape of the microstructures as well as the...
width and spacing of the electrodes to improve sensitivity with reduced hysteresis. The finalized design can sense a pressure from as low as 0.55 kPa to 5.5 kPa with an accuracy of 93%. The sensor demonstrates excellent proportionality between the acquired signal and force applied with 91% consistency under small loads while retaining its flexibility, biocompatibility and sterilizability. The sensor will also enhance more intuitive force feedback for surgeons to use the dexterous neurosurgical tool, ensuring the safety and quality of operations for minimally invasive surgeries involving brain tumor and epilepsy practice.

SB07.06.21
Epidermal Electronics as a P300-Based Wireless Brain-Computer Interface Joohwan Shin and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Progress in highly conformal epidermal electronics led electrophysiology recording based on dry electrodes which breakthrough critical problems such as low skin-electrode impedance and motion artifact issues. These astonishing advances give a new opportunity to Brain-Computer Interface (BCI) which is using non-invasive electroencephalography (EEG) recording. Nevertheless, researches so far have just reported electrical and mechanical performance of electrode or suggested elementary exemplification about recording EEG. Here, we introduce a comprehensive wireless BCI system which can be used in daily life such as driving situation, based on depth study about Event-Related Potential (ERP) and tattoo-like epidermal electrode. P300, which is one of the main components of ERP, is considerably used in BCI application and occurred from brain when a person recognizes unexpected stimulus. In this study, P300 wave was thoroughly analyzed from 10 different subjects, three different oddball paradigm tests, both epidermal and conventional electrode simultaneously and motion induced situations to ensure compatibility of epidermal electronics and P300-based BCI. In addition, we present device structures and fabrications, electrical and artifact characteristics of epidermal electrode, epidermal electrode positioning strategy, skin mounting methods, P300 wave recording procedures, and design of miniaturization FPCB chip to measure EEG and communicate wirelessly. As a proof-of-concept, mobile RC car was used as target platform and we compared braking distance between BCI based autonomous driving car and manually controlled driving car in the emergency situations.

SB07.06.22
Correlating Electromechanical Patterns with Hand Gestures Based on Cytoadhesion-Inspired Hybrid Electrodes Pingqiang Cai, Jing Yu and Xiaodong Chen; Nanyang Technological University, Singapore

Hand gesture recognition based on muscle activity monitoring has been implemented in robust human-machine interactions, bionic prosthetics, and prognosis of neuromuscular disorders. Muscle activities involve myoelectrical trigger of motor neurons at neuromuscular junctions and the mechanical actuation of muscle fibers. Monitoring the functionality of either single event has been fulfilled with various electromyogram electrodes or skin-mountable strain sensors. However, the patterns of myoelectrical triggers and mechanical shortening of myofibers can be different spatiotemporally, intrinsically arising from the excitation-contraction coupling process. Hence, the fidelity of interpretation muscle activities by retrieving either single event is disputed. There is an unmet demand on establishing the electromechanical coupling of the myoelectrical triggers and mechanical responses in muscle for the high-fidelity hand gesture recognition. To address this, we developed the hybrid electrode to spatiotemporally couple the surface electromyogram (sEMG) signals and the mechanical strain of local skin. By resembling the transmembrane architecture of cytoadhesion, the electrode utilized discrete “adhesion plaques” to mechanically and electrically integrate the microcracked metallic nanofilms for strain sensing at a gauge factor, and the ionic gel with low contact impedance for sEMG collection at a high signal-to-noise ratio. By establishing the electromechanical patterns of forearm muscle contraction, the electrode was able to distinguish loose and tight fist clenching, as well as the flexion of different fingers. In addition, the electrode was able to orthogonally recognize the hand gesture dynamics, which could be transferred to robotic hands for recapitulating human grip gestures with varying dynamics.

A Wireless-Powered, Biosensing Soft Contact Lens Taiki Takamatsu, Lu Chen, Te Xiao, Lunjie Hu, Shujie Fang and Takeo Miyake; Waseda University, Japan

Smart contact lenses—contact lenses with built-in electronics—are a next-generation wearable product with capabilities beyond simple vision correction. Since the electrical lenses are in continuous contact with the eyeball
surface, they have three main applications: (i) biomedical sensing of tears to monitor health conditions, (ii) wearable displays for augmented reality (AR), and (iii) actively regulating eye accommodation to ensure perfect vision. Thus, a smart contact lens has substantially greater functionality than an electrical eyeglass. Here we demonstrate electrochemically (EC) printing a wireless-powered circuit onto a moist, soft contact lens. EC printing involves adding a conductive polymer at the interface between a metal contact and a hydrogel-based contact lens, resulting in strong adhesion of the circuit to the lens without losing high power transfer efficiency (50%) from an eyeglass transmitter to the printed receiver lens. Our wireless powered system is combined with an AC/DC rectifier circuit for a single LED display and for electrochromic filter applications.

SB07.06.24
An Eco-Friendly and Flexible pH Sensor for Chronic Wounds Monitoring Manni Yang and Kwang-leong Choy; University College London, United Kingdom

Different from normal wounds, chronic wounds often have a large and deep wound area and patients often experience long-term suffering from inflammation and bacterial infection. In chronic wounds healing process, pH is a key parameter, indicating the state of bacterial infections. For a healthy skin, the typical pH is 5.5-6.5, while in chronic wounds, the pH can be above 8 due to the by-products created by bacteria in the process of cell proliferation. In order to treat wound promptly and effectively, pH monitoring requires multiple measurements from the wound area with high spatial resolutions. However, current wound sensors are mostly in solid forms and cannot detect in different depth of wound area comprehensively, while some flexible sensors are costly and with some chemical-based fabrication methods or materials that could be potentially harmful in human body. Herein we proposed an eco-friendly fabrication of, flexible and highly sensitive pH sensor for chronic wounds based on bio-derived materials. The resulting composite sensor has near Nernst limit pH sensitivity in the pH range from 4-10, with low Young’s modulus, and also has a long-term sensitivity lasting for at least 24 hours. This renders its applications in flexible bio-sensors and smart wound dressings.

SB07.06.25
Novel Optical Polymers and Patterning Technologies for Flexible Bio-Optoelectronics Komal Kampasi, Jenny Zhou, Alicia Calonico Soto, Vu Nguyen, Susant Patra and Razi Haque; Lawrence Livermore National Laboratory, United States

Advanced nano-science and patterning technologies are constantly evolving to meet the ever-growing expectations for improved flexible optical MEMS. In this work, for the first time to our knowledge, we compare state-of-art commercially available photo-definable optical polymers, namely Ormoclear FX and Ormocomp (hybrid polymers called ormocers), IP-Dip (UV resin) and Epocore (an improved SU8-like epoxy) and explore their suitability for design of flexible bio-optoelectronics. We demonstrate micro- and nano-technologies to pattern optical films on polymer substrates and evaluate their characteristics such as optical transmission and clarity, in vivo lifetime and resistance to photodamage.

Flexible optical materials can be used for applications ranging from waveguide circuits in optical interconnects to micro-lens for CCD/CMOS imagers to optical sensors in bioimplants and wearables. The advantages of polymers include lightweight, flexibility, thin film formation at lower temperatures and wide range of molecular designs. Unlike semiconductor material growth and deposition approaches which are carried out at higher temperatures, polymers can be spun at room temperature and cured at relatively lower temperatures to achieve wide range of thicknesses. With the aid of computational models, polymer molecular formations can be synthesized to tune in optimal physical properties like elasticity, tensile strength and so forth. However, common drawbacks of polymers are narrow range of controllable optical properties such as transmittance, transparency, durability and high moisture absorption. Recently, nano-hybridization of polymers with metallic or inorganic nano-particles has been proposed as a promising technique to overcome polymers’ drawbacks without reducing their inherent advantages. Our results show that hybrid polymers Ormoclear FX and Ormocomp are indeed most flexible (1-1.2 GPa Young’s modulus) with highest transmissivity in visible and near infrared spectrum, high optical transparency and good photodamage resistance. These characteristics make ormocers most preferable for polymer optics including long-term biomedical applications such as waveguiding and imaging. Epocore and IP-Dip are comparable to polyimide and parylene in flexibility (~3GPa of Young’s modulus) but exhibit lower optical transmission in UV/near-UV range with average optical clarity. All polymers withstand a 6-month equivalent accelerated saline soak with only 2-6% decrease in transmissivity over 300-800nm spectral range demonstrating appreciable resistance to in vivo degradation. The results conclude that unique polymer characteristics combined with compatible patterning technologies can be
applied to target different optoelectronic applications. While nanoscribe printing (with IP-Dip and Ormocomp) was found suitable for high precision 3D printing of microstructures like diffractive optical elements, optical bonds and hollow guides; 2D microfabrication (with Ormoclear FX and Epocore) was better suited for reliable design of continuous and longer optical structures such as waveguides.

Xanthommatin-Based Electrochromic Displays Inspired by Squid Skin

Amrita Kumar¹,² and Leila Deravi¹;
¹Northeastern University, United States; ²University of Connecticut, United States

Color is a signature visual feature in nature; however, the ability to trigger color change in the presence of different environmental stimuli is unique to only a handful of species in the animal kingdom. We exploit the natural color changing properties of the predominant pigment in arthropods and cephalopods - xanthommatin (Xa) - and describe its utility as a new broad-spectrum electrochromic material. To accomplish this goal, we explored the spectroelectrochemical properties of Xa adsorbed to an indium-doped tin oxide (ITO) coated substrate chemically modified with poly (3,4-ethylene dioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS). We identified a synergistic role between PEDOT:PSS and Xa that contributed to its absorption profile which could be modulated across multiple cycles. This bio pigment was encapsulated into polymeric material and investigated color tunability in response to pH and electrochemical reaction. Enhanced visible through SWIR scattering makes this nano material as a potential candidate for IR colorant.

SB07.06.27

Synthesis and Characterization of Phosphonated PEDOT—A Novel, Water-Processable Conjugated Polyelectrolyte

Jonathan A. Hopkins, Kristina Fidanovski, Lorenzo Travaglini and Damia Mawad; University of New South Wales, Australia

Conjugated polymers have great potential as flexible, electroactive materials for cell stimulation, but their application is often hindered by their limited processability in non-toxic solvents. A promising solution lies in conjugated polyelectrolytes (CPEs) bearing ionizable pendant groups; these materials are processable in water and exhibit “self-doping” behaviour without the need for external dopants or dispersants. We report the synthesis and characterization of a novel CPE, poly(ethylenedioxythiophene) doped with ionizable phosphonate groups (PEDOT-Phos), which is soluble in several solvents including deionized water, phosphate-buffered saline, and dimethylformamide. Raman spectroscopy confirms the presence of both the conjugated PEDOT backbone and the phosphonate pendant groups. The polymer undergoes changes in ultraviolet-visible light absorption and photoluminescence spectra as a function of pH, indicating polaron formation. This pH-dependence is attributed to the tunable ionization behaviour of the phosphonate pendant groups. The polymer is readily processed directly from aqueous solution into semi-crystalline films, which exhibit strong visible-light photoluminescence and reversible redox behaviour. The morphology of cast films can be controlled by modifying the casting solvent and performing thermal annealing. With its intriguing optoelectronic properties and easy processing from aqueous media, PEDOT-Phos has significant potential as a novel, electroactive substrate material for bioelectronic devices.

SB07.06.28

Flexible Biomimetic Polymer Thin Films for High Resolution Temperature Measurement

Tae Hyun Kim, Zhun Zhou, Vincenzo Costanza, Luca Bonanomi, Linghui Wang and Chiara Daraio; Caltech, United States

Flexible thermal sensing devices have shown great potential towards many biomedical applications and robotic/machine interfaces in which direct conformal measurement over complicated geometry is necessary. However, conventional inorganic materials widely used to fabricate the sensory element either inherently lacks flexibility and sensitivity, or often requires high temperature processing steps which complicates their integration with flexible plastic substrates. Recently, we have demonstrated that organic thin films composed of plant-derived polysaccharide, pectin, can detect temperature changes with more than two order of magnitude higher sensitivity compared to those state-of-art temperature sensing layers. However, the characteristics of these natural products are complex and their properties can vary widely. In addition, pectin films exhibit poor mechanical properties over repeated stress and bending solicitations. Here we report a multifunctional polymer scaffold inspired by pectin. The chemical structure and mechanical properties of the polymer are tailored to retain the thermal response with flexible functionality. Through impedance characterization as a function of temperature, we show that the ionic conductivity within the polymer film is strongly related to temperature and demonstrate its ultra-high temperature responsivity.
and reproducibility that also allows device scalability for large scale integration.

**SB07.06.29**
**Functional Polythiophene Deposition and Biocompatibility with SH-SY5Y Neuroblastoma** Peter Sitarik, David C. Martin, Quintin Baugh, Samadhan Nagane and Yuhang Wu; University of Delaware, United States

We have been investigating the electrochemical deposition of functionalized polythiophenes around neural cells with the goal of creating stable, directly biointegrated electronic devices. Our previous efforts have primarily focused on the well-studied 3,4-ethylenedioxythiophene monomer (EDOT). While the corresponding polymer (PEDOT) has shown considerable potential, its highly hydrophobic character leads to issues when depositing it around living cells. Here, we discuss recent efforts to examine the potential of an EDOT monomer with a pendant carboxylic acid moiety (EDOT-acid). We have examined the cell viability of EDOT-acid relative to EDOT and have found that EDOT-acid solutions are much more cytocompatible. We have also seen variations in the growth mechanisms when P(EDOT-acid) is deposited around living cells. P(EDOT-acid) grows in a manner that is more attached directly to the cell surfaces, rather than to the electrodes as seen with PEDOT. Most recently, we have been examining the deposition of a bifunctional monomer that combines EDOT with dopamine, creating what we call EDOT-dopamide. P(EDOT-dopamide) polymers can also be grown electrochemically and show low impedances over a broad frequency range. The morphological, physical and chemical characterization of these materials with optical and electron microscopy, spectroscopy, and other techniques will be discussed and compared with PEDOT.

**SB07.06.30**

Although peripheral nerves possess the inherent ability to regenerate, nerve transections require surgical intervention to optimize functional recovery. While small gaps (≤5 mm) may be directly coapted without tension, larger gaps may require interposition grafting with nerve auto- or allografts or conduits to provide tension-free mechanical support, axon guidance, and protection from fibrous tissue ingrowth. Conduits avoid the substantial disadvantages of autografts, i.e. a second surgical site, donor site morbidity, limited availability, high treatment cost, but current FDA approved devices are limited to use in defects ≤30 mm. Cadaveric nerve allografts are used only for defects ≤70 mm due to the limited regenerative capacity of neurons through such grafts. Thus, autografts remain the gold standard and outcomes remain suboptimal with only 50% of patients with mixed nerve injuries regaining meaningful motor and sensory function, and less than 15% regaining full functionality.

Nerve guidance scaffolds (NGS), in which piezoelectric nanoparticles (PNPs) are homogeneously distributed enable the possibility of fractionated stimulation of the PNPs using ultrasound (US) to aid speed and quality of regeneration over several weeks and months. Innovative are the application of a straightforward, benign processing technique, freeze casting, to the manufacture of multifunctional scaffolds from a novel PNP composite. The freeze-cast scaffold architecture emulates that of the natural tissue and, through composition and processing parameters, can be custom-designed in its structural, mechanical, and piezoelectric properties. Presented will be a summary of key experimental and modeling results, and correlations obtained during the design, manufacture and testing of the piezoelectric NGS, from the poling of the PNP to enhance their piezoelectric conversion to their structural and piezoelectric characterization, and finally in vitro and in vivo testing. The results suggest that piezoelectric scaffolds and their US stimulation offer a very promising approach for neuroregenerative devices with comparative ease of translation into clinical application.

Are Conducting Polymer Electrodes Capacitive or Faradaic? George G. Malliaras; University of Cambridge, United Kingdom

Organic electrochemical devices, which use conjugated polymers in contact with an electrolyte, have applications in bioelectronics, energy storage, electrocatalysis, and sensors. Their operation relies on the oxidation (electron loss) or reduction (electron gain) of the polymer, which are traditionally described as Faradaic processes that transfer charge. However, recent evidence from various devices based on poly(3,4-ethylenedioxythiophene) chemically doped with poly(styrene sulfonate) (PEDOT:PSS) is consistent with a purely capacitive process that stores charge. To clarify whether PEDOT:PSS is an exception or the rule and determine which processes are capacitive and which are Faradaic, solid-state physics methodology developed to understand the operation of organic light-emitting diodes can be used. Such studies can pave the way for device optimization.

Fiber-Based and Nanomagnetic Neural Interfaces Polina Anikeeva; Massachusetts Institute of Technology, United States

Within 1.3L of human brain billions of neurons connected by trillions of synapses are continuously exchanging signals. These signals govern the inner workings of the nervous system, and the aberrations in communication between neurons and other cells within the brain are manifested as the neurological and mental conditions that increasingly affect our aging society. While clinically available devices lack the finesse of the neural circuits and drugs often come with unwanted side effects, our team leverages the principles of optoelectronics and magnetism to develop tools matching the signaling complexity of the nervous system and cause minimal disruption to natural physiological function.

My talk will discuss how multimaterial fiber technology can be leveraged to produce compliant and miniature devices capable of electrical and optical recording and stimulation of neural activity, and delivery and sensing of neurochemicals. I will further highlight how multimaterial fibers can be employed for neural repair following traumatic injury as well as the potential candidates for artificial muscles with future applications in prosthetics. The second half of my talk will focus on using iron-containing nanomaterials as transducers of magnetic fields to biologically relevant stimuli such as heat and force. By tuning magnetic nanomaterials properties in conjunction with magnetic field conditions, it is possible to independently control multiple heat- or force-dependent biological processes. Finally, iron-containing nanomaterials can be used to aid minimally-invasive delivery of neurochemicals via magnetothermal and electrocatalytic means.

9:30 AM *SB07.07.03/SB08.06.03
Microfabricated, Conformable Auditory Brainstem Implants—Materials and Technology Advances towards Clinical Translational Nicolas Vachicouras¹, Christina Tringides², Osama Tarabichi³, Vivek Kanumuri³, Yohann Thenaisie¹, Florian Fallegger¹, Chris Brown³, Daniel Lee³ and Stephanie P. Lacour¹; ¹Ecole Polytechnique Federale de Lausanne, Switzerland; ²Harvard University, United States; ³Massachusetts Eye and Ear Infirmary, United States

The auditory brainstem implant (ABI) is a neuroprosthesis that provides sound awareness to deaf individuals who are not candidates for the cochlear implant. The ABI electrically stimulates the surface of the cochlear nucleus (CN) in the brainstem. The complex anatomy and physiology of the CN together with the poor spatial selectivity of electrical stimulation and inherent stiffness of contemporary implants lead to only modest auditory outcomes in ABI users.

We propose a soft conformable ABI electrode array to improve the biomechanical match of the man-made implant to the curved CN surface. The conformable implant provides stable positioning of the implant in vivo and enables higher selectivity of electrical stimulation. The soft neurotechnology leverages miniaturization, high performance thin-film materials, and engineered mechanical compliance to produce implants compatible with the demanding ABI surgical insertion and conformability to the curvature of the brainstem. We developed elastic micro-structured multilayers, a soft electrode coating, and transient surgical features that allowed the fabrication of a scalable ABI from miniaturized mouse implants to human-size arrays.

This talk will report on the microfabrication and scaling process, mechanical and electrochemical characterization of the compliant ABIs. The soft electrode specifications are very similar to those measured in clinical ABIs with average impedance at 1 kHz of 5.78 ± 0.62 kΩ (electrodes of 0.385 mm² surface area). In a mouse model, we show that soft neurotechnology can be implemented to reliably activate auditory neurons in vivo for up to 4 weeks, a mandatory step before evaluating longer, chronic use of the technology. In a human cadaveric model, we
demonstrate that the soft ABI is robust to surgical manipulation and insertion into the lateral recess of the IVth ventricle, and displays improved electrochemical performance compared to current clinical devices.

Conductive Hydrogel-Coated Cochlear Implants Improve Electrical Performance In Vivo
Ulises A. Aregueta Robles1, Mario Huynh2, Ashley Dalrymple2, Bryony Nayagam3, James Fallon2, Rob Shepherd2, Rylie Green4 and Laura Poole-Warren1; 1UNSW Sydney, Australia; 2Bionics Institute, Australia; 3The University of Melbourne, Australia; 4Imperial College London, United Kingdom

Aim: This study aimed to compare the chronic in vivo charge transfer properties of conductive hydrogel (CH) coated cochlear implant (CI) electrodes to traditional platinum (Pt) CI electrodes.

Background: CIs can improve quality of life in profoundly deaf people by restoring sound perception. Ideally, bionic devices should safely operate for a lifetime; however, host responses such as protein adsorption, inflammation and fibrosis can impact electrode impedance. These host responses can lead to inefficient stimulation and formation of toxic byproducts. CH coatings, based on poly(vinyl alcohol) (PVA) anti-fouling polymers modified with conductive polymers (CPs), can provide enhanced electrical properties, superior to those of traditional Pt electrodes. This technology can be directly coated onto metallic substrate of state-of-the-art bionic devices1. This study tested the hypothesis that PVA conductive hydrogels can enhance safe charge injection and improve the quality of neural recordings.

Methods: CIs with 4 electrodes specifically designed for the rat cochlea were implanted for up to 5 weeks. The CH coating was fabricated using PVA hydrogel modified with 20 taurine groups for electrical doping and 5 methacrylate groups for crosslinking. The CP poly(ethylene dioxythiophene) (PEDOT) was galvanostatically grown through the hydrogel and arrays were ethylene oxide-sterilized (ETO) prior to implantation. Electrochemical impedance (EI), charge injection limits (CIL) and charge storage capacity (CSC) of electrodes was compared before and after implantation using a 3-electrode cell (vs Ag/AgCl). Sprague Dawley rats were unilaterally implanted with CH coated or uncoated Pt CIs. The animals were chronically stimulated using charge balanced biphasic pulses for ~20 hrs/week over the implantation period. To evaluate electrode performance in vivo, voltage transient impedance was measured 5 days/week, and EI, CIL and CSC was also recorded over the implantation period. Explanted electrodes were imaged using scanning electron microscopy (SEM) for evaluation of the CH attachment and for signs of Pt oxidation.

Results: Before implantation, EI of CH coated electrodes over a frequency range of 10Hz-50kHz was more than 3 times lower than uncoated Pt implants. CSC and CIL of CH-coated electrodes was over one and two orders of magnitude higher than Pt electrodes, respectively. During implantation periods, common ground impedance of CH-coated electrodes increased from ~4kW in the first week, and stabilized thereafter at ~6kW. In contrast, the impedance of Pt electrodes was approximately double that of CH immediately after surgery at ~8kW and after 2 weeks at ~13kW. Following implantation electrochemical impedance was maintained at close to pre-implantation levels in CH coated electrodes, which was significantly lower than in Pt. CSC and CIL decreased by ~40% and ~60% in CH coated electrodes following implantation, but both were still ~10 times higher than the Pt CSC and CIL. Preliminary observations of SEM images (n=2) showed that the CH coat remained attached to the cochlear implant throughout studies. However, further histological analysis will assess potential CH residues in cochlear tissue. Following removal of CH no signs of Pt oxidation were observed.

Conclusion: CH-coated cochlear arrays maintained enhanced electrical properties during and after implantation. These results support the potential of CH as an advanced electrode coating for cochlear implants with superior electrochemical performance than Pt electrodes.

Towards Seamless Neural Implants/Tissue Integration
Xinyan T. Cui; University of Pittsburgh, United States
Microelectronic devices placed in the nervous system present tremendous potentials for mapping neural circuits and treating neurological disorders. Currently, these devices often experience failures in part due to the electrical, mechanical, and biochemical, mismatch between the artificial device and neural tissue. Quantitative histology and 2 photon imaging have revealed neuronal damage and degeneration, inflammatory gliosis, blood brain barrier leakage and oxidative stress at the site of implants which may compromise the intended recording/stimulation/neurochemical sensing function. We use several biomaterial strategies to minimize these mismatches in order to achieve seamless and stable device-tissue interface. First, various conducting polymer based nanocomposites have been investigated as electrode coatings and facilitate the signal transduction/charge transfer between the ionically conductive tissue and the electrical device. Nanostructuring is employed to improve the adhesion, stability and charge injection and drug delivery capability of the conducting polymers to meet the material challenges in chronic interface. Secondly, to minimize the mechanical mismatch at the device-brain tissue interface, novel soft and elastomeric electrode materials have been developed with Young’s modulus approaching that of neural tissue (less than 1 MPa). Soft implants demonstrated reduced inflammatory tissue response in both CNS and PNS compared to stiff implants of similar geometry and surface chemistry. Thirdly, bioactive approaches are being developed to modulate the biological responses. One approach is to modify the implant surface with biomolecules or biomimics. Surface immobilization with these bioactive molecules significantly improved neuronal health and inhibited the inflammatory tissue response around the implants. Alternatively, therapeutics that control inflammation, neurodegeneration and oxidative stress have been delivered systemically or locally. These bioactive approaches have demonstrated significant benefit in neural recording quality and longevity. The ultimate solution to a seamless device/tissue interface may be a combinatorial approach that takes advantage of multiple biomimetic strategies discussed above and beyond.

Design and Fabrication of Tissue-Mimicked Parylene C Based Neural Microelectrode Arrays Yu-Chih Chiu and Pochun Chen; National Taipei University of Technology, Taiwan

In recent years, implantable bioelectronics has raised huge interest, especially for neural diseases. Among them, devices with a nerve guidance to guide neuron growth can enhance neural regeneration for traumatic peripheral nerve injury. However, the commonly used nerve conduit cannot provide a spatiotemporal regulation and in-situ monitoring for localized neurons. Accordingly, in this study, an implantable neural device that is built with microelectrode arrays on transparent and flexible substrate was developed to enhance cell growth through applying electrical stimulation and neural signals recording in a tissue-mimicked microenvironment. A new type of flexible substrate, nanoporous Parylene C, was designed and fabricated to exhibit tissue-mimic structural and mechanical properties. The microelectrode array, iridium oxide electrode for both neural stimulation and recording, was pre-deposited on a water-soluble sacrificial layer of poly acrylic acid (PAA) prior to the transfer print process. Such transfer printed tissue-mimic neural microelectrode array enabled conformable adhesion on a curvilinear nerve surface and electrical signals transduction from the microelectrode site, which is expected to provide higher performance of peripheral nerve regeneration. In addition, we characterized and evaluated the microelectrode array of iridium oxide film, including charge storage capacity, charge injection capability, and electrochemical impedance.

11:30 AM SB07.07.08/SB08.06.08
Conductive and Tissue-Adhesive Interfaces for Bioelectronics Jue Deng1, Hyunwoo Yuk1, Chuanfei Guo2 and Xuanhe Zhao3; 1Massachusetts Institute of Technology, United States; 2Southern University of Science and Technology, China

Various bioelectronic devices have attracted broad attentions and they inevitably require stable integration with biological tissues to ensure their reliable functions without compromising their electrical performance. Due to the intrinsic wet, dynamic, and deformable nature of biological tissues, the poor combination and the potential tissue damages during integration is undoubtedly interfered with the accuracy and reliability of electrical communication between biological tissues and bioelectronics. Here, we present a new family of conductive tissue-adhesive (CTA) interface capable of offering a general strategy for integrating various bioelectronics with wet and dynamic tissues to develop stable electrical communication between them seamlessly and instantly. The soft, stretchable, patternable and biocompatible CTA interface can adhere diverse materials of electronics and different biological tissues, as well as provides stable electrical properties in wet physiological environment and under deformation \textit{ex vivo} and \textit{in vivo}.
The study provides a new powerful platform for diverse bioelectronics to address the long-standing challenges in human-machine interface.

Nanoscale Solid-State Glucose Fuel Cell for Energy Harvesting in the Human Body Philipp Simons¹, Marco A. Gysel¹,², Steven A. Schenk¹,³, Kierstin P. Torres¹ and Jennifer L. Rupp¹,¹; ¹Massachusetts Institute of Technology, United States; ²ETH Zürich, Switzerland; ³EPFL, Switzerland

Efficiently powering the next generation of highly miniaturized bio-sensors, implantable drug delivery systems and bio-electronic devices for the human body defines a new era of medicine to track, support and operate body functions. Here, glucose fuel cells have seen a renaissance in recent years as an implantable power source harvesting energy from readily available fuels in the human blood stream.¹ Compared to existing implantable batteries, glucose fuel cells do not require frequent replacement surgery, due to the abundance and perpetual availability of glucose inside the human body. However, state-of-the-art glucose fuel cells are primarily based on polymer electrolytes being relatively bulky, suffer from long-term stability issues and exhibit low power densities. Here, we innovate a miniaturized glucose fuel cell, which is fully composed of solid state materials based on thin film processing.² This all-solid-state glucose fuel cell can be scaled down to the sub-micrometer range for unprecedented miniaturization and is built on a Si-chip using standard semiconductor fabrication methods suitable for integrated and direct powering of bio-electronic devices and implants. Through the use of abiotic catalysts instead of conventional biological catalysts such as enzymes and microbes, long term stability and increased power density are in perspective. Free-standing fuel cell membranes based on a proton conducting oxide on Si-chips were assembled using a microfabrication route with standard semiconductor processing techniques. Oxide thin films were prepared via pulsed laser deposition.³ The anode is in contact with glucose in phosphate buffered saline solution to mimic blood, whereas the cathode is in contact with oxygen. Performance characterizations were carried out via electrochemical impedance spectroscopy and galvanostatic polarization curve measurements. During this presentation we will present that the proposed cell is electrochemically active and reproducibly functions as the first all-solid-state glucose fuel cell with a roughly 100-fold lowered thickness of the device (only 250 nm) compared to polymer-based glucose fuel cells. In addition, we will present our recent efforts in developing a new, cheap and scalable route of fabricating our newly invented glucose fuel cell using spray pyrolysis.

Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate), PEDOT:PSS, has been regarded as one of the most successful semiconductor polymers for organic electrochemical transistors (OECTs) due to their solution-processability and aqueous stability. The ability to operate in aqueous environments make OECTs excellent candidates for a variety of applications, especially in the area of sensing. Incorporation of plasticizers or pre-treatment, such as ethylene glycol or sulfuric acid, have been done to boost the electrical performance of PEDOT:PSS-based OECTs by changing the PEDOT domain, crystallinity and nanostructure. In our previous work, we have introduced ionic-liquids in PEDOT:PSS induced a highly ordering molecular packing, and enable good
device characteristics, including high transconductance, controllable operating window and fast response time with long-term stability. Here, we expand our work further to study the various ionic liquids in PEDOT:PSS and their effects in the structural realignments of PEDOT and therefore on OECT performance. In addition, we demonstrate a facile patterning method via spray-coating to fabricate ionic liquid doped PEDOT:PSS-based OECTs, instead of the conventional complicated photolithography process, with great electrical performance and excellent device stability. More importantly, this facile technique makes it possible to fabricate high-performance OECTs on diverse substrates such as biodegradable flexible substrates based on ethyl-cellulose and natural leaf, wearable type substrate based on the commercial adhesive bandage, and deformable elastic substrate based on polystyrene-block-poly(ethylene-ran-butylene)-block-polystyrene (SEBS) elastomer. Using these substrates, the fabricated OECTs maintained high electrical performance with a transconductance of $\sim 3.7 - 7.4$ mS at $V_G = 0$ V. Overall, the results indicate that the spray-deposition technique provides a convenient route to prepare high performing OECT channels and exhibits great prospects in various ubiquitous electronics and bio-integrated organic electronics, such as flexible, conformal biological sensors and foldable wearable integrated circuits.

Stretchable and Transparent EEG Sensor Based on Metal Nanowire and Dry Bioelectrode Teppei Araki, Takafumi Uemura, Shusuke Yoshimoto, Yuki Noda, Shintaro Izumi and Tsuyoshi Sekitani; Osaka University, Japan

A stretchable and transparent sensor enables to monitor electroencephalogram (EEG) with less psychological stress. Here, an Au-plated Ag nanowire (AgNW/Au) is reported to enhance properties of a conductive track in the sensor on conductivity, stretchability, and electrochemical durability without the loss of transparency. With a newly-developed dry bioelectrode, the sensor wirelessly records EEG with low noise less than 1 microvolt and can contribute to diagnose brain disorders in relaxed state. Recently, stretchable and transparent conductive electrodes (stretchable TCE) including conductive tracks have been demonstrated to be applicable in biosensors. [1] The softness, as being closely equal to biological body, steps forward to long lasting therapeutic.[2,3] However, there is a challenge on recording small biopotential such as EEG having amplitude of 1–100 microvolt using stretchable TCE. Signal to noise ratio is impacted from an exogenous noise that is usually related high skin-electrode contact impedance. Here, conductive materials that show biocompatibility meeting the ISO standards and exhibit low skin contact impedance less than 50 kilo-ohm are reported and integrated in a stretchable and transparent sensor. AgNW/Au-based TCE shows an improved sheet resistance by 20–30% and stretchability up to 100 cycles between 0–60% strains although pristine AgNW-based TCE could not achieve them. No severe change of electrical resistance is also confirmed under accelerated test by high current on AgNW/Au-based TCE in the presence of water. Meanwhile, a stretchable and transparent adhesive as the dry bioelectrode is developed based on anisotropic conduction mechanism in order to reduce cross-talk. Finally, EEG is successfully recorded under wireless communication with low noise during continuous 12 h usage of the developed sensor. The technologies that lead to the development of the stretchable and transparent sensor will provide a new way for long therapeutic system.
Recent advances in medical technologies have enabled a new generation of implantable devices to treat neurological disorders, restore and repair lost functions, and to modulate neural circuitry to control mood and behavior. Tapping into the nervous system to monitor its state and achieve the desired output, however, requires understanding the fundamental neural processes underlying function, behavior, and disease. The rapid development of neural microelectrodes operating in close proximity with neural circuits, has enabled mapping and modulating neural dynamics at fine spatial and temporal scales. Yet, establishing a stable, safe, long-term functional interface between these man-made artificial components and the host neural tissue, still remains an unsolved challenge. Furthermore, while the brain naturally operates across multiple domains, neural microelectrodes can only transduce either electrical, chemical or optical signals, thus completely missing the interplay between the different signaling modalities.

Nanostructured materials are uniquely positioned to address these challenges because they combine high electrical conductivity with intrinsically high mass-specific surface area and mechanical flexibility. Furthermore, they can interact with biological systems on a molecular scale and can be processed into thin films with tunable optical properties, thus opening new and exciting opportunities for neuroelectronic interfaces. In this talk I will present the ongoing work in my lab leveraging the unique properties of nanostructured materials, such as nanocarbons and MXenes, to engineer novel devices for neural recording and stimulation at high spatial and temporal resolution, as well as for integrating multiple mapping modalities within the same platform. I will also present examples of applications in animal models of neurologic disorders and discuss the potential for future translation of these technologies in the clinical domain.

With the development of low power neuromorphic systems, novel paradigms based on combining artificial intelligence (AI) and machine learning with local adaptive biological systems can be envisioned. This could have applications in a variety of smart “trainable” devices, notably in adaptive prosthetics. However, to achieve a feedback mechanism between the biological systems and AI, a neuromorphic memory must act as an adaptive mechanism that is responsive to biological systems and can close the loop. In this talk, I will bridge the gap between artificial and biological synapses by creating a neurotransmitter-sensitive organic neuromorphic device. We combine microfabricated neuromorphic devices in a microfluidic channel to form a neuromorphic-neurotransmitter biohybrid interface. Voltage pulses at the pre-synaptic electrode drive the oxidation of the excitatory neurotransmitter dopamine (DA), leading to both a short-term potentiation of the channel from ionic drift as well as a long-term potentiation due to the chemical reaction with dopamine at the biohybrid interface. This demonstrates the direct translation of dopamine secreted by PC12 neuron-like cells to a change in memory state in artificial synapses. These results are opening the pathway to combine artificial neural networks with biological systems and develop biohybrid and bidirectional closed-loop sensing platforms.

Synaptic devices that can emulate biological neuron functionality and be reliably programmed to a continuum of resistance states at low energy cost are highly desirable for neuromorphic computing. Despite recent progress in demonstrating neuromorphic arrays using conventional inorganic resistive memories, no architecture to date can...
operate with comparable efficiencies to that of the human brain due to limitations at the device level. State-of-the-art filament-forming metal oxides (FFMOs) and phase change memory (PCM) based synaptic devices still suffer from excessive write-noise and device non-linearities, preventing massively parallel information processing at a comparable efficiency to that of the human brain. We show that polymer-based devices relying on mixed ionic-electronic conduction are highly promising to address these challenges [1].

To demonstrate this, we have developed a new class of polymer-based devices which can be linearly and symmetrically programmed over 100× distinct states by low voltage pulses (<1 V) at low power (<1 pJ per write) while retaining low write noise. Reversible switching in our devices relies on controlled insertion/extraction of ions into a transistor-like channel, similar to the synaptic cleft in the brain, whereas device non-volatility is enabled by a supercapacitor-like architecture. Our devices can be reliably programmed using <1 μs pulses and endure >10⁸ write-read events without notable deterioration in device performance, thus exceeding the endurance of conventional FLASH memories, subject to oxide stresses. This shows that polymer-based devices can meet the stringent speed, endurance and linearity requirements necessary for efficient neuromorphic computing.

As a proof of concept integration into synaptic arrays, we have combined our polymer-based device with an inorganic diffusive memristor, serving as an access device. Using this two-device combination as an addressable memory cell, we built prototype 3×3 organic/inorganic neuromorphic arrays [1]. The linear switching characteristics of our polymer-based devices allowed the arrays to be programmed in parallel, resulting in an n² latency advantage compared to conventional crossbar memories, where n is the array size. Architectural simulations predict that a scaled 1024×1024 organic/inorganic synaptic array would have an energy, latency and area advantages of 476×, 16× and 9.5×, respectively, compared to an optimized 8-bit static random-access memory (SRAM) accelerator, highlighting the yet untapped potential of polymer-based synaptic devices for brain-like computing.

Ferritin as a 3D Bioelectronic Material Sudipta Bera and Rupa Mukhopadhyay; Indian Association for the Cultivation of Science, India

Ferritin is an intracellular iron-storage protein that maintains iron balance by storing and releasing iron in response to physiological need. It is present in almost all living organisms, which means that it is an environment-friendly material and is easily available. It is a stable protein that remains functional in both solution and solid phases in a wide range of temperatures (up to 85 °C) and pH 4.0–9.0. It sustains its electronic integrity in solid-state condition for a long period of time (about one year). Ferritin has a unique spherical structure, having an 8 nm semiconducting iron oxy-hydroxide core. Ferritin has been suggested for use in wide ranging device applications - the nano-battery, FET, and memory device. Ferritin appears to be a versatile protein as its electron transport properties can be tuned and it can be anchored onto a solid substrate (silicon, Au, Al, ITO, HOPG, glass etc.) as per device requirement by various means of chemisorption and physisorption. In this presentation, the suitability of ferritin as a 3D bio-electronic material is discussed. It is first ensured that the native ferritin and the different reconstituted ferritins along with apoferritin show their electron accessibility and statistically distinct band gap characteristics in the monolayer configuration on heavily doped silicon substrate by using conductive atomic force microscopy and spectroscopy (C-AFM and C-AFS) [1]. Here, ferritin has been treated as an insulator-conductor composite as the core modification results in a change in overall electronic state of the ferritin. The successful tuning of band gap of the different metal core reconstituted ferritins indicate that band gap engineering is possible in case of ferritins which is quite useful in synthetic semiconductor technology. The success with ferritin-monolayer-based bioelectronics on silicon surface prompted us to prepare a purely proteinaceous iron-loaded holoferritin multilayer
using layer-by-layer electrostatic deposition of successive cationized and native ferritin layers. This ferritin multilayer is found to be capable of long-range electron transport in solid-state configuration - the maximum range being ~40 nm for vertical transport (across the multilayer) as observed in a C-AFS study and ~40 μm for lateral transport (along the multilayer) as observed by an interdigitated electrode-based measurement [2]. The ferritin multilayer is largely an electronically homogeneous material as found in a KP-AFM study, and it shows less substrate influence than the monolayer configuration. Importantly, the holoferritin multilayer exhibits Z-electronic confinement with a high exciton radius of 45 nm [2]. This is one of the longest exciton radii reported so far. This is also the first report of electronic confinement inside any biomaterial. The bulk electron transport capacity of the ferritin multilayer as presented here indicates its potential for use as a component in futuristic molecular 3D circuit.

**Bio-Sourced Eumelanin Pigments—Charge Transport Properties and Beyond**

Manuel Reali, Abdelaziz M. Gouda and Clara Santato; Polytechnique Montréal, Canada

Organic electronic materials have been widely investigated as a valid complement to conventional electronic technologies, owing to their mechanical properties and large area printability. Green electronics recently opened new research avenues to use bio-sourced, biocompatible (possibly biodegradable) materials to limit the environmental impact of the electronics sector. Within bio-sourced carbon-based materials, eumelanin, a black-brown conjugated biopigment, emerged as an excellent candidate for green electronics. A rapid interest grew around eumelanin due to its fascinating physicochemical properties (e.g. broadband optical absorption, metal-ion chelation, mixed ionic/electronic conductivity and biocompatibility). The conjugated sp² backbone of eumelanin suggests that it would be a naturally occurring semiconductor. The amorphous semiconductor model (ASM) was proposed for the first time in the 70s after the reports on resistive switching behavior in wet melanin pellets. Recent investigations on the role of adsorbed water on eumelanin charge carrier transport challenged the ASM by proposing mixed electronic/protonic and proton membrane models. None of the current models can provide a comprehensive understanding of the charge carrier transport properties of eumelanin.

In this work we fabricated wet and dry sepia melanin pellets included between Cu and stainless-steel electrodes. We report for the first time the electrical response of dry eumelanin pellets. As opposed to previous studies that indicated dry eumelanin as an insulating material, dry pellets switch. Surprisingly, the electrical response of dry pellets features a quasi-linear, metallic-like behaviour. On the other hand, wet pellets show a reversible and reproducible resistive switching, in agreement with McGinness et al. Scanning Electron Microscopy (SEM), X-Ray Diffraction (XRD), X-Ray Photoemission Spectroscopy (XPS) and Raman Spectroscopy did not reveal neither the formation of metallic filaments bridging the electrodes nor a phase transformation (i.e. amorphous to graphitic carbon) possibly induced by Joule heating. We can, therefore, exclude the formation of metallic filaments or graphitic carbon in the interpretation of the electrical response. These findings suggest that dry pellets would be predominant electronic conductors. Our results show that despite huge effort, certain fundamental aspects of eumelanin’s transport physics need to be radically reconsidered and confirm the tremendous potential of the biopigments for green electronics and bioelectronics.

Mesoscale Structure-Ionic Transport Relationship of Eumelanin
Zhen Tian1, Wonseok Hwang2 and Young Jo Kim1; 1University of New Hampshire, United States; 2University of Maryland, United States

Recent advances in biodegradable electronics exhibit a huge potential to transform the conventional implantable biomedical devices into transient ones by obviating many challenges associated with chronic implants. Biocompatible/biodegradable packaging materials, naturally-sourced electronic components, or biodegradable charge storages would be the ideal building block to fabricate these types of devices. Recent researches have shown that eumelanin pigments can be served as promising electrode materials due to the exceptional biodegradability, the ease of processing, and the capability of binding various cations. Coordination bonding with cations can be formed mostly with semiquinone radicals that are induced by comproportionation reaction of indoles. These electrochemical properties are largely dependent upon the chemical functional groups as well as the structural characteristics. Eumelanins are mainly composed of the aggregated network of oligomers that include two subunits of 5,6-dihydroxyindole (DHI) and 5,6-dihydroxyindole-2-carboxylic acid (DHICA) in various ratios. These subunits are randomly crosslinked into planar protomolecules by Pmel17 proteins that are further p-stacked to form spherical nanostructures. The protomolecules of natural eumelanins have been known as the unique structural feature that cannot be observed in the synthetic counterparts synthesized from the template free autoxidation. Despite numerous efforts with a wide range of techniques, little has been known about the macromolecular topography that links the configuration of two subunits. Furthermore, the structural effect on charge transport is still elusive due to the disordered nature during melanogenesis. We report herein the presence of the meso-scale protomolecule structures of natural eumelanins using x-ray scattering, electrochemical techniques and spectroscopic analysis. Increased understanding of structure-property relationship can provide insight into the template-assisted self-assembly in melanosome. In addition, controlling the charge transport would be advantageous to design the device quality bioinspired materials as well as the high performance energy storage devices for biodegradable transient biomedical electronics.

Biological Model Membranes Supported on Electroactive Polymer Devices for Measuring Protein Ion Channel Activities
Han-Yuan Liu1, Anna-Maria Pappa2, Charalampos Pitsalidis2, Quentin Thiburse1, Surajit Ghosh1, Alberto Salleo3, Roisin Owens1 and Susan Daniel1; 1Cornell University, United States; 2University of Cambridge, United Kingdom; 3Stanford University, United States

The effective treatment of pain remains a challenge as current therapeutics still lack desired levels of efficacy and tolerability. Around 80 protein ion channels have strong links to pain sensation, but only a small number of these channels have been successfully drugged for pain management. One reason for the bottleneck in discovery is the inadequacy of conventional platforms for drug discovery that monitors modulation in ion channel activity. Current methods require a skilled hand, yet are still very laborious, time-consuming, and low throughput. There is an urgent need to develop faster, authentic, and high throughput assays that give direct and quantitative information on ion channel function, drug interactions, and insight on the efficacy of a developed therapy. The platform presented here features a biomimetic membrane that provides an authentic lipid environment, native cell membrane material to support the natural transmembrane ion channel function, and a sensor made from an electroactive polymer surface upon which the biomembrane is supported. Of focus here is the ATP-gated P2X family ion channels. These protein ion channels are considered important therapeutic targets for multiple pain modalities including neuropathic, inflammatory, and chronic pain states. This biomembrane sensor is capable of reading and transducing ion channel activity as it depends on the availability of ATP. Critically, this platform captures these essential features: 1) it preserves native plasma membrane, protein orientation, fluidity, and activity; 2) is robust and long-lasting; and 3) is compatible with high throughput expansion. Given the considerable amount of research focus and development on identifying drug targets and engineering new drugs for the treatment of pain,
this new biosensing platform may prove to be a useful new approach for ion channel research and drug screening.

SB07.09.05
A Versatile Zwitterionic Conjugated Polyelectrolyte Platform for Bioelectronics Gang Cheng; University of Illinois at Chicago, United States

Implantable bioelectronics has drawn huge attention in recent years since they can monitor the levels of biomarker(s) continuously. For example, the implantable glucose sensor is highly desired for diabetic people. Implantable sensors were used to monitor electrical signal and bio-analytes in the brain and they can be coupled with implantable drug delivery system for controlled release of drugs. The performance and lifetime of implantable sensors are significantly influenced by interfacial phenomena at the interface of the sensor/biological system, including biofouling, foreign body reaction, loss of structural integrity, and infection. In electrochemical bioelectronics, bioelectrodes are a core component for the delivery of charge and recording of an electrical signal. Conventional electrodes are fabricated from platinum and gold, which require surface modification to increase their integration with biological tissue and minimize foreign body encapsulation at the electrode/tissue interface. As emerging biomaterials, conjugated polymers have attracted significant interests for bioelectronics; however, traditional conjugated polymers, which were originally designed for non-biological applications, lack biocompatibility, functionality to conjugate biomolecules, tunable mechanical properties and antimicrobial properties to prevent infection. In the past five years, we have developed a versatile zwitterionic conjugated polyelectrolyte (CP) platform to address key challenges of conjugated polymers for biomedical applications. Zwitterionic CPs, consisting of conjugated backbones and multifunctional zwitterionic side chains, integrate all essential functions and tunable properties into one material at monomer level. Zwitterionic materials gain tunable conducting, optical and antimicrobial properties through conjugated backbones. Low-biocompatible conjugated polymers obtain outstanding biocompatibility, controllable antifouling properties, enhanced ionic conductivity, sensitivity to environmental stimuli, functionality for bioconjugation and tunable mechanical properties via zwitterionic side chains. In this presentation, I will show you why and how we designed the zwitterionic conjugated polyelectrolytes and how we synthesized and characterized this versatile platform. In the end, I will show you how we used this zwitterionic CP platform to improve the performance of bioelectronics using the glucose sensor as an example.

SB07.09.06
Quantification of Nanoparticles Surface Grafted Groups by Electrokinetic Sonic Amplitude, ESA Alexander M. Renner, Markus B. Schütz, Daniel Moog, Thomas Fischer and Sanjay Mathur; Institute of Inorganic Chemistry, Germany

In recent years, nanotechnology developed into a promising field in cancer research by using various kind of magnetic nanoparticles such as magnetite (Fe3O4) in early diagnosis and prompt treatment of cancer. In this context, nanomaterials loaded with different biomolecules and imaging agents contribute to the improved delivery of drug at the target site and minimizing its exposure to the healthy tissues. At this point, active surface chemistry is considered essential for the specific uptake of nanoparticles to the cancer cells. Nevertheless, surface grafted molecules and their quantification is an immense challenge in nanoparticle surface modification but indispensable in regard of their possible medical applications. Nearly all known quantification methods of surface-bound molecules including direct and indirect methods are affected by their size, surface consistency, composition or charge distributions of particles, resulting in scattering of measurement results. To fill up this knowledge gap, we present a novel quantification method in which freely accessible hydroxide groups located on the surface of SiO2 particles, utilizing the electrokinetic sonic amplitude (ESA) effect supported by simultaneous conductivity measurements. ESA techniques itself became one of the most innovative methods for analyzing particle-ligand interactions. The zeta potential of charged particles located in an alternating electric field is calculated from the resulting sound wave, opening insights into the surface chemistry of nanoparticles. Furthermore, the degree of surface functionalization of phase-pure quasi-cubic hematite (Fe2O3) particles with a zeta potential value of +50 mV was monitored through their reaction with 10-undecynoic acid and citric acid as ligand molecules, paving a profound approach of ligand quantification. Thereby, all results highlight the usage of ESA techniques by its high potential as quantification method in nanoparticle surface modification.

SB07.09.07
Translocation Properties of Analytes through Asymmetric Nanopores Chenyu Wen, Shuangshuang Zeng, Shiyu
Nanopore sensing technology has been developed for detection of various biomolecules such as DNA, RNA, proteins, and metabolites in order to exploit the single-molecule discrimination capability of a nanopore. Succinct device structure, easy fabrication process, and simple electrical readout facility are additional features for this technology [1]. Solid-state nanopores are usually formed in a solid-state membrane such as SiNx, SiO2, graphene, MoS2, etc., to benefit from the mechanical robustness and fabrication compatibility with traditional semiconductor processes. As such, they offer great potential for low-cost, large-scale, high-throughput sensing applications [2, 3].

Here, we present a novel asymmetric nanopore with a truncated-pyramid shape (TPP) realized in silicon-on-insulator wafers. This unique pore structure facilitates the formation of electroosmotic vortex in the nanopore and offers a unique platform to study the interaction between analytes and the pore through the corresponding apparent translocation behaviors.

In general, two forces simultaneously act on an analyte in an electric field formed inside a nanopore under external bias voltage. They are electrophoresis force, \( F_{\text{ele}} = Eq \), and viscosity drag force by electroosmotic flow, referred to as electroosmotic force, \( F_{\text{EOF}} = 6\pi \eta vr \). where, \( E \) is electric field intensity, \( q \) charge on the analyte, \( \eta \) electrolyte viscosity, \( r \) analyte radius, \( v \) velocity of the analyte. The direction and intensity of the two forces determine the translocation direction, which are further influenced by carried charge on the analyte, surface charge density of the pore sidewall, size and shape of the nanopore, concentration and pH of the electrolyte, etc. [4].

In our experiments, DNA and protein IgG1 are selected to perform the translocation in TPPs. DNA is a long strand and heavily charged. Therefore, the electrophoresis force is expected to dominate the translocation. IgG1 is disk-like with low density of charge. Thus, the electroosmotic force dominates. In addition, by varying pH, the polarity and amounts of charge for a protein can change, which may lead to alternation of direction and intensity of the electrophoresis force. Changing pH can also tune the surface charge density of the pore sidewall, which can further influence the velocity of electroosmotic flow, as well as the size and intensity of the aforementioned electroosmotic vortex. Hence, the electroosmotic force is affected. Comprehensively considering the effects of many related factors, reflected as the competition between \( F_{\text{ele}} \) and \( F_{\text{EOF}} \), the translocation behavior of analytes can be understood. By clarifying the kinetic mechanism of analyte translocation, it paves the way to practices of versatile applications of nanopore sensing.

**Parallelized Single-Molecule Translocations in Arrayed Silicon Nanopores Coated with a Lipid Bilayer**

Shiyu Li, Shuangshuang Zeng, Zhen Zhang, Klas Hjort and Shi-Li Zhang; Uppsala University, Sweden

Solid-state nanopores have been recognized as a versatile tool for single-molecule detection with high sensitivity. They have been extensively studied for analysis by nanopore translocation of biomolecules, such as DNA, RNA, and proteins. As a complement to the electrical sensing readout, optical sensing of labeled molecules on a solid-state nanopore array can notably enhance the sensing capacity with high throughput. However, the widely used silicon nitride (SiN\(_x\)) nanopore produces significant photoluminescence (PL) background under blue-green laser illumination, which can severely limit, e.g., multicolor sensing for DNA barcode discrimination. In addition, the occasionally occurring irreversible DNA clogging in a solid-state nanopore, because of DNA molecules interacting with the nanopore channel wall during translocation, can seriously affect the sensing efficacy and accuracy. To address these problems, we have developed an optical sensing system dedicated to nanopore arrays fabricated in a free-standing silicon membrane with its surface functionalized by lipid bilayer coating.

A silicon nanopore array with pores of sub-20 nm diameter is fabricated in a silicon-on-insulator wafer using electron beam lithography in combination with anisotropic etching. The 55 nm thick free-standing silicon membrane shows negligible PL emission in the 550 to 800 nm spectral range under blue-green laser illumination, which greatly improves the optical signal-to-background ratio for single-molecule detection in comparison with standard SiN\(_x\) devices. The formation of a lipid bilayer on the nanopore walls is successful as inferred by monitoring in situ the homogenous fluorescence emitted from a labeled lipid bilayer. As a demonstration, we perform the optical sensing measurements with a conventional wide-field microscope to detect the translocation of fluorophore-labeled DNA strands (120 kbp). With the low background PL of the silicon membrane, the optical signal of individual DNA
translocation events is more clearly identified than when using similarly processed SiN, nanopore devices. Moreover, the coated fluidic lipid bilayer provides a nonstick surface to minimize the non-specific interaction of DNA molecules with the silicon pore walls. The results show that the DNA clogging is substantially reduced in the lipid bilayer coated nanopores as compared to uncoated nanopores. These results demonstrate that using silicon nanopores coated by a lipid bilayer is a promising strategy to realizing massively-parallel single-molecule optical detection.

**Percolated Metal Films on Graphene and Hexagonal Boron Nitride for Biocompatible Piezoresistive Sensors**
Armando Urbina, Darren J. Lipomi and Julian Ramirez; University of California, San Diego, United States

This talk describes how single layer graphene functionalized with thin metal films was functionalized to form piezoresistive (increasing resistance with strain) sensors capable of resolving 10ppm strain. Our group has demonstrated the strong bio-compatibility, substrate flexibility, and exceptional piezoresistive capability of graphene/gold films by monitoring contractions of stem-cell derived human cardiomyocyte cells and fabricating wearable heart rate sensors. These sensors exhibit a dynamic range of 9% strain with a sensitivity of 10ppm. By utilizing image analysis software, the relationship between fractional metal film coverage and thermal coefficient of resistivity (TCR) was studied. A sensor with near-zero TCR was created, mounted on flexible tape, and affixed to a subject’s wrist for non-invasive heart rate monitoring. While these composite films have demonstrated notable mechanical and electrical properties, the mechanisms for piezoresistance have not been thoroughly studied. To understand the mechanisms for strain sensing, graphene was replaced with hexagonal boron nitride (hBN). This semiconducting 2D material has gained interest in recent years due to its near insulator bandgap and exceptional chemical stability. Image analysis of ultra-thin gold films on hBN and graphene demonstrate the effect of the 2D scaffold on the metal film morphology (i.e. surface coverage and density of discrete islands). In replacing graphene with hBN, thus removing the conduction path through the 2D scaffold, the piezoresistance of percolated gold films could be compared to intrinsic graphene and graphene decorated with gold. Electromechanical characterization of strain sensor devices comprising these composite films determined the morphologies with highest strain sensitivity. By optimizing the gold film morphology that gives the highest piezoresistive sensitivity, we were able to fabricate piezoresistive sensors capable of resolving 1ppm strain.

SB07.09.10
**Kirigami Engineering of Transparent Conductor for Highly Stretchable Electronic Skin Applications**
Phillip Won¹, Jung Jae Park¹, Inho Ha¹, Seongguen Han¹, Sukjoon Hong² and Seunghwan Ko¹; ¹Seoul National University, Korea (the Republic of); ²Hanyang University, Korea (the Republic of)

Recent research progress of relieving the discomfort between electronics and human body involves serpentine designs, ultra-thin films and extraordinary properties of nanomaterials. However, these strategies addressed thus far each face own limitation for achieving desired form of electronic-skin (E-skin) applications. Evenly-matched mechanical properties anywhere on the body and imperceptibility of electronics are two essentially required characteristics for E-skin devices. Yet accomplishing these two main properties simultaneously is still very challenging. Hence, we propose a novel fabrication method borrowing an idea from kirigami, Japanese ancient cutting art, to pattern highly conductive and transparent electrode into diverse shapes of stretchable electronics with multi-variable configurability for E-skin applications. These kirigami engineered patterns impart tunable elasticity to the electrodes, which can be stretched over 400% tensile strain with strain-invariant electrical property and show excellent strain reversibility even after 10,000 cycles of 400% stretching while exhibiting high optical transparency (more than 80%). The transparent kirigami electrodes with customizable elasticity pave the way of offering facile construction and providing appropriate geometries for achieving multi-functional transparent and wearable electronic skin applications. The versatility of this work is demonstrated by ultra-stretchable transparent kirigami heater for personal thermal management and conformal transparent kirigami electrophysiology (EP) sensor for continuous health monitoring of human body conditions. Finally, by integrating E-skin sensors with a quadrotor drone, we have successfully demonstrated human-machine interface using our stretchable transparent kirigami electrodes.

SB07.09.11
**Stretchability of PMMA-Supported CVD Graphene and of Its Electrical Contacts**
Hongwoo Jang, Zhaohe Dai,
The remarkable mechanical robustness and excellent electrical/thermal properties make graphene a strong candidate for future flexible, stretchable and bio-integrated electronics. In practice, many soft electronics such as the graphene electronic tattoos (GETs) demand the chemical vapor deposited (CVD) graphene to be supported by a deformable substrate. Moreover, various conductive overlayers need to directly laminate on graphene to make electrical contacts. In such cases, the overall device performance relies dominantly on the substrates and the interfaces, especially when subjected to deformations. To investigate the mechanical reliability of CVD graphene in these situations, we fabricated CVD monolayer graphene supported by 300-nm-thick poly(-methyl methacrylate) (PMMA) substrate and also placed gold/polyethylene terephthalate (Au/PET) and graphene/PMMA (Gr/PMMA) overlayers on graphene. The stretchability of the Gr/PMMA and the overlayer-Gr/PMMA interface was characterized by electrical resistance change during uniaxial tensile tests. Combined with semi-
in situ microstructure and Raman investigation, we identified four deformation/fracture stages of Gr/PMMA – elastic deformation, microcracking in graphene, macrocracking in PMMA, and full rupture. While microcracks emerged in graphene at very small strain (~0.9%), electrical conductivity of the Gr/PMMA specimen remained up to tensile strains of ~14.5%. In contrast, 100-nm-thick Au film supported by the same PMMA substrate fully ruptured after tensile strains of ~1%. When laminating Au/PET and Gr/PMMA over Gr/PMMA, we found that the Au/PET-Gr/PMMA interface is very vulnerable but the Gr/PMMA-Gr/PMMA interface behaves very similar to intact Gr/PMMA electromechanically. The present experimental study provides fundamental insight into the fracture and interface behaviors of polymer-supported graphene, which is critical for designing future graphene-based soft electronics.

SB07.09.12

Wearable and Transparent Strain and Temperature Sensors Based on Patterned Ag Nanowire Networks for Health Monitoring Seung-Rok Kim and Jin-Woo Park; Yonsei University, Korea (the Republic of)

Healthcare monitoring devices assess the state of a person by detecting the physiological signals such as heart beat, respiration rate, and temperature measured directly or in relation to the deformation and vibrations of the human body. The body deformation strains provide useful information about the body movement, which helps people optimize their performance in sports and physical activities as well as provide warnings to avoid serious injuries especially in athletes and the elderly population. The body temperature is one of the most important vital signal since it reflects the overall health condition of a person. An abnormal rise or drop in body temperature may indicate infections and/or diseases in a patient. However, conventional rigid physiological measuring devices could not achieve complete and efficient contacts with the skin of the human body without the use of additional interfacing gels due their non-deformable configuration that also limits the mobility of the patient. Hence, many researchers have struggled to make these physiological sensors into conformable and stretchable wearable devices as part of non-invasive diagnostic system that enables remote and continuous healthcare monitoring outside the clinical settings. In this work, we fabricated both capacitive strain sensors patterning Ag nanowire networks (AgNWs) and capacitive temperature sensor using pyroelectric polymer P(VDF-TrFE) as dielectric material. The AgNWs were patterned using capillary force lithography (CFL) method and were embedded onto the surface of the elastomeric polydimethylsiloxane (PDMS) substrate. The strain sensor was patterned as the interdigitated shape, while the temperature sensor was patterned as the serpentine shape. The interdigitated capacitive strain sensor (ICSS) had a -2 gauge factor (GF) at 30% strain (ε), which is much higher than the sensitivity of conventional parallel plate-type capacitive strain sensors. The ICSS had no hysteresis behavior up to ε of 15% and showed stable ε sensing performance during the repeated stretching test at ε of 10% for 1000 cycles. Furthermore, there was no crosstalk between the ε and pressure sensing in the AgNW-based ICSS, which was found to be insensitive to externally applied pressure. The ICSS was then used to detect the finger and wrist muscle motions of the human body in order to simulate its application to large and small ε sensing. The pyroelectric capacitive temperature sensor (PCTS) had 0.23 %/°C sensitivity in the range of 25 to 40°C. This sensitivity was maintained under mechanical stretching under 10% strain although the initial value of the strain is changed. Using those strain sensor and temperature sensor, we could successfully measure the physiological breathing rate and body temperature.

SB07.09.13

Laser Direct Writing of Electrically Conductive Structures with Anisotropic Sensitivity to Strain on an Elastic Polymer Shuichiro Hayashi, Yasutaka Nakajima and Mitsuhiro Terakawa; Keio University, Japan

Electronic devices with high degrees of flexibility have been attracting considerable amount of attention, owing to
their potential novel applications such as electronics skins, wearable textiles, and real-time health monitors. Flexible electronic devices have been demonstrated by combining electrically conductive materials, including metals and carbon-based materials, with flexible substrates, such as polydimethylsiloxane (PDMS), polyimide (PI), and natural rubber. Various fabrication techniques have been developed to fabricate such composite structures for flexible devices applications, such as transfer printing techniques, lithography techniques, as well as laser-based techniques. Recently, our group reported the fabrication of electrically conductive structures composed of crystalline silicon carbide (β-SiC) directly on the surface of PDMS by femtosecond-laser-based-modification of PDMS. The degradation of PDMS into β-SiC is hypothesized to be a result of photolysis, due to the high laser energy, as well as thermal degradation, due to the thermal effects resulting from the high repetition rate. To investigate the potential of the fabricated structures for future flexible device applications, the effects of strain on the electrical conductance of the fabricated structures were investigated in the present study. Electrically conductive structures, 8 mm x 3 mm, were patterned on the surface of a PDMS thin-film by focusing laser pulses onto the surface and raster scanning the beam over the surface. Two types of structures were individually fabricated by different raster scanning directions, longitudinal scanning and transverse scanning, respectively. Both structures were bent in the longitudinal direction, and the structures showed changes in electrical conductance with bending. However, the structures showed different sensitivity to bending, i.e. the change in electrical conductance with bending was significantly less for the structures fabricated with transverse scanning, indicating anisotropic directional sensitivity to strain. SEM observations revealed the generation of micro-cracks on the surface when the structures were bent parallel to the laser scanning direction, while significantly less generation of micro-cracks when the structures were bent perpendicular to the laser scanning direction. The changes in electrical conductance of the fabricated structures could be attributable to the formation of such cracks on the surface. The findings of this study indicate that the structures fabricated by femtosecond-laser-based direct modification of PDMS can be applied for strain sensing, and could allow for a simple one-step method to fabricate directional strain sensors. Furthermore, by focusing the femtosecond pulses into bulk PDMS, arbitrary 3D electrically conductive structures could be directly written inside PDMS via multiphoton process.

Laser Micro-Patterning of Graphene Oxide Functionalized Silk Fibroin

Cleber Mendonça¹, Kelly Paula¹, Moliria Santos¹, Murilo Facure², Marcelo Andrade¹, Francineide Araújo¹, Daniel Correa¹ and Sidney Ribeiro³;
¹University of Sao Paulo, Brazil; ²Embrapa Instrumentação, Brazil; ³University of São Paulo State–UNESP, Brazil

Graphene-based materials have been attracting a great deal of attention as candidates for a variety of applications, from electronics to biology, thanks to its unique set of properties. Therefore, patterning graphene-based materials is of foremost relevance for the development of devices. Novel transferring/printing methods have been developed for fabricating high-resolution patterns, such as direct laser writing (DLW), as alternatives to standard lithographic processes. In this direction, Laser Induced Forward Transfer (LIFT) has been attracting considerable attention because it allows patterning different materials, from metals to polymers, to distinct types of substrates. In the LIFT technique, a laser pulse with enough intensity is focused onto the donor material, which is ejected towards the receiver substrate, allowing the production of micro-scale patterns.

In this work, we used fs-LIFT to fabricated graphene oxide functionalized silk fibroin micrometric patterns on a glass substrate. In such structures, graphene oxide is dispersed in silk fibroin, which is a natural biopolymer that has numerous applications due to its excellent biocompatibility, chemical stability, and mechanical properties. Scanning electron and atomic force microscopy results revealed a localized, controllable and reproducible deposition, with lines widths on the order of 1 µm, when the proper parameters are employed. Furthermore, Raman spectroscopy reveals the reduction of graphene oxide upon fs-LIFT, which is in agreement with the observed increase in the electrical conductivity of the transferred material. It is worth mentioning that femtosecond pulses offer advantages to LIFT in terms of resolution and transferring of intact material, thanks to the reduced thermal effects and minimal collateral damage resulting from the nonlinear light-matter interaction. Such results offer novel perspectives on the use of graphene/biopolymer composites for the development of electronic and biomedical devices.

SB07.09.15

Three-Dimensional Structuring of Block Copolymers on Flexible Substrates Using Wrinkle Confinement

Young-Ah Lucy Lee, Victor Pryamitsyn, Dongjoon Rhee, Monica Olvera de la Cruz and Teri W. Odom;
Northwestern University, United States
Patterning three-dimensional (3D) architectures into elastomeric substrates can advance development of stretchable bioelectronics, sensors, and data storage devices. Block copolymer (BCP) self-assembly under topographical confinement has shown promise in generating 3D nanostructures down to sub-10 nm scale. Experimental efforts in directed BCP assembly, however, have focused on using hard pre-patterned substrates that require top-down processing, which limits scalability for large-area patterning. Also, the fabrication steps involving BCP film casting and thermal/solvent annealing typically deform polymeric substrates and damage complex 3D geometries. Here we present an all-soft templated assembly of PS-b-PDMS BCPs using polymeric nanowrinkle confinement. We precisely structured BCPs in highly aligned, densely packed arrays on the wrinkled substrate. We also selectively tuned the BCP alignment parallel or perpendicular to the wrinkle orientation by manipulating the pre-strain. Furthermore, self-consistent field theory modeling revealed that wrinkle curvature and surface affinity drove the aligning behavior. Controlled BCP structuring was demonstrated with complex wrinkle geometry, various copolymer molecular weights, and functional skin layers such as graphene and gold. This integration of BCP patterning with flexible 3D architectures will serve useful in lithographic applications for nano-bio interfaces and next-generation soft electronics.

SB07.09.16
Simple 3D Printing-Based-Fabrication of Micromixer Chips for Detecting Hemagglutination Sunwoong Lee¹, DongIl Won² and SungWook Nam¹; ¹Kyung-Pook National University School of Medicine, Korea (the Republic of); ²Kyung-pook National University Hospital, Korea (the Republic of)

3D printing technology has an importance for manufacturing microfluidic chip since it offers high-resolution complex structures. We designed a micromixer chip in which liquid solutions are mixed for detecting hemagglutination. To fabricate the chip, we prepared a mold structure by employing digital light processing (DLP), one of the most popular 3D printing methods. Upon the 3D printed mold, polydimethylsiloxane (PDMS) fluidic device was prepared, which was with another PDMS layer. The assembled micromixer chip consists of multi-level geometry: The first level has meander channels for liquid solution guiding, and the second one has microwell structures to capture blood cell droplets. Inside the micromixer chip, blood cells were initially loaded and captured in the microwells, followed by being mixed with the subsequently loaded antibody solutions, either anti-A or anti-B solutions. As a result, we identified a mixing between blood cell droplets and antibody solutions. In particular, hemagglutination behaviors were identified inside the micromixer chip, which was further characterized by conventional colorimetric microplate-readers. Interestingly, once the hemagglutination occurs, the mixed solution has transparent regions in between the dispersed aggregates of blood cells and antibody solutions. Therefore, the measured absorbance value, optical density (OD), through the channel was significantly decreased. Our method provides an insight for 3D printing technology to be coupled with the existing the benchtop analysis tools.

SB07.09.17
Fibrous Elastomer for Bio-Integrated Epidermal Electronics Matthew S. Brown, Melissa Mendoza, Gretchen Mahler and Ahyeon Koh; The State University of New York at Binghamton, United States

Although research in bio-integrated electronics has been advancing at a rapid pace, the substrates of these systems haven’t been fully optimized for their developed applications (e.g., on-skin, cardiac, and neural lamination). Current wearable electronics rely on impenetrable, non-porous platforms that obstruct the natural diffusive and convective fluid flow and gas transfer, which consequently increase inflammation, contributes to device delamination, and sensor inaccuracies. Furthermore, the microspatial mechanical mismatch at the interface between flexible electronics and soft biological tissue continuously evokes shear stress and thus further exacerbates biomedical complications. To solve critical challenges in soft bioelectronics, we have developed a device capable of being fully breathable, an open-mesh structural design with comparable mechanics to the epidermis (e.g., elastic modulus = 10–500 kPa, 30% ≥ strain). Polydimethylsiloxane (PDMS), a common substrate material because of its soft mechanics and ability to be used in soft lithography makes it a desirable material for breathable electronics. Here, we developed an elastomorphic network of PDMS fibers by utilizing coaxial electrospinning, where a non-spinnable material, PDMS was encapsulated with a spinnable polymer of polyvinylpyrrolidone (PVP). Coaxial electrospinning was capable of producing a core-shell structure of PDMS-PVP fibers. Post electrospinning the PVP encapsulation was able to be fully removed through submergence in ethanol, leaving behind a fibrous network of PDMS micro sized fibers. The fibrous mesh presented
a fiber diameter (1.99 ± 0.56 µm) and mechanically biomimicry structure similar to native tissue, with a viscoelastic response, nonlinear region, and a soft elastic modulus response (129.07 ± 14.85 kPa) comparable to the epidermis. Furthermore, performing mechanical testing under wet conditions the fibrous mat was capable of exhibiting dynamic properties, a more prominent non-linear region, and viscoelastic effect. The water was capable of expanding the fiber pores and decrease the fiber-fiber interaction. To establish biocompatibility, human keratinocyte (HaCaT) immortalized cells were seeded in static culture over a film of PDMS and the PDMS fibrous mesh. The fibrous PDMS demonstrated greater cell viability and proliferation in comparison to the PDMS film. In application, this PDMS fibrous mat can be utilized for implantable biomedical devices where cell integration is required. Furthermore, through soft lithography techniques, microfabricated sensors were capable of fully bonding to the PDMS micromesh and conformally laminating onto the skin while enabling biopotential (e.g. electrocardiogram (ECG)) measurement. Applying this elastomeric mesh platform to stretchable electronics can attribute to the development of the next class of wearable electronics for innovation in chronic health diagnostics, multifunctional sensing, and a more quantitative understanding of dynamic physiochemical biological microenvironments.

SB07.09.18
Fabrication and Use of PDMS Based MEA with Porous Platinum Electrodes as a Multimodal Tool in Neuroscience Aline F. Renz1, Christopher Lewis2, Jihyun Lee3, Klas Tybrandt4, Maciej Brzezinski1, Mouna Cheraka1, Fritjof Helmchen2 and Janos Vörös1; 1ETH Zurich, Switzerland; 2University of Zurich, Switzerland; 3Linköping University, Sweden

Stretchable electronics for seamless implant integration attracted increased attention in the last years, by overcoming the mechanical miss-match between implant and soft organic tissues such as the brain. Enhancement of the implant-tissue interface to both reduce the foreign body response as well as achieve improved electrode properties has been the main focus of many new devices. However, with the increased focus on non-invasive techniques such as in vivo optical recordings, new challenges arise to incorporate temporal and spatial resolution in future brain monitoring implants. Especially for basic neuroscience, where the interplay between single neurons and complete neuronal networks are crucial to understand origins of diseases such as Parkinson and Epilepsy. Here, we present the combination of optical and electrical recording using PDMS based electronic implants to gain scattering free optical recordings through this transparent base material. The highly porous platinum electrodes allow for electrical recording with high temporal resolution while the PDMS insulator is sufficiently transparent for 2-photon imaging of neural activity with single cell resolution. We were able to generate multimodal neuronal recordings in living animals in first proof-of-concept experiments. By fabricating PDMS based electronic implants with a newly generated protocol, new designs, sizes and unconventional shapes can be incorporated within a short time frame and show distinct electrical performance for electrode sizes between 30-100 µm. This approach shows promising results for the versatile use of PDMS based implants for complex brain activity recordings.

SB07.09.19
Characterization of Electrochemically Coated Pt-Ir Microelectrode Arrays Elena della Valle, Elissa J. Welle and James D. Weiland; University of Michigan, United States

Next-generation brain-machine interfaces may use thin-film metals or non-metallic materials (e.g. carbon) for electrical connection to the brain. However, thin-films are not robust to electrical stimulation and carbon is not a low impedance material. Thus, improving the electrical and mechanical stability of neural microelectrodes is a major challenge facing chronic brain interfaces. Electrochemical deposition of a rough, robust material onto an electrode surface is a promising technique that increases real surface area, which facilitates charge transfer, while maintaining geometric area for targeted recording from and stimulation of small neural populations. In this study, a Pt-Ir alloy is electrodeposited on two different multi-electrode arrays to investigate the impedance, durability and morphology at both the surface and within the film. Polymide electrodes array consisted of a 4 µm base and top layer of polymide 2611, a middle layer of a metal stack of 20/80/400 nm of Ti-Pt-Au, respectively. Standard photolithography was used to define 17 circular gold electrodes with a diameter ranging from 30 to 200 µm. Carbon fiber arrays consist of 8 fibers (~8 µm diameter) of 2 or 5 mm length, coated with parylene-C [1, 2]. Pt-Ir was deposited using a potential cycling technique following the process in Petrossians et al. that utilizes sonication to improve the surface coating rate [3]. Electrode impedance was measured with the electrochemical impedance spectroscopy (EIS) method. EIS consistently was decreased after coating, for example a carbon fiber probe showed decreases in impedance modulus of 96 % @10 Hz, 89 % @1 kHz and 10 % @ 1 MHz. The surface morphology of the Pt-Ir coated electrodes was
characterized using both scanning and transmission electron microscopy (SEM, TEM). The chemical composition analysis was then acquired with the energy-dispersive X-ray spectroscopy (EDS) on both microscopy systems. An average percentage of 65 – 35 % of Pt-Ir composition was measured in selected regions up to 10 x 7 µm² and up to 200 x 200 µm² for the carbon fiber probes and gold probes, respectively. Further, inspection of images, delineating Pt and Ir with false colors, show uniformity with respect to distribution of Pt and Ir across the electrode surface. To analyze the interface between the base electrode and the Pt-Ir coating, a focused ion beam (FIB) was used to cut a thin region of the interface to be examined at the TEM. It was then possible to establish the coating thickness and the distribution of the Pt-Ir molecules on the coating surface using EDS analysis. The FIB cut performed on one carbon fiber showed a ~400 nm thick and well homogenous Pt-Ir coating closely adherent to the carbon fiber surface.

A heated soak test was performed on the carbon fibers arrays to mimic an in vivo environment by immersing the fiber tips in PBS by 1mm at 50 °C for 36 days. Some probes electrically failed after 10 days, but still showed the Pt-Ir coating on the surface, indicating a connector failure. Other fibers displayed an impedance increase of 8 % after 36 days.

Overall, from the electrochemical characterization, a low electrode impedance has been achieved while having a homogenous and well distributed Pt-Ir coating on two different material testing arrays. Further analysis will be performed to characterize the stability of the coated arrays by the means of electrical pulsing tests.

Patel et al., Journal of neural engineering, 2016
Patel et al., Journal of neural engineering, 2015

Dr. James D. Weiland has a commercial interest in Pt-Ir electrode materials.

SB07.09.20
Mediating Interfacial Electron Transfer with Biologically Reduced Graphene Oxide Yixin Zhang and Xiaocheng Jiang; Tufts University, United States

Biological electron transfer represents critical processes upon which many essential biological functions depend. Its seamless integration with artificial electronics offers tremendous potential in various engineering applications including biosensing, biocomputing, and bioenergy conversion. The effective coupling at their interface, however, remains challenging, the active redox centers involved in biological electron transfer are typically buried inside the insulating protein matrix, creating large contact resistance with inorganic electrodes. To overcome this challenge, we explored a bottom-up, bio-synthetic strategy to actively “wire” these redox centers to the electronics. In this approach, graphene oxide (GO) were exploited as the solid-state electron acceptors, which can be reduced by G. sulfurreducens as a result of extracellular electron transfer through their membrane cytochrome C (cytCs). Since EET can only occur within the tunnelling distance of cytCs, reduced graphene oxide (rGO) can naturally link the redox centers of cytCs to the external electrodes to facilitate the interfacial charge transport. Through this strategy, the contact resistance at the biofilm-electrode interface can be effectively reduced by 90%, which enables unambiguous characterization of the inherent DC and AC transport across the electroactive biofilm independent of the contact barrier. The current work represents a strategically new approach to seamlessly interface the charge transfer between biological and artificial electronic systems, which is expected to open-up new opportunities for tackling the fundamentals and implications of biological charge transfer.

SB07.09.21
Biocompatible Microneedle Array Dry Electrodes for Bioelectric Potentials Measurement in Organic-Electronic Wearable Health Monitoring Applications Marco V. Alban, Haechang Lee, Hanul Moon and Seunghyup Yoo; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Dry electrodes are an important component of organic-electronic wearable devices for future human-centric Internet of Things (IOT) applications such as health monitoring and diagnostic; measuring brain, heart, and muscle bio potentials can allow early diagnosis of diseases relating to these organs as well as prevention, treatment, and therapy. In addition, they may provide means to monitor auxiliary brain-related information when used, for example, together with OLED-based photo biomodulation (PBM) devices that activate brain activity by light; as well as in electrical impedance tomography (EIT), an emerging imaging technology used to detect brain injury and stroke.
Likewise, they may allow one to realize a wearable device combining both electrocardiogram (ECG) and
photoplethysmography (PPG), the latter of which can be realized with OLEDs and organic photodiodes. Similarly,
they can be part of human-machine interfaces (HMI) used to control organic fiber strands for muscle-like actuators.
If realized, such devices will deliver continuously measured vital information beyond only heart rate in a way that
diminishes any disturbances on everyday life.

Existing clinical-use electrodes have limited wearable and external use capabilities due to the use of gels, a long
time to set up the electrodes, and lack of comfort. Dry electrodes have shown to improve on these issues, but still
lack the signal quality of gel electrodes required for accurate and relevant measurements. Some research has been
done on dry electrodes based on soft polymers with different structures on the surface, and covered by metallic
layers and nanowires, as well as carbon nanotubes among other conductive materials; these approaches are
successful in measuring bio potentials but are often bulky and show high electrode-skin impedance compared to gel
electrodes, this directs to a lower signal performance.

In this study, we propose microneedle array dry electrodes that demonstrate decreased electrode-skin impedance
compared with current dry electrodes in a flexible substrate and able to be fitted on wearable devices; as well as
comparable characteristics to gel electrodes. The proposed electrodes were fabricated using a biocompatible
conductive-filled polymer on top of an also biocompatible flexible substrate, reducing skin irritation and increasing
the comfort of the electrode. By constructing the electrode with a microneedle array structure, we provide a better
contact over hairy skin and an enhanced conformality to different places on the body, ensuring the reduction of the
electrode-skin impedance while keeping the electrode comfortable to wear due to the absence of skin preparation.
The proposed electrodes are characterized by impedance and signal quality; to be compared with clinical-use gold
cup electrodes, and Ag/AgCl standard-use electrodes. The impedance of the electrodes is measured using impedance
spectrometry over typical bio potential frequencies in a two-electrode configuration; and the signal quality is
determined by recording EEG, ECG, and EMG, to later calculate the signal-to-noise ratio (SNR) of the recorded
data. We believe the proposed electrodes can be used on wearable health monitoring applications requiring long-
term measurement, comfort, and high performance, and can do the groundwork for future Internet of Humans
devices, such as active electrodes for remote health data monitoring.

Ischemia-on-a-Chip Model with Integrated Extra- and Intra-Cellular Bioelectronic Interfaces for Monitoring
Cardiac Electrophysiology under Acute Hypoxic Stress Olurotimi A. Bolonduro1, Haitao Liu1, Akshita Rao1,
Breanna Duffy1, Lauren D. Black1,2 and Brian Timko1; 1Tufts University, United States; 2Sackler School for
Graduate Biomedical Sciences, United States

Cardiovascular disease is the leading cause of death in the US, accounting for 630,00 deaths in the US each year.
Ischemic stresses substantially alter cardiac electrophysiology, yet there are few tools that enable multiplexed, real-
time studies of cardiac function under controlled ischemia-like conditions. Such a platform would have substantial
implications for disease modeling and drug screening. Herein, we present an integrated microfluidic and
bioelectronic platform that exposed cultured HL-1 cells to controlled hypoxic stresses while simultaneously
providing extra- or intracellular electrophysiological readouts from up to 16 distinct recording sites. Planar device
arrays provided extracellular readouts which allowed for construction of isochronal maps and calculation of signal
propagation velocities. Vertical nanopillar arrays entered the cytosol following localized electroporation, enabling
direct readouts of the intracellular action potential.

Immunohistochemical analysis of HIF-1a expression demonstrated that HL-1 cells became hypoxic upon exposure
to deoxygenated media (1.0 – 1.3% O2). During a five-hour window of hypoxia HL-1 cells exhibited episodes of
tachycardia followed by bradycardia and arrhythmia. During that same window the action potential shortened from
4.89 ±1.54 to 1.68 ±3.34 ms (APD50). Normal cardiac function resumed after exposure to normoxic medium. Our
microfluidic platform enabled rapid modulation of media profiles to achieve acute hypoxic stresses similar to those
present during a cardiac infarct. Our ability to simultaneously read electrophysiological activity—including
intracellular action potentials—provides information not readily achievable using other electrophysiological
techniques. The noninvasive nature of our platform enables a wide range of long-term studies, including hypoxic
conditioning or chronic hypoxia and is also amenable to more complex biological systems including 3D tissue
models. Ultimately, these advances could provide new insights into the role of hypoxia in cardiac function.

Addressing the Stability Limitations of Miniaturized Ion Sensors Using a Thin Protective Film Deposited by a Non-Vacuum Low-Cost Technique Antonio R. Ruiz Gonzalez and Kwang-leong Choy; University College London, United Kingdom

The measurement of electrolytes has a high value in the clinical routine. Ions are present in all body fluids with variable concentrations and are involved in multiple pathologies such as heart failures and chronic kidney disease. In the case of dissolved potassium, although a high concentration in the blood (hyperkalemia) is relatively uncommon in the general population, it is one of the most frequent acute electrolyte abnormalities. In recent years, the integration of thin films technologies in this field has allowed the development of highly sensitive biosensors with ultra-low limits of detection for the assessment of metals in liquid samples. However, despite the current efforts in the miniaturization of sensitive devices and their integration into portable systems, only a limited number of successful examples used commercially can be found. This fact can be attributed to a high cost involved in their production and the sustained degradation of the electrodes over time, which causes a signal drift in the measurements. Thus, there is an unmet necessity for the development of low-cost and robust sensors for the real-time monitoring of analyte concentrations in patients to allow the early detection and diagnosis of diseases. This work reports a thin film ion-selective sensor for the evaluation of potassium ions in aqueous samples. As an alternative for this fabrication method, aerosol assisted chemical vapor deposition (AACVD), was applied due to cost-effectivity and fine control over the film deposition. Such a technique does not require vacuum and is suitable for the coating of large surface areas and structures with complex geometries. This approach allowed the fabrication of highly homogeneous surfaces with well-defined microstructures onto 50 nm thin gold layers. The degradative processes of the ubiquitously employed poly(vinyl chloride) membranes in contact with a biological solution were studied, including the polymer leaching process, mechanical desorption of nanoparticles and chemical degradation over time. A rational design of a protective coating based on an organosilicon material in combination with cellulose to improve the long-term stability of the sensors was then carried out, showing an improvement in the performance after 5 weeks. The antifouling properties of such coating were assessed using a cutting-edge quartz microbalance sensor, allowing the quantification of the adsorbed proteins in the nanogram range. A correlation between the microstructural properties of the films with the surface energy and biomolecules adhesion was then found and used to optimize the protective film.

SB07.09.24
The Virus Bioresistor—Wiring Virus Particles for the Direct, Label-Free Detection of Target Proteins Apurva Bhasin; University of California Irvine, United States

Advances in organic bioelectronics have urged to bridge the gap between interfacial compatibility and electrical charge transfer. Establishing communication between the electronic device and bio-entities surfaces the challenge of complexity involved in translating a biological event into an electronic signal. The goal of this project is to learn how to electrically communicate with virus particles. The virus particles of interest are M13 bacteriophage that have been engineered to recognize and bind a protein disease marker. This capability will provide the basis for a new type of biosensor in which M13 bacteriophage (or “phage”) supplant antibodies for the detection of protein disease markers in bodily fluids, such as urine.

It is demonstrated that M13 phage particles (dimensions 6 nm (w) x 1 mm (l)) can be wired into an electrical circuit by first embedding them in an electronically conductive polymer composed of poly(3,4-ethylene dioxythiophene) or PEDOT. This virus-PEDOT composite material, which is prepared by electrodeposition, acts as a resistor, and its resistance is increased when the entrained virus particles recognize and bind a target protein. The virus-PEDOT material provides a convenient means for electrically communicating with virus particles which are electrically insulating. An increase in resistance of the virus-PEDOT material signals the presence of the target protein and the amplitude of the resistance change allows its concentration in the contacting solution to be measured.

More information is obtained by measuring an electrical impedance spectrum for the virus-bioresistor (VBR), across a frequency range from 1 Hz to 40 kHz. These semi-circular Nyquist plots can be interpreted in terms of an equivalent circuit with three circuit elements: A channel resistance (RVBR), a solution resistance (RSOL) and an interfacial capacitance (CVBR). Information on target binding is extracted from RVBR that increases upon target recognition and binding, producing a signal DRVBR.

The VBR concept is tested on a model system in which a dynamic range of 7.5 nM – 900 nM human serum albumin (HSA, 66kDa) is detected in phosphate buffer solution. The high DRVBR (>200 W) induced by HSA binding capacitates the sensor to achieve a coefficient of variation <15% for a total of 20 devices tested for 7 different
protein concentrations. The reliability of signals is testified by the control experiments; followed by real-time sensing measurements. The VBR does not employ a redox probe or reagents for signal amplification. The Nyquist plot also allows the electrical resistance of the solution, R_{soln} to be deconvoluted from the electrical resistance of the virus-PEDOT channel which contains information about the target concentration. This means that the VBR is able to detect and measure the concentration of a target protein irrespective of the salt concentration of the solution, and this capability will be demonstrated.

Higher sensitivity for the VBR can be achieved by reducing the conductivity of the PEDOT-PSS base layer in order to force maximum current through an ultra-thin (<80 nm) virus-composite channel. This modification enabled picomolar detection of a 22kDa cancer biomarker, DJ-1 in synthetic urine. The signal produced by the modified VBR for 10 pM DJ-1 is 50 – 60 W, compared to the 5 W signal generated by the controls accounting for non-specific binding. The new VBR with the inherited ability to distinguish between the R_{soln} and R_{VBR}, produces maximum signal 500-600 W for DJ-1 in synthetic urine which has a total concentration of 160 mM. VBRs are characterized by extreme sensor-to-sensor reproducibility of 2-9% across the entire binding curve for DJ-1. Response time for sensing of 1.0 min. is also demonstrated. The mechanism of VBR transduction will also be discussed.

**SB07.09.25**

**Electrical Detection of Antibiotic Resistant Bacteria in Graphene Field Effect Transistors**

Narendra Kumar¹, Wenjian Wang¹, Juan C. Ortiz-Marquez¹, Matthew Catalano¹, Mason Gray¹, Kitadai Hikari², Xi Ling², Tim van Opijnen¹, Jianmin Gao¹ and Kenneth Burch¹; ¹Boston College, United States; ²Boston University, United States

Antibiotic resistance is one of the most serious threats to global health and food security. Misuse and over-prescription of antibiotics accelerates the promotion of resistant bacteria. To prevent and control this process, the development of new diagnostics which can specifically test for the specific bacterial strain is an urgent need. Graphene field effect transistor (GFET) based label free biosensors have shown great promise due to their highly sensitive Dirac voltage to any chemical/biological modification that occurs on the channel, fast response time, and flexibility to different substrates, which make them capable to be utilized for point of care diagnostics. In this study, the specific probes were synthesized, which are selective to clinical bacterial strains of Staphylococcus aureus (Sa) and Acinetobacter baumannii (Ab). The GFET devices fabricated using CVD monolayer graphene transferred over SiO2/Si substrates were functionalized with these probes in the single step process via non-covalent binding using π-π interaction with the graphene surface. In the talk I will discuss the various controls employed to ensure the selectivity of our probes. In addition, I will discuss device fabrication and measurement protocols to reduce the concentration required. These results point to the utility of gFET sensors for future point of care devices to rapidly detect bacteria strain and resistance.

**SB07.09.26**

**High-sensitive and Fast Detection of C-Reactive Protein and Troponin Biomarkers Using Liquid-Gated Single Silicon Nanowire Biosensors**

Yurii Kutovyi¹, Jie Li¹, Ihor Zadorozhnyi¹, Hanna Hlukhova¹, Nazarii Boichuk¹, Dmytro Yehorov¹, Marcus Menger² and Svetlana Vitusevich¹; ¹Forschungszentrum Jülich, Germany; ²Fraunhofer Institute for Cell Therapy and Immunology, Germany

Fast, precise, and reliable detection of cardiac biomarkers is essentially important for early diagnosis and prognosis of cardiovascular diseases, the most common life-threatening illnesses. However, the current commercially available diagnostic methods either lack of the sensitivity needed for the proper detection of cardiac biomarkers at the very early disease development stage or still suffer from the long-term process of enzymatic labeling. In this work, we designed and fabricated liquid-gated single silicon nanowire field-effect transistors (NW FETs) for label-free sensing of cardiac biomolecules. We demonstrate selective and direct detection of C-reactive protein (CRP) and cardiac troponin I (cTnI) proteins as gold standard biomarkers for prediction and detection of cardiovascular diseases at the early stage. A detailed electrical characterization of fabricated nanosensors, as well as the proof-of-principle experiments such as pH response, were performed before sensing measurements. Sensor characteristics reflect high working stability and nearly ideal Nernstian sensitivity confirming the high-quality of fabricated structures. High specific recognition elements like aptamers and antibodies were immobilized on functionalized nanowire surfaces. A novel attachment approach was shown by using dibenzocyclooctyne (DBCO)-linked aptamers for cardiac troponin to azide-functionalized nanowire surface. The approach has several advantages: fast covalent and directed attachment of aptamers to the azide-terminated surface of nanowires, efficient linkage and high-yield covering of nanowire surface with cTnI-specific aptamers. In particular, the DBCO-linked aptamers do not react with amines or hydroxyls presented in most of the biomolecules, which makes functionalization of nanowires more
efficient and specific. After covalent immobilization of cTnI-specific aptamers and CRP-specific antibodies on the silicon nanowires surface, the highly sensitive and fast electrical detection was performed. A 1 fg/ml detection limit concentration was achieved for both CRP and cTnI biomolecules. The target biomolecules on the Si NW surface are confirmed by atomic force microscopy (AFM) characterization. Moreover, application of nanowire structures with different sizes allowed us to detect biomarkers in a wide concentration range (from 1 fg/ml to 1 µg/ml). This range covers the dynamic concentration range of CRP and cTnI biomarkers release during the early disease stage and progression. Thus, we demonstrate that our specifically functionalized silicon NW FET biosensors integrated with polydimethylsiloxane (PDMS) microfluidic channels can be effectively used as highly sensitive diagnostic tools for early prediction and prevention of cardiovascular diseases.

SB07.09.27
Polymeric Nanofilter-Based Bioelectrical Interface for Potentiometric Small-Biomolecule Recognition Shoichi Nishitani and Toshiya Sakata; The University of Tokyo, Japan

Small biomolecules are often recognized as significant biomarker candidates in the field of in vitro diagnostics. In this study, we propose a novel concept of a biointerface, a polymeric nanofilter, for the potentiometric detection of small biomolecules using an extended-Au-gate field-effect transistor (EG-Au-FET). A Au electrode has the potential capability to detect various small biomolecules with high sensitivity at nM levels on the basis of a surface redox reaction, but it exhibits no selective response to such biomolecules. Therefore, a suitable polymeric nanofilter is designed and modified on the Au electrode, so that a small target biomolecule reaches the Au surface, resulting in an electrical signal, whereas low-molecular-weight interferences not approaching the Au surface are captured in the polymeric nanofilter. The polymeric nanofilter is composed of two layers. The first layer is electrografted as an anchor layer by a cyclic voltammetry method [1]. Then a filtering layer is precisely polymerized as the second layer by a photo-mediated surface-initiated atom transfer radical polymerization method [2]. As a model case, serotonin, a well-known stress marker, is detected by filtering a series of stress markers including catecholamine-related small biomarkers using the polymeric nanofilter-grafted EG-Au-FET on the basis of the following mechanism. The phenylboronic acid (PBA) that copolymerizes with the polymeric nanofilter captures catecholamines through diol binding, whereas serotonin reaches the Au surface through the filter layer. The polymeric nanofilter can also effectively prevent the interaction between biomacromolecules, such as amylase and human-serum albumin, and the Au electrode. A platform based on a polymeric nanofilter-grafted EG-Au-FET biosensor is suitable for the ultrasensitive and specific detection of a small biomolecule in biological samples such as tears and sweat, which include small amounts of low-molecular-weight interferences, which generate nonspecific electrical signals.

SB07.09.28
Investigation of Normal Cell and Cancer Cell Attachment and the Effects of Ganoderma Lucidum Using Electric Impedance Sensing Technique Steffi Kong, Alejandra Martinez and Maddy Behravan; Converse College, United States

This research focuses on analyzing the attachment of normal cells (HaCAT) and cancerous cells (A431), and the effects of Ganoderma Lucidum (reishi) treatment on the attachment of HaCAT and A431 cells. Cell attachment is an important property of the cell membrane; cells are held together through direct membrane contact and adhesion to the extracellular matrix. Cell attachment is essential to maintain tissue structure. Cells with poor attachment can detach and enter into the body’s fluid stream, which in cancer results in metastasis. It has been shown by researchers that reishi is commonly used as a nutritional supplement and is known to improve immunity. There have been previous reports that there has been an increase in the rate of apoptosis of cancer cells after being treated with reishi. In this study, attachment of HaCAT and A431 cells has been investigated using an impedance sensing system. An impedance sensing system is used to characterize the cell membrane attachment quantitatively. This technique is noninvasive and allows for observation and analysis of various aspects of cell behavior, particularly attachment and spreading in real time. An impedance sensing system measures changes in impedance with respect to an applied alternating current (AC) in real-time. Cell attachment and the epithelial layer formation limit current flow between the basal membrane and the cell. The attachment of HaCAT cells and A431 cells, and the influence of reishi with various dosages of 0.005, 0.01, 0.02 g/mL on these cells has been examined. The impedance analysis will be used to compare the attachment and the spreading rate of HaCAT cells and A431 cells, and the effect of reishi on the
epithelial cell layer. The initial set of data shows that the impedance of HaCAT cells and A431 cells increases with time; cell attachment and spreading impedes current flow. There is a significant difference between the impedances of normal cells and cancer cells detected over time. The time dependent response of HaCAT and A431 cells shows a characteristic behavior and reveals junction formation of these epithelial cells. The impedance of HaCAT and A431 cells continued to increase after 24 hours. The effect of reishi on cell attachment of HaCAT and A431 cells will be compared. The first series of reishi treatment reduced cell attachment of A431 cells. Various dosages of reishi could potentially slow down the rate of cancer cell attachment. Further experimental analysis could reveal the possible therapeutic or unwanted side effects due to reishi, a widely used supplement.

SB07.09.30
Low-Cost Implantable Transient Electronic Memory Devices for Patients Using Magnetic Resonance Imaging Akshita Mishra, Henam Sylvia Devi and Madhusudan Singh; Indian Institute of Technology Delhi, India

Electronic implants in the human body present safety challenges when exposed strong external magnetic fields, such as those encountered in magnetic resonance imaging (MRI). Metallic and other conductive interconnects, being ubiquitous in electronic devices, including memories, are susceptible to displacement forces and torques that can result in potentially lethal projectile effects. The Food and Drug Administration (FDA) provides guidance on listing implants as MR safe/unsafe/conditional under ASTM F2503-13. Cancer patients, who may need real-time monitoring of tumor growth offered by implants, as well as MRI scans for charting the progress of the therapy, are sometimes forced to accept less than ideal choices in their treatment as they often make poor candidates for repeated extractive surgeries needed to extract the implants. The cost of implanted electronic devices presents another challenge. In this work, we have developed an exemplar biocompatible memory device that is biodegradable at a specific pH. Cleaned commercial thermal silicon dioxide (500 nm) wafers (University Wafers) were drop cast with ~100 µl of polyvinyl alcohol (PVA), and then heated at 80°C for 30 minutes (thickness ~600nm). Bottom contacts of the device were next grown using shadow masks using successive DC sputtering (Cr ~200Å) and thermal evaporation (Au ~300Å) at 4 x 10^-6 Torr (Angstrom Engineering). A titania sol was synthesized using the sol-gel method, and spin-coated (spin NXG-P2) was next deposited as the active layer. Top contacts (Ag ~500Å) were thermally deposited to complete the metal-insulator-metal structure. Current-voltage characteristics of the device were acquired using a Keithley 4200-SCS semiconductor parameter analyzer in dual sweep mode with a grounded bottom electrode. Pristine devices were assumed to be in a high resistive state (HRS, off). On the application of bias voltage [-8, 5] V, the device switches to low resistive states (LRS, on) and exhibits a repeatable pinched hysteresis loop. Retention measurements were carried out at a constant readout voltage (0.01 V) to obtain the retention ratio (R_wt/R_off) of (~10^6). After the device characterization, these devices were dipped in three different media: acidic (pH=3), neutral (pH=7) and basic (pH=9). The devices were found to completely vanish (visual inspection) due to PVA dissolution in 15 min, 150 min, and 90 min respectively. As titania, silver and gold are all biocompatible materials, and present in minute quantities in the device, the dissolution of such devices over 150 minutes in neutral blood (modeled with pH ~7.4) presents few health challenges. Further, it was found that PVA films were easily removable from the silica substrate through peeling, thus enabling the use of the flexible memory device directly in the human body. Operationally, such biologically transient devices could be used to monitor patient vitals and permitted to completely dissolve prior to any MRI scans, without any extractive surgery with its deleterious health effects. Owing to the low cost of the implant, a patient can be injected with the device as many times as necessary during treatment.

SB07.09.31
Device Physics and Transient Behavior of Microfluidic Ion Pumps Shao-Tuan Chen, Christopher Proctor and George G. Malliaras; University of Cambridge, United Kingdom

Targeted drug delivery devices have flourished in recent years due to their superior biocompatibility and lower possibility of side effects compared to systematic drug treatments. Following recent advances of microfluidic ion pumps (µFIPs) [1,2], it has been demonstrated that drugs can be delivered to targeted cells with temporal and spatial precision with applied electric field.

In the µFIP, drugs are electrophoretically pumped from the microfluidic reservoir through an ion exchange
membrane into the targeted area. The ion exchange membrane bears fixed charges in the polymer matrix, which allow the membrane to selectively transport oppositely charged ions while blocking ions with the same charge. Hence, µFIP can actively deliver the drug of interest when electric field is applied while preventing passive drug diffusion when device is switched off.

An ideal µFIP should have a perfectly selective membrane and passive leakage should be minimal. Parameters such as device geometry, fixed charge concentration in the membrane and initial drug concentration in the microfluidic reservoir would all affect the efficiency and performance of µFIP.

Having fundamental knowledge and accurate quantitative models therefore are crucial to the design and optimization of such implantable medical devices. As the range of applications for µFIP continue to expand, there is an urgent need for deeper understanding of their device physics.

Here we report a numerical model for µFIP platforms. The transient behavior of µFIP during operation is described by time-dependent governing equations for the ionic/electronic coupled model. We identified three performance indices to characterize the device performance, namely, the pumping efficiency, amount of drug transported, and the ON/OFF ratio. Performance contour plots for these three indices were obtained by varying two parameters—initial drug concentration in the microfluidic reservoir and fixed charge concentration in the membrane, both by three orders of magnitude.

The parameter space covered in this study encompasses a concentration range far wider than those commonly found in membrane materials and drug molecules used today, thereby giving a comprehensive view of the device performance of µFIPs and possible new avenues for material development and design optimization for such devices.

The model is able to describe both steady state and transient behavior of the ionic and electronic transport across the ion exchange membrane over a wide range of parameter space. Dynamic phenomena, such as electric double layer relaxation within the conducting polymer coated at the electrodes and concentration polarization at the electrolyte-membrane interface, are also captured by the time-dependent numerical model.

The results from this study allow us to design advanced µFIP platforms and push forward the development of targeted drug delivery devices for higher efficiency and extend its range of applications.

SB07.09.32 Design of a Sensor Platform Using Bacterial Outer Membranes on Organic Electrochemical Surfaces

Antibiotic resistance is a growing global health concern in part due to changes in membrane properties and composition of Gram-negative bacteria that affect antibiotic efficacy. The alteration in membrane properties of Gram-negative bacteria influences response to antibiotics and mediates resistance; consequently, the antibiotic is unable to control or kill these bacterial strains, instead, they survive and multiply in the presence of an antibiotic. Therefore, understanding the interactions between bacteria membrane and antibiotics and the transport across the membrane is important for elucidating membrane properties that can be used for the design of novel antimicrobial drugs. The outer membranes of Gram-negative bacteria containing protein and complex lipopolysaccharides that helps to protect them from external harsh conditions. To study outer membrane-antibiotic interactions, we created an electrochemical sensing platform based on a surface-supported planar bacterial outer membrane on an optically transparent conducting polymer surface poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS). The bilayer platform is fabricated using outer membrane vesicles (OMVs) of different clinically-relevant Gram-negative
bacteria in order to incorporate native lipids, membrane proteins and liposaccharides to the supported bilayer. The supported bilayer formation and their fluidity are characterized using Fluorescence Recovery After Photobleaching (FRAP) technique, which also enables measurement of the diffusion coefficient using fluorescently labelled molecules/phospholipids. The change in electrical properties of surface-supported bacteria membrane during formation and their interaction with disrupting compounds have been monitored by electrochemical impedance spectroscopy (EIS). The optical transparency and conducting properties of the polymer allowed us to monitor the bilayer formation by both microscopic techniques and changes in ion flux by electrical readout. This sensor platform introduces a method containing biologically-complex membranes to the study of antimicrobial drug testing, a much-needed intermediate between very simple bilayer platforms and whole cell readouts.

SB07.09.33
Electrocaloric (EC) Solid-State Heat Pump without Involvement of Moving Parts Farrukh Najmi, Lorenzo Cremaschi, Wenxian Shen and Zhongyang Cheng; Auburn University, United States

One of the challenges in the development of Electrocaloric (EC) based solid state cooling device/heat pump is the involvement of moving parts – either active material or regenerator needs to be moved to extract energy from source (hot end) and releasing it to the sink (cold end). This not only reduces the efficiency but also adds the complexities in the device design limiting its exploitation in small scale applications. In this study, a two-layered solid-state heat pump is being devised in which the EC layers have been sandwiched between source and sink and the heat is pumped from source to sink in a complete silent operation (no moving parts). An electric field cycle is applied on the EC layers alternatively in such a way that it creates a temperature gradient to achieve a directional heat flow in a system of bodies (Sink/ECs/Source) which are otherwise in thermal equilibrium. This transient heat conduction problem has been solved analytically and gives promising results specially for interfaces having lower contacting coefficients. This technique can offer viable solutions to address the cooling issues in high power electronics and other portable medical applications.

SB07.09.34
Defect-Induced Magnetism in Copper(I) Oxide as a Biocidal Tool Yinying Hua, Brian Lejeune, Xiaoyu Zhang and Laura Lewis; Northeastern University, United States

Antimicrobial materials that are less susceptible to evolved resistances are one approach for combatting the rise in antibiotic resistance, which is a growing concern for public health [1]. Metallic materials have been widely used as a biocidal tool since ancient time and copper-based materials are a key component because of their observed ability to generate radicals and cause cell membrane damage. According to reports which discussed the antibacterial activities of elemental copper, copper(II) oxide and copper(I) oxide [2], Cu(I) and metallic Cu show higher antibacterial activity than Cu(II) state, although the mechanism remains unclear. At the same time, it is known that lattice defects in transition-metal oxides donate local charges that can enhance catalytic properties [3]. To test the hypothesis that lattice defects, such as oxide sublattice vacancies, underlie the noted biocidal activity of Cu$_2$O, initial studies of the relationship between degree of lattice damage and defect concentration in this material were undertaken.

The structural and the electronic states, as revealed by magnetic characterization, were assessed in Cu$_2$O powders (Alfa Aesar, < 200 mesh powder) that were subjected to cryo-milling for up to two hours. Decreases in the cubic $a$-lattice parameter, the unit cell volume $V$ and an increase in both the Pauli paramagnetic and the Curie-Weiss susceptibilities with an increase of cryo-milling time were observed. These observations, which are consistent with changes in the defect state of the lattice, will be correlated with the potential catalytic state of the processed material. Clarification of these structure/property correlations demonstrates the relationship between the lattice defects and the potential catalytic state, which may be a promising way to tailor the antibacterial activity of Cu$_2$O.

Acknowledgement: This research was conducted under the auspices of Northeastern University.

Carbon Composites with Improved Properties of for Wearable Electronics Ji-Young Hwang\textsuperscript{1,2}; \textsuperscript{1}Korea University, Korea (the Republic of); \textsuperscript{2}Korea Institute of Carbon Convergence Technology, Korea (the Republic of)

Wearable electronics has progressed dramatically and has opened the prospective future, including electric circuits, flexible displays, stretchable energy storages, electronic skins, wearable devices, \textit{etc}. For flexibility and elasticity are hardly a matter, these have to be surmounted beyond convergence of state-of-the-art technologies. Here, we developed simple and cost-effective fabrication method of nanohybrid composites with carbon nanotubes (CNTs) and polydimethylsiloxane (PDMS) elastomer for improving its electrical and mechanical properties for wearable electronics. CNT/PDMS composites provide high flexibility, elasticity, and electrical conductivity itself and are also biocompatible and mechanically stable. The CNT/PDMS composites are demonstrated to create functional materials that are used for effective bio-signal monitoring of brain, heart, and muscle signals, as well as devices with incorporated integrated flexible circuits. This simple and cost-effective fabrication method provides a promising process and material for various applications of flexible, stretchable and wearable electronic devices, particularly considering the growing global interests in wearable healthcare monitoring system.

SB07.09.36
Fabrication of Nanopore Ion Transistor via Conformal Metal-Film Deposition of Gate-Electrode Structure Kwanjung Kim\textsuperscript{1}, Sunwoong Lee\textsuperscript{1}, Seung-Min Han\textsuperscript{2}, Soo-Hyun Kim\textsuperscript{2} and Sung-Wook Nam\textsuperscript{1}; \textsuperscript{1}Kyungpook National University, Korea (the Republic of); \textsuperscript{2}Yeungnam University, Korea (the Republic of)

Electrofluidics is an emerging technology of combining electronics and nanofluidics. One important device in electrofluidics is an ion transistor in which the ionic current through a nanopore is regulated by gate voltage bias. Here, we suggest a fabrication method of nanopore ion transistors by introducing focused ion beam (FIB) and atomic layer deposition (ALD). We deposited 100 nm-thick silicon-nitrite layers on both sides of silicon wafer by low-pressure chemical vapour deposition (LPCVD). We fabricated rectangular patterns by photolithography followed by reactive ion etching (RIE) on the backside of the wafer. Anisotropic silicon etching by KOH was performed. The front side of the chip was patterned by photolithography followed by Ti/Au deposition for the fabrication of electrode structures. We drilled 50 ~ 100 nm pores in the Si\textsubscript{3}N\textsubscript{4} membrane by FIB. By the ALD process, we deposited highly-conformal metal film, either Platinum (Pt) or Ruthenium (Ru) to shrink nanopores by a self limiting process. We expect that the gate modulation of ionic current through the nanopore is efficiently controlled by the gate-surrounding structures.

SB07.09.38
Detection of IL-10 Cytokine on Roll-to-Roll Nanoimprinted Au Localized Surface Plasmon Resonance Chip Assisted by Au Nanoparticle Seung Hee Baek, Hyun Woo Song, Moon Kyu Kwak, Hye Jin Lee and Sung-Wook Nam; Kyungpook National University, Korea (the Republic of)

Localized surface plasmon resonance (LSPR) is a highly sensitive platform for detecting biomolecules including protein, nucleotide, and vesicle. Although LSPR signal is easily taken by ultraviolet-visible (UV-Vis) spectroscopy, the shift of LSPR peak by the attachment of target molecules is small, which makes it challenging the precise evaluation of the peak shift. Here, we report an Au LSPR sensor platform in which the Au nanoparticle assists the precise evaluation of LSPR peak shift by offering a stable reference peak in UV-Vis spectroscopy. For LSPR sensor fabrication, we employed a roll-to-roll nanoimprint process to create nanograting structures on polyethylene (PET) film. By angled deposition of Au, we demonstrated double-bent Au structures which have strong LSPR peak at \textasciitilde 740 nm. Upon the Au structures, we introduced IL-10 capture antibody to Au LSPR chip by using cross-linking chemistry. Afterward, we loaded IL-10 target protein for specific adsorption to the IL-10 capture antibody. To form a sandwich assay platform assisted by Au nanoparticle, we conjugated Au nanocube (AuNC) with IL-10 detecting antibody and induced it to bind with IL-10 capture antibody/IL-10 complex specifically. We note that AuNC has a stable peak at \textasciitilde 530 nm in the solution state. By using the characteristic peak of AuNC as a reference, we estimated the red shift of the LSPR peak of Au strip structures with high accuracy, which is caused by the formation of IL-10 capture antibody/IL-10/IL-10 detection antibody sandwich assay. We expect that the Au nanoparticle assisted LSPR sensor platform can be used as diagnostic tools for detecting various biomarkers.

SB07.09.39
Characterization of Proton Conducting Materials Manping Jia, John A. Selberg and Marco Rolandi; University of California, Santa Cruz, United States
Proton conduction is important in many natural phenomena including oxidative phosphorylation, enzyme reaction, and is extensively studied and developed in bioelectronic technologies and renewable energy, like actuators, sensors, and fuel cells. Recently, with the rapid development of bioelectronics, efforts are expended on developing proton conducting materials to bridge the gap of the biological system and electrical devices. Natural biomolecules, like peptides, glycosaminoglycans, DNA, etc., show great potential to be proton conducting materials because of their intrinsic biological function and biocompatibility. The sulfate group in glycosaminoglycans, amino acid residues in peptides, and the helix structure of two hydrogen-bonded complementary strands of DNA, provide good environments for proton transfer. Here we compare the results of AC electrochemical impedance spectroscopy (EIS) on several proton-conducting natural materials with the DC data obtained with Pd/PdHx proton-conducting electrodes and show that the two techniques are consistent with each other.

Enhancing Diabetic Wound Healing with Therapeutic- and Cell-Loaded Alginate Bandages

Sahar Rahmani1,1, Georgios Theocharidis1,2, Evan Thompson1, Selena Zhang1, Konstantinos Kounas2, Ting-Yu Shih1,1, Aristidis Veves1,1,2 and David J. Mooney1,1; 1Harvard University, United States; 2Beth Israel Deaconess Medical Center, United States

An estimated 285 million adults suffered from diabetes mellitus worldwide in 2010, a number that is expected to exponentially grow. Approximately 15% of diabetics develop diabetic foot ulcers (DFU) and one-in-five are estimated to suffer from a lower extremity amputation in their lifetime. While a number of methods have been developed for wound healing, most are not applicable for DFUs due to their unique pathophysiology, especially their impaired immune response during the wound healing process. In healthy patients, macrophages have an integral part in homeostasis and tissue repair and orchestrate the wound healing process through various mechanisms. Unfortunately, a decrease in the number of macrophages is observed in diabetic wounds, and those present tend to be pro-inflammatory (M1s) instead of pro-healing and/or anti-inflammatory macrophages (M2a/c, respectively). As a result, the wound healing progression is delayed, or prevented, which can lead to non-healing wounds and amputations.

To address this challenge, we hypothesized that increasing the number of macrophages at the wound site and redirecting them to a more pro-healing state can enhance healing in diabetic wounds. To this end, we have developed alginate, cryogel bandages to deliver various factors to wounds. The hydrogel bandages can be manufactured on a large scale as off-the-shelf products and be loaded with therapeutics (cells or factors) during or after the manufacturing process.

Using this bandage system, bone marrow derived macrophages were polarized to inflammatory or healing states, loaded into bandages, delivered to diabetic wounds in a murine model of type 2 diabetes, and the wound size was monitored over a 10-day period. Additionally, the wounds’ cellular components were analyzed by immune-histochemistry and immunofluorescence. Wounds treated with macrophage had smaller wound sizes as compared to the empty bandages. Normalized wound size at Day 10 was 23, 18, 22, 19, and 14% of the original wound size for wounds treated with empty bandages, non-polarized (M0), M1, M2a, and M2c macrophages, respectively. Furthermore, wounds treated with M2c loaded bandages were significantly more healed than those treated with M1 loaded macrophages. These results confirmed our hypothesis that the addition of macrophages, especially anti-inflammatory macrophages, to the wound site can enhance healing in diabetic wounds.

Currently, we are exploring the use of therapeutic-loaded bandages for the recruitment of macrophages to the wound site (MCP-1) and their polarization to the pro-healing state (IL-4 and IL-10) to aid in the healing process. This approach can be advantageous over the delivery of cells in several aspects, including processing time, cost, patient compliance, and feasibility. Depending on the therapeutics’ properties such as surface charge, molecular weight, and heparin binding affinities, we have fabricated bandages with different material compositions to create a prolonged therapeutic release profile for each factor that can be tuned-in to range from a few hours to days and weeks. Using these bandages, we have demonstrated that more immune cells, specially macrophages, are recruited to the wound site as compared to traditional bandages. Here, MCP-1 loaded bandages were placed on wounds over a 3-day period and the cell types and numbers present in the wound were analyzed via flow cytometry. A significantly higher number of macrophages were recruited to the wound site in samples treated with MCP-1 loaded bandages as compared to traditional bandages (approximately four times more). Our next step is to assess the capability of bandages loaded with IL-4 and IL-10 to polarize the local macrophages to the M2 state and, thereby, enhance wound healing. Such bandage systems can potentially provide significant improvement in the lives of diabetic patients by using their body’s own immune system to directly address their impaired healing mechanism.
SESSION SB07.10: 3D Printing and Tissue Engineering
Session Chairs: Tzahi Cohen-Karni, Anastasia Elias, Sahika Inal and Christoph Tondera
Thursday Morning, December 5, 2019
Hynes, Level 3, Ballroom B

8:30 AM *SB07.10.01
Engineering Personalized Tissue Implants—From 3D Printing to Bionic Organs  Tal Dvir; Tel Aviv University, Israel

In this talk I will describe cutting-edge technologies for engineering functional tissues and organs, focusing on the design of new biomaterials mimicking the natural microenvironment, or releasing biofactors to promote stem cell recruitment and tissue protection. In addition, I will discuss the development of patient-specific materials and 3D-printing of personalized vascularized tissues and organs. Finally, I will show a new direction in tissue engineering, where, micro and nanoelectronics are integrated within engineered tissues to form cyborg tissues.

9:00 AM SB07.10.02
Bioelectronics with Food—Celery, Vegemite and Jelly  Rhiannon Morris, Charles Hamilton, Alex Keller, Holly Warren and Marc In het Panhuis; University of Wollongong, Australia

Bioelectronics from edible materials (e.g. food) can be defined as the design of circuits and devices that incorporate edible materials into electronic components and/or uses edible materials to perform the function of electronic components.

I will discuss the (bio-)electronic behaviour of three different types of common food products, i.e. breakfast spreads (Vegemite, Marmite), a vegetable (celery) and a desert (jelly).

The characteristic breakfast spreads Vegemite and Marmite were 3D printed into edible circuitry onto bread substrates. We demonstrated the importance of characterising the rheological behaviour of the food products in retaining the structural integrity of the printed materials (e.g. pyramids on bread). The electrical conductivity (20 +/- 3 mS/cm) of Vegemite and Marmite was used to 3D print edible circuits on “breadboards.”

The edible gelatin product Jell-O (or Aeroplane Jelly) was turned into an electrode structure via the inclusion of table salt during preparation of the hydrogel material. It was shown that the resulting hydrogels prepared using a one-pot synthesis method displayed suitable conductivity values (190 +/- 20 mS/cm) at high water content (70% by weight).

Celery is a marshland plant that has been cultivated as a vegetable. We show that its vascular system (xylem) can be used to facilitate the uptake of the conducting polymer, poly(3,4-ethylenedioxythiophene) poly(styrene sulfonate) PEDOT:PSS. Our results indicate that PEDOT:PSS is an ideal candidate for enhancing the electrical behavior of the biological system, i.e. celery. The celery-PEDOT:PSS bioelectrical system exhibit conductivity value of 500 +/- 30 mS/cm, suitable to function as components in electrical devices.

9:15 AM SB07.10.03
Morphing Electronics for Growing Tissue  Jinxing Li, Yuxin Liu and Zhenan Bao; Stanford University, United States

Bioelectronics for modulating nervous system, such as the vagus nerve stimulator, demonstrate great promise in treating various neurological diseases. However, their fixed sizes and shapes cannot accommodate the rapid tissue growth and negatively influence normal developmental functions. For infants, children and adolescents, once the implanted devices are ‘outgrown’, additional surgeries are usually needed for device removal, followed by replacement. These tedious processes inevitably lead to repeated intervention and elevated complication rates. Although stretchable electronics with high elasticity is ideal for repeated motion and volumetric expansion of
In this work, we demonstrated an innovative method of rapid in-situ fabrication of conductive-bacterial-composite on carbon electrodes. The conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) was electrochemically polymerized by 3D printing the monomer precursor directly onto the surface of electrode submerged in an aqueous suspension of *Shewanella oneidensis* wild type MR1, creating an electrochemically active biocomposite within 35 min. Using cyclic voltammetry (CV), the biocomposite showed enhanced bio-electrochemical activities, opening up new avenues to the development of bioenergy harvester, biosensor and biomedical device. Ever since the discovery of conductive polymers, their electroactive properties have been extensively examined by researchers and engineers alike. Particularly, the biocompatible conductive polymers have been given significant attention in recent years as a promising bridge between biology and electronics. Applications as microbial fuel cell (MFC), water-quality sensor, glucose sensor, or body-machine interface have shown great potentials in the fields of energy harvesting technology, biosensing, bioelectronics and health care. Bioelectrochemical systems (BES) utilizing conductive polymer and electroactive bacteria biocomposite to directly transduce biological processes to electrical signals are of unique interest as their immediate application in bioenergy harvesting and biosensing. Comparing to the natural biofilms, the electrochemically active biocomposite offers distinctive advantages as enhanced extracellular electron transfer (EET) rate, denser cell attachment onto the electrode, higher signal-to-noise ratio, and more controllable and versatile composite constitution and functions. Yet, current conductive biocomposite formation procedures such as polymer coating over bacteria cells and electrode surface, cell absorption onto polymer matrix, or cell immobilization by polymerization often involve prolonged cell exposure to cytotoxic chemicals, species-specific procedures, or complicated experimental process and setup. Thus, a more rapid, non-specific and simple biocomposite fabrication method is urgently needed to fully unleash the full potential of conductive-polymer-based BES. Using 3D printing, we present a novel, rapid and simple method to fabricate conductive biocomposite by
The electropolymerization was conducted with plenary 3-electrode electrochemical cells containing *S. oneidensis* in M9 medium in room environment. While a constant potential (1V versus Ag/AgCl) was applied to the carbon working electrode (WE) by a potentiostat in chronoamperometry (CA) mode, 10mM EDOT (in M9 medium) was patterned over the WE surface by a 3D printer. Cells attached to the WE were entrapped by the in-situ synthesized PEO-DT whereas their exposure to the cytotoxic monomer was minimized. The dimension of the conductive biocomposite can be controlled by the printing pattern and number of repeated iterates. A settling time of 10 min between each print and iterate repeat of 3 times were selected in this work.

Three-Dimensional Printing of Conducting Polymer Baoyang Lu1,2, Hyunwoo Yuk1, Jingkun Xu2 and Xuanhe Zhao1; 1Massachusetts Institute of Technology, United States; 2Jiangxi Science & Technology Normal University, China

Three-dimensional (3D) printing is one of the most transformative technologies in modern manufacturing that offers unprecedented capabilities of programmable, rapid, and flexible fabrication of materials. Despite their unique benefits and growing importance, conducting polymers have yet remained as an inaccessible class of materials for 3D printing. Here we introduce a 3D printable high-performance conducting polymer based on poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) to take full advantage of advanced 3D printing. Superior 3D printability of the conducting polymer ink enables high resolution (over 30 µm), high aspect ratio (over 20), and reproducible fabrication of conducting polymer in microscale, seamlessly integrable with multi-material printing with other 3D printable materials such as insulating elastomers. The 3D printed conducting polymer structures can readily be converted into highly conductive and flexible pure PEDOT:PSS both in dry and hydrogel states. Both of the 3D printed PEDOT:PSS films and hydrogels exhibit interesting properties that are desirable for optoelectronic and bioelectronic applications, such as high electrical conductivity, low Young's modulus, superior mechanical, electrical and electrochemical stability in wet physiological environments. We further demonstrate various functional applications of the 3D printable conducting polymer including a high-density flexible electronic circuit and a soft neural probe capable of *in vivo* single-unit recording, all fabricated by 3D printing. This work not only widens the choice of materials for 3D printing but also provides a promising new fabrication strategy for a broad range of applications in flexible electronics, wearable devices, and bioelectronics.

10:45 AM SB07.11.02

Modularized Field-Effect Transistor Biosensors Xiaochuan Dai1,2, Richard Vo1 and Xiaocheng Jiang1; 1Tufts University, United States; 2Massachusetts Institute of Technology, United States

Field-effect transistors (FETs), when functionalized with bioactive receptors (such as antibodies or enzymes), represent a unique platform for real time, specific, label-free transduction of biochemical signals with unprecedented sensitivity and spatiotemporal resolution. However, direct functionalization of bio-receptor on FETs places limitations on reprogrammability, sensor regeneration and sensitive bio-receptor handling. Here we demonstrate a modularized design of FET biosensors with separate recognition module and transducer module, which are capable of reversible assembly and disassembly. Successful detection of penicillin down to 0.25 mM was achieved by integrating penicillinase-encoded hydrogel module onto graphene FETs, demonstrating effective signal transduction across the interface. Moreover, sequential integration of urease- and penicillinase-encoded modules on the same FET device allows us to reprogram sensing modality without cross-contamination. Except for the variation of bio-receptor encoding, the modular design also fosters sophisticated modulation of the biophysical/biochemical microenvironment in the recognition modules for controllable diffusion dynamics. Specifically, the tuning of
hydrogel porosity with polyethylene glycol and gelatin enables the selective detection of poly-L-lysine (MW 150-300 kDa). Recognition modules designed with standardized interfacing geometry towards transducer modules have also been shown to be capable of being mass fabricated by 3D printing and batch photopolymerization, demonstrating potential for low cost, ease of storage, multiplexing and great customizability for personalized biosensor arrays. This generic concept presents a unique integration strategy for modularized bioelectronics and could impact broadly hybrid device development.

11:00 AM SB07.11.03
From 2D to 3D Material—New Strategies for Cell-Chip Coupling in Bioelectronics Francesca Santoro; Istituto Italiano di Tecnologia, Italy

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. For instance, electroactive materials in contact with cells can have very different composition, surface topography and dimensionality. Dimensionality defines the possibility to have planar (2D), pseudo-3D (planar with nanomicropatterned surface) and 3D conductive materials (i.e. scaffolds) in bioelectronic devices. Their success for both in vivo and in vitro applications lies in the effective coupling/adhesion of cells/tissues with the device’s surface. In fact, the tight contact between the cellular membrane and the electrode surface massively affects the quality of the recorded signals or ultimately the stimulation efficiency of a device. However, it is largely unexplored how the patterning and ultimately the dimensionality of bioelectrodes are enhancing the cell-chip coupling.

Here, we explore how the transition from planar to pseudo-3D nanopatterned materials (i.e. conductive vertical nanostructures, nanogrooves, nanofibers) have introduced a new strategy of integrating with biological cells. Although a spontaneous penetration does not occur, adhesion process are extremely distinct when bioelectronics devices are engineering with those patterned materials. These materials have been further exploited towards fully 3D dimensional solutions, moving closer to complex 3D architectures which could directly resemble tissue-like architectures. In this way, cells recognize the bioelectrodes as being embedded in their own matrix and thus fully integrate with the device.

11:30 AM SB07.11.04
A Novel 3D In Vitro Model of the Human Gut-Microbiome Axis—A Bioelectronics Approach Chrysanthi-Maria Moysidou, Charalampos Pitsalidis, Janire Saez and Roisin Owens; CEB, University of Cambridge, United Kingdom

The human gut microbiome plays an essential role in health and disease. Gastrointestinal disease phenotypes (e.g. coeliac disease (CeD), colorectal cancer), have been linked with an impaired gut microbiome, while increasing evidence suggests that microbiome alteration effects extend beyond the gut, reaching other organs, and particularly, the brain. However, the cross-talk interactions of the ‘gut-brain-microbiome axis’ remain a mystery, mainly due to the lack of a human clinical model. Over the last decade, organ-on-chip technology has arisen as powerful alternative to animal models for studying human (patho-)physiology. Integration of this technology with organic electronics can be particularly favourable for delivering robust, biomimetic models, with in-line, multiparametric monitoring.

Here, we report the first version of an in vitro intestinal model integrated with a novel 3D bioelectronic device (i.e. Tubistor), based on scaffolds made from the conducting polymer poly(3,4-ethylenedioxythiphene)poly(styrenesulfonate) (PEDOT:PSS). To emulate the intestinal epithelial barrier we established co-cultures of enterocytes, along with fibroblasts which are used for their ability to secrete extracellular matrix and render the surface of the scaffolds more appealing for cell adhesion. This co-culture system is generated inside Tubistors, both under static and flow conditions, where PEDOT:PSS scaffolds serve both as cell host and as the active material for monitoring cell integrity and activity. During a 25-day growth period, we continuously monitor the model electrically and at the end of this period, these data are cross-validated with traditional optical assays (i.e., Scanning Electron Microscopy and immunofluorescence staining). The soft, tissue-like nature of PEDOT:PSS scaffolds provides a favourable microenvironment for tissue growth and differentiation, exhibiting typical in-vivo-like characteristics of the native tissue (e.g. brush border formation, tight junction and mucin expression). To generate a complete gut-microbiome model, we are currently working on co-culturing bacterial cells – representative of the human microbiome - with our intestinal model.

We anticipate that this bioelectronic platform will serve as a powerful tool for studying host-microbiome
interactions, as well as a diagnostic tool for personalised medicine applications.

**11:45 AM SB07.11.05**
**High Aspect Ratio Semiconducting Polymer Pillars for 3D Cell Cultures**
Gabriele Tullii1, Federica Giona2, Francesco Lodola1, Silvio Bonfadini1, Caterina Bossio1, Andrea Desii3, Luigino Criante1, Carlo Sala1, Maria Cecilia Pasini3, Chiara Verpelli2, Francesco Galeotti3 and Maria Rosa Antognazza1; 1Istituto Italiano di Tecnologia, Italy; 2University of Milan, Italy; 3Consiglio Nazionale delle Ricerche, Italy

Hybrid interfaces between living cells and nano/micro-structured scaffolds have been extensively investigated over the latest decades, due to their huge application potential in biotechnology, spanning from regenerative medicine and stem cells therapies to localized drug delivery, from biosensing and tissue engineering to neural computing. In particular, 3D scaffolds based on organic conductors have recently gained increasing interest, due to the combination of excellent biocompatibility properties with versatile fabrication techniques and good electrical conductivity. In this scenario, however, architectures based on semiconducting polymers, endowed with responsivity to visible light as an additional interesting feature, have never been considered.

Here, we originally develop a push-coating technique to realize high aspect ratio (HAR) polymeric pillars, based on polystyrene. The organic semiconducting structures show optimal biocompatibility and allow for the realization of soft, three-dimensional cell cultures, as tested with both primary neurons and cell line models. HEK-293 cells cultured on top of polymer pillars display a remarkable change in the cell morphology. Interestingly, we observe a sizable enhancement of the cell membrane capacitance as due to the cell membrane thinning in correspondence of the pillars’ top surface. Importantly, however, this does not negatively affect cells proliferation. Electrophysiology properties and synapses number of primary neurons are also very well preserved.

HAR semiconducting polymer pillars represent the first necessary step towards the realization of 3D, electro-optically responsive organic structures. In perspective, they may find interesting applications as soft, photoactive elements for cell activity sensing and modulation.

**1:30 PM *SB07.12.01**
**Ultimately Sensitive Bioelectronic Sensor by Materials and Device Structures Design**
Luisa Torsi1,2, Rosaria Anna Piccia1,2, Kyriaki Manoli1, Lucia Sarcina1, Eleonora Macchia1,2, Davide Blasi2, Nicola Cioffi1,2, Gerardo Palazzo1,2, Gaetano Scamarcio4,5, Cinzia Di Franco6, Ronald Österbacka3 and Fabrizio Torricelli6; 1University of Bari Aldo Moro, Italy; 2Centre for Colloid and Surface Science - CSGI, Italy; 3Åbo Akademi University, Finland; 4Università degli Studi di Bari Aldo Moro, Italy; 5CNR - Istituto di Fotonica e Nanotecnologie, Italy; 6Università degli studi di Brescia, Italy

Organic bioelectronic sensors are gaining momentum as they can combine high performance sensing level with flexible and stretchable large-area processable materials. This opens to potentially highly powerful biomarkers sensing systems for point-of-care health monitoring and diagnostics. Prominent to detect biochemical recognition events are the Electrolyte-Gated Organic Field-Effect Transistors (EGOFETs) and Organic ElectroChemical Transistors (OECTs) as they are easy to fabricate and operate. Relevantly, the EGOFETs have been recently shown capable of label-free single-molecule detections even in blood serum.

This lecture aims to provide a critical perspective through a selected overview of the literature on both EGOFETs and OECTs organic bioelectronic sensors. Attention is paid to correctly attribute them to the potentiometric and amperometric categories which is important to set the right conditions for quantification purposes. Moreover, to deepen the understanding of the sensing mechanisms, also with the support of unpublished data, focus is put on two among the most critical aspects, namely: the capacitance interplay in EGOFETs and the role of faradaic currents in OECTs. The final aim is to provide a general rational encompassing both EGOFETs and OECTs sensors, to improve materials and devices design taking full advantage of the processes that enhance the sensing response enabling the
extremely high-performance level resulting in ultimate sensitivity, selectivity and fast response.

2:00 PM SB07.12.02
Ultrasensitive Detection of Nucleic Acids Using Deformed Graphene Channel Field Effect Biosensors Michael Hwang, Mohammad Heiranian, Yerim Kim, Yuhang Jing, Seungyong You, Vahid Faramarzi, Juyoung Leem, Amir Taqieddin, Arend M. van der Zande, SungWoo Nam, Narayana R. Aluru and Rashid Bashir; UIUC, United States

Field effect transistor-based electrical biosensors are capable of label-free detection of nucleic acids and proteins by measuring the intrinsic charge of these biomolecules. However, the ultimate detection limit of these sensors is determined by the Debye screening from counter ions in solution, the proximity of the biomolecules to the surface of the sensor, and the operating conditions of the transistor sensor. Here, we use field effect transistors with a deformed monolayer graphene channel for the detection of DNA molecules and DNA/RNA hybridization. We find that these devices with even millimeter scale long channels show an ultra-high sensitivity detection in buffer and human serum sample down to 20 aM in 50 µL, which is equivalent to ~600 DNA/RNA molecules. Molecular dynamic simulations reveal that the nanoscale deformations can result in the formation of ‘electrical hot spots’ in the sensing channel which reduce the charge screening at the concave regions allowing improved detection of the molecular charge. These hot spots also exclude mobile charges, thus exhibiting a high local potential due to the charge of the DNA/RNA. In addition, the deformed monolayer graphene could exhibit a band-gap allowing an exponential change in the source-drain current due to a small number of unscreened biomolecular charges at those hot spots. Collectively, these phenomena can allow for ultrasensitive electronic biomolecular detection in millimeter scale structures, opening the way to many applications in biology and medicine.

2:15 PM SB07.12.03
Aerosol Jet Printed Organic Electrochemical Transistors with NHC Functionalized Gate for Biosensing Applications Jiaxin Fan, Alexandra Predy, Darren R. Majak, Krystyn Dubicki, Florence Williams and Manisha Gupta; University of Alberta, Canada

In the past decades, wearable biosensors have attracted a great amount of attention due to the increasing demands for affordable, non-invasive, and continuous monitoring of physiological parameters for disease prevention, early medical diagnostics, and personalized medicine. These rapid diagnostic biosensing devices should be sensitive, robust, and compact. They do not require conventional clinical laboratory infrastructures to perform the tests, which potentially contributes to reducing healthcare service costs. Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT: PSS) based organic electrochemical transistors (OECTs) have been demonstrated to have great potentials for customizable biosensors due to their simple device structure, great material stability, capability to operate in aqueous environment with low operation voltage, and most importantly high transconductance (g_m).[1–3] Devices with high g_m show high sensitivities and transduce biological and chemical signals into electrical signals with high signal to noise ratio (SNR). Functionalization is essential for improving the sensing selectivity and sensitivity, which involves modifying the channel and/or gate surface of OECT with functional groups and linking the desired biomolecules. N-heterocyclic carbene (NHC) forms extremely strong bonds with transition metals and has been demonstrated as surface-ligands on different metal surfaces, which can be used as linkers for the conjugation of needed biological recognition elements.[4]

In this study, we have integrated NHC modified Pt wire as the gate for 3D printed OECTs. The OECTs were printed by Optomec Aerosol Jet 5X system on both rigid and flexible substrates with silver source and drain electrodes, PEDOT:PSS channel, and UV-curable polydimethylsiloxane (PDMS) as the passivation layer. All materials used for OECT printing are commercially available. The printed OECTs exhibit high g_m of 30.63 mS (L = 104 µm, W/L = 4, d = 570 nm) tested with 100 mM NaCl electrolyte and Ag/AgCl gate. A distinctive shift in the transfer characteristic was observed when measuring with the NHC modified Pt gate compared to the pristine Pt wire gate. This is due to the work function change of the Pt wire with NHC functionalization. We have demonstrated biosensing capability of the sensor by attaching biotin to the NHC functionalized group via click chemistry and then detecting streptavidin.

Benchmarking the Role of Additives on the Electrochemical Performance of an Ethylenedioxythiophene Based Copolymer Georgios Nikiforidis, Shofarul Wustoni, Cyril Routier, Victor Druet and Sahika Inal; KAUST, Saudi Arabia

Poly(3,4-ethylenedioxythiophene), PEDOT, has been widely used in an array of applications spanning from energy storage to biomedical devices due to its high conductivity, good chemical stability, biocompatibility, and feasibility of functionalization. Herein we present a new strategy to copolymerize PEDOT, and its hydroxyl terminated counterpart (PEDOT-OH) through electropolymerization in the presence of different additives. A fixed amount of the monomers is introduced in the presence of ClO₄⁻ or PSS⁻ anions. The range of additives spans from MXene, CNTs, Au nanoparticles to ionic liquids such as 1-ethyl-3-methylimidazolium trifluoromethanesulfonate. We study the impact of these components on the physicochemical and electrochemical properties of the resulting films. The roughness and topography amongst the various electrodes are compared by AFM and SEM-FIB and correlated with the results stemmed from electrochemical impedance spectroscopy, cyclic voltammetry and galvanostatic charge-discharge cycling performed in an aqueous environment (0.1 M NaCl). The best performing copolymers are further used to build state-of-the-art electrodes for oxygen reduction and electrodes for neural recordings.

3:30 PM SB07.13.01
Precise Attachment of Living Cells to Electroactive Surfaces Ariel L. Furst; Massachusetts Institute of Technology, United States

The ability to control the interaction between living systems and electroactive surfaces has been a longstanding goal of many scientific disciplines, ranging from healthcare to clean energy. For bioelectric applications, maintaining the specificity of cell placement while facilitating electron transfer between cells and the surface remains a challenge. DNA is capable of both imbuing specificity through self-recognizing hybridization and wire-like behavior, making it ideal to address key issues with the interfacing of cells with electroactive surfaces. Through DNA hybridization-based cell adhesion, we have captured and monitored non-adherent mammalian cells, yeast, and microbes on DNA-modified electrodes. Importantly, we have applied this method to the rapid assembly of low-density monolayers of current-producing cells. Through DNA-based immobilization, we have found that these cells maintain their electron transfer abilities prior to biofilm formation. We attribute this feature, at least in part, to the conductivity of DNA. This DNA-based technique to interface cells with inorganic surfaces has broad applications, including diagnostic tools and biofuel cells.

3:45 PM SB07.13.02
Supported Biomembranes on Electronic Devices for Sensing Pathogen Interactions That Occur at the Cell Surface Susan Daniel; Cornell Univ, United States

The cell membrane is the first point of contact for pathogen entry. It is the interface that defines the inside of the cell from the environment and a surface that presents an array of biological moieties that pathogens can use to recognize
a specific host cell target. Pathogens or pathogenic material, such as viruses or bacterial toxins, target these surface moieties, which are often specific proteoglycans or glycolipids. Binding occurs first, then various mechanisms are used to gain entry into the cell by crossing the membrane barrier. Bacterial toxins poke holes in membranes, which causes catastrophic leakage of ions and nutrients from the cell, while allowing external materials enter. Viruses can inject genetic material across the plasma membrane directly or get endocytosed into the cytosol to later release their genetic code after membrane fusion. With the constant evolution of resistant bacteria and viruses that can evade the immune system, being a step ahead of them by defining new ways to disarm them is progressively more difficult. Here we present a new biomembrane sensing platform that mimics host cell membranes and takes advantage of the natural propensity of these pathogens to want to interact with these surfaces. Binding, membrane disruption, or membrane fusion can be sensed using an electroactive polymer film that supports the biomembrane as an element in an electronic circuit that monitors the electrical properties of the membrane when pathogens attack.

Bio-Hybrid Membrane for Solid-State Devices

Bio-Hybrid Membrane for Solid-State Devices Xingyao Feng, Teng Ma, Daisuke Tadaki and Ayumi Hirano; Tohoku University, Japan

Bilayer lipid membranes demonstrates an ultrathin thickness (3–5 nm) and ultrahigh ionic resistivity (>100 GΩ). Here, we propose that by utilizing the outstanding properties of bilayer lipid membranes, functional bio-hybrid membranes can be formed by doping the lipid membrane with organic molecules. In this work, organic molecules Copper (II) 2,9,16,23-tetra-tert-butyl-29H,31H-phthalocyanine (CuPc), which has been widely used in the fields of catalysis, solar cells, and transistors, were used to dope the lipid membranes. It is supposed that hydrophobic CuPc molecules can be inserted into the hydrophobic tails of bilayer lipid membrane, forming a sandwiched binary hybrid membrane structure. Therefore, these nano-scale hybrid membranes can be functionalized by inserting nanoparticles, without disturbing the natural ordered membrane structure. Since the lipid membrane have good insulativity and ultrathin thickness, this hybrid membrane can be used as a basic framework of bio-hybrid devices. The bio-hybrid membranes composed of lipids and CuPc molecules were formed by using self-assembly at water/air interface. Lipid molecules DPhPC and CuPc were dissolved in organic solvent. At room temperature, the prepared solution was dropped onto water surface. As the solvent evaporated, hybrid membranes immediately formed on the water surface. Finally, the self-assembled hybrid membranes were transferred onto Si substrate by gradually lowering water level.

The bio-hybrid membranes composed of lipids and CuPc molecules were formed by using self-assembly at water/air interface. Lipid molecules DPhPC and CuPc were dissolved in organic solvent. At room temperature, the prepared solution was dropped onto water surface. As the solvent evaporated, hybrid membranes immediately formed on the water surface. Finally, the self-assembled hybrid membranes were transferred onto Si substrate by gradually lowering water level.

To investigated the surface morphology, atomic force microscope (AFM) was used. By measuring 74 samples, it is concluded that all the thicknesses of membranes are very close to multiples of 5 nm, such as 10 nm, 15 nm, 20 nm and so on. Therefore, it is highly possible that the hydrophobic CuPc molecules combined hydrophobic tails of two lipid molecules to form a hybrid sandwich structure. X-ray diffraction (XRD) measurement were used to examine the structure of hybrid membranes. The patterns did not show any peak representing the CuPc packing. This result indicated that CuPc molecules did not aggregate to form small crystals in the hybrid membrane. Furthermore, an experiment was designed based on fluorescence resonance energy transfer (FRET) theory by adding fluorescent labeled lipids into hybrid membranes. The experimental results indicated that the CuPc molecules are closer to the tails rather than heads of lipid molecules in the membranes, which is corresponding to former speculation. And these hybrid bilayer membranes can stack up to form multilayer structures whose thicknesses are integral multiples of 5 nm. With this insulator-semiconductor-insulator structure, the hybrid membrane can be used as a framework for novel nano-devices.

Carbon Nanotube Fibers for Neural Stimulation and Recording

Carbon Nanotube Fibers for Neural Stimulation and Recording Noe T. Alvarez, Elke Buschbeck, Ilya Vilinsky, Sydney Miller, Vandna Agrawal, Chethani Ruhunage and Anh D. Le; University of Cincinnati, United States

Recordings and stimulations of neuronal electrical activity is a topic of great interest in neuroscience. Multiple neurological disorders can benefit from a microelectrode that is flexible, chemically inert, electrically conducting, and preferentially transfers electrons via capacitive charge-injection. Commercial electrodes that currently exist and other electrodes that are being tested with the purpose of facilitating and improving the electron transport between solid electrode materials and biological tissue still have some limitations. This paper discusses a carbon nanotube-based microelectrode from its synthesis, fiber assembly, polymer coating and application as microelectrode for neural recording and stimulation. We compare electron transport capabilities of carbon nanotube fibers to noble metals Au and Ag wire microelectrodes to biological tissue. The recording ability of microelectrodes is demonstrated through Electroretinography (ERG) on Sarcophaga bullata fly eyes, where light stimulation generates
potential changes that were detected by our microelectrodes. Stimulation is demonstrated through Au wire and carbon nanotube fiber implants in Madagascar hissing cockroach (Gromphadorhina portentosa) antennas to control their locomotion directions. A comparison of their impedance, charge injection capacity and electrical conductivity demonstrates that carbon nanotube fibers have great potential as microelectrodes in neuroscience.

Pseudo 3D Graphene for Enhancing Cell-Chip Coupling Laura Matino1,2, Sahil Rastogi1, Michele Dipalo1, Francesco de Angelis1, Tzahi Cohen-Karni1,3,3 and Francesca Santoro1; 1Istituto Italiano di Tecnologia, Italy; 2University of Naples, Federico II, Italy; 3Carnegie Mellon University, United States

Bioelectronic devices interact directly with biological systems to monitor cellular electrical activity and promote cell reaction to electrical stimulation. The capabilities of such devices, in terms of recording and stimulation, are affected by the effective cell-platform coupling. Therefore, during the last years, the development of engineered 3D micro and nanostructures has improved the effectiveness of biosensors using protruding structures to achieve a more intimate contact between cells and substrates. In parallel, the rising of carbon-based materials for bioelectronics has gained attention during the last years because of their outstanding chemical properties which allow improved cell-device interface. Given this scenario, 3D out-of-the-plane graphene structures has been designed and grown on planar platforms, exploiting the electrical, mechanical and optical features of this promising material. 3D fuzzy graphene (3DFG) and nanowire-templated 3DFG (NT-3DFG) were realized as electrode surface (1). Here we report a comprehensive study of the interface by using fluorescence and electron microscopy for characterizing cell-materials interactions at micro and nanoscale. First, we investigated the biocompatibility and the adhesion effect (cell stretching) of the diverse graphene-based pseudo-3D surfaces. Then, we examined the membrane deformation and the actual cell-device coupling via scanning electron microscopy/focused ion beam sectioning (2,3). Finally, as outlook we will present preliminary results on how the material surface can affect the recording of spontaneous action potentials from electrogenic cells. We found out an enhanced cells adhesion on the substrates, suggesting that out-of-the-plane platform could improve the coupling between cells and sensors.

Mixed-Conducting Particulate Composites for Soft Electronics Patricia Jastrzebska-Perfect1, Georgios Spyropoulos1, Claudia Cea1, Zifang Zhao1, Omri Rauhala1, Ashwin Viswanathan2, Sameer Sheth2, Jennifer Gelinas1 and Dion Khodagholy1; 1Columbia University, United States; 2Baylor College of Medicine, United States

Bioelectronic devices should optimally merge a soft, biocompatible tissue interface with capacity for local, advanced signal processing. Here, we introduce an organic mixed-conducting particulate composite material (MCP) that can form functional electronic components by varying particle size and density. We created MCP-based high performance anisotropic films, independently-addressable transistors, resistors, and diodes that are pattern-free, scalable, and biocompatible. MCP enabled facile and effective electronic bonding between soft and rigid electronics, permitting recording of neurophysiological data at the resolution of individual neurons from freely moving rodents and from the surface of the human brain through a small opening in the skull. We also acquired high spatiotemporal
resolution electrophysiological signals non-invasively by directly interfacing MCP with human skin. MCP provides a single material solution to facilitate development of bioelectronic devices that can safely acquire, transmit, and process complex biological signals.

Case Studies of Bio-Iontronic Devices for Detecting the Concentration of Glucose and Monovalent Ions John A. Selberg, Chunxiao Wu and Marco Rolandi; University of California, Santa Cruz, United States

The control of ion concentration gradients and ionic currents is ubiquitous in tissue-level and cell-level processes such as enzyme activation, oxidative phosphorylation, neuronal excitation, and immune response. Bioelectronic devices with functional materials that can transduce between electronic and ionic signals allow researchers to use existing knowledge of electronics to perform unique tasks with ions in solution. Devices of this nature are well-suited to these biological ion-driven applications. Here, I report on recent progress towards developing and using iontronic devices for activating metal oxide catalysis in aqueous solutions with the application of glucose sensing.

9:00 AM *SB07.14.03
Interfacing Human Cell Membrane Models with Bioelectronics for Ion Channel Monitoring Walther Traberg-Christensen1, Anna-Maria Pappa1, Han-Yuan Liu2, Quentin Thiburce3, Alberto Salleo3, Susan Daniel2 and Roisin Owens1; 1University of Cambridge, United Kingdom; 2Cornell University, United States; 3Stanford University, United States

Cellular membranes represent an obvious, yet relatively neglected target for fundamental understanding of the mechanisms of disease and for therapeutic optimization. Existing membrane models suffer from incompatibility at the biotic/abiotic interface and lack molecular complexity, compromising their reliability. To address these issues we have developed human membrane models by fusing native extracellular material on top of conducting polymer transducers. This unique platform rises above the state of the art by providing a physiologically relevant biomimetic environment close to that of native membranes, as well as by providing integrated functionality to transduce biological events at the molecular level. The use of conducting polymers and in particular poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), overcomes the issue of the commonly used solid substrates (ie., glass, Au) for signal transduction, by facilitating mobility of the transmembrane proteins, enhancing the native structural and functional properties of the membrane. Simultaneously, it allows for the electrical characterization of the membrane properties and its interactions, by transducing the ionic flux to an electronic signal. In this work, we demonstrate the formation of native cell membranes from human embryonic kidney 293 cells (HEK) in the form of supported lipid bilayers (SLBs) on top of PEDOT:PSS electrodes and transistors. We monitor the formation of the native SLBs and characterize them using both optical and electronic methods. We show dynamics of membrane fusion by electrically monitoring the changes on the membrane properties. Finally, we show that the h-TREK-1 potassium ion channel overexpressed in HEK cells can be monitored within its native membrane context. We show that our devices can transduce the action of clinically important molecules that are able to open or block these channels. Our results suggest that this platform could be an excellent in vitro assay for drug testing, providing a scalable and cost-efficient alternative to using whole cells e.g. patch clamp assays.

10:00 AM SB07.14.04
Direct Printing of Transparent and Substrate-Free PEDOT:PSS Fibre Arrays Yan Yan Shery Huang and Wenyu Wang; University of Cambridge, United Kingdom

Ultra-thin conducting fibres possess unique mechanical, optical and electrical properties due to the high aspect-ratio, low bending stiffness and transparency. Those fibre arrays made with different conducting materials could enable a variety of novel applications, ranging from transparent textile-based circuits to bio-sensors. Current fibre fabrication techniques usually deposit fibres onto substrates, and the optomechanical properties of substrates largely compromise the advantages of ultra-thin fibres. Herein, we present an efficient fibre printing method to produce conducting and substrate-free sub-micron fibres arrays. The fibre printing and fibre to circuit connection are completed in one step under a sub-80°C mild temperature, without needing post processing steps such as annealing. With this printing method, we demonstrate the capability to print conducting polymer based (PEDOT:PSS, (poly(3,4-ethylenedioxythiophene) polystyrenesulfonate)) fibres. The high resolution fibres can span across a
freestanding distance up to 10mm, having both ends attached to outer circuit with negligible contact resistance. Floating electronics are demonstrated where small electronics such as LEDs and photodiodes can be mechanically supported and electrically connected by suspended fibre arrays. Cell attachment and viability results with the PEDOT:PSS fibre arrays also show their potential use as biosensors.

10:15 AM SB07.14.05
Δ9-THC Sensing for Cannabis Detection Using 3D Printed Organic Electrochemical Transistors Darren R. Majak, Jiaxin Fan and Manisha Gupta; University of Alberta, Canada

Traditional electronics is based on the silicon transistors for a number of decades. However, the emergence of organic, conductive polymers leading to organic transistors has allowed for research into non-traditional electronic devices that combine organic and inorganic material. Organic transistors [3,4] have shown many benefits and applications, by using organic semiconductors, devices can be flexible, solution processable, 3D printable and economical. Organic Electrochemical Transistors (OECTs)- a specific subset of organic transistors - are perfectly suited for biological sensing. OECTs have specifically been used to sense dopamine, DNA, pH, lactate, glucose, ion concentration and more. OECTs operate in a similar manner to traditional silicon transistors but the channel is made of an organic polymer and uses the ions in an electrolyte as part of the gate contact. OECTs operate with both electrical and ionic current, meaning they can be driven at lower voltages and have lower power consumption. In addition, they have built-in amplification, which means higher sensitivity and lower power consumption. By operating with ionic current, OECTs can be used for bio-sensing as they can detect ions present in biological environments.

Canada is the first nation in the G7, and the second in the world to legalize the recreational use of cannabis. However, despite legalization, a number of challenges remain that need to be solved. One of the main issues is the detection, and quantization of impairment. The psychoactive cannabionoid, Δ²-Tetrahydrocannabinol (THC), is the cause of impairment, however the extent of it is difficult to determine because THC remains in blood, urine and other bodily fluids long after exposure and therefore does not correlate to impairment. Currently, all the Δ9-THC detection techniques are based on either utilising mass spectroscopy or gas chromatography (GC) for oral fluids. Both of these techniques are accurate but require extensive measurement equipment and are not cheap. The other Δ9-THC measurements are based on blood or urine pathological measurements which also require more sampling equipment along with the issues of hygiene and can take several hours to obtain results. A better approach is to test the concentration of THC present in the saliva [1, 2] of the user, as THC concentrations in saliva can more closely be correlated with cognitive and motor impairment. OECTs are perfectly suited for this application, due to the high transconductance and sensitivity. Our 3D printed OECTs [6-8] can detect concentrations down to 0.05 nM, in DI water, without functionalization of the OECT. This limit of detection is well within the required level to be able to detect the THC levels present in cannabis users’ saliva. These sensors are entirely 3D printed, which means that they can be easily and cost effectively fabricated, as compared to traditional nano and micro fabrication methods. These sensors show repeatable results with low drift (~3.6%), as well as a fast response (163s average). The next step is to improve the detection capability of the sensors in saliva rather than water and this can be achieved by functionalization of the gate electrode to detect only the Δ9-THC. Results from this study will be presented.

10:30 AM SB07.14.06
Label-Free Aptamer-Based Detection of Amyloid Beta Proteins on SiO2 Covered Silicon Structures Hanna Hlukhova¹, Yuriy Kutovyi², Marcus Menger², Andreas Offenhäusser² and Svetlana Vitusevich¹; ¹Forschungszentrum Jülich, Germany; ²Fraunhofer Institute for Cell Therapy and Immunology, Germany

Neurodegenerative processes in the brain became an important challenge with increased age of the population.
Usually, relatively bulky optical methods are used to detect Amyloid β peptides, which are linked to the pathogenesis of Alzheimer disease. To prolong effective and healthy memory and thinking capability as well as to stop the factors resulting in Alzheimer’s disease new high-sensitive and direct methods for the early detection of peptides involved in Alzheimer’s disease have to be developed. In this contribution, we report on successful demonstration of a new label-free approach for detection of amyloid beta proteins by high-selective aptamers immobilized onto the SiO₂ surface. A nucleotide aptamer was synthesized to detect the target Amyloid beta-40 sequence. Functionalized structures based on thin SiO₂ dielectric layer has been developed to detect ultra-low concentrations of the target protein. The detection technique utilizes high-efficient aptamer immobilization on the SiO₂ surface of the sensor system configured with a liquid-gate. The introduction of amyloid beta protein of different concentrations in a wide range from 0.1 pM to 1 μM to the surface of the sensor results in a change of surface potential. Obtained experimental data demonstrate high-sensitive and reliable detection of ultra-low concentrations of the amyloid beta protein, which opens the perspective for the development of real-time electrical sensors for studies and understanding of different stages of Alzheimer’s disease utilizing nanostructures fabricated on the basis of cost-efficient CMOS-compatible technology.

Large-Scale Neural Interface Devices Dion Khodagholy; Columbia University, United States

As our understanding of the brain’s physiology and pathology progresses, increasingly sophisticated technologies are required to advance discoveries in neuroscience and develop more effective approaches to treating brain disease. There is a tremendous need for advanced materials solutions at the biotic/abiotic interface to improve the spatiotemporal resolution of neuronal recording. Organic electronic devices offer a unique approach to these challenges, due to their mixed ionic/electronic conduction, mechanical flexibility, enhanced biocompatibility, and capability for drug delivery. We designed, developed, and characterized conformable organic electronic devices in the form of transistors and electrodes to efficiently interface with the brain and acquire neurophysiological activity not previously accessible with recordings from the brain surface. These devices have facilitated large-scale rodent neurophysiology experiments and uncovered a novel hippocampal-cortical oscillatory interaction. The biocompatibility of the devices allowed intra-operative recording from patients undergoing epilepsy surgery, highlighting the translational capacity of this class of neural interface devices. In parallel, we are developing the high-speed electronics and embedded acquisition and storage systems required to make high channel count, chronic
neurophysiological recording from animals and human subjects possible. This multidisciplinary approach will enable the development of new devices based on organic electronics, with broad applicability to the understanding of physiologic and pathologic network activity, control of brain-machine interfaces, and therapeutic closed-loop devices.

High-Speed Enhancement Mode Ion Driven Transistors for Bioelectric Device Claudia Cea¹, Georgios Spyropoulos¹, Jennifer Gelinas² and Dion Khodagholy¹; ¹Columbia University, United States; ²Columbia University Medical Center, United States

Technological leaps to improve brain-machine interface devices require sophisticated integrated circuits based on ion driven transistors. These devices should be capable of forming complementary logic and analog circuits to allow acquisition, processing and manipulation of a biological environment. However, the lack of readily available p-type polymers for use in enhancement mode transistors and their complicated synthesis significantly limits the investigation and application of such devices in bioelectronics. To address this challenge, we propose a simple route for creation of enhancement mode Ion Gated Transistors (IGT) by combining a highly conductive poly(3, 4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) and a reducing agent polyethyleneimine (PEI) to enable doping of the polymer in an aqueous environment. The protonated PEI bonds with the PSS- and dedopes the PEDOT:PSS chain resulting in an initial off-state of the transistor. A subsequent application of negative gate voltage dopes the PEDOT:PSS switching the channel on. Furthermore, we introduce a novel operation mode of these organic transistors by utilizing contained mobile ions within the conducting polymer channel to permit shortened ionic transit time and high transconductance. The embedded ions within the channel are obtained through the addition of D-sorbitol, a biocompatible hydrophilic sugar alcohol, which uptakes water molecules keeping the channel hydrated through the generation of ion reservoirs. The distance ions have to travel to modulate the transistor is shorter compared to the one of electrolyte-based transistor resulting in substantially faster devices (time constant of 2.6 μs). To determine an optimal transistor configuration and material composition, we microfabricated transistor arrays of varying geometrical parameters. In doing so, we were able to extract conductivity, contact resistance, and electrochemical impedance values for all the critical interfaces of various composites. The resulting high-transconductance, high-speed enhancement-mode transistors were realized in the form of conformable depth probes fabricated on thin film plastics to enable in vivo electrophysiological recording of cortical activity from neonatal rats and conformable surface devices to be utilized for electrocardiography, electroencephalography and electromyography from human subjects. The ultra-high speed, improved transconductance and stability of these arrays were demonstrated by recording biosignals covering a full biological frequency band varying from single unit activity to local field potentials, cardiac and muscular activity, (0-1000 Hz) paving the way for use as a reliable neural interface device.

11:00 AM SB08.01.05
A Flexible IrOx-Based Microneedle Electrode Array with Integrated Electrically Driven Drug Delivery Hsiang-Ping Liao, Fu-Erh Chan and Pochun Chen; National Taipei University of Technology, Taiwan

Implantable neurostimulation devices have been attracted considerable attention recently since neural disordered disease can be treated by electrostimulation. Microneedle electrode arrays have high aspect ratio that can sufficiently penetrate to the depth of target without causing any damage. Additionally, electrically controlled drug release has been particularly attractive for bioelectronics because the electrical signal is portable and controllable on-demand, without the requirement of large or special equipment. However, protein-based bioactives such as growth factors or antibodies are easily denatured to lose their bioactivity in response to external stimulation. It is challenging to develop a bio-electrode system that permits the electrically responsive drug release without damage. In this study, we designed and fabricated an IrOx-based microneedle electrode array on a flexible Parylene C
substrate. Then, the microneedle electrode array has been treated by a facile method to form a hybrid film of iridium oxide and bovine serum albumin (BSA). We carried out a cyclic voltammetry approach to co-electrodeposit iridium oxide and plasma protein on the microneedle electrode array. We characterized and evaluated the hybrid electrolytes and deposited films for bio-electrode applications. We also demonstrated the electrically controlled release triggered by pulse current stimulation. In addition, the biocompatibility of the microneedle electrode array was also investigated by testing the cell viability.

SESSION SB08.02: Materials and Devices for Neural Interfaces II

1:30 PM *SB08.02.01
Interfacing with the Brain Using Organic Electronics George G. Malliaras; University of Cambridge, United Kingdom

One of the most important scientific and technological frontiers of our time is the interfacing of electronics with the human brain. This endeavour promises to help understand how the brain works and deliver new tools for diagnosis and treatment of pathologies including epilepsy and Parkinson’s disease. Current solutions, however, are limited by the materials that are brought in contact with the tissue and transduce signals across the biotic/abiotic interface. Recent advances in organic electronics have made available materials with a unique combination of attractive properties, including mechanical flexibility, mixed ionic/electronic conduction, enhanced biocompatibility, and capability for drug delivery. I will present examples of novel devices for recording and stimulation of neurons and show that organic electronic materials offer tremendous opportunities to study the brain and treat its pathologies.

2:00 PM SB08.02.02
High Throughput Evolution of Near-Infrared Serotonin Nanosensors Sanghwa Jeong, Darwin Yang, Abraham Beyene, Anneliese Gest and Markita Landry; University of California, Berkeley, United States

Release and reuptake of neuromodulator serotonin is central to mood regulation and neuropsychiatric disorders, whereby imaging serotonin is of fundamental importance to study the serotonin signaling system. Herein, we present a reversible near-infrared optical probe for serotonin that reports physiologically-relevant serotonin concentrations on relevant spatiotemporal scales, and is compatible with pharmacological tests. The probe responds with ΔF/F₀ of up to 194% in the near-infrared fluorescence emission window of 1000-1300 nm, and is constructed from semiconducting single-walled carbon nanotubes (SWNT), which have shown utility for non-invasive through-skull imaging in rodents. Synthetic molecular recognition for serotonin was conferred by evolving molecular recognition between single stranded DNA (ssDNA) and SWNT. To do so, we developed a high-throughput screening platform for evolution of serotonin molecular selectivity, in which systematic evolution of ligands by exponential enrichment is implemented on carbon nanotube surfaces, a process we’ve termed SELEC. 10¹¹ unique SWNT-ssDNA constructs can be screened for their ability to bind a target analyte and provide a selective near-infrared fluorescence signal. Iterative selection of analyte-binding polymers that form a SWNT-surface-adsorbed phase for serotonin recognition are identified through ionic desorption of sub-optimal polymers, and exponential amplification of nucleotides that recognize serotonin. The best-responding serotonin nanosensor is shown to bind serotonin with a K_d of 6.3 µM, is shown to be reversible, and exhibits unaltered performance in artificial cerebrospinal fluid. We show that our serotonin nanosensor does not respond to serotonin metabolites 5-hydroxyindoleacetic acid (HIAA), 5-hydroxytryptophan (HTP), and 5-methoxytryptophan (MTP) and of importance to understanding pharmacology in the context of serotonin signaling, we additionally show serotonin receptor-targeting drugs fluoxetine, MDMA, 25I-NMOMe, and quetiapine do not interfere with nanosensor performance. Lastly, nIRHT can be introduced into the brain extracellular space in acute brain slices, and can be used to image exogenous serotonin reversibly. Our results suggest evolution of nanosensors could be generically implemented to rapidly develop other neuromodulator probes, and that these probes can image neuromodulator dynamics at spatiotemporal scales compatible with endogenous neuromodulation. While we’ve implemented SELEC to develop an optical probe for serotonin herein, the platform
is fundamentally generic for generating other optical probes of neurological relevance.

2:15 PM SB08.02.03
Ultra-Thin, Flexible, Inkjet-Printed Neural Probes with Mechanically Gradient Structure Toshinori Fujie\textsuperscript{1,2,3}, Nana Kokubo\textsuperscript{1}, Kento Yamagishi\textsuperscript{1}, Shinji Takeoka\textsuperscript{1} and Hiroyuki Ohta\textsuperscript{1}; \textsuperscript{1}Tokyo Institute of Technology, Japan; \textsuperscript{2}Japan Science and Technology Agency, Japan; \textsuperscript{3}Waseda University, Japan; \textsuperscript{4}National Defense Medical College, Japan

Flexible materials are important for the development of insertable neural probes for recording stable signals (spikes) \textit{in vivo}. However, conventional neural probes such as silicon probes have several drawbacks, including high rigidity compared with soft brain tissues and poor mechanical properties during manipulation. In addition, the operator must handle the probe carefully because its tip is extremely small, sharp, and brittle, so it can be easily damaged if touched by a finger or dropped on the floor. To overcome these problems, here, we show inkjet-printed, flexible neural probes for spike recording by using polymeric ultra-thin films (nanofilms). The neural probes were constructed from 400 nm-thick poly(D,L-lactic acid) nanofilms, inkjet-printed lines consisting of Au and poly(3,4-ethylenedioxythiophene):polystyrenesulfonate nanoinks, and insulating fluoropolymer layers. The neural probe was prepared as following steps: i) 50-µm-wide conductive lines were inkjet-printed on the nanofilm, which was dip-coated with a fluoropolymer solution to make insulating layers. ii) The tip of the insulated nanofilm was trimmed with a razor, exposing the microelectrodes. iii) The resulting 6-µm-thick flexible electrode was twisted from a 2D sheet into a 3D needle, allowing it to be inserted into brain tissues. The electrode was also integrated into an optical fiber (i.e., optrode) to enable optogenetic recording. iv) To connect the electrode to the external amplifiers, the stiffness was gradually increased from the flexible nanofilm to the rigid device and fabricated pre-assembled connection. The nanofilm-based probe with a needle shape recorded not only \textit{in vivo} neuron spikes from mouse thalamus, but also spontaneously and optogenetically evoked individual spikes from rat hippocampus with the optrode. The flexible and robust structure of the present neural probes will allow for tailor-made customization for various research requirements, such as changing the complex geometry, increasing the number of electrodes for spike signal sensing, and segmenting the electrode tips to precisely record \textit{in vivo} neuronal activity.

2:30 PM SB08.02.04
Breaking Longitudinal Symmetry of Fiber-Based Neural Probes via In-Fiber Photolithography Youngbin Lee\textsuperscript{1,1}, Andres Canales\textsuperscript{1,1}, Gabriel Loke\textsuperscript{1,1}, Yoel Fink\textsuperscript{1,2} and Polina Anikeeva\textsuperscript{1,1,1}; \textsuperscript{1}Massachusetts Institute of Technology, United States; \textsuperscript{2}Advanced Functional Fabrics of America, United States

Thermal drawing has been applied to produce flexible, microstructured polymer fibers integrating diverse functionalities. Because of their small size, flexibility, and biocompatibility of the component materials, these multifunctional fibers are attractive for applications in neuroscience to probe and modulate neural activity. Despite the advantages of thermal drawing, including simplicity of materials integration and high device yield, the functionality of thermally drawn fibers is constrained by the symmetry of the fiber along its axial direction. In the present work, we suggest two hybrid fabrication methods combining thermal drawing and photolithographic process to break this symmetry and enable interactions of fiber-based probes with multiple neural populations along their shaft following implantation into the brain.

We employed thiol-epoxy/thiol-ene click chemistry to produce a novel photoresist with low polymerization shrinkage stress and low oxygen inhibition during polymerization. The system is polymerized via two steps - thermal and photo curing. Thermal polymerization yields formation of linear chains through a reaction between thiol and epoxy functional groups resulting in a thermoplastic compatible with fiber drawing. In contrast, photo curing occurs only at areas exposed to ultraviolet light, generating an insoluble network structure through the thiol-ene reaction, allowing for the development of desired patterns. The reported photoresist can be applied either prior to or following fiber drawing allowing for the design of functional features along the fiber shaft.

In addition to offering greater utility of fibers for neuroscience and neural engineering, our technique will likely find broader applications in fields of optoelectronics, sensors and smart textiles.

2:45 PM SB08.02.05
Transparent Organic Electrochemical Transistor Array toward Flexible Multielectrode Dish Yasutoshi Jimbo\textsuperscript{1}, Daisuke Sasaki\textsuperscript{2}, Sunghoon Lee\textsuperscript{1}, Takashi Ohya\textsuperscript{2}, Masaya Nishinaka\textsuperscript{1}, Tomoyuki Yokota\textsuperscript{1}, Tatsuya Shimizu\textsuperscript{2} and Takao Someya\textsuperscript{1}; \textsuperscript{1}The University of Tokyo, Japan; \textsuperscript{2}Institute of Advanced Biomedical Engineering and Science, Tokyo Women’s Medical University, Japan
We fabricated a transparent organic electrochemical transistor (OECT) using ultrathin Au (14 nm), and successfully recorded extracellar potential of induced pluripotent stem cell-derived cardiomyocytes.

OECT has attracted interests in both material engineering and biological engineering fields because its high transconductance and simple structures enable versatile applications by combined with other flexible materials. Monitoring electrophysiological activity of cells is one of those applications[1]. By using OECT instead of conventional electrodes, we could expect better data quality and high density measurement without lack of flexibility, which is usually realized on gel and provides bio-tissues with free movement and better maturity. Although transparency is also an advantage of OECT, cell monitoring with transparent OECT have never been reported as far as we know. OECT usually consists of three layers other than substrates: metal source and drain electrode, organic semiconductor as channel, and passivation. Unlike other organic transistors, the channel of OECT can be made from poly(3,4-ethylenedioxy- thiophene):poly(styrenesulfonate) (PEDOT:PSS), which is a transparent semiconductor. Therefore, by replacing metal source and drain electrode for transparent conductors, you can make the whole device transparent. It enables the support of imaging technologies including fluorescence imaging or image based force mapping.

Transparent OECT for in vivo optogenetic experiment was previously reported[2], but its grid structured metal electrode may bother imaging in micro-meter scale cell monitoring. Thus in our previous report, we used Indium-tin-oxide/Au/Indium-tin-oxide (ITO/Au/ITO) structure as highly conductive transparent electrode instead[3]. Here we further optimized its structure. ITO/Au/ITO structure was replaced by simple ultrathin Au supported by polyimide coated parylene substrate. The photoresist used as passivation layer was also replaced for parylene to ensure its biocompatibility. Owing to the small total thickness, which is less than 5 µm, it can be used as highly flexible, foldable device. The mechanical robustness was limited so far due to the ITO layer. The ultrathin Au showed stable operation under bending test which is equivalent to 1.25 % tensile strain whereas ITO/Au/ITO started failing at 0.9 %. The sheet resistance was 8.6 ohms/sq. so that you can achieve sufficiently low parasitic resistance against channel resistance (~500 ohms). Owing to the simplified structure and low sheet resistance, transparent active matrix fabrication and extracellar potential recording were successfully demonstrated.

3:00 PM BREAK
Our ability to treat neurological disease is severely limited by the complexity of the nervous system and the quality of the information derived from recording devices. A device that holds great potential for recording high quality electrophysiology signals is the organic electrochemical transistor (OECT). OECTs are transistors in which the output current is regulated by the injection of ions from an electrolyte. They are fabricated from biocompatible materials and have been shown to provide higher signal-to-noise ratio compared to electrodes. Their unique properties pave the way for enhanced performance neural interfaces while minimising the invasiveness of the recording method. We report on how different parameters such as device geometry and bias conditions affect the noise characteristics of OECTs. These results show how to minimise noise and boost signal-to-noise ratio. We further show how these new design rules are applied to reduce the footprint of OECTs and drastically improve their recording capability when used in neural interface applications.

4:15 PM SB08.02.08
Nanofluidic Sampling Platform for Micro-Invasive Membrane-Free Tracking of Neurochemical Biomarkers
Ritu Raman, Erin Rousseau, Michael Wade, Allison Tong, Max Cotler, Alejandro Lugo, Forest White, Michael Cima and Robert Langer; Massachusetts Institute of Technology, United States

Introduction: Neural pathology is characterized by electrical and chemical dysregulation in distinct brain circuits. Chemical dysregulation can be monitored by measuring the local composition of interstitial fluid (ISF). The current state-of-the-art in neurochemical sampling, microdialysis, enables the collection of small, highly concentrated neurochemicals from ISF via diffusion across a semipermeable membrane. Large probe sizes (> 150 μm) limit spatial resolution, which can lead to tissue scarring and limit chronic recording. Moreover, relying on diffusion limits spatiotemporal resolution and increases detection limits. Membranes particularly limit measuring neuropeptides, which are prone to non-specific absorption (average recoveries < 20%) and are present at very low concentrations in ISF, and preclude measuring dense core extracellular vesicles (EVs), which play a critical role in cell-cell signaling. We have built a novel micro-invasive membrane-free sampling platform that enables direct sampling of ISF. This is a fundamental shift from microdialysis, which tracks small and abundantly present neurotransmitters, to a device that samples the complete biochemical milieu with pinpoint spatiotemporal resolution. We anticipate this will enable a deeper understanding of the onset and progression of neural pathologies.

Methods: We have manufactured a sampling platform composed of micro-invasive probes (80 μm outer diameter, 50 μm inner diameter) coupled to a custom-made nanofluidic pump (nanopump). Fluid flow within custom tubing (100 μm inner diameter) in the pump is driven by the sequential contraction of nitinol wires (shape memory alloy), and back flow is prevented by a nitinol powered valve. The nanopump is capable of bidirectional flow control with single nanoliter precision and negligible dead volume, a capability not demonstrated by the current state-of-the-art, and is fully portable for in vivo use. Flow is controlled via the electrically-triggered contraction of nitinol wires (Fig. 1A) and flow rates (1 nL/s) and sampling volumes (100-1000 nL) safe for in vivo operation in the brain were used. Sampled fluid is analyzed via liquid chromatography-tandem mass spectrometry (LC-MS/MS) to detect neuropeptides at physiological concentrations (1-20 femtomolar).

Results & Discussion: We have shown that our micro-invasive probes minimize gliosis when chronically implanted in rodent brains, and retain fluidic functionality for 12 mos. post-implantation. Extensive characterization of nanopump-driven infusion into and sampling from agarose brain phantoms in vitro has enabled optimization of platform performance in response to a variety of parameters including wire number and pre-tension, tube diameter and length, capillary size, and flow control algorithm. Ex vivo infusions into rodent striatum have been characterized using both histology and 3D fluorescence imaging, showing bolus volume control as a function of infusion time. Nanopump-driven sampling from ex vivo and in vivo brains has also been performed, with confirmed presence of proteins specific to neural extracellular space, including brain acid soluble protein 1, myelin basic protein, and gamma enolase. Sample stability in different cryo-storage/processing conditions has been thoroughly characterized. Ongoing in vivo sampling studies will enable chronic tracking of covariant neuropeptides and EVs in physiological and pathological states. A first step will be long-term tracking of the spatiotemporal dynamics of dynorphin, a neuropeptide associated with stress, anxiety, and substance use disorders, a capability that is not possible with current tools.

Conclusions: We have developed a novel tool for biomedical engineers and neuroscientists to investigate the biochemical basis for neural pathology. Our micro-invasive ISF sampling platform has the potential to generate new fundamental knowledge and enable more accurate diagnosis and treatment of neural disorders in the future.

*Induction of Calcium Elevations in Hippocampal Neural Networks by Intracellular Stimulation*  
Juyoung Kwon¹, Sukjin Ko², Jaejun Lee¹, Jukwan Na¹, Hyojung Lee¹, Seonghyeon Lee¹, Seungsoo Chung² and Heon-Jin Choi¹; ¹Yonsei University, Korea (the Republic of); ²Yonsei University College of Medicine, Korea (the Republic of)

Recent advances in the field of neural interfaces have been developed to improve the precision with high resolution and specificity of stimulation to the level of individual cells. To activate neurons with enhanced selectivity, the efficient coupling between the cell membrane and electrodes is required. Here, we demonstrate a vertical nanowire multi-electrode array (VNMEA) with feature sizes and densities comparable to neural circuits which enable the individual stimulation by forming tight junctions with cell membranes. This study demonstrated stimulation-induced Ca²⁺ elevations in individual primary hippocampal neurons by direct intra-neuronal stimulation with a vertical nanowire multi-electrode array (VNMEA). VNMEA-mediated stimulation showed superior properties of peak amplitude of Ca²⁺ elevation and kinetics of recovery than those through field stimulus. Moreover, tight physical/electrical coupling with the individual neuron enables targeted stimulation of a specific neuron without activation of nearby neurons, and localization of spiking neurons in response to depolarization due to intra-neuronal stimulation, which is considered the connection and activation pathway of the neurons. From the results of simulation models, we demonstrate the spatial and temporal confinement of intracellular stimulation by 6.9-fold higher current density built in intracellular space compared to extracellular space. Considering the activation modalities of separate neurons are essential for a complete understanding of neural circuit dynamics, the VNMEA platform could further provide a versatile tool for both manipulating single neurons and probing the functional connectivity of specific neural networks.

SB08.03.02

*Conducting Polymer Nanofibers for Articulating Artificial Muscles*  
Mohammadjavad Eslamian, Fereshtehehsadat Mirab, Vijay K. Raghunathan, Sheereen Majd and Mohammad Reza Abidian; University of Houston, United States

Conducting polymer actuators are promising materials for biomedical applications ranging from artificial muscles to drug delivery devices. These devices rely on bulk volume changes of conducting polymers (CPs) which arise from electrochemical redox processes. The changes in polymer chains conformation combined with the transportation of ions and solvent in and out of the polymer matrix are responsible for the micro and macro-scale expansion/contraction of the CPs. Construction of bilayer/trilayer bending devices is a very common strategy to convert the reaction-driven volume changes into macroscopic motions, where electrical energy is transduced into mechanical energy via electrochemical redox reactions in the active CP layer. In such devices, the CP layer is adhered to a passive thin layer to convert the in-plane actuation strain generated in the CP layer into macroscopic bending movements. Prior works have focused on the actuation of bilayer/trilayer actuators based on polypyrrole (PPy) films. We have previously proposed a novel structure for PPy:polystyrene sulfonate (PSS) in the form of randomly-oriented nanotubes and studied their ion transport behavior during cyclic voltammetry (CV) via electrochemical quartz crystal microbalance. Here, we report a bilayer actuator based on PPy nanofibers doped with PSS and constructed on a passive layer of Au-coated polypropylene (PP) film (length= 20 mm, width= 1 mm, PP thickness= 30 μm, Au thickness= 180 nm, PPy thickness= 12 μm). The PPy nanofibers were fabricated using electrochemical deposition of PPy (charge density 3.6 C/cm²) around electrospun poly-L-lactide nanofibers with the average diameter of 140±4 nm. The average diameter of the resultant PPy nanofibers was 626±16 nm. The bending behavior of the PPy nanofibers was investigated by measuring the tip deflection of actuator in both liquid and agarose gel (0.2%) electrolytes containing 0.1 M NaPSS. The PPy nanofibers were subjected to CV in the potential range of −0.8 V to +0.4 V at various scan rates of 10, 50, 100, and 200 mV/s for 20 cycles. The actuator showed a
reversible bending movement during each potential cycle. The maximum deflection of actuator decreased in both liquid and gel electrolytes by increasing the scan rate. The maximum deflection in liquid was 7.89±0.08 mm, 5.38±0.04 mm, 3.81±0.01 mm, and 2.52±0.01 mm, respectively at the scan rates of 10, 50, 100, and 200 mV/s. The maximum deflection in gel was 432±11 µm, 301±2 µm, 222±1 µm, and 148±1 µm, respectively at the scan rates of 10, 50, 100, and 200 mV/s. Ultimately, the actuation moment generated during cycling at various scan rates was calculated using linear bending beam theory and Bernoulli’s equation for fluid drag force. The findings in this study may have a great impact on the utilization of CP nanofibers for development of bioactuators.

SB08.03.03
Spatial Modulation of Conducting Polymer Surface Properties—Template-Free Preparation of Variable-Surface Roughness Gradients of Conducting Polymer Film for Neural Interfaces
Anthony M. Kisucky, Martin Antensteiner and Mohammed R. Abidian; University of Houston, United States

Peripheral nervous system injuries are a common accessory to trauma, constituting tens of thousands of cases per year. Without intervention, these injuries can compound into a permanent reduction or loss of limb function. Clinical treatments are limited to performing an autograft to close the gap. While effective, this method has some drawbacks, primarily nerve-tract mismatch in the host area and dysesthesias in the donor region. Artificial conduits have been widely studied as an additional intervention, but outcomes are not yet on par with autografts. Conducting polymers (CPs) have garnered much interest in neuroprosthetic applications due to their combination of unique electrical, physical, and chemical properties. Due to their biocompatibility, CPs can guide growing or regenerating axons, but the quantitative relationships between CP surface properties and axonal outgrowth are not yet clear. Characteristic feature size is known to be a crucial element in biomaterial substrates, enhancing, hindering, or entirely blocking the growth of cells cultured upon the biomaterial. Studies have demonstrated the effect of various substrate morphologies on neuron behavior and morphology, but the effect of spatially-variant surface features remains an unstudied realm.

Here we have investigated poly(pyrrole) (PPy) films fabricated using galvanostatic (GSTAT) electrodeposition at 0.5mA/cm² current density and poly(styrene-sulfonate) (PSS) dopant. An agarose gel was incorporated into the electrodeposition circuit to selectively apply Py:PSS monomer solution to controlled areas of an Au substrate. By positioning the gel on a computer-controlled motion stage, different regions of the substrate could be sequentially polymerized upon. Additional control software permits precise and variable control of the stage velocity; by changing the movement speed, residence time of the monomer liquid bridge may be adjusted. Increases in residence time caused increases in layer thickness and surface roughness. For example, by sequentially decreasing the stage velocity from 10.42µm/s to 3.21µm/s over 25 minutes, the PPy surface roughness (Rq) increased linearly from 2.75±0.69nm to 7.52±1.73nm, and the thickness increased from 318.5±75.9nm to 1,199.0±129.3nm. Various stage-velocity profiles allowed fabrication of multiple surface morphologies; constant-thickness, linear-increase (wedge-shaped), exponential-increase, and increase-decrease (hill) velocity profiles were successfully applied to 10 millimeters of Au substrate. Materials confocal microscopy was used to characterize film thickness and surface roughness as a function of substrate position.

SB08.03.04
Electropolymerized Poly(3,4-ethylenedioxythiophene) Coatings for Implantable Stimulating Microelectrodes
In Vivo
Jo‘Elen R. Hagler1, Côme Bodart1, Nicolò Rossetti1, Bénédicte Amilhon2 and Fabio Cicoira1;
1Polytechnique Montreal, Canada; 2University of Montréal, Canada

Implantable neural electrodes are important tools for recording and manipulating functions of the nervous system. Neural network interfaces, such as electrodes, have been used to better understand neural network plasticity through recording brain signals, and stimulating neural electrodes have been used clinically for therapeutic and assistive purposes in people with disease and injury. The challenges facing neural interface engineering is to develop materials that can seamlessly interface with the biological environment of the brain over long time periods, consistently provide the desired therapeutic results, and mitigate health risks associated with chronic implantation. Coating electrodes with conductive polymers such as poly (3,4-ethylenedioxythiophene) (PEDOT). PEDOT has shown to enhance the performance of metal electrodes by decreasing the impedance and increasing the charge storage capacitance. PEDOT is an excellent candidate for interfacing with the brain because of its mixed ionic-electronic conductivity, biocompatibility, and electrochemical stability.

Here, stimulating platinum-iridium (PtIr) neural microelectrodes were coated with PEDOT:tetrafluoroborate through
electrodeposition in the solvent propylene carbonate. Coated and uncoated stimulating electrodes along with tungsten recording electrodes were implanted in the hippocampus of mice. The coated/uncoated PtIr electrodes were stimulated daily, the recording electrodes measured the local field potentials generated by the stimulation, and the impedance before and after stimulation was measured at each electrode. The coated electrodes were able to effectively stimulate neuronal activity in the brain, thus demonstrating that PEDOT-coated electrodes are a viable alternative to bare PtIr recording electrodes.

SB08.03.05
Porous Boron Doped Diamond Based MEAs / Microprobes for Dual Mode Neural Recording
Andrew Taylor¹, Petr Ashcheulov¹, Ladislav Klimša¹, Jaromír Kopeček¹, Vincent Mortet¹, Silvia Sedláková¹, Jan Krášek², Ivan Dittert², Václav Petrák³, Veronika Benson¹,³, Silvana Baluchová¹,³, Mariola Brycht³, Karolina Schwarzoňová-Pecková¹,³, Alexandr Laposa⁴ and Vladimíra Petráková³;¹FZU - Institute of Physics of the Czech Academy of Sciences, Czechia; ²Institute of Physiology of the Czech Academy of Sciences, Czechia; ³Faculty of Biomedical Engineering, Czech Technical University in Prague, Czechia; ⁴Institute of Microbiology of the Czech Academy of Sciences, Czechia; ⁵Charles University, Faculty of Science, Czechia; ⁶Czech Technical University in Prague, Czechia

In this presentation we focus on fabrication pathways established for development of a system for dual recording of neuroelectrical and electrochemical signals based on porous boron doped diamond (pBDD) microelectrode arrays (MEAs) and microprobes, enabling alternate, or even simultaneous, recording of two types of information from one biological sample during one measurement session, i.e. detection of action potentials and neurotransmitters. pBDD based MEAs were fabricated via a novel combination of ink-jet printing and microwave linear antenna plasma enhanced chemical vapour deposition (MW-LA-PECVD) techniques. Nanodiamond seeded SiO₂ nano-spheres in a dispersion of ethylene glycol were ink-jet printed onto a Ti/quartz MEA with 20 electrode pads. Following seeding the MEA substrate was loaded into a MW-LA-PECVD system for layer deposition. The selected growth conditions enabled co-deposition of conductive pBDD on seeded areas and insulating silicon carbide (SiC) on unseeded areas, and thus matching the functionality requirements of layers for in-vitro MEAs. This novel combination of techniques negates the need for complicated and time consuming lithography/masking/etching steps. Fabricated pBDD/SiC MEAs were then used to culture hippocampal neurons and record their activity using a MEA amplifier USB-MEA64. Regular measurements revealed neuronal activity on day 10 -12 in-vitro. Activity was maximal 19-22 days in vitro, later declined and after 40 days disappeared. Comparison of electric activity between neurons grown on commercial TiN MEAs and pBDD MEAs showed a 2x lower standard deviation of voltage noise recorded for pBDD MEAs.

For electrochemical recording, we aim to employ pBDD based microprobes positioned in close proximity to a firing neuron on a pBDD MEA electrode in order to record neurotransmitter (e.g. dopamine) activity. pBDD µprobes were fabricated following anisotropic chemical etching of metallic wires (W or Ti) and then coated with BDD using the same MW-LA-PECVD system. Electrochemical characterization of model planar and porous BDD electrodes has been performed by recording cyclic voltammograms (CVs) of the inner-sphere [Fe(CN)₆]⁴⁻/³⁻ and the outer-sphere [Ru(NH₃)₆]³⁺/²⁺ redox markers. The acquired ΔEp values approach 59 mV (a value for reversible one-electron system), thus confirming fast electron transfer kinetics as well as the high quality of the fabricated electrode materials. In addition, the electrochemical behaviour of 0.1 mmol L⁻¹ dopamine was investigated by CV. Results indicate that both BDD materials can be applied for dopamine detection in media used for neuron culturing, e.g. HEPES.

In conclusion, we have demonstrated a simplified fabrication regime for the preparation of BDD based MEAs and microprobes with enhanced surface area. Functionality of the developed electrodes is shown by electrical recordings from firing neurons along with detection of neurotransmitters.

Control of a Microfluidic Three-Ring Chemical Oscillator Network
Maria Eleni Moustaka, Michael M. Norton, Chris Simonetti and Seth Fraden; Brandeis University, United States

We study synchronization patterns in microfluidic networks containing Belousov-Zhabotinsky (BZ) chemical oscillators. In our experiments, the auto-catalytic, light-sensitive, BZ reaction is confined to micro-fabricated wells constructed from the elastomer PDMS. Using soft lithography, PDMS networks are arranged into wells with
controlled topology. Each well can be regarded as a single network node that sends and receives inhibitory signals. Here we present the dynamics of a 3-node ring network. This network has two equivalent circular traveling waves of excitation. Control over the chirality of the wave can be achieved by exploiting the light sensitivity of the BZ catalyst, which can modulate the frequency of an individual node. In experiment, we perturb the network by changing the light intensity and duration of each of the three BZ wells. This network provides a model of gait switching in central pattern generators and a dynamic method of information storage.

*We acknowledge financial support from the U. S. Army Research Laboratory and the U. S. Army Research Office under contract/ grant number W911NF-16-1-0094, and the microfluidics facility of the NSF MRSEC DMR-1420382.

High-Resolution Organic Electrochemical Transistors Defined by Mould-Guided Drying of PEDOT:PSS Liquid Suspension Xin Chang1, Jin Li1, Shunpu Li2 and Daping Chu1; 1Centre for Photonic Devices and Sensors, University of Cambridge, United Kingdom; 2Shenzhen Technology University, China

Ion-sensitive transistors with nano- or micro-scale dimensions are promising for high-resolution electrophysiological recording and synaptic transistors. Technologies that are capable of patterning polymer functional materials directly from solution can effectively avoid any chemical damage induced by conventional lithography techniques. We report a method and process to pattern PEDOT:PSS-based transistors directly from their water-based suspension with high resolution. Gold electrodes with nanoscale channel width were also fabricated by firstly creating high-resolution polymer lines with mould-guided drying and subsequent pattern transferring, and PEDOT:PSS lines were then created through mould-guided drying on the predefined electrodes. The small devices with both nanoscale channel length and width exhibited good performance in electrical amplifying, high-frequency and multiple-frequency response. In addition, the assembled PEDOT:PSS lines showed anisotropy in electrical conductivity due to modified polymer chain alignment during drying.

Novel Nanostructured Scaffold for Neural Tissue Guidance and Regeneration Walaa Abbas and Nageh K. Allam; American University in Cairo, Egypt

Neural regeneration treatment after spinal cord injury (SCI) is still unsatisfactory despite the advances made in the field. One of the main challenges in neural tissue engineering is axonal growth and directionality. Cell and molecular therapies can enhance the axonal attachment and growth, however, axons may be unsuccessful to maintain their native organization and may grow in a disorganized fashion. Nanofiber scaffolds represent a potential solution for the problem of neural regeneration and axon guidance, as they can mimic the neural tissue extra cellular matrix (ECM) and combine the advantages of the combinatorial therapy for nerve injury in SCI cases. In this work, we aimed to fabricate a nanostructured scaffold that can be used as a physical support for maintaining axonal growth and regeneration in the lesion site. In addition to providing a suitable environment for the axonal extension to reconnect with their target neural tissues and restore their functional recovery. Anodized TiO2 nanotube powder incorporated into Chitosan and Poly Vinyl Alcohol (PVA) nanofibers with different percentages as 0.5, 1 and 3%. The composite scaffold was fabricated using rapid break down anodization and electrospinning techniques for TiO2 nanotubes and polymeric composite respectively. Characterization techniques such as Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), and Fourier transform infrared spectroscopy (FTIR) in addition to the viability assessment test using MTT assay with neural cell line were conducted. The results revealed that the scaffold with 0.5 and 1 % showed high biocompatibility material with neural cells which mimic the properties of the neural tissues in terms of biological and architectural properties and can be considered a regenerative treatment for axonal neural guidance of SCI.

Free-Standing Artificial Synapse Based on Ferroelectric Organic Field-Effect Transistor for Wearable Neuromorphic Computing Systems SeongHoon Jang1, Sukjae Jang2, Minji Kang2, Tae-Wook Kim2 and Gunuk Wang3; 1KU-KIST Graduate School of Converging Science and Technology, Korea University, Korea (the Republic of); 2Applied Quantum Composites Research Center, Institute of Advanced Composite Materials, Korea Institute of Science and Technology, Korea (the Republic of)

Recently, the field of neuromorphic electronic system for mimicking diverse functionalities of biological synapse
and massively parallel neural network found in human brain has been emerging as a promising approach toward energy-efficient computing technology1. For wearable electronic technology, an ultra-flexible neuromorphic device platform could be envisioned as an on-body intelligent integrated circuits to instantly and proactively interact with a wearer for general or specific information and sensing technology purposes. Here, we introduce a new class of artificial synapse as a basic unit for flexible and wearable intelligent device applications2. We fabricated a large scale of ferroelectric organic field-effect transistor memory (~ 500 nm total thickness) in a free-standing form using a pentacene and a ferroelectric copolymer, PVDF-TrFE, and utilized it as a free-standing artificial synapse. The device exhibits the reliable switching properties even in free-standing form, and it can also properly operated on various corrugated surfaces such as a thermal-shrink plastic film, a jelly, a textile, a candy, a teeth brush, and a brain mold. By applying diverse electrical pulses with modulated relative time correlation between pre-synaptic (gate electrode) and post-synaptic neuron (drain electrode), diverse synaptic activities such as STP, LTP, LTD, and STDP have been implemented. Furthermore, it features sustainable synaptic functions for more than 6,000 times of input signals under extreme conditions such as transferred on the corrugated brain-like mold and completely folded with very small banding radius (R = 50 µm). Our demonstration suggests that the ultrathin conformable organic artificial synapse platforms are considered as one of key technologies for realization of wearable intelligent electronics in the future.

Wireless Optogenetics with Multifunctional Integrated Fibers Atharva Sahasrabudhe1,1, Tural Khudiyev1, Tomo Tanaka1,2, Sirma Orgue1, Marc-Joseph Antonini1,3, Jimin Park1,1, Andres Canales1, Yoel Fink1,1, Anantha Chandrakasan1 and Polina Anikeeva1,1,1; 1Massachusetts Institute of Technology, United States; 2NEC Corporation, Japan; 3Harvard-MIT Division of Health Science and Technology, United States

Reliable operation of neural probes over time scales ranging from minutes to years is essential to longitudinal studies of development, aging, and chronic neurological diseases. Recently developed fiber-based neural probes offer a promising platform for integrating multiple functions in a miniature, flexible form factor that is also biocompatible with the soft neural tissue.

In this presentation, I will describe strategies for further expanding the array of functions delivered by fiber-based neural probes by outfitting them with programmable, wireless optogenetics capability. The traditional approach to light delivery into the brain for optogenetics studies relies on tethering implanted fibers to external sources via optical cables, which limits the range of possible experiments, particularly those involving complex motor functions or social interactions among multiple animals. Here we present multifunctional fiber-based neural probes capable of complete wireless and programmed optical neuromodulation using integrated microscale LEDs for control of complex behaviors in freely moving untethered animals. The same fibers incorporate conducting electrodes that enable chronic extracellular electrophysiology and microfluidic channels for delivery of drugs and genes to the target neural tissue. The devices still maintain a miniature footprint (~270×200 µm²). A detachable wireless transponder with an on-board battery for power and low-energy Bluetooth for data transmission permit straightforward application of these probes in a multitude of behavioral assays.

Biomaterials for iPS Cell-Derived Sensory Neurons—Biocompatibility and 2D/3D Patterning Minoru Hirano1,2, Daniel V. Jarquin1, Rosakaren Ludivina De la Garza Hernández1, Yasamin Aliashrafi Jodat1, Yike Huang1 and SuRyon Shin1; 1Brigham and Women's Hospital, United States; 2Toyota Motor North America, Inc, United States

Ever since stem cell technologies were developed several decades ago, researchers have produced a variety of cells without ethical issues which arise in obtaining cells from animal. Since embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) can proliferate rapidly and infinitely, and possess multipotency, they are promising cell sources for bioengineering and regenerative medicine. Recently, efficient sensory neurons (SNs) differentiation methods from ESCs and iPSCs have been developed by using small chemicals and growth factors. The engineered
SNs could be used to develop sensible neuroprosthetic devices and regenerated skin tissues for treating severe traumatic injuries or congenital malformations. However, there are still many issues remaining for current stem cell technologies regarding differentiation efficiency and controlling the structures and alignment of SNs. For example, matured SNs interconnected via dendrites were not amenable to enzymatic dissociation for reseeding due to the inevitable cell damage during dissociation process. Although immature SN progenitor cells (SNPCs) can be reseeded, they still possess stemness, resulting in differentiation into non-neuronal cells. To solve the issue, at first, we investigated the optimal seeding method of SNPCs on a two-dimensional (2D) substrate. SNPCs reseeded onto a crude laminin-coated dish survived and elongated with neurites but a small amount of non-neuronal cells selectively proliferated and dominated to the culture space over the time. DAPT[11] was used to efficiently inhibit the non-neuronal differentiation and the proliferation. Besides, subtypes of recombinant laminin were screened, revealing that specific subtypes of recombinant laminins retained SNPC as a neuronal progenitor cell and selectively induced matured SNs. Second, we compared the biocompatibility of several hydrogels for SNs such as gelatin methacryloyl (GelMA), collagen type I, and Matrigel. Although GelMA is well-known as an appropriate biomaterial for creating various 2D and 3D tissue constructs, SNPCs showed less viability and no-elongated neurites in the GelMA hydrogel. On the other hand, SNPCs were able to elongate neurites in both collagen type I hydrogel and Matrigel and then they matured and connected to the adjacent neurons forming dense neuronal networks in 3D hydrogels. Next, we performed 2D patterning of SNs using bioprinting techniques. Laminin solutions were printed onto conventional plastic tissue culture plates, SNPCs were then seeded, and specifically attached and elongated with neurites on the printed lines. However, the weakly attached neurons on the printed line were easily destroyed by mechanical stress such as medium replacement, and the patterned SNs couldn’t be sustained for a long time. [12] In order to overcome this situation, SNPC patterns were embedded into collagen type I hydrogel. To do this, a sacrificial bioprinting technique was used, so SNPCs suspended in gelatin bioink were printed on the laminin-coated tissue culture plate and then physically crosslinked on ice. The printed SNPCs-laden gelatin lines were covered by collagen type I solution and solidified at 37°C. The printed gelatin was then gradually dissolved into the culture medium and hollow microchannels were left. The SNPCs originally suspended in gelatin bioink were attached on the laminin-coated plate. SNPCs were elongated with neurites following the hollow microchannel structures and connected to each other, forming straightforward lines at the centimeter level. Now, we are developing and improving this method to form 3D neuronal wiring with printing SNPCs-embedded gelatin bioink in hydrogel bath constructs and connecting them to electrical devices like CMOS sensors to record the action potential of SNs later. These techniques above are expected to be applicable in generating 3D sensible prosthetics or skin tissues with complex wired sensory neuron networks in the future.

**Needle-Based Electrochemical Sensors on Flexible Substrates with Bio-Compatible Coating** Wonryung Lee¹, Young-Woo Lim¹, Hyunjae Lee², Injun Lee¹, Shingo Kobayashi³, Masaru Tanaka³ and Byeong-soo Bae²; ¹Korea Advanced Institute of Science and Technology, Korea (the Republic of); ²Samsung Electronics Semiconductor R&D Center, Korea (the Republic of); ³Kyushu University, Japan

Recently, flexible electronic devices have shown their ability as tools for in vivo electrophysiological or electrochemical recordings of organs due to their conformability and biocompatibility [1]. However, flexible devices only can make contact on the surface of biological tissue. In general, the ability to insert sensors into the precise location of biological tissue also yields important capability to get signals from origins. Accessing the origins of the complex signal landscape over the organs of larger mammals will require conformal substrates, insert sensors, and biocompatibility simultaneously. Here we present electrochemical and physiological needle based sensors on integrated substrates between rigid microneedle and soft flexible substrates. The microneedle (300-μm- caliber and 700-μm-height) is fabricated by epoxy hybrid materials on the 40-μm-thick PDMS substrate and passivation. The electrode channel is formed by Au/Ti which has a 35nm/5nm thickness, respectively. The electrode on the microneedle is coated by polyaniline through the electrochemical deposition. Polyanieline is formed well on the microneedle, which can be confirmed by scanning electron microscope (SEM) image. And their electrode shows low site impedance as 800Ω (1kHz) due to their porous structure, when the surface area is 0.5 mm². Additionally, the ability of pH detecting of flexible microneedle electrode is demonstrated by open circuit potential (OCP). As an analyte, phosphate-buffered saline (PBS) which has different pH controlled by hydrochloric acid, is used. The OCP measurement is performed between silver chloride and polyaniline microneedle, and it shows the 30 mV/pH. Finally, we successfully made 5×5 large areas flexible electrochemical needle array with 4.5 mm spacing. To enhance the biocompatibility of the
microneedle, poly(3-methoxypropyl acrylate) (PMC3A) which has ion-permeability [1,2] is deposited by dip-coating. Such integration of rigid and soft materials as one substrate could make the device to have the flexibility and insert sensors at the same time. This electrochemical and physiological sensor arrays hold great promise for medical applications including local field potential (LFP) measurement on the complicated organs of mammals.

SB08.03.13
Nanotopological Effects of Collagen-Based Fiber Patterns on Neurite Outgrowth and Axon Guidance JR Kim and Juhea Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Most animals have the nervous system consisting of the central nervous system and the peripheral nervous system. Damage or malfunction of the nervous system causes serious diseases such as spinal cord injury, Alzheimer’s disease, and neurodegenerative disorders. Current in vitro nervous systems such as microarray have a limited ability to mimic a single cell-cell connection of neural networking and do not enable control over diverse aspects of the neural microenvironment.

In this study, we developed collagen-based various nanofibrous patterns (uniaxial, perpendicular, diagonal patterns) to mimic the extracellular matrix (ECM) and investigated neurite outgrowth and axon guidance depending on the patterns and the density of nanofibers. In general, neurons displayed the accelerated outgrowth and synaptic connection on fibrous patterns and showed nanofiber-guided growth of cell body. However, in this system, axon growth showed various directions and the interaction between nanotopography and neurons. Calcium imaging also showed different rate and intracellular calcium signals released from neuronal activity depending on arrangement and density of nanofibrous patterns.

This paper will discuss how nanotopological cues of collagen-based fibrous patterns to regulate neurite outgrowth and axon guidance, and optimize the neural activity within this system. The patterned nanofibrous system developed by our group could be extended to serve as a model for pathophysiological study of the nervous system and artificial 3D neural tissue engineering. Furthermore, our findings offer new insights into the design of nanofiber-based scaffolds for nerve injury repair and will provide new guidelines for the construction of neuronal network architecture.

Biocompatible Electrode Materials for Electrophysiological Sensor and Stimulation Pochun Chen and MingTing Hsieh; National Taipei University of Technology, Taiwan

ITO coated mica has been a promising flexible substrate for implanted electrochemical sensor of in situ sensing, monitoring of biological conditions (i.e. pH) and detect multiple species simultaneously. (i.e. glucose, dopamine and uric acid). Minimizing the pH sensor for implanting and long-term record could minimize the local tissue damages and improve the special resolution. Study the sheet resistance and curvature of substrate also discussed in this study. Iridium oxide has been an attractive material due to its advantages of electrochemical applications and electrophysiological sensing due to its excellent chemical stability, sensitivity, electrochemical catalytic activity and good biocompatibility. We developed a flexible iridium oxide based on ITO coated mica electrode for application in electrophysiological sensing by chemical bath deposited iridium oxide film. The characterization of thin film was investigated by SEM, XRD, XPS and XAS. Three-electrode system was selected as the sensing stimulation with pH varying from 1 to 11. The sensitivity was up to 80 mV/pH with an accuracy of 0.1 mV/pH. Moreover, the as-deposited sensor had an attractive properties of detecting multiple species of uric (AA) and dopamine (DA). The stability test was demonstrated by 1000 cycles of CV scanning. After finishing stability test, the charge storage capacity (CSC) and the charge injection capacity (CIC) maintained 96.3 % and 92 % of efficiency, respectively. Great electrochemical properties, high sensitivities, wide pH ranges, fast response time and great reversibility presented that the chemical bath deposited iridium oxide film presented well in electrophysiology electrodes.

NIH/NINDS Funding Opportunities for Technology Development and Translation Eric Hudak, Kari R Ashmont, Brooks A. Gross and Nick B Langhals; NIH, United States

The mission of the NINDS Division of Translational Research (DTR) is to accelerate basic research findings towards patient use for neurological disorders and stroke by providing funding, expertise, and resources to the research community. DTR provides funding and resources through grants, cooperative agreements, and contracts to academic and industry researchers to advance early-stage neurological technologies, devices, and therapeutic programs to industry adoption (i.e. investor funding and corporate partnerships). We have created a variety of programs that support the design, implementation, and management of research activities critical to translational challenges in the treatment of neurological disease. In addition, DTR plays an active role in the NIH BRAIN Initiative, SPARC Program, and HEAL Initiative. NINDS DTR is actively managing programs that support small molecule, biologic, and neural device therapeutics, biomarkers, and training through grants, contracts, and consultants. These programs cover all stages of translational research from early assay/biomaterial/device development and optimization to preclinical development and early clinical development. Funding opportunities and resources are actively supporting translational research in preclinical discovery and development of new therapeutic interventions for neurological disorders and stroke, as well as neuropsychiatric disorders and neurotraumatic injuries (BRAIN Initiative) and pain (HEAL Initiative). An overview of NIH/NINDS translational programs and resources will be presented.

Towards Full Colour Artificial Retina via Inkjet-Printed Conjugated Polymers Devices Maxim Shkunov1, Manuela Ciocca1,2, Pavlos Giannakou1 and Thomas M. Brown2; 1University of Surrey, United Kingdom; 2University of Rome - Tor Vergata, Italy

Photo-sensitive conjugated polymers provide highly promising platform for visual prosthesis offering novel retinal biocompatible devices. Their high absorption coefficients, chemically tuneable bandgaps, the ability to be processed at room temperatures on flexible substrates, and signal transduction mechanisms that do not require external power sources make them ideal materials for retinal prosthetic applications. Despite ongoing research efforts in artificial retina field with organic semiconductor materials, full-colour sight restoration remains very challenging. We demonstrate tri-colour optoelectronic devices based on three different band-gap conjugated polymers with absorption in red, green and blue spectral regions, mimicking absorption of human retinal cones responsible for full colour vision, as well as high-sensitivity broadband absorption polymer/small molecule blend imitating rods absorption. Photo-response of these devices, interfaced with biological electrolyte solution, is demonstrated with long-pulsed excitation from monochromator-filtered light source, and spectral response is shown to deviate from optical absorption of dry polymeric films. We compare polymers’ films response with retinal photoreceptors colour sensitivity and discuss the role of polymer-electrolyte interface for photo-transduction mechanisms, identifying the role of capacitive charging, and ions interactions with the polymer layers during light excitation process. Ink-jet printed devices are fabricated in the form of an array of semiconducting 50 to 90 micron diameter polymeric round pixels-photoreceptors with specific red, green and blue colour sensitivity. The devices do not require wiring or external bias to operate, and are stable in aqueous physiological conditions. Due to biological compatibility of organic semiconductors, high absorption and wide spectral tuneability, this device technology is expected to find medical applications as retinal bio-engineered prosthesis towards the restoration of human vision lost due to common eye diseases, including Age Related Macular Degeneration and Retinitis Pigmentosa.

Melt Electrowriting (MEW) of Novel Conductive Polymer Composites for Electroactive Fibers Julian Heck1, Robert Luxenhofer2, Paul Dalton1, Josef Goding1 and Rylie Green1; 1Imperial College London, United Kingdom; 2University of Würzburg, Germany

Current scaffolds for soft tissue regeneration and rehabilitation are limited in that they are commonly fabricated from non-conductive polymers or have low-conductivity due to poor percolation of conductive components within
an insulating polymer. When electroactive particles such as carbon nanotubes or metal nanoparticles are suspended within a polymer matrix, the conductive path is inadequate as the particles must be in close proximity to maintain conduction. This necessitates high concentrations of particles to facilitate sufficient conductivity, which in turn can be detrimental to the mechanical properties of the polymer system.

Conductive polymers (CPs) can have high conductivity, but are often stiff and friable, with typical moduli of 20 to 100 MPa. These poor mechanical characteristics have driven the need for new electroactive materials with softer, more robust mechanics. In addition, thermal processing of CPs, including MEW has not been achieved due to the thermal breakdown of CPs prior to reaching a melt phase. To achieve flexibility, conduction and thermal processability in a CP system, it is necessary to develop new CP based building blocks that can retain the CP chains in close apposition, while enabling movement and fabrication into devices.

New macromers of melt processable poly(2-oxazine) (POx) functionalized with thiophene have been developed. Using the synthesis strategy of Seeliger and Wittig et al. several thiophene-oxazoline/oxazine monomers were produced with a range of properties. The first isolated crystal structures of 2-oxazoline were observed. Using ring-opening polymerization (ROP) it was possible to polymerize homopolymers, copolymers and block copolymers. This broad variation is expected to enable control over material properties such as glass transition temperature (Tg) and fiber flexibility.

These new polymer building blocks were shown to retain the processability of the POx and enable the printing of a CP monomer using MEW for the first time. Specifically, poly(2-thiophene-2-oxazine) can be printed in continuous fibres with ~200 µm diameter. The MEW printing temperature was 160 °C, with voltages ranging up to 4kV. This molecule can polymerized to obtain a product with conductive properties reflective of a CP chain formation. Free PEDOT chains can be added to the co-polymer to improve conductivity, however, future work will focus on developing co-polymers where CP chain alignment can be facilitated during the printing process.

Direct Writing of Soft and Bioactive Conducting Polymer Microstructures for Organic Bioelectronics Applications Milad Khorrami, Vijay K. Raghunathan and Mohammad Reza Abidian; University of Houston, United States

Fabrication of 3D conductive microstructures is a great of interest in the field of bioelectronics and biosensors. However, the main challenges are (1) inability of the commercially available 3D-printers to precisely control the spatial architecture and failure to maintain a high resolution and (2) incompatibility of the printing inks to fabricate functionalized and biocompatible structures. To overcome these challenges, we introduced a novel electronically conductive and biocompatible ink for fabrication of sub-micron resolution 3D-structures using two photon polymerization technique. The ink is consist of poly(ethylene glycol) diacrylate (Mn=700) as a crosslinker, ethyl (2,4,6-trimethylbenzoyl) phenylphosphinate as a photoinitiator, and high conductive grade conductive poly(3,4-ethylenedioxythiophene)-poly(styrene sulfonate) dispersion in water. The 3D conductive microstructures were fabricated using a Laser uFAB Microfabrication Workstation (Newport, USA) at wavelength 800 nm with laser power 3.5 mW. Electrical conductivity of bar-shaped (800 µm length, 20 µm width and 1 µm height) structures with PEDOT:PSS concentration of 0 wt%, 0.1 wt%, 0.2 wt%, 0.3 wt%, 0.4 wt% and 0.5 wt% were 3.1 ± 0.6 S/m, 137.8 ± 11.9 S/m, 5502.9 ± 586.2 S/m, 13857 ± 927.9 S/m, 19042 ± 1302.1 S/m, and 25034 ± 886.3 S/m, respectively. These results showed the significant improvement of conductivity of 3D-structures up to 4 orders of magnitude (P<0.001). Furthermore, laminin protein was incorporated within conductive microstructure during fabrication process to enhance the cell attachment. Atomic Force Microscopy results revealed that the young modulus conductive microstructures was in the range of 200-500kPa. The development of conductive and bioactive 3D microstructures can be utilized in the field of bioelectronics and can be potentially utilized for neural interfaces. The future work will be focused on 3D-printing of organic neural microelectrode for recording brain signals.

10:15 AM *SB08.04.05

Functionalized Polythiophene Copolymers for Electronic Biomedical Devices David C. Martin, Samadhan Nagane, Yuhang Wu, Vivek Subramanian, Shrirang Chhatre, Peter Sitarik and Quintin Baugh; University of Delaware, United States
We continue to investigate the design, synthesis, and characterization of electrically and ionically active conjugated polythiophene copolymers for integrating a variety of biomedical devices with living tissue. This talk will focus on our most recent results, including the development of several new monomers that be used to tailor the surface chemistry, adhesion, and biointegration of these materials with neural cells. Our recent efforts have focused on copolymers of 3,4-ethylenedioxythiophene (EDOT), functionalized variants of EDOT (including EDOT-acid and the trifunctional EPh), and dopamine (DOPA). The resulting PEDOT-based copolymers have electrical, optical, mechanical, and adhesive properties that can be precisely tailored by fine tuning the chemical composition and structure. We have also been investigating the ability of these materials to be deposited directly around living tissue, particularly peripheral nerves. We will present results on EDOT-dopamine bifunctional monomers, including EDOT-dopamide and EDOT-dopimine and their corresponding polymers. We will also introduce an EDOT-aldehyde monomer and show how it can be used as the starting point for a wide variety of functionalized monomers and polymers.

10:45 AM SB08.04.06
Polymeric Memristors from Poly(n-Alkyl Methacrylate) as an Artificial Synapse Benjamin T. Grant, Stephen Foulger and Yura Bandera; Clemson University, United States

Memory devices based on organic materials are a promising alternative towards the next generation of nonvolatile nanoelectronics. The memristor is defined as any two-terminal electronic device that alters its conductivity based on its electronic history. In this effort, a methacrylate polymer is derivatized with an electronically active carbazole. Under an applied electric field, the carbazole groups rearrange their alignment, thus facilitating easier electron carrier delocalization and charge transport through molecular conformational changes. By tuning the structure of the polymer, the flexibility of the chain and the number of conductivity states can be further modified. The ability to have a multitude of conductivity states according to applied voltage makes the memristor a major candidate for emulating synapses in artificial neural networks – offering both the high connectivity and the high density required for efficient computing. Memristors, with a simple sandwich device architecture of ITO/poly(n-(9H-carbazol-9-yl)n-alkyl methacrylate)/Al, exhibit essential synaptic plasticity and learning behaviors, including short-term plasticity and spike-timing-dependent plasticity, through programmed waveforms inspired by neuronal action potential. Variations to the length of side chains that attach the carbazole moiety to the polymer backbone were studied for their effects on the optical and electrical properties of these materials.

11:00 AM SB08.04.07
Softening Polypyrrole-Coated Cryogel Electrodes for Deep Brain Stimulation in Mice Taylor J. Morrison¹, Elana Sefton¹, Milos R. Popovic¹,², Cindi M. Morshead¹,²,¹, Hani E. Naguib¹,¹,¹ and Tianhao Chen¹; ¹University of Toronto, Canada; ²University Health Network, Canada

Deep brain stimulation (DBS) is a well-established tool that is widely used in the clinical treatment of neurological disorders such as Parkinson’s disease and depression. However, treatment advances can be limited by not fully understanding how the brain is affected, and thus animal studies in vivo are needed to investigate the mechanisms involved. In vivo studies using DBS require one or more electrodes be implanted in the brain so that an electric field can be applied across the targeted area. As these electrodes may stay implanted for several days to months, it is crucial to the success of the trial that the electrode materials are fully compatible with the brain. However, the electrodes currently available to scientists are rigid, causing significant inflammation and damage to the contrastingly soft brain tissue. While research is ongoing to develop soft electrodes capable of replacing their rigid counterparts, meeting the many requirements of stimulating electrodes, including biocompatibility, high electrical conductivity, low Young’s modulus, and a functional insertion mechanism, has posed a significant challenge to researchers.

To address this challenge, we have developed novel electrodes that are biocompatible, conductive, stiff during insertion, but soft once placed in the brain. The polyvinyl alcohol (PVA), cellulose nanocrystal (CNC), and carbon nanotube (CNT) composite is repeatedly frozen and thawed in fiber form to produce a soft, highly elastic, conductive cryogel material, which is then coated in polypyrrole to further increase conductivity and reduce excess swelling of the electrode that could damage surrounding tissue. When dry, the fiber can be made as thin as 90 microns diameter, and with a compressive modulus of 1.8 MPa, can apply enough force without bending to penetrate tissue (>1 mN). Once saturated, the Young’s modulus reduces to 3 kPa, approximately matching that of
the brain (1-2 kPa). With wet conductivity as high as 150 S/m, we demonstrate that these electrodes can effectively stimulate mice in vivo. Furthermore, this material is shown to be 3D printable, with potential to print more complex electrode designs for advanced stimulation experiments.

Biocompatible Materials for Memory and Neuromorphic Applications Min-Kyu Kim, Youngjun Park, Dongshin Kim and Jang-Sik Lee; Pohang University of Science and Technology, Korea (the Republic of)

Biopolymers have been utilized as a matrix for filamentary resistive switching memory due to its abundant, inexpensive, and biodegradable properties. Resistive switching characteristics can be governed by diverse factors, and ionic conductivity of the matrix is one of the most critical factors in filament formation. Here, we report biocompatible memory and synaptic devices based on the biopolymer matrix [1-2]. Filament formation dynamics are controlled by modulating the ionic conductivity of biopolymer matrix. In biopolymer matrix with low ionic conductivity, the volatile resistive switching behavior is observed. Synaptic characteristics such as short-term plasticity, paired-pulse facilitation and transition from short-term to long-term plasticity are emulated by exploiting the similarities between the volatile filament formation dynamics in the biopolymer matrix and Ca^{2+} dynamics in biological synapse. The devices also exhibit good non-volatile memory characteristics such as fast switching speed, low operation voltage, and high on/off ratio by improving ionic conductivity via chemical modification. This study may provide a new possibility for biomaterials to be used as biocompatible memory and artificial synapse devices. In this presentation, resistive switching behavior in biopolymer for memory and neuromorphic applications will be presented in detail.

**Biographene and Neural Communications** Gordon Wallace; University of Wollongong, Australia

Graphene has been shown to exhibit an extraordinary range of tunable properties. High electrical and thermal conductivity coupled with exceptional mechanical properties and tunable chemical/biological activity has the materials science community enthralled. This combination of properties has led to the use of graphene to form electrodes for use in energy conversion and storage as well as in medical bionics.

We have been particularly interested in the processing of graphene from graphite in such a way that the above properties are retained but also the materials produced are amenable to a range of fabrication protocols. One approach to fabrication that has had a marked impact on the bionics area is our ability to produce long lengths of micron dimensional fibers with high electrical conductivity and exceptional mechanical properties. Our latest version of this is a fiber that can be sutured around individual nerves to enable stimulation and recording with unprecedented spatial resolution and sensitivity (1).

Here we will present the impact of these developments on the emerging field of electroceuticals - the use of electrical stimulation to treat disease.

**Ionic Communication for Implantable Neural Interface Devices** Zifang Zhao and Dion Khodagholy; Columbia University, United States

High-speed, low-power, and biocompatibility are the main requirements of neural implantable devices at can acquire electrophysiological signal at high spatiotemporal resolution. However, the high ionic conductivity of biological tissue limits effective transmission of conventional electromagnetic based waves from inside of the body. In addition, such approaches often require complex implantable electronic components and circuits that increase the size and power consumption of the implanted device.

Here, we introduce a novel ion-based high-speed, low power consumption communication.

Three forms of ionic communication including capacitive, galvanic, and RF coupling were evaluated and characterized for their bandwidth, cross talk and scalability. Physical and geometrical factors of ion transport and movement including the distance between electrode pairs, implantation depth, electrode size, electrode material, ion concentration were determined to establish optimal high-speed ionic communication. To further increase the communication bandwidth, we investigated the feasibility of multiple parallel communication lines through manipulation of the spatial extent of ionic waves in the medium. Conducting polymer-based hexagonal electrodes were fabricated on conformable substrates to improve flexibility and maximize the electrode density. We evaluated the error rate of the ionic communication at different speeds and established four ion-based communication lines for validating the efficacy of this transmission in animal experiments.

We have performed in vivo electrophysiological recordings of heart cells and neurons in anesthetized and freely moving rats. High-resolution electrophysiological signals were transmitted via ionic communication across the animal’s body without any extruding element, creating an imperceptible communication path between inside and outside the body. The proposed ionic communication scheme has broad applicability to implantable bioelectronics that require data exchange with external elements such as deep brain stimulators, pacemakers, implantable pumps, and brain machine interfaces. It will also enable development of novel implantable bioelectronic devices, with the potential to improve the care of patients who rely on medical devices to diagnose and treat disorders.

**Photoswitchable Spiropyran-Calmodulin Mimicked Peptide for Calcium Brain Imaging** Zinah H. Al Hammad, Do Hyun Bae, Soo-Yeon Lee and Yong Ho Kim; Sungkyunkwan University, Korea (the Republic of)
Calcium ions (Ca\(^{2+}\)) plays an important role in neuronal signaling, challenges to analyze various neuronal calcium sources is that they are not active one at a time, overlapping activity with strong interactions. An advance in this field would come from the development of selective, reversible fluorescent chemosensors, capable of repeated measurements. To this end, the rational design and fluorescence-based photophysical characterization of calmodulin calcium binding motif spiropyran-based chemosensors for Ca\(^{2+}\) are presented. Incorporation of spiropyran-based sensors into a peptide conjugation system in a crown shape has a promising results to yield significant signal to background changes with minimal sample volumes, a real advance in biological sensing that enables measurement on subcellular scale samples. In order to demonstrate chemo-peptide sensor compatibility within the light intense microenvironment photoswitching and photostability, revealing reversible Ca\(^{2+}\) binding with improved photostability compared to the non-photoswitchable calmodulin calcium binding motifs. The spiropyran-based peptide chemosensor reported here highlight untapped opportunities for a new class of photoswitchable Ca\(^{2+}\) probe and present a first step in the development of a light-controlled, reversible sensor for Ca\(^{2+}\) .

2:45 PM SB08.05.05

**Diamond as a New Encapsulating Material for Neuronal Implants**

Lionel Rousseau\(^1\), Emmanuel Scorsone\(^2\), Gaelle Lissorgues\(^1\), Blaise Yvert\(^3\) and Serge Picaud\(^4\); \(^1\)ESIEE Paris, ESYCOM, UPEM, France; \(^2\)LIST/LCD, France; \(^3\)BrainTech Laboratory U1205 Inserm, France; \(^4\)Institut de la vision UMR 7210, France

Today Brain Computer Interface (BCI) offers a way to restore neuronal dysfunction due to degenerative diseases or accidents. Thus it becomes possible to restore vision with retinal implant or to offer tetraplegic a way to control a robotic tool by thought with electrodes implanted in the cortex. One major limitation of these systems is their insufficient stability. After several months of implantation, some modification can appear such as swelling of the passivation polymers thus inducing current leakage, or degradation of the electrode material. Moreover neuronal prostheses are poorly accepted by tissues and a glial reaction may appear at the vicinity of the implant. Hence for future generation of implants it will be crucial to limit glial reactions and fabricate a full hermetic implant. Several research teams proposed to protect the metallic tracks by encapsulating them in multilayers of in-organic materials like AL2O3 or TiO2 obtained by ALD. But in case of pin holes or adhesion problems between each layer, metallic parts will not be well protected. To overcome these issues we propose to fabricate a full hermetic diamond implant. Diamond properties are very attractive for medical applications. Indeed diamond is a biocompatible material and it has no native oxide, so there is no degradation when the structure is placed in water or harsh environment. Being also a high density material, there are no species that can migrate inside diamond. Conductive diamond obtained by introduction of Boron dopants, called boron doped diamond (BBD) has a wide electrochemistry window compare to classical metallic electrodes. In parallel CVD growth diamond reactor offers a way to achieve a thin diamond film on silicon or glass wafer. This technology is compatible with classical micro fabrication process and offers an elegant way to achieve a full diamond implant. Using the same material for passivation and electrodes offers a way to achieve a full hermetic structure compatible with long term in vivo usage.

To validate this technology we started with the fabrication of a full diamond strip composed of Boron doped diamond for the electrodes and intrinsic diamond for the encapsulation. We have also produced several strips with more conventional encapsulating materials used for implants such as parylene, AL2O3 or Si3N4 and with several electrode materials like platinum, gold, PEDOT or black Pt. To compare both electrode and encapsulation materials, we designed strips with 3 electrodes (of diameter 60 µm or 30 µm) covered with same protective material. Two electrodes were continually stimulated during all the experiments while one was used as a reference (no electrical stimulation). To follow the evolution of the electrode and encapsulating materials, impedance spectroscopy was used periodically in buffer media (PBS) over several weeks, and first results clearly showed the advantage of diamond over the classical materials.

In parallel of these developments we have also achieved a preliminary version of a soft full diamond implant which will be used to test the surgical implantation procedure and to optimize the total thickness.

**Immobilized Laminin Gradients on Conducting Polymer Films for Axonal Regeneration**

Omid Dadras Toussi,
Axons navigate along specific pathways based on the gradients of guidance cues. Following substantial neural injury, axons may fail to fully regenerate without external intervention due to limited intrinsic axonal growth capacity and/or interference from scar tissue. Hence, development of platforms capable of providing gradients of guidance cues to facilitate axonal regeneration is crucial in the field of neural tissue engineering. Even though numerous technologies have already been established, effective axonal guidance over long distances is still challenging.

Here we report a novel method for creation of gradient of laminin on conducting polymer film. Conducting polymers (CPs) such as Poly(3,4-ethylenedioxythiophene) (PEDOT) have been widely used for neural interfaces, owing to their excellent biocompatibility, soft mechanical properties, relatively high conductivity and outstanding chemical stability. Laminin is a major substrate-bound molecule for axonal growth, known as a chemoattractant. In an effort to mimic the extra-cellular environment, this study aims to provide different gradient shapes of laminin such as linear, hill, and exponential to modulate axonal regeneration in the nervous system. First, using micro-scale motorized X-Y-Z stages and nano-syringe pump, lines of laminin have been printed with various concentrations (based on the gradient profile) ranging from 20-100 ug/ml on the surface of a 2% agarose hydrogel slab (hydrogel thickness was 10 mm). The laminin concentrations can be accordingly adjusted to create different gradient shapes. Processing parameters including injection flow rate and stage velocity have been optimized to create minimum line widths (i.e. 200 um) which leads to generation of high-resolution 10mm-long laminin gradients on 10 mm length of agarose gel. The whole pattern is then transferred onto the surface of a Poly (L, Lysine)-treated PEDOT film. PEDOT was previously electropolymerized on the surface of gold coated silicon substrate using galvanostatic mode with charge density of 0.18 C/cm². Immunohistochemistry was used to quantify various immobilized laminin gradients on the PEDOT surface.

We aim to culture dorsal root ganglion explants and cortical neurons on top of CP substrates printed with laminin gradient patterns. This will allow us to assess the neurite response to various gradients and compare these responses to find the optimum gradient type and concentration range for effective axonal regeneration. The outcome of this project will pave the way towards development of more effective engineered conduits for nerve regeneration and will help us unravel fundamental questions of axonal regeneration in the nervous system.

3:30 PM SB08.05.07
Patterned Semiconducting Multi-Electrode Arrays for the Optical Stimulation of Neuronal Cells
Frano Milos1, Maria Rosa Antognazza2, Gabriele Tullii2, Maria Cecilia Pasini3, Francesco Galeotti3, Dirk Mayer1 and Andreas Offenhäusser1; 1Forschungszentrum Juelich, Germany; 2Istituto Italiano di Tecnologia, Italy; 3ISMAC-CNR, Italy

Photoconductive organic polymers are attracting considerable interest in tissue engineering and bioelectronics due to their remarkable light absorption along with tunable optical and mechanical properties. Moreover, these materials can be easily processed into precisely defined topographical patterns with large area coverage and low fabrication costs. We present a novel photoconductive biointerface which combines a multi-electrode array (MEA) functionalized with a semiconductive conjugated polymer patterned into defined microscale topographical features. In previous studies, photoexcitation of a light-sensitive semiconductive polymer, poly(3-hexylthiophene-2,5-diyl) (P3HT), was used to induce variations in the membrane potential of HEK-293 cells and the occurrence of capacitive charging was observed at the P3HT/electrolyte interface that could potentially lead to photo-capacitive stimulation of the cell membrane. Our aim is to further this approach by developing a functional non-invasive tool for the optical and topographical modulation of primary cortical neurons in vitro. Poly(3-hexylthiophene-2,5-diyl) was deposited on MEAs and patterned into conical micropillars to improve the cell-electrode coupling. Since P3HT is excited by visible light, the presented device can be easily implemented in any electrophysiological set-up without requiring complex optical systems. We observed that polymer photoexcitation leads to a significant decrease in the electrode impedance. Furthermore, we cultured primary cortical neurons and observed that microscale pillars significantly promote neurite growth and their alignment to the underlying topography in comparison to flat substrates commonly used in cell culture. Since light treatment did not result in significant detrimental effects on cell viability, we aim to optically stimulate primary cortical neurons using the presented device and further investigate whether polymer photoexcitation influences neuronal development on flat and patterned P3HT substrates.

In conclusion, the presented system is a step towards light-controlled manipulation of neuronal development and network activity which could have considerable implications for neural regeneration and the design of neuro-
prosthetic devices.

3:45 PM SB08.05.08
Neuritogenic Potentiating Effects of Controllable Electrically-Induced Polarization of Poly (L-lactic) Acid
Paula Maria Vilarinho, Nathalie Barroca, Ana Marote, Sandra Vieira, Odete Silva and Maria Helena Fernandes; Univ de Aveiro, Portugal

Electrical stimulation is known to be beneficial for neuronal function, particularly on neurite growth. Electroactive materials as conductors and piezoelectrics are known to provide extra stimulatory signals for neural repair and have shown promising results. Poly (L-lactic) acid (PLLA) is a biodegradable and piezoelectric polymer studied as a scaffolding material and drug delivery system. It demonstrates and FDA-approved biocompatibility and biodegradability for particular applications, as screws for fixing fractures in orthopaedics [20] or in injectable filling for lipotrophy.

In our work, we are exploiting the feasibility of combining electrical polarization in PLLA films and aligned nanofibers and investigate the biological outcome of these electrically-induced poled PLLA platforms on neuronal relevant *in vitro* models. Here we report on the production of electrically polarized PLLA aligned nanofibers along with a precise quantitative analysis of their polarization and stability. We advocate that electrical poling causes C=O dipoles orientation, which brings tensile piezoelectricity, and results in charged surfaces. Our results show the neuritogenic potentiating effects of this controllable electrically-induced polarization on human SH-SY5Y neuroblastoma cells and rat embryonic cortical neuronal differentiation.

4:00 PM SB08.05.09
Transparent, Flexible, Penetrating Microelectrodes Arrays with Capabilities of Single-Unit Electrophysiology
Kyung Jin Seo¹, Pietro Artoni², Michela Fagiolini² and Hui Fang¹; ¹Northeastern University, United States; ²Boston Children's Hospital, United States

Accurately mapping neuronal activity across brain networks is critical to understand cortical phenomena, yet it is challenging due to the need of tools with both high spatial and temporal resolutions. Here, penetrating arrays of flexible microelectrodes made of low-impedance nanomeshes are presented, which can record single-unit electrophysiological neuronal activity and at the same time, are transparent, allowing to bridge electrical and optical brain mapping modalities. These 32 transparent penetrating electrodes each with a small site area, 225 μm², have a low impedance of ~ 149 kΩ at 1 kHz, an adequate charge injection limit of ~ 0.76 mC cm⁻², and 100% yield. Mechanical bending tests reveal that the arrays are robust up to 1,000 bending cycles, and their high transmittance of 67% at 550 nm makes them suitable to combine with various optical methods. A temporary stiffening using polyethylene glycol allows the penetrating nanomesh arrays to be inserted into the brain minimally invasively, with in vivo validation of recordings of spontaneous and evoked single-unit activity of neurons across layers of the mouse visual cortex. Together, these results establish a novel neurotechnology—transparent, flexible, penetrating microelectrode arrays—which possesses great potential for brain research.

4:15 PM SB08.05.10
Soft, Flexible and Conductive Elastomers for Bioelectronics
Estelle Cuttaz, Alexey Novikov, Christopher Chapman, Josef Goding, Catalina Vallejo Giraldo and Rylie Green; Imperial College London, United Kingdom

Flexible, polymeric-based electronics have the potential to fundamentally change the design, fabrication and performance of bioelectronic devices. Contemporary bioelectronic devices are restricted to metals for charge transduction and injection in the body. The use of metallic conductors hinders the design and fabrication of truly stretchable and flexible electronics. The mechanical mismatch between metals and insulative polymers such as
polydimethylsiloxane (PDMS) used in bioelectronic devices can lead to device failure due to issues such as mechanical failure and fluid ingress. Furthermore, the mechanical mismatch between metallic conductors and soft tissues contributes to chronic inflammatory responses upon implantation of bioelectronic devices.

Carbon-based conductors such as carbon nanotubes and conducting polymers provide a potential avenue for the synthesis of fully organic electrical conductors. In this study several approaches for the fabrication of soft, flexible organic conductors have been investigated and the resultant materials have been used in the fabrication of fully polymeric electrode arrays. Two key approaches for fabrication of conductive elastomers were explored. The first approach is the fabrication of a poly(ethylenedioxythiophene):polystyrenesulfonate (PEDOT:PSS) hydrogel which is impregnated with PDMS resulting in a bulk composite of an embedded PEDOT network within a PDMS matrix. The second approach entails dispersion of PEDOT fibres and nanowires within a polyurethane (PU) matrix to produce films via solvent casting. The effect of PEDOT loading on electrochemical and mechanical characteristics were investigated. Elastomers with 15 wt% PEDOT loading were identified as ideal for device fabrication, having conductivity of 4.15 S.cm⁻¹, young’s modulus of 20.5 MPa, an ultimate tensile strength of 7.4 MPa and strain at failure of approximately 265%. Cytocompatibility of conductive elastomers was assessed in vitro using ReNcell VM human neural precursors. Cultures on conductive elastomers were found to have an increased neural cell population compared to neat PU (33% compared to 53% of the cell population) due to increased surface roughness. However this was accompanied with a decrease in average neurite length due to the accompanied increase in Young’s modulus (298.4 ± 16.9 µm for PU versus 45.2 ± 1.5 µm for CE).

Flexible, fully polymeric electrode arrays were fabricated from conductive elastomers using conventional laser micromachining techniques. Methods to connect the polymeric arrays to traditional electronics were also developed. Arrays were comprised of nine, 900µm electrode sites in a hexagonal array. Charge injection limits (CIL) of the CE array were determined using biphasic stimulation with a phase length of 0.2 ms. CE electrodes were found to have a CIL of 0.020 ± 0.002 mC.cm⁻² compared to 0.013 ± 0.001 mC.cm⁻² for platinum electrodes of the same geometry. CE arrays were also found to have high charge storage capacity, 205 ± 55 mC.cm⁻² but also a high track impedance of 0.41 ± 0.16 Ω. Electrode arrays were demonstrated to maintain charge conduction and injection under strain and flexural deformation.

The formation of PEDOT networks within elastomeric polymer matrices has been demonstrated as a promising approach for the fabrication of soft, flexible bioelectronic materials. CEs facilitated the fabrication of a fully polymeric, flexible electrode array using conventional laser fabrication techniques. CE arrays were found to have favourable charge injection properties compared to platinum electrodes, however track conductivity is a current limitation which needs to be addressed in order to open up the application of CEs in the next generation of flexible bioelectronics.

4:30 PM SB08.05.11
Modular Peptide Hydrogels for Tissue Regeneration after Brain Injury Biplab Sarkar, Xiaotang Ma, James Haorah and Vivek Kumar; New Jersey Institute of Technology, United States

Traumatic brain injuries (TBI) affect more than 2 million people in the US annually. Major causes include falls, motor-vehicle crashes, and assault/self-harm. Sports-related injuries suffered by athletes and blast injuries affecting soldiers are also notable contributors to the TBI patient population. Native brain microenvironment has low intrinsic regenerative capability and such injuries may lead to long-term effects such as dementia.

We describe a class of injectable materials that can manage and possibly reverse the harmful biological responses to TBI. These hydrogels, with material properties similar to native matrix in the brain, can liquefy during injections and be reconstituted in the brain after injection. We apply lessons learned from self-assembly of short peptides to create materials that can promote blood vessel formation, modulate the immune microenvironment, and facilitate survival and reconstitution of the functional neuronal circuit in and around the injury site. Our multi-disciplinary approach bridges chemical principles with neurobiological insights to set up a modular neuroprotective therapeutic platform with both stationary and diffusive biologic signals. This integrative approach will increase our understanding of the response of injured brain microenvironment to implanted biomaterials and solve a major problem in clinical management of injured brain tissue without complicated surgical intervention. The biomaterial scaffolds are based on functional self-assembling peptide hydrogels.
There are three distinct post-TBI responses that we can control with such implantable biomaterials: (a) enhanced angiogenesis, (b) immunomodulation, and (c) improved neuronal survival, recruitment of neural progenitor cells, neural sprouting, and synaptic restoration. Following implantation in the injured site in the brain, the peptides disassociate from the bolus, inducing angiogenesis, immunomodulation, and neuronal survival. The biocompatibility, tunable biodegradability, and facile material properties of the biomaterial platform complement the therapeutic efficacy of the peptide formulations. We compare the in vivo efficacy of the hydrogels in the injury site in a rodent model of TBI (fluid percussion injury) and determine the biodistribution of the hydrogels away from the injection site in a time-dependent fashion.

Self-assembled peptide hydrogels with covalently attached bioactive epitopes and sequestered immunomodulatory agents are promising materials for promoting neuro-regeneration after debilitating brain injury. Such injectable scaffolds that can create a neuroprotective niche after being injected in vivo have great potential for treatment of TBI, non-TBI stroke, and other ischemic conditions of the central nervous system.

4:45 PM SB08.05.12
Bioinspired Neuron-Like Electronics for Minimally Invasive Brain Probes Xiao Yang, Tao Zhou, Theodore Zwang, Guosong Hong, Yunlong Zhao, Robert Viveros, Tian-Ming Fu, Teng Gao and Charles M. Lieber; Harvard University, United States

As an important application of functional biomaterials, neural probes have contributed substantially to studying the brain. Bioinspired and biomimetic strategies have begun to be applied to the development of neural probes, although these and previous generations of probes have had structural and mechanical dissimilarities from their neuron targets that lead to neuronal loss, neuroinflammatory responses and measurement instabilities. Here, we present a bioinspired design for neural probes—neuron-like electronics (NeuE)—where the key building blocks mimic the subcellular structural features and mechanical properties of neurons. Full three-dimensional mapping of implanted NeuE–brain interfaces highlights the structural indistinguishability and intimate interpenetration of NeuE and neurons. Time-dependent histology and electrophysiology studies further reveal a structurally and functionally stable interface with the neuronal and glial networks shortly following implantation, thus opening opportunities for next-generation brain–machine interfaces. The NeuE subcellular structural features are shown to facilitate migration of endogenous neural progenitor cells, thus holding promise as an electrically active platform for transplantation-free regenerative medicine. Finally, I will discuss the potential application of NeuE to facilitate the recovery of brain injury.

Are Conducting Polymer Electrodes Capacitive or Faradaic? George G. Malliaras; University of Cambridge, United Kingdom

Organic electrochemical devices, which use conjugated polymers in contact with an electrolyte, have applications in bioelectronics, energy storage, electrocatalysis, and sensors. Their operation relies on the oxidation (electron loss) or reduction (electron gain) of the polymer, which are traditionally described as Faradaic processes that transfer charge. However, recent evidence from various devices based on poly(3,4-ethylenedioxythiophene) chemically doped with poly(styrene sulfonate) (PEDOT:PSS) is consistent with a purely capacitive process that stores charge. To clarify whether PEDOT:PSS is an exception or the rule and determine which processes are capacitive and which are Faradaic, solid-state physics methodology developed to understand the operation of organic light-emitting diodes can be used. Such studies can pave the way for device optimization.

9:00 AM *SB08.06.02/SB07.07.02
Fiber-Based and Nanomagnetic Neural Interfaces Polina Anikeeva; Massachusetts Institute of Technology,
Within 1.3L of human brain billions of neurons connected by trillions of synapses are continuously exchanging signals. These signals govern the inner workings of the nervous system, and the aberrations in communication between neurons and other cells within the brain are manifested as the neurological and mental conditions that increasingly affect our aging society. While clinically available devices lack the finesse of the neural circuits and drugs often come with unwanted side effects, our team leverages the principles of optoelectronics and magnetism to develop tools matching the signaling complexity of the nervous system and cause minimal disruption to natural physiological function.

My talk will discuss how multimaterial fiber technology can be leveraged to produce compliant and miniature devices capable of electrical and optical recording and stimulation of neural activity, and delivery and sensing of neurochemicals. I will further highlight how multimaterial fibers can be employed for neural repair following traumatic injury as well as the potential candidates for artificial muscles with future applications in prosthetics. The second half of my talk will focus on using iron-containing nanomaterials as transducers of magnetic fields to biologically relevant stimuli such as heat and force. By tuning magnetic nanomaterials properties in conjunction with magnetic field conditions, it is possible to independently control multiple heat- or force-dependent biological processes. Finally, iron-containing nanomaterials can be used to aid minimally-invasive delivery of neurochemicals via magnetothermal and electrocatalytic means.

*Microfabricated, Conformable Auditory Brainstem Implants—Materials and Technology Advances towards Clinical Translational*  
Nicolas Vachicouras¹, Christina Tringides², Osama Tarabichi³, Vivek Kanumiri³, Yohann Thenaisie¹, Florian Fallegger¹, Chris Brown³, Daniel Lee³ and Stephanie P. Lacour¹; ¹Ecole Polytechnique Federale de Lausanne, Switzerland; ²Harvard University, United States; ³Massachusetts Eye and Ear Infirmary, United States

The auditory brainstem implant (ABI) is a neuroprosthesis that provides sound awareness to deaf individuals who are not candidates for the cochlear implant. The ABI electrically stimulates the surface of the cochlear nucleus (CN) in the brainstem. The complex anatomy and physiology of the CN together with the poor spatial selectivity of electrical stimulation and inherent stiffness of contemporary implants lead to only modest auditory outcomes in ABI users.

We propose a soft conformable ABI electrode array to improve the biomechanical match of the man-made implant to the curved CN surface. The conformable implant provides stable positioning of the implant in vivo and enables higher selectivity of electrical stimulation. The soft neurotechnology leverages miniaturization, high performance thin-film materials, and engineered mechanical compliance to produce implants compatible with the demanding ABI surgical insertion and conformability to the curvature of the brainstem. We developed elastic micro-structured multilayers, a soft electrode coating, and transient surgical features that allowed the fabrication of a scalable ABI from miniaturized mouse implants to human-size arrays.

This talk will report on the microfabrication and scaling process, mechanical and electrochemical characterization of the compliant ABIs. The soft electrode specifications are very similar to those measured in clinical ABIs with average impedance at 1 kHz of 5.78 ± 0.62 kΩ (electrodes of 0.385 mm² surface area). In a mouse model, we show that soft neurotechnology can be implemented to reliably activate auditory neurons in vivo for up to 4 weeks, a mandatory step before evaluating longer, chronic use of the technology. In a human cadaveric model, we demonstrate that the soft ABI is robust to surgical manipulation and insertion into the lateral recess of the IVth ventricle, and displays improved electrochemical performance compared to current clinical devices.

*Conductive Hydrogel-Coated Cochlear Implants Improve Electrical Performance In Vivo*  
Ulises A. Aregueta Robles¹, Mario Huynh², Ashley Dalrymple², Bryony Nayagam³, James Fallon², Rob Shepherd², Rylie Green² and Laura Poole-Warren¹; ¹UNSW Sydney, Australia; ²Bionics Institute, Australia; ³The University of Melbourne, Australia; ⁴Imperial College London, United Kingdom

Aim: This study aimed to compare the chronic in vivo charge transfer properties of conductive hydrogel (CH) coated cochlear implant (CI) electrodes to traditional platinum (Pt) CI electrodes.
Background: CIs can improve quality of life in profoundly deaf people by restoring sound perception. Ideally, bionic devices should safely operate for a lifetime; however, host responses such as protein adsorption, inflammation and fibrosis can impact electrode impedance. These host responses can lead to inefficient stimulation and formation of toxic byproducts. CH coatings, based on poly(vinyl alcohol) (PVA) anti-fouling polymers modified with conductive polymers (CPs), can provide enhanced electrical properties, superior to those of traditional Pt electrodes. This technology can be directly coated onto metallic substrate of state-of-the-art bionic devices. This study tested the hypothesis that PVA conductive hydrogels can enhance safe charge injection and improve the quality of neural recordings.

Methods: CIs with 4 electrodes specifically designed for the rat cochlea were implanted for up to 5 weeks. The CH coating was fabricated using PVA hydrogel modified with 20 taurine groups for electrical doping and 5 methacrylate groups for crosslinking. The CP poly(ethylene dioxythiophene) (PEDOT) was galvanostatically grown through the hydrogel and arrays were ethylene oxide-sterilized (ETO) prior to implantation. Electrochemical impedance (EI), charge injection limits (CIL) and charge storage capacity (CSC) of electrodes was compared before and after implantation using a 3-electrode cell (vs Ag/AgCl). Sprague Dawley rats were unilaterally implanted with CH coated or uncoated Pt CIs. The animals were chronically stimulated using charge balanced biphasic pulses for ~20 hrs/week over the implantation period. To evaluate electrode performance in vivo, voltage transient impedance was measured 5 days/week, and EI, CIL and CSC was also recorded over the implantation period. Explanted electrodes were imaged using scanning electron microscopy (SEM) for evaluation of the CH attachment and for signs of Pt oxidation.

Results: Before implantation, EI of CH coated electrodes over a frequency range of 10Hz-50kHz was more than 3 times lower than uncoated Pt implants. CSC and CIL of CH-coated electrodes was over one and two orders of magnitude higher than Pt electrodes, respectively. During implantation periods, common ground impedance of CH-coated electrodes increased from ~4kW in the first week, and stabilized thereafter at ~6kW. In contrast, the impedance of Pt electrodes was approximately double that of CH immediately after surgery at ~8kW and after 2 weeks at ~13kW. Following implantation electrochemical impedance was maintained at close to pre-implantation levels in CH coated electrodes, which was significantly lower than in Pt. CSC and CIL remained stable, and ~60% in CH coated electrodes following implantation, but both were still ~10 times higher than the Pt CSC and CIL. Preliminary observations of SEM images (n=2) showed that the CH coat remained intact and did not cause any damage or signs of Pt oxidation were observed.

Conclusion: CH-coated cochlear arrays maintained enhanced electrical properties during and after implantation. These results support the potential of CH as an advanced electrode coating for cochlear implants with superior electrochemical performance than Pt electrodes.

10:45 AM *SB08.06.05/SB07.07.05 Towards Seamless Neural Implants/Tissue Integration Xinyan T. Cui; University of Pittsburgh, United States

Microelectronic devices placed in the nervous system present tremendous potentials for mapping neural circuits and treating neurological disorders. Currently, these devices often experience failures in part due to the electrical, mechanical, and biochemical, mismatch between the artificial device and neural tissue. Quantitative histology and 2 photon imaging have revealed neuronal damage and degeneration, inflammatory gliosis, blood brain barrier leakage and oxidative stress at the site of implants which may compromise the intended recording/stimulation/neurochemical sensing function. We use several biomaterial strategies to minimize these mismatches in order to achieve seamless and stable device-tissue interface. First, various conducting polymer based nanocomposites have been investigated as electrode coatings and facilitate the signal transduction/charge transfer between the ionically conductive tissue and the electrical device. Nanostructuring is employed to improve the adhesion, stability and charge injection and drug delivery capability of the conducting polymers to meet the material challenges in chronic interface. Secondly, to minimize the mechanical mismatch at the device-brain tissue interface, novel soft and elastomeric electrode materials have been developed with Young’s modulus approaching that of neural tissue (less than 1 MPa). Soft implants demonstrated reduced inflammatory tissue response in both CNS and PNS compared to stiff implants of
similar geometry and surface chemistry. Thirdly, bioactive approaches are being developed to modulate the biological responses. One approach is to modify the implant surface with biomolecules or biomimics. Surface immobilization with these bioactive molecules significantly improved neuronal health and inhibited the inflammatory tissue response around the implants. Alternatively, therapeutics that control inflammation, neurodegeneration and oxidative stress have been delivered systemically or locally. These bioactive approaches have demonstrated significant benefit in neural recording quality and longevity. The ultimate solution to a seamless device/tissue interface may be a combinatorial approach that takes advantage of multiple biomimetic strategies discussed above and beyond.

11:15 AM SB08.06.07/SB07.07.07
Design and Fabrication of Tissue-Mimicked Parylene C Based Neural Microelectrode Arrays Yu-Chih Chiu and Pochun Chen; National Taipei University of Technology, Taiwan

In recent years, implantable bioelectronics has raised huge interest, especially for neural diseases. Among them, devices with a nerve guidance to guide neuron growth can enhance neural regeneration for traumatic peripheral nerve injury. However, the commonly used nerve conduit cannot provide a spatiotemporal regulation and in-situ monitoring for localized neurons. Accordingly, in this study, an implantable neural device that is built with microelectrode arrays on transparent and flexible substrate was developed to enhance cell growth through applying electrical stimulation and neural signals recording in a tissue-mimicked microenvironment. A new type of flexible substrate, nanoporous Parylene C, was designed and fabricated to exhibit tissue-mimic structural and mechanical properties. The microelectrode array, iridium oxide electrode for both neural stimulation and recording, was pre-deposited on a water-soluble sacrificial layer of poly acrylic acid (PAA) prior to the transfer print process. Such transfer printed tissue-mimic neural microelectrode array enabled conformable adhesion on a curvilinear nerve surface and electrical signals transduction from the microelectrode site, which is expected to provide higher performance of peripheral nerve regeneration. In addition, we characterized and evaluated the microelectrode array of iridium oxide film, including charge storage capacity, charge injection capability, and electrochemical impedance.

Membrane Nanomaterials with Controllable Mechanics for Delivery Applications Fereshtehsadat Mirah, Yifei Wang, Mohammad Reza Abidian and Sheereen Majd; University of Houston, United States

Lipid vesicles, also known as liposomes, present simple yet highly versatile nanocarriers for delivery of therapeutic and diagnostic agents. Composed of one of the most abundant biological molecules, lipids, these carriers have similarities to biological membranes and are thus, biocompatible, biodegradable, and easy to decorate on the surface. The lipid membrane in a liposome encloses an aqueous volume and therefore, liposomes are soft and highly deformable. Recent studies on delivery nanomaterials have suggested a prominent role for the mechanical aspects of these materials in their delivery performance (e.g. biodistribution). To enable variation of mechanical properties in liposomes, here we incorporate hydrogel materials in the lumen of liposomes. In this study, we present a straightforward and reliable technique for fabrication of nano-scale liposomes filled with photo-crosslinkable hydrogel, poly(ethylene glycol diacrylate) (PEG-Da). This technique relies on the lipid film hydration, extrusion, and proper incorporation of the photoinitiator into the liposomes followed by UV exposure to form a cross-linked hydrogel within the lumen of liposomes. We assess the resultant gel-filled liposomes for size and morphology using dynamic light scattering and scanning electron microscopy and confirm the presence of PEG hydrogel in the lumen of liposomes. We demonstrate that the present approach can successfully produce gel-filled liposomes with size range of 150-300 nm size. These gel-filled liposomes show good colloidal stability under physiological condition for at least 6 days. We demonstrate that this method allows for (i) changing the lipid composition of membrane and (ii) changing the hydrogel volume percentage. Mechanical testing of bulk hydrogels with various PEG-Da volume
percentages revealed that increasing the PEG-DA volume percentage (10-40%) results in a significant increase in the elastic modulus of the hydrogel (0.1-6 MPa). The resultant gel-filled liposomes can, therefore, offer various levels of mechanical elasticity. Such membrane nanomaterials provide exciting and controllable platforms for delivery of therapeutic and/or diagnostic agents for different medical or biomedical applications.

SB08.07.02
Investigating Neurogenic Differentiation of Dental Pulp Stem Cells Using PLA and Graphene Thin-Film and Electrospun Fiber Scaffolds in Vitro Dipen Mehta, Michael Stabile, Nicholas Stabile, Daniel Luo, Kuan-Che Feng, Marcia Simon and Miriam Rafailovich; Stony Brook University, United States

Dental pulp derived cells are pluripotent stem cells which can be differentiated along odontogenic, osteogenic, adipogenic, or neurogenic lineages. Odontogenic and osteogenic differentiation, in the absence of dexamethasone, have been shown to be highly dependent on substrate morphology and mechanics. Here we focus on neurogenic differentiation, using the protocol described in [1], and its dependence on substrate nature. DPSCs were cultured on PLA, a biodegradable polymer approved for internal use. The upregulation of genetic markers was compared with that of cells plated on standard TCP. The role of substrate morphology was investigated by plating on electrospun fibers approximately 2.0 ± 1.0 μm in diameter and on spin-cast thin films. The influence of electrical conductivity was investigated through the addition of 3% and 10% graphene nanoparticles to the films and fibers respectively. The aspect ratio of the cells was measured using confocal microscopy. Cells grown on graphene containing substrates had larger aspect ratios than their non-graphene counterparts, and cells grown on microfibers were longer than their counterparts on the flat films. But the cell aspect ratio did not necessarily correlate with genetic differentiation. The results after 21 days of incubation indicated that early markers (TBP, β-III tubulin), decreased uniformly on all substrates relative to day 0, with the largest decrease occurring on the PLA flat film with graphene. The late stage marker, NEFM, which indicates differentiation, was upregulated to a significantly larger extent on all PLA substrates. No difference was observed between the fibers and the flat film in the absence of graphene, thus morphology did not play a significant role on this polymer. Addition of graphene did not affect the outcome on the fibers, but significantly suppressed the gene expression on the flat films. These results indicate that PLA is a promising scaffold material for neurogenic differentiation.

SB08.07.03
Development of Novel Cerebral Aneurysm Embolization Method via Injection of Pluronic® F-127 Multiblock Copolymer Hydrogel Ikshu Pandey1, Divya Rai-Gersappe1, Rithu Paramesh1, Kevin Yang1, Finnur Christianson1, Aaron Sloutski2, Daniel Cohn2, Dennis Galanakis1, Chandramouli Sadasivan1, Juyi Li1 and Miriam Rafailovich1; 1Stony Brook University, The State University of New York, United States; 2The Hebrew University of Jerusalem, Israel

Intracranial aneurysms are a serious condition, affecting approximately 6 million people annually. The current method of treatment, endovascular coiling, utilizes a catheter to release platinum coils directly into the aneurysm which promotes diversion of blood flow. However, coiling is reported to be thrombogenic, and induces recanalization[1]. In order to circumvent these problems, we propose an alternative approach, where polymer gels are directly injected into the aneurysm. In this manner, the polymer can be engineered to occlude blood flow, while promoting endothelialization and minimizing thrombogenesis. A silicone model was 3-D printed from a cone CAT scan of a goat aneurysm. The model was connected to a peristaltic pump which simulated the pulsatile blood flow in the carotid artery. The polymer gels were then injected directly into the model, maintained at 37°C, via a Stryer Catheter, under radiological imaging. Two types of gels were tested. A physical gel composed of F127 Pluronic micelles was injected at 4°C, but warmed above the gelation temperature immediately after reaching the aneurysm. The retention time of the gels was then probed by x-ray imaging with induced contrast. Mixtures of F127 copolymer with multipblock (n=6), PF127 were tested in order to optimize retention time and injection viscosity. The F127 group of polymers are non cell-adhesive, and may need further modification to promote endothelial migration. Gelatin, was mixed with matri-gel or fibrinogen, injected, and gelled 37°C, using MTG. Endothelization was found to be successful on this surface. In this case, retention times in excess of 76 hours were determined. Even though both gelatin and Pluronic copolymers are presumed to be minimally thrombogenic, thrombus formation in both cases will be probed directly by circulation of platelet rich plasma across the aneurysm.

SNAPflex—A Paper-Based Nucleic Acid Preparation, Storage and Shipping Device for Molecular Diagnostics  
Catherine Klapperich1, Nikunja Kolluri1, Mario Cabodi1, Nikolas Albarran2, Jose Gomez-Marquez2 and Anna Young2;  
1Boston University, United States; 2Makerhealth, Inc, United States

One strategy to decrease the cost and increase the use of nucleic acid amplification tests is developing sample collection technologies that reduce or eliminate the need for a cold chain for storage and transport. Blood is usually collected at a satellite collection site (SCS) via venipuncture and shipped to the testing laboratory. The cost of sample preparation steps are borne by the central lab, and the cost per test varies per result delivered to the patient depending on the local health system. The cost of transport and associated sample preparation is about 80% of the total cost per result for many important tests in low resource settings. Removing the cold chain for blood sample transport would greatly reduce costs of blood testing for the patient, the SCS and the central lab. Without a cold chain requirement, sample collection can be carried out closer to the patient, reducing travel and opportunity costs. If the SCS does not have to maintain special storage on site, samples can be collected, batched and sent on a regular schedule to the central testing facility, thus reducing costs. If the sample collection method also prepares the sample for direct input to a NAAT, significant costs can be offset at the central lab.

We translated our three dimensional microfluidic blood sample preparation technology (SNAP) into a two dimensional flexible blood sample nucleic acid (NA) sample preparation card (SNAPflex). The final prototype uses commodity grade self-laminating plastic sheet for the top cover, heat sealing thermal plastic (5 mil) for the waste pad cover and base layers, Ahlstrom 320 thick chromatography paper for the waste pad, and a Millipore 0.7um glass fiber filter without binder for the nucleic acid capture membrane. Everything except the capture membrane was cut on Trotec Speedy 100 laser cutter. The capture membrane was cut on Graphtec FCX200-60VC cutter plotter. The design allows for roll-to-roll processing with two pick and place steps to add the waste pad and the sample capture filter. These parts can be die cut from separate materials in another roll-to-roll process.

We demonstrate the utility of SNAPflex in extracting HIV RNA from whole virions spiked into whole blood. Our
results indicate consistent recovery across four logs of input virion concentrations. An initial comparison with QIAGEN QIAamp viral extraction kit shows that SNAPflex has superior recovery. QIAGEN extraction requires an initial plasma separation prior to viral RNA extraction requiring centrifugation while SNAPflex can process whole blood using passive wicking only, indicating not only performance improvement but also simplified sample processing. In stability experiments, in vitro transcribed RNA for the HIV gag gene was prepared. Samples were processed on the SNAPflex devices. For Day 0 and no template control conditions, samples were immediately eluted and analyzed by RT-qPCR analysis. For extended time point samples (Days 1 – 14), after drying, the sample capture membranes were transferred to mylar zip-top bags containing silica packets that were sealed using a heat sealer. At the appropriate time points (1, 7, or 14 days post sample processing), the samples were eluted and analyzed by RT-qPCR. In vitro transcribed RNA for the HIV gag gene was used for standard curve analysis with input concentration ranging from $10^4$ cp/mL to $10^7$ cp/mL. These data indicate that RNA extracted by SNAPflex remains stable on the capture membrane for 14 days, demonstrating its potential for use in a field-based HIV viral load monitoring program without the need for a cold-chain.

9:00 AM *SB09.01.02
**Single-Cell Functional Profiling of CAR-T Cell Activation States** Rong Fan; Yale University, United States

The activation of CAR-T cells is through the binding of CAR to a surface marker such as CD19 expressed on the tumor cells and the subsequent signal transduction to its intracellular domain such as CD28/CD3z to elicit effector responses, which is independent of the conventional T-cell receptor (TCR) and peptide major histocompatibility complex (p-MHC) pathway. Therefore, the mechanism of CAR-T activation could differ substantially from that of classic T cells, which still remains inadequately studied but essential to the quality control of CAR-T products and the design of future CAR therapies. In this talk, I will present single-cell level transcriptional and cytokine profiling of anti-CD19 CAR-T cell activation states upon antigen-specific stimulation. We found that the predominant response is a highly mixed $T_{HL1}/T_{HL2}$ functional state in the same cell and the regulatory T cell ($T_{reg}$) activity, although observed in a small fraction of activated cells, emerges from this hybrid $T_{HL1}/T_{HL2}$ population. Surprisingly, the cytokine response is largely independent of differentiation status. This explains in part the functional proteomics data generated through collaborations with Novartis and Kite Pharma, showing that ‘polyfunctional’ CAR-T cells correlate with antigen-specific activation as well as the objective response of patients in clinical trials. Our work provides new insights to the mechanism of CAR activation and implies the necessity for cellular function assays to characterize the quality of CAR-T infusion products and monitor therapeutic responses in patients.

9:30 AM SB09.01.03
**Increasing the Dimensionality of Single Cell Transcriptomics to Address Systems Biology—Proteins, Imaging and More** Alexander Xu1,2, Qianhe Liu1, Kaitlyn Takata1, Sarah Jeoung1, Yapeng Su2, Sisi Chen1, Igor Antoschechkin1, Matthew Thomson1 and James R. Heath1; 1California Institute of Technology, United States; 2Institute for Systems Biology, United States

Systems biology is concerned with the complex interactions within and between cells that animate biology and create organisms that are more than the sum of their parts. This is currently exemplified in the field of single cell transcriptomics, where thousands of cells are analyzed with thousands of degrees of freedom, revealing novel cell types and interactions in heterogeneous tissues and diseases like cancer. One caveat however, is that single cell transcriptomics addresses a single class of molecules, poly-A-tailed mRNA, while systems biology has proven that proteins, lipids, metabolites, and more all play important roles. Here we demonstrate new methods to extend the functionality and dimensionality of single cell transcriptomics methods to address the concurrent biology of single cells beyond transcriptomics. This addresses the critical question of how different classes of molecules interact in single cells, and how this multi-modal heterogeneity manifests in biology. Current methods of multi-modal single cell analysis require interconversions of measurements, resulting in inevitable signal losses. Here we show that a microfluidic chip can integrate proteomic and transcriptomic measurements by embedding location information within transcriptomic measurements. The transcriptome is sequenced, while proteins are measured by fluorescent immunoassays. This is done with a location encoding strategy and microfluidic flow patterning, linking single cell transcriptomics captured by Dropseq-style bead based methods to single cell protein measurements made using DNA-Encoded Antibody Libraries. With this method, we measure full transcriptomes as well as proteins localized to the cytosol, mitochondria, and nucleus within the same single cells. We then show how this generalized strategy
can be extended to augment single cell transcriptomics with completely orthogonal measurements, such as fluorescent measurements of glucose uptake and imaging analyses, to extend the reach of multi-modal single cell measurements in new directions.

9:45 AM SB09.01.04
A Standalone, Reusable and Portable Microfluidic Device for Single-Cell Transcriptomic Analysis of Breast Cancer in Hypoxic Tumor Microenvironment Yanxiang Deng and Rong Fan; Yale University, United States

We present a standalone, reusable, and portable microfluidic device for single-cell transcriptomic analysis. The microchip platform is designed for performing single-cell capture and lysis directly toward 3’ mRNA sequencing. The presented approach offers format flexibility with a simplified, widely adoptable workflow that reduces the number of preparation steps and hands-on time, with the quality of data and cost per sample matching that of the state-of-the-art scRNA-seq platforms. Through this approach, we profiled thousands of single cells from mouse whole breast tumor and successfully identified different cell types from tumor microenvironment (e.g. tumor cells, tumor-associated macrophages, fibroblasts, B cells, and T cells). In addition, we studied the heterogeneity in tumor hypoxia in human breast cancer cells both in vitro and ex vivo and found a unique cell subset in the ex vivo model.

Single-cell RNA-sequencing (scRNA-seq) is becoming a popular tool in biology research to examine the heterogeneity of complex samples, identify distinct cell subsets, and dissect cell differentiation processes and lineage commitment. While many platforms are now available utilizing various approaches, one of the most commonly used techniques involves co-isolating each single cell with a uniquely barcoded mRNA capture bead as the enabling step for preparing barcoded libraries. Droplet-based microfluidic techniques and microwell arrays have been one of the widely used approaches to achieve such cell-bead co-isolation, however, they require major capital, peripheral equipment, and complex fabrication process, which limits their wide-spread adoption. Therefore, a more accessible method should be developed to be practically used for potential applicability in numerous cell biology and clinical applications.

Our platform is composed of three components: (1) PDMS microwell array, in which single cells and mRNA capture beads are co-isolated; (2) parafilm flow channel, which is to introduce cells and reagents using a laminar flow profile; and (3) acrylic clamp, which is to create a closed environment. This format is particularly advantageous due to increased consistency, higher cell loading efficiency (~50%), reduced cell consumption (~500 cells total), and high beads loading efficiency with minimal waste of barcoded beads (>99% bead loading efficiencies). It also should be noted that the easier fabrication and assembling process can facilitate the wide-spread adoption of this platform across different laboratories.

To validate the device’s overall workflow and its technical performance in resolving populations of cells in complex primary samples, we profiled thousands of cells from a mouse breast tumor. After sequencing and alignment, unsupervised graph-based clustering was implemented, revealing unique subpopulations in the breast tumor microenvironment, including tumor cells, tumor-associated macrophages, fibroblasts, B cells, and T cells.

Finally, the heterogeneity in tumor hypoxia in human breast cancer was studied both in vitro and ex vivo. Single cells from normoxia and hypoxia conditions were processed by this platform separately, and the downstream data analysis revealed heterogeneous cellular responses under hypoxia environment and found a unique cell subset in the ex vivo model.

10:30 AM SB09.01.05
Developing Upconverting Nanoparticles as a Novel Tool to Probe Mechanical Forces of the Immune Synapse Claire A. McLellan, Stefan Fischer, Chris Siefe, Alice Lay, Abhinav Parakh, Vincent Van Unen, Mark M. Davis, Miriam B. Goodman, Wendy Gu and Jennifer A. Dionne; Stanford University, United States

Mechanical forces play a prevalent role in the immune system, particularly during the formation and duration of an immune synapse. During the synapse, a T-cell must latch onto a pathogen-primed antigen-presenting cell (APC) while enduring shear flow forces. These mechanical forces, which range from 10 pN to 100 nN, are thought to be crucial to immune cell-to-cell interactions but directly measuring them remains an open challenge. Traditional
methods of measuring cellular forces such as traction force microscopy (TFM) and FRET sensors have limitations when measuring the immune synapse. TFM cannot be employed in vivo or between cells, while FRET sensors generally bleach over the multi-hour-long duration of the synapse.

Here, we present a novel mechanical force sensor based on upconverting nanoparticles (UCNPs), which can detect inter-cellular forces throughout the formation and duration of an immune synapse. These nanoparticles absorb near-infrared light and emit visible light, with a ratiometric color response that depends on the applied force. Using solvothermal techniques, we synthesize ~11 nm diameter UCNPs comprised of alkaline-earth rare-earth fluoride host lattices (CaLuF, SrLuF, and BaLuF) doped with 30% Yb\(^{3+}\) and 2.9 % Er\(^{3+}\). As a control, we also synthesize cubic-phase NaYF\(_4\) host lattice particles doped with 28% Yb\(^{3+}\) and 2.8% Er\(^{3+}\). X-ray diffraction and transmission electron microscopy confirm that the synthesized nanoparticles are all phase-pure (cubic) and monodisperse. We record upconversion spectra as a function of applied pressure using a diamond anvil cell. When excited at 980 nm, the nanoparticles emit predominately at 550 nm (green) and 660 nm (red), with a red-to-green intensity ratio (I\(_{R}\)/I\(_{G}\)), and hence color that depends on pressure. For the four materials, CaLuF, SrLuF, BaLuF, and NaYF\(_4\), we measure a percent change in (I\(_{R}\)/I\(_{G}\)) per pressure response. The pressure responses for the particles are 38 ± 4, 16.3 ± 0.6, 12.8 ± 0.9, and 40 ± 4 %IR/IG/GPa for CaLuF, SrLuF, BaLuF, and NaYF\(_4\) respectively. The response of all particles measured remains consistent over three pressure cycles, demonstrating their cyclability. Upconversion quantum yield was also studied to determine the brightness of the particles. The upconversion quantum yields for the CaLuF, SrLuF, and BaLuF particles are 0.18%, 0.53%, 0.19% at 80 W/cm\(^2\) respectively \[1\]. We find that SrLuF particles are our most sensitive particles with the highest quantum yield of 0.53% at 80 W/cm\(^2\) and the lowest noise force response at 16.3 ± 0.6 %IR/IG/GPa. We can detect mechanical pressures down to 37 MPa corresponding to 27 nN of force, a value within the range useful for the immune synapse.

Furthermore, we are exploring how to integrate UCNPs into an immune synapse between T-cells and APCs. Through charge stabilization and adding amino-functionalization groups to our UCNPs we are working towards functionalizing UCNPs to attach to the cell membrane of APCs. We will also investigate the cytotoxicity of our particles. With our highly force sensitive UCNPs, we are working towards unraveling the mechanisms of the immune synapse.

Magnetic Isolation and Identification of Exosomes Using Magnetic Nanowires Zohreh Nemati Porshokouh\(^{1,1}\), Javier Alonso Masa\(^{2}\), Mohammad Reza Zamani Kouhpanji\(^{1}\), Joseph Um\(^{1}\), Yali Zhang\(^{1}\), Lucía Gandarias\(^{3}\), David Gandia\(^{4}\), Alicia Muñal\(^{5}\), Maria Luisa Fdez-Gubieda\(^{4,3}\), Rhonda Franklin\(^{1}\), Jaime Modiano\(^{1,1}\) and Bethanie Stadler\(^{1,1}\); 1University of Minnesota, United States; 2Universidad de Cantabria, Spain; 3Universidad del País Vasco, Spain; 4BCMaterials, Spain

We are developing segmented magnetic nanowires (MNWs) as a new platform for highly specific biolabels. We found that cancer cells internalize MNWs and package them into exosomes, which are then secreted for several days. These MNWs thus enable magnetic isolation of exosomes, which could prove useful in future diagnosis. Our immediate goals are to study how cells internalize MNWs, to determine the timing and reproducibility of exosome secretion, and to improve the magnetic isolation of exosomes. Following this work, we aim to use ferromagnetic resonance (FMR) to identify specific MNW biolabels, similar to radio frequency identification (RFID). In addition, we can compare the isolation efficiency we have employed high quality magnetite nanoparticles synthesized by magnetotactic bacteria (magnetosomes).

In this study, we incubated osteosarcoma (OSCA-8) cells with Fe/Au segmented MNWs with and without PEG coating for 48 hours. Internalization of MNWs as a function of concentration (5-40 μg/ml) was followed by fluorescence and transmission electron microscopy (TEM). We obtained quantitative estimates of MNW internalization by magnetic measurements. Our experiments indicated better internalization of the MNWs using PEG as a capping agent. As we increased the concentration of MNWs, both the number of cells with MNWs and the number of MNWs per cell increased. TEM images show that after uptake by cancer cells, MNWs were predominantly located within lysosomes, and they appeared to be fragmented into small segments of similar size as exosomes. These segments were mostly composed of either Fe or Au, suggesting that fragmentation occurred at or near the boundary of segments. In the case of magnetosomes, we also observed that they were internalized inside lysosomes, but their morphology remained intact.
We used two different methods for exosome isolation: non-magnetic isolation (centrifuge and ExoQuick TC) as a control and magnetic isolation. We incubated OSCA-8 cells with different concentrations of MNWs (0 to 35 μg/ml), and exosomes were isolated for up to 11 days. We analyzed the exosome size distribution using a nanoparticle tracking analyzer (NanoSight) and found that exosomes isolated magnetically, both with MNWs and magnetosomes, had similar size distributions as those isolated non-magnetically. A minimum concentration of 25 μg/ml MNWs in 3×10⁵ cells was required for appreciable magnetic isolation. Increasing the concentration of MNWs progressively; however, isolated microvesicles that had wider and more heterogeneous size distributions. TEM images of exosome isolated magnetically show that these exosomes packaged small pieces of MNWs.

Next, we successfully identified two different types of MNW biolabels by FMR. MNWs were fixed in a polymer that was placed onto an RFID chip. Each type of MNW exhibited a unique RF signature as the sample was exposed to an external magnetic field.

Our preliminary data show that MNWs appear to allow fast, inexpensive magnetic exosome isolation and is our future goal is MNW identification of exosomes. The methodology developed in this study should be transferable to develop comparable approaches to isolate and identify exosomes from virtually any type of cell.

Aptasensor-Encoded DNA Flowers for Monitoring ATP Dynamics in Living Cancer Cells
Nayoung Kim, Eunjung Kim, Hyemin Kim, Michael R. Thomas and Molly Stevens; Imperial College London, United Kingdom

There is a fundamental interdependence of adenosine triphosphate (ATP) dynamics and cancer development, given that ATP is required for a range of biosynthetic pathways during cancer cell proliferation, migration, and invasion. As a facile tool to monitor the ATP dynamics, biologically-deliverable nanoprobes have drawn increasing attention as an alternative to protein-based biosensors that require extensive genetic engineering for sensor-encoded cells. Nonetheless, challenges have remained with in vitro stability and toxicity issues of the nanoprobes, false positive signals that derive from cellular autofluorescence, and difficulties in normalisation of the intensimetric signals. Here, we present a programmable DNA-inorganic hybrid composite (termed as DNA flower, DNF) as a conjugation-free nanoprobe, enabling imaging of ATP dynamics in living cells upon the selective receptor-mediated internalization. The aptasensor-encoded DNF with two dye pairs achieved FRET-based ratio-metric imaging, where ATP recognition events trigger conformational changes of the aptamer within the composites and change the two fluorescence emission profiles. To the best of our knowledge, this system represents the first example of intracellularly deliverable probes that allow ratio-metric, spatial and temporal measurements of ATP levels in living cells. Capitalising on the structural stability of the DNF against nuclease degradation [1, 2], the developed probes achieved reliable and sensitive detection of changes in cytosolic ATP levels under exposure to various therapeutic agents over the time period. Given the versatility and robustness of the proposed DNA-based nanoprobes, it paves the way for facile, semi-quantitative tool-kits to monitor abundance of intracellular biomolecules during biological processes in cells.

Molecular Recognition and Sub-Cellular Detection of Temozolomide and 4-amino-5-imidazole-carboxamide for Glioblastoma Using Fluorescent Nanosensors
Manki Son, Freddy Nguyen, Punit Mehra, Michael A. Lee, Naveed Bakh and Michael Strano; Massachusetts Institute of Technology, United States

The efficacy of chemotherapeutics such as temozolomide and its decomposition, active product 4-amino-5-imidazole-carboxamide is often affected by the timing, quantity and frequency of dosages. There is strong interest in facilitating the ability to monitor efficacy in individual patients for specific subtypes of cancer. Real-time, dynamic measures of potency may also supplement or in some cases replace reliance on bio-imaging. Towards this end, in this work we develop new, synthetic molecular recognition sites for temozolomide, and its decomposition product AIC, grafting them onto near infrared fluorescent nanoparticles capable of forming optode or other biosensor interfaces to monitor drug efficacy in real-time. Infrared fluorescent single-walled carbon nanotubes, which have a specific DNA wrapping, are encapsulated with poly(ethylene glycol) diacrylate hydrogels and enable the selective recognition of an anti-cancer drug, temozolomide, on U-87 MG human glioblastoma cells. In both solution phase and hydrogel form, the sensors were responsive to temozolomide and show detection limit of 30 uM. Furthermore,
cells exhibited no changes in viability for 7 days when in interfaced with the hydrogel. The sensors were used to track the progression of glioblastoma death following temozolomide administration. By providing real-time information of local chemotherapeutic concentration, our technology has the potential to increase the efficacy of cancer treatments.

11:30 AM SB09.01.09
Tumor-Specific Extracellular Vesicles Unveiled by Size-Specific Single-Vesicle Analysis Yoon-Kyoung Cho1,2, Dongyoung Kim1, Hyun-Kyung Woo2, Chaehee Lee2 and Yoo-hong Min1; 1Institute for Basic Science, Korea (the Republic of); 2UNIST, Korea (the Republic of)

Extracellular vesicles (EVs) are nano-sized vesicles that carry complex cargoes of lipids, proteins, and nucleic acids depending on the biogenesis and the cell origin. Tumor-derived EVs have emerged as a promising circulating biomarker for liquid biopsy application. However, finding tumor-specific EVs among a heterogeneous population of EVs remains as a major challenge. Here, we extend our EV isolation disc to enrich EVs in three different size fractions; large EVs (L-EVs; 200–1,000 nm), medium EVs (M-EVs; 100–200 nm), and small EVs (S-EVs; 20–100 nm). This centrifugal microfluidic platform allows not only enriching EVs in three size portions but also fluorescently staining for the protein profiling of individual EVs. Combining single-particle localization techniques in super-resolution microscopy and machine learning-based classification analysis, we visualize and analyze the biomarker contents in individual EVs. As a proof-of-concept, we analyzed the presence of human epidermal growth factor receptor 2 (HER2) or prostate-specific membrane antigen (PSMA) in breast cancer cell- or prostate cancer cell-derived EVs, respectively, using the three different size fractions at the single-EV level. By reducing the complexity of EV heterogeneity in each size fraction, we found that HER2-positive breast cancer cells showed the greatest expression of HER2 in S-EVs, whereas PSMA expression was the highest in L-EVs derived from prostate cancer cells which were further confirmed using plasma-derived EVs obtained from prostate cancer patients. Our study suggests the EV heterogeneity will be broken down in several populations in specific size fraction, cell type, and biomarker using the size fraction disc with single EV analysis. Our study demonstrated that single-EV analysis could successfully identify potent subpopulations of cancer type-specific EVs, which has promising translational implications for cancer theranostics.
samples, computational approaches, and decellularized ECM models we found that breast adipose tissue contains more M2-biased than M1-biased macrophages across all body mass index (BMI) categories. Obesity further increased M2-biased macrophages but did not affect M1-biased macrophage density. Gene Set Enrichment Analysis (GSEA) suggested that breast tissue macrophages from obese women are more similar to tumor-associated macrophages (TAMs) than macrophages from lean women. These changes positively correlated with adipose tissue interstitial fibrosis, and in vitro experiments indicated that obese ECM directly stimulates M2-biased macrophage functions. Importantly, however, mammographic density cannot be used as a clinical indicator of these changes. Collectively, our data suggest that ECM microarchitecture can be an independent driver of obesity-associated fibrosis, but may also promote tumorigenesis by stimulating a macrophage phenotype similar to TAMs. These studies suggest a novel, ECM-driven link between obesity and breast cancer.

A 3D Bone Marrow Hydrogel to Study Metastatic Cancer Cell Drug Resistance and Dormancy Shelly Peyton; Univ of Massachusetts Amherst, United States

Three-dimensional (3D) synthetic hydrogels have recently emerged as desirable in vitro cell culture platforms capable of representing the extracellular geometry, elasticity, and water content of tissue in a tunable fashion. Hydrogels are typically decorated with 1-3 peptide moieties to direct cell behavior, which vastly underrepresents the proteins found in the extracellular matrix (ECM) of real tissues and provides a critical limitation in their biological functionality. Further, peptides chosen are ubiquitous in ECM and are not derived from specific proteins. We developed an approach to incorporate the complex protein signature of specific tissues into biomaterial design. Our hydrogel mimics the elasticity of marrow and has 20 marrow-specific cell-instructive peptides. Compared to generic PEG hydrogels, our marrow-inspired hydrogel improves stem cell differentiation and proliferation. Additionally, this hydrogel can be easily tuned to probe ECM-mediated cell signaling. Here, we made a collagen-null marrow hydrogel, and show that prostate cancer cell growth is dependent on this peptide in a nutrient depleted, marrow-like environment. We propose this tissue-centric approach as the next generation of 3D hydrogel design for applications in tissue engineering.

Engineering Oxygen-Depleting Cryogel Scaffolds for Anti-Cancer Drug Screening Thibault Colombani¹, James Sinoimeri¹ and Sidi Bencherif²,¹; ¹Northeastern University, United States; ²Harvard University, United States

Hypoxia, defined as low oxygen tension, is a characteristic feature of solid tumors and a hallmark of aggressive cancers. Metabolic adaptation to hypoxia leads to tumor cell growth and invasion, resistance to apoptosis, and multidrug resistance. For decades, a number of solid tumor models have been engineered to emulate key aspects of tumor biology such as hypoxia. However, challenges with tumor formation and reproducibility, inadequate biomechanical cues provided to cells, and uncontrolled oxygen depletion among other limitations led to non-physiological tumor cell responses and inaccurate clinical predictions to anticancer drugs. To model solid tumors more accurately, we have recently developed an innovative approach using porous cryogel scaffolds inducing rapid oxygen depletion while enabling cellular rearrangement into spherical-like cell aggregates within a three-dimensional (3D) polymer network. Our main objectives were: (1) to engineer hypoxia-inducing cryogels to induce cellular hypoxia; (2) to provide a biophysical support enabling tumor cell attachment, proliferation, and remodeling, and (3) to evaluate acquired resistance of hypoxic B16-F10 melanoma cells to anti-cancer drugs. Engineered oxygen-depleting scaffolds are capable of inducing local hypoxia while promoting tumor cell remodeling and aggressiveness, leading to anti-cancer drug resistance. Our preliminary data suggest that the tumor-cell laden hypoxia-inducing cryogels mimic key aspects of the native tumor microenvironment, making these advanced cellularized scaffolds a promising platform for drug screening in 3D and potentially improving anti-cancer drug development and discovery.

In Vitro Models for Design of Novel Cancer Metastasis Markers Kalpana Katti, Sumanta Kar, Haneesh Jasuga,
Bone tissue engineering is a promising technology for next generation regenerative medicine based therapies. In addition, these tissue engineered scaffolds can be used as testbeds to create humanoid cancer tumors at primary site and at metastatic site. In particular, breast and prostate cancer have the propensity to metastasize to bone at which point the disease is incurable. The design of in vitro testbeds is particularly attractive due to lack of availability of human samples at this stage of metastasis and failure of animal models (since animals die before metastasis to bone).

We have designed an amino acid modified nanoclay based polymeric scaffold for bone tissue engineering. This scaffold uses biomimetic mineralization of hydroxyapatite inside nanoclays galleries mimicking remodeling human, characterized by low Ca/P stoichiometry bone, a niche to which cancer cells migrate. On seeding the tissue engineered bone scaffolds with prostate and breast cancer cell lines led to the creation of tumoroids of cancer. The tumoroids exhibited a late stage metastasis as indicated by the gene expression and protein expression. Tumors were extracted from scaffolds and we conducted FTIR experiments as well as nanomechanical experiments at cancer metastasis progression from 0 to 20 days. Softening of tumors as well as increase in plastic deformations were captured at metastasis. In addition unique spectral markers of DNA, RNA, proteins and lipids were obtained that indicate progression of metastasis. Unique bone-biomimetic scaffolds provide new opportunities as testbeds to evaluate cancer metastasis.

Cancer Extracellular Vesicles Derived Supported Bilayers as a Cell Culture Platform to Understand Surface Interactions between Stem Cells and Extracellular Vesicles

Cancer is the second leading cause of death in the US and 92% of such casualties are due to metastasis. Thus, discovering mechanisms employed by cells to promote metastasis and developing strategies to stop them, are the main targets of cancer research. In particular, extracellular vesicles (EVs) shed from cancer cells, have been recently implicated as important mediators of cellular communication and are suspected to play an important role in metastasis. EVs are membrane-encapsulated vesicles known to shed from several types of eukaryotic cells. Extensive research has shown the existence of two major EVs subtypes, exosomes and microvesicles (MVs). Exosomes are vesicles generated from multivesicular bodies and secreted to the extracellular space by fusing with the plasma membrane. Exosomes are between 20 -120 nm in diameter. The second type, MVs, has a larger size range between 120 nm - 1μm in diameter. MVs are directly shed from the plasma membrane into the extracellular space, preserving native properties from the mother cell. EVs of both types contain different cargo including mRNA, DNA, proteins, and receptors. MVs and exosomes differ in biogenesis, cargo, and surface makeup. Research findings suggest that they have different intracellular routes and functions in cell communication. Therefore, it is imperative to distinguish between them since their functions and communication pathways may have different effects on cells. Both populations have been highlighted in research due to their capacity to facilitate intercellular communication. In that manner, interactions between EVs and host cells have been shown to lead to modifications in cellular behavior of the recipient cell. In the context of cancer, EVs are known to influence proangiogenic activity and transformation on adipose derived stem cell (ADSC) leading to cancer progression. How these interactions occur in the molecular level is not clear. Cues most certainly come from both membrane components on EVs, as well as their internal cargo. Yet, there is a lack of techniques to study those interactions in vivo. Hence, we developed an in vitro platform that allows the isolation and study of interactions between EVs surface and ADSCs. Using hybrid supported lipid bilayer techniques developed by our group and EVs derived from cancer cells, MDA-MB-231, we originated an EVs derived supported bilayer (ESB) as a model of EVs membrane. ESB is a planar, tunable platform that can serve as a cell culture substrate to study the effects and insights of interactions between EVs surface and ADSCs. To assure preservation of EVs membrane materials in our generated ESBs, TIRF microscopy was employed to detect expression of EVs markers specific to each EV population. Furthermore, ADSCs were cultured on ESBs and cell adhesion and spreading, cell viability, and cell VEGF production were analyzed. Our results showed that ADSCs cultured on ESBs displayed higher cell spreading, stronger focal adhesions, and higher VEGF production than cells on synthetic supported lipid bilayers. Therefore, we observed that EVs surface interactions with ADSCs enhances cell adhesion, spreading, viability, and proangiogenic activity.
related to high VEGF production. In all cases, the influence of ESB from both EVs populations followed the same pattern with MVs derived ESB having a larger effect on ADSCs behavior compared to exosomes derived ESBs. Consequently, we present our developed ESB, containing native composition of EVs membranes, as a cell culture platform to study interactions between EVs and stromal cells. Our method allows the production of different EVs populations derived ESBs to study individually the interactions of EVs and stromal cells and to decouple the biological outcomes produced by each of the EVs population. It could be utilized as a method to investigate cell to cell interactions, and extracellular particles to cell interactions for different types of cells and for several disease scenarios.

3:45 PM OPEN DISCUSSION

4:00 PM SB09.02.07
Polymer Nanoparticles for Detection and Ablation of Colorectal Cancer Tumor Organoids Bryce D. McCarthy1,1,2, Amit Cudykier1, Shay Soker1,2 and Nicole Levi-Polyachenko1,2; 1Wake Forest University, United States; 2Virginia Tech, United States

Our group has recently developed Hybrid Donor-Acceptor Polymer Particles (HDAPPs), nanoparticles composed of the fluorescent polymer poly[(9,9-dihexylfluorene)-co-2,1,3-benzothiadiazole-co-4,7-di(thiophen-2-yl)-2,1,3-benzothiadiazole] (PFBDTB10) and the heat-generating polymer poly[4,4-bis(2-ethylhexyl)cyclopenta[2,1-b;3,4-b']dithiophene-2,6-diy-alt-2,1,3-benzoselenadiazole-4,7-diyl] (PCPDTBSe) to create a theranostic platform. HDAPPs can be activated via 450 nm laser exposure for fluorescent imaging within the NIR tissue absorption minimum by exploiting an amplified energy transfer between the PFBDTB10 and PCPDTBSe polymer components, emitting at 825 nm. Additionally, HDAPPs can be activated by 800 nm laser exposure for photothermal ablation of colorectal cancer (CRC). To actively target CRC, HDAPPs were functionalized via hyaluronic acid (HA) coating of the NP surface to exploit overexpressed CD44 receptor on CRC. A major hurdle for the clinical translation of NPs is their interaction with the 3D tumor microenvironment, where NP transport and photothermal heat dosing may be isolated to the outermost shell of the tumor that maintains direct exposure to the nanotherapeutic. To study the targeted fluorescent detection and heating potential of HDAPPs in the 3D tumor microenvironment, we investigated the encapsulation of tumor cells in a specialized hydrogel (3D organoid) in vitro. Further, to monitor HDAPPs-mediated ablation in real-time within organoids, we demonstrated the utility of a unique fiber-optic-based (FOB) imaging system capable of laser-induced point excitation and fluorescent image reconstruction in opaque media. HDAPPs were first synthesized using the nanoprecipitation technique, where an aqueous phase consisting of Pluronic F127 surfactant is interfacial via sonication with an organic phase of the polymer constituents to create HDAPPs nanoemulsions. HDAPPs were then coated with chitosan and further targeted to CD44 receptor via coupling of HA to the surface. Selective binding and ablation of CT26 CRC cells in 2D was demonstrated with HA-targeted NPs under photothermal activation with 800 nm stimulation, where HA-targeted NPs displayed increased binding relative to non-functionalized NPs and, upon photothermal activation with laser, CT26 cells incubated in 2D with HA-targeted NPs demonstrated a respective decrease of viability by 40%. Photothermal ablation of CT26 cells expressing green fluorescent protein (CT26.GFP) and encapsulated in 3D organoids was next assessed. HA-targeted NPs decreased cell viability in organoids by 60%, though ablation in 3D organoids occurred only under increased laser fluences in comparison to 2D culture, demonstrating decreased efficiency of photothermal therapy in 3D-tumor like conditions. A major therapeutic hindrance in therapy is diffusion limitation in tumors, where HDAPPs diffusion was measured by exposing HDAPPs to the outer surface of organoids and monitoring via confocal microscopy for up to 24 hrs. Diffusion studies showed that at least 12 hours exposure to therapeutic concentrations is necessary to achieve ablative potential. Finally, to demonstrate FOB imaging compatibility with the 3D tumor environment, organoids with CT26.GFP cells and non-functionalized HDAPPs were imaged by FOB laser excitation and fluorescent images were successfully reconstructed that map to control images. The results of this work demonstrate the performance of a unique NP platform capable of detecting and ablating CRC within the tumor microenvironment. Coupling of organoids with the FOB imaging device demonstrates a preclinical system that can simultaneously assess CRC detection and ablation with NP therapeutics, where we aim to both develop an organoid platform for proper preclinical translation of photothermal nanotherapeutics while investigating the properties of our own HDAPPs.

4:15 PM SB09.02.08
Breast Cancer Cells Transition from Mesenchymal to Amoeboid Migration in Tunable 3D Silk-Collagen
Hydrogels Amanda S. Khoo, Thomas M. Valentin, Susan E. Leggett, Dhananjay Bhaskar, Elisa M. Bye, Blanche C. Ip and Ian Y. Wong; Brown University, United States

Invading cancer cells adapt their migration phenotype in response to mechanical and biochemical cues from the extracellular matrix. For instance, mesenchymal migration is associated with strong cell-matrix adhesions and an elongated morphology, while amoeboid migration is associated with minimal cell-matrix adhesions and a rounded morphology. However, it remains challenging to elucidate the role of matrix mechanics and biochemistry, since these are both dependent on protein concentration. Here, we demonstrate a composite silk fibroin and collagen I hydrogel where stiffness and ligand density can be independently controlled. Using an overlay assay geometry, we show that the invasion of metastatic breast cancer cells exhibits a biphasic dependence on silk fibroin concentration at fixed collagen I concentration, with an optimum occurring at intermediate stiffness. Indeed, mesenchymal morphology exhibits a similar biphasic dependence on silk fibroin concentration, while amoeboid morphologies were favored when cell-matrix adhesions were less effective. We used exogenous biochemical treatment to perturb cells towards increased contractility and a mesenchymal morphology, as well as to disrupt cytoskeletal function and promote an amoeboid morphology. Overall, we envision that this tunable biomaterial platform in a 96-well plate format will be widely applicable to screen cancer cell migration against combinations of designer biomaterials and targeted inhibitors.

4:30 PM SB09.02.09
Programming Cellular Mechanophenotype Using Magnetically-Aligned Nanofiber Architectures Alex Hruska, Michelle Adler and Ian Y. Wong; Brown University, United States

Introduction: Cell polarity, morphology, and migration are regulated bidirectionally by nanotopographical cues from the extracellular matrix (ECM). In particular, ECM architecture may become dysregulated during wound healing or tumor progression with highly aligned and crosslinked fibrillar nanostructures. However, these fibrillar architectures are biophysically coupled to ligand density, stiffness, and other ECM properties, making it challenging to elucidate their individual contributions. Here, we elucidate how cells respond to 3D nanotopography using a composite hydrogel consisting of magnetically aligned ECM-coated nanoparticles embedded within a background hydrogel of gelatin methacryloyl. We show that by systematically varying the biophysical parameters of the fibrillar nanostructures or the background matrix, cell protrusions and morphology can be tuned to direct cell polarization and migration.

Materials & Methods: ECM-coated 300nm magnetic nanoparticles were dispersed in gelatin methacryloyl (GelMA) precursor solution and exposed to a magnetic field gradient, inspired by previous work from Tanner et al (Biomaterials, 197, 101-118, 2019). Nanoparticles assembled into chain-like fibrillar structures under optimized field gradients, which mimicked the dimensions of ECM fibers observed in vivo. Next, the GelMA was photocrosslinked using UV light with LAP as the photoinitiator. Various cell lines (e.g. MDA-MB-231 overexpressing GFP in the cytoplasm) were then cultured in this composite hydrogel and imaged using spinning disk confocal microscopy with environmental control. Time-lapse images were then analyzed using Bitplane Imaris and custom MATLAB code.

Results & Discussion: Nanoparticle assembly and GelMA hydrogel polymerization were optimized using a custom magnetic apparatus to uniformly disperse fibrillar nanostructures over millimeter scales in 3 dimensions. We optimized the length and diameter of these fibrils based on magnetic field gradient, and further characterized GelMA as a “blank slate” with amorphous topography, tunable stiffness, pore size, and RGD-binding sites. Finally, we show that by systematically tuning either the fibrillar topography or the background matrix, cell protrusive activity as well as migration velocities can be altered. For instance, highly metastatic MDA-MB-231 cells exhibit directed migration along fibers, where providing no magnetic alignment yields a uniform dispersion of particles and yields slow, random migration with short protrusions. In comparison, a stiff background matrix of highly cross-linked GelMA limits protrusive activity and migration, while softer more porous background matrix allows cells to extend long protrusion along engineered fibers and enables higher migration velocities. These migratory behaviors were perturbed by biochemical inhibition of integrins and the cytoskeleton, which were profiled using computer vision and machine learning.

Conclusion: We demonstrate a composite 3D biomaterial with orthogonally tunable fibrillar architecture, hydrogel chemistry, and stiffness to elucidate bidirectional interactions between cells and the ECM. We find that cell protrusions, morphology, and migration are biased by varying degrees of magnetic nanoparticle chaining, which dominate over the mechanochemical cues from the surrounding GelMA hydrogel. We implement this in a scalable...
format that is compatible with multiwell plates, which could be extended for high content screening. Thus, we envision that this technology could be utilized to systemically characterize mechanotransduction of ECM cues in the context of targeted drug perturbations.

Organ-on-chip systems are useful tools to fundamentally study the physiology of organs and tissues, to evaluate the efficacy or toxicity of drug compounds, or to study the effect of tensors on human tissues. However, to design and fabricate an organ-on-chip system is not a trivial task. Here we present an example of a step-by-step fabrication and validation of a 3D-printed microfluidic system that can be generically used to culture cells, micro-tissues, and organoids under well-controlled environments. The system is conformed by three compartments. The left and right compartments have one inlet and one outlet each, providing means to continuously feed liquid streams to the system. The central compartment is designed to host a cell-laden hydrogel where a microtissue can be confined and culture. A transparent lid and bottom can be adapted to enable visual inspection under a microscope.

We conducted fluorescent and saline tracer experiments to characterize the hydraulic performance of the system. In addition, we cultured MCF7-spheroids embedded in a cell-laden hydrogel construct (placed in the central chamber), to illustrate the use of this system to sustain long term micro-tissue culture experiments. We present experimental results that illustrate the flexibility and robustness of use of this 3D-printed device for tumor-on-chip experiments. This “open-source” organ-on-chip system is intended to be a general-purpose resource to facilitate democratize the development of new organ-on-chip applications.

Tristen Head¹, Suhasini Gattu¹, Rojin Jafari², Xianjun Ye², Natalya Tokranova¹, John Condeelis², David Entenberg² and Nathaniel Cady¹; ¹SUNY Polytechnic Institute, United States; ²Albert Einstein College of Medicine, United States

Simultaneous observation and induction of biomolecular changes in the tumor microenvironment are challenging to accomplish over extended periods of time. The effect of therapeutics on the target site is often obfuscated by systemic on- and off-target effects inherent in drug administration. Thus, localized delivery and high-resolution imaging are necessary to assess cellular response to changes in the tissue microenvironment. Here, we report on the design, fabrication and testing of a novel microfluidic imaging window (MFIW) using glass and SU-8 photoresist microfabrication techniques to actively deliver agents (e.g. drugs, antibodies, inhibitors, etc.) to underlying living tissue. Microfluidic channels were fabricated using multi-layer SU-8 patterning techniques on 12 mm glass coverslips. Point spread functions were compared between standard glass windows and MFIWs and optical performance of the MFIWs was validated with 2-photon microscopy (at 880nm) on transgenic MMTV-PyMT Dendra2 fluorescent tumors, which confirmed device applicability for biological studies. Microfluidic delivery and diffusion of fluorescent dye into tissue surrogates was measured via confocal microscopy and then compared to COMSOL simulations to characterize agent delivery depth and concentration profile. These results demonstrate the ability of the device to deliver sub-microliter quantities of fluid, and the ability to control the depth and diameter of the diffusion profile. Ongoing studies are focused on insertion and testing of devices in mice, including validation of...

**A Scalable 3D Printed Spheroid Capture Device for Rapid Immunotherapy Cancer Diagnostics**  
Alex W. Markoski¹ ², Ian Y. Wong² and Jeffrey T. Borenstein¹; ¹Draper Laboratory, United States; ²Brown University, United States

Immunotherapies such as immune checkpoint inhibitors (ICI) show great promise as more efficacious treatments for various cancers compared to current methods such as chemotherapy. However, preclinical evaluation of immunotherapies typically relies on mouse models that have limited relevance to human responses, or on *in vitro* culture methods that suffer from small sample sizes, limited cell viability, a lack of physiologically relevant stimuli such as flow, and an absence of tumor-immune cell interactions. To address these limitations with current models, we have developed a scalable 3D printed microfluidic devices capable of capturing multicellular tumor spheroids and perfusing them in the presence of circulating tumor infiltrating lymphocytes (TILs). Finite element modeling was first used to optimize flow conditions for capturing spheroids as well as for extended viability. Next, we experimentally characterized how T cells interacted with multicellular tumor spheroids in varying flow conditions, as well as after anti-PD-1 immune checkpoint treatment. Ultimately, these microfluidic devices will enable researchers and clinicians alike to test various immunotherapies in a scalable, rapid, and *in vivo* relevant manner.

SB09.03.03
**Peptide Self-Assembly into a Three-Dimensional Scaffold for Cell Growth and Encapsulation**  
Michael Jorgensen and Jean Chmielewski; Purdue University, United States

Self-assembling peptides have been used in recent decades for a variety of medical applications, including but not limited to tissue engineering, drug delivery, and biosensing. One peptide of particular interest, the leucine-zipper of the transcription factor GCN4, can exist in multiple oligomeric states based on the hydrophobic interface. Through functionalizing these GCN4 peptides with metal-binding ligands on the hydrophilic faces of the coiled coil, metal ion-mediated self-assembly can be promoted radially, and by altering the C- and N-termini of the peptide, self-assembly can be facilitated linearly. A design which merges these two modifications to create crosslinked coiled coil biomaterials will be reported.

**Selective Capture and Identification of Liver Cancer Related microRNAs and Intracellular Proteins through Antisense-Vectorized Magnetic Nanobeads**  
Isabel Gessner¹, Xiaojie Yu², Christian Jüngst³, Annika Klimpel¹, Lingyu Wang² ³, Thomas Fischer¹, Ines Neundorf⁴, Astrid Schauss², Margarete Odenthal² ³ ⁵ and Sanjay Mathur⁶; ¹University of Cologne, Germany; ²University Hospital Cologne, Germany; ³Cluster of Excellence - Cellular Stress Responses in Aging-Associated Diseases (CECAD), Germany; ⁴Center for Molecular Medicine (CMMC), Germany; ⁵Center of Integrative Oncology, Germany

MicroRNAs (miRNAs) are small non-coding nucleotides playing a crucial role in posttranscriptional expression and regulation of target genes in nearly all kinds of cells. In this study, we demonstrate a reliable and efficient capture and purification of miRNAs and intracellular proteins using magnetic nanoparticles functionalized with antisense oligonucleotides. For this purpose, a tumor suppressor miRNA (miR-198), deregulated in several human cancer types, was chosen. Magnetite nanoparticles carrying the complementary sequence of miR-198 (miR-198 antisense) on their surface were delivered into cells and subsequently used for the extracellular transport of miRNA and proteins. The successful capture of miR-198 was demonstrated by isolating RNA from magnetic nanoparticles followed by real-time PCR quantification. Our experimental data showed that antisense-coated particles captured 5-fold higher amounts of miR-198 when compared to the control nanoparticles. Moreover, several proteins that could play a significant role in miR-198 biogenesis were found attached to miR-198 conjugated nanoparticles and analyzed by mass spectrometry. Our findings demonstrate that a purpose-driven vectorization of magnetic nanobeads with target-specific recognition ligands is highly efficient in selectively transporting miRNA and disease-
relevant proteins out of cells and could become a reliable and useful tool for future diagnostic, therapeutic and analytical applications.

*Non-Thermal Atmospheric Pressure Plasma as an Effective Tool to Activate the Expression of Cytokines and Growth Factors to Induce Proliferation of Various Mesoderm-Derived Adult Stem Cells*  
*Kwon Song1, Jeongyeon Park1, Hyunyoung Lee2 and Hae June Lee2; 1Yonsei University, Korea (the Republic of); 2Busan National University, Korea (the Republic of)*

Non-thermal atmospheric pressure plasma (NTAPP) is described as a partially ionized gas containing charged particles and radicals at atmospheric pressure. Recently, some studies have reported the application of NTAPP to regenerative medicine for wound healing and activation of immune responses. In this study, we demonstrate that NTAPP activates the proliferation of various mesoderm-derived adult stem cells including adipose tissue-derived stem cells (ASCs), bone marrow-derived stem cells (BM-MSCs) and hematopoietic stem cells (HSCs) to develop NTAPP as an efficient tool for adult stem cell therapy. In our study, NTAPP induced the proliferation of these adult stem cells by 1.5 to 2-fold, compared with unexposed cells. Also, NTAPP exposure increased the expression of stem cell-specific surface markers, CD44 and CD105, by 5-fold in BM-MSCs, compared with that in unexposed cells in a low glucose medium with a low concentration of basic fibroblast growth factor (b-FGF), and augmented the expression of well-known pluripotent genes including Oct4, Sox2 and Nanog in ASCs and BM-MSCs compared to that in unexposed control cells, suggesting that NTAPP activated the proliferation of various adult stem cells without affecting the stem cell properties. The whole genome expression profiles of ASCs whose proliferation is highly activated by NTAPP showed that NTAPP upregulated genes for cytokines and growth factors, while it downregulated genes functioning in the intrinsic apoptotic pathway. With genes that showed more than two-fold increase or decrease in NTAPP-exposed ASCs by whole RNA-sequencing, we also confirmed the increased mRNA expression of leukemia inhibitory factor (LIF), heparin-binding epidermal growth factor (HBEGF), interleukin-6 (IL-6), IL-11, fibroblast growth factor 16 (FGF16), and IL-1β by 2 to 12-fold and decreased expression of bel-2-binding component 3 (BBC3), death-associated protein kinase 1 (DAPK1), caspase 10 (CASP10), tumor protein p53 (TP53), and receptor interacting serine/threonine kinase 3 (RIPK3) by 2 to 4.5-fold by real-time PCR, compared with the unexposed control. The increased expression of various cytokines and growth factors was highly declined comparing with NTAPP-treated ASCs in the presence of a nitric oxide (NO) scavenger, indicating that NO generated from NTAPP is mainly responsible for the enhanced expression of cytokines and growth factors by NTAPP. Collectively, these results strongly demonstrated that NTAPP would be an excellent tool to control the expression of cytokines and growth factors to trigger the activation of adult stem cells *in vitro* for stem cell therapy.

*A Nanoparticle-Enabled Focused Ultrasound-Stimulated Magnetic Resonance Imaging Spotlight*  
*Tian Deng, Le Zhang, Holden Wu and Jeffrey I. Zink; University of California Los Angeles, United States*

High-intensity focused ultrasound (HIFU) guided by Magnetic Resonance Imaging (MRI) is used as a therapeutic technique in clinical practice. To improve its efficacy, it is essential to accurately identify, or spotlight, target tissues for treatment. In this talk, we present a novel contrast enhancement method based on MRI-guided HIFU and mesoporous silica nanoparticles (MSNs). HIFU modulation was applied to MSNs modified with a thermo-responsive and biocompatible polymer to generate MRI T1 relaxivity changes in regions of interest. A modulation enhancement map (MEM) was reconstructed to spotlight the region of interest with almost two orders of magnitude increase in contrast compared to conventional enhancement methods. HIFU provides a 1.5 mm³ focal point that is spatially controllable in three-dimensions. The data acquisition time for the experiments in our study was 100 s, and it is practical for imaging during clinical applications. The small (2 °C) temperature change would cause minimal tissue damage. This non-invasive method can be applied in improving the identification of target tissues, such as delineation of tumor margins, for MRI-guided HIFU therapies.

**SB09.03.07**

*Downconversion Luminescent Nanoparticles Harnessing Changes in the Surface Dipole as a Novel Approach for Small Molecule Detection*  
*Khashayar R. Bajgiran, James A. Dorman and Adam T. Melvin; Louisiana State University, United States*

Traditional sensing techniques such as enzyme-linked immunosorbent assay (ELISA) offers limits of detection
(LOD) in the pM-fM range, however, it is labor-intensive, require multiple washing steps, and most importantly utilize expensive antibodies for analytical detection which limits their utility for point of care (POC) applications. To address these issues, colloidal nanoparticle (NP) biosensors can be designed to provide precise analytical detection without requiring antibodies and extensive post-processing steps. Optical NPs offer a wide range of biosensing applications such as ultrasensitive detection of cancer biomarkers in human serum, multiplexed, point of care (POC) detection of analytes, and in vivo sensing of reactive oxygen species. Optical nanoparticles, such as quantum dots (QDs) have exhibited comparable LOD to ELISA in some cases with high signal to noise ratios (SNR>10). However, the heavy-metal content of QDs results in high cytotoxicity prohibiting the wide-scale use of QDs particularly in clinical applications. Luminescent upconversion NPs have been introduced as biocompatible alternatives with comparable LODs (~6 nM). However, they require expensive, high energy infrared lasers and are limited in their ability for multiplexing. We have recently developed a Bi³⁺-doped YVO₃:Eu³⁺ core-shell nanoarchitecture that can utilize the changes in surface dipole moments as a novel mechanism for detection. It was found that the downconversion luminescent signal of the NPs can be modulated with respect to the dipole moment. The developed NP sensor was then functionalized with D-biotin to be used for label-free detection of avidin. Decorating the surface of the NPs with D-biotin generated a positive dipole moment (i.e., electron withdrawing) resulting in a decreased luminescent signal. The surface coverage of the biotin decorated NPs was evaluated using thermogravimetric analysis (TGA) to perform by time and concentration-dependent studies into how avidin binding further altered the luminescent properties of the NPs. Exposure to avidin resulted in a further decrease in the luminescent signal of the NPs suggesting that the interaction of avidin with biotin resulted in a positive dipole moment with a larger magnitude. This decrease in luminescent signal was found to be specific and concentration-dependent with respect to the free avidin concentration in solution. The downconversion NPs exhibited a similar SNR to upconversion NPs (SNR~15) with a LOD comparable to those of the QDs. This novel approach in biosensing can be expanded to the label-free detection of disease biomarkers or pathogens at low limits of detection in bulk fluid which is paramount for POC applications.

SB09.03.08
Dual-Gel Dual-Porosity Metamaterial as 3D Cell Culture Matrix for Studying Effects of Interstitial Flow on Cell Migration Jing Fan and Alimohammad Anbari; City College of New York, United States

Interstitial flow, the slow fluid flux occurring in the interstitial space of extracellular matrix (ECM), is mostly negligible in normal soft tissues, yet it could play crucial roles in regulating cellular behaviors in some pathological tissues or bone tissue. With the speed up to a few microns per second, the interstitial flow not only provides direct mechanical cues to the resident cells through shear stress and normal stress, but also couples with biomolecular diffusion to induce biochemical cues to the cells. Previous in vitro and in silico studies have implied that interstitial flow can regulate individual cell migration through at least two mechanisms: autologous chemotaxis and integrin-mediated focal adhesion activation [1-2]. The effectiveness of the former depends on interstitial fluid velocity; the effectiveness of the latter depends on both interstitial fluid velocity and ECM permeability. However, even in vitro, these two mechanisms cannot be rigorously examined due to the inevitable inverse correlation between permeability and stiffness of hydrogel matrices. Specifically, stiffness is another important mechanical cue that influences cell migration. Therefore, developing a thorough understanding of cellular behaviors regulated by interstitial flow requires an ability to independently control permeability and stiffness of the matrix, interstitial fluid velocity, as well as other relevant properties, such as ligand composition and density in the matrix; this independent control is still an unmet challenge in existing 3D in vitro models.

To address this challenge, we developed a dual-gel dual-porosity metamaterial integrating with a microfluidic platform for studying the effects of interstitial flow on cellular behaviors. This novel in vitro model, consisting of GelMA-PEGDA microgels and collagen, allows for independently controlling stiffness, cell-binding cites, permeability, and interstitial flow, as well as live imaging of migrating dynamics. We will present our preliminary results showing the effectiveness of our dual-gel metamaterial based cell culture model by characterizing the migration of breast cancer cells under different flow conditions and ECM properties.

Agarose Beads with Controlled Pore Structures for High Precision Clinical Diagnostics in Biosensing
Deniz Vurmaz¹ and John T. McDevitt²,¹; ¹NYU Tandon School of Engineering, United States; ²NYU college of dentistry, United States

Increasing the precision and reliability in biosensing is critical for accurate clinical disease diagnosis and rapid implementation of relevant treatment modalities. A key factor in high precision detection is the reduction of the coefficient of variation in a biosensing platform. A variety of polymer-based microbeads have been used as the medium to immobilize probes for a wide range of targets. Microbeads have been an attractive platform for diagnosis of diseases by targeting specific biomarkers in body fluids such as serum, saliva and urine, that are complex media with a large background of large variety of non-specific biomolecules, including proteins, peptides, mRNA and other small and large biopolymers. Among the several problems associated with the bead-based systems, the key issues are related to bead-to-bead signal variation because of the size and the surface versus internal bead structural variations. These limitations also include the variability and inefficiency of immobilization approaches as well as the formation and mechanical properties of the beads.

We have developed a mechanical methodology by which to mass produce agarose gel-based nanoporous microbeads with controlled internal and surface structures which facilitates a closer control over the surface functionalization. We demonstrate herein a covalent biofunctionalization of disease-specific probes and show high signal-to-noise ratio biomarker detection. For proof-of-concept demonstration, two key biomarkers were used, CRP and CTNI, that raise substantially after injury for multiple organ failure, respectively. Specifically, using gloxylation method we biofunctionalized the agarose beads with a capturing antibody protein both on the surface and throughout the porous internal structure to systematically analyze the capture of disease-specific antigens with significantly enhanced signal-to-noise ratio. The ease of manufacturing and performance characteristics of agarose microbeads demonstrated herein show a significant promise in the rapid and high precision diagnostic of disease-specific biomarkers paving the way for potential clinical implementations where the detection of the disease-specific antigens rapidly and with high efficiency is of prime importance. Funding was provided by the NIH through the National Institute of Dental and Craniofacial Research (NIH Grant Nos.3 U01 DE017793-02S1 and 5 U01 DE017793-2) and the ARO - contract No. W911NF-16-P-0030.

Cancellous Bone Characterization Using Ultrasonic Spectroscopy
Alina Karki¹, Xiaoman Shen² and Junru Wu¹; ¹The University of Vermont, United States; ²Beijing Institute of Technology, China

Ultrasound spectroscopy has evolved as a great potential non-invasive tool in the osteoporosis diagnosis and bone assessment since ultrasonic parameters such as normalized broadband ultrasound attenuation (nBUA) and speed of sound (SOS) have been used to characterize cancellous bone. However, the bone characterization is limited to the study of their relations to bone mineral density (BMD). An understanding of the underlying mechanisms responsible for the ultrasound propagation in cancellous bone is still lacking. There is also no evidence on the feasible frequency range for the assessment of bone. We have used the ultrasonic spectroscopy technique in transmission geometry to measure nBUA and speed of longitudinal ultrasonic waves in twenty-two beef cancellous bones at frequencies ranging from 2.25-7.5 MHz, with the goal of finding suitable frequency range for bone assessment. Bone porosity is another important parameter which greatly affects interaction or scattering of ultrasound in cancellous bone, which in turn affects ultrasound speed and influences the elastic properties of bone. In our study, bone porosity of each bone specimen is determined using x-ray micro CT scan and the relationships between bone porosity and ultrasonic parameters like nBUA and SOS are explored in the above-mentioned range of ultrasonic frequencies. We have utilized a systematic approach, beginning with the investigation of a polyethylene disk, moving on to the investigation of bone specimens.

SB09.03.11
Chimeric Solid-Binding Peptide-PNA Probes towards Cancer Bionanosensors
Richard V. Lee, Hadi Zareie and Mehmet Sarikaya; University of Washington, United States

Key aspects of designing effective biosensors include i) Tethering probes onto the sensing substrate while maintaining their proper orientation to appropriately bind target molecules, ii) Efficient signal transduction across
soft bio/nano interfaces of the sensing surface, and iii) Reusability of the sensor chip. Solid-binding peptides (SBPs) present a viable method for non-covalent immobilization of probes onto single-atomic layer substrates—providing unprecedented prospects for sensor design. This approach delivers functionalization while eschewing the challenges posed by covalent modification, such as the introduction of lattice defects that could adversely affect sensing properties, and is therefore especially relevant to sensors based on two-dimensional materials like graphene and MoS2. In addition, nucleic acid biomarkers, e.g., microRNA, cell-free DNA, etc., hold great potential for disease diagnosis and prognosis. Herein we design and construct heterofunctional chimeric PNA-SBP biomolecules that facilitate hybridization of nucleic acid targets onto the sensor surface. Using surface plasmon resonance spectroscopy (SPR), we demonstrate detection of DNA with these chimeric probes against a complex biological fluid, e.g., fetal bovine serum, in aqueous environment. We interrogate the effect of steric hindrance on optimal probe assembly using fluorescence microscopy and atomic force microscopy (AFM) imaging techniques, which reveal that lesser probe packing density results in greater target capture. We also demonstrate the sequential biomolecular assembly of the modular PNA-SBP system on the sensor surface and assess its performance under variety of solution conditions. These results provide a highly effective methodology for defect-free functionalization of 2D material-based bionanosensors through non-covalent means while enabling probe immobilization onto the sensing substrate. The latest results include design criteria of the chimeric probes, immobilization/biofunctionalization protocols, sensor architectures, and data acquisition and analysis procedures.

Technical help by Rebekah Khajehpour and Jessica Ahrens-Tran were appreciated. The research is supported by NSF-DMREF program through the grant DMR-1629071 as part of Materials Genome Initiative (MGI).

New Single Cell Methods for Oncology and Immuno-Oncology James R. Heath1,2, Yapeng Su1,2 and William Chour1,2; 1California Institute of Technology, United States; 2Institute for Systems Biology, United States

In this talk I will discuss new algorithms and analytical technologies associated with single cell analysis, with an emphasis on capturing and analyzing multiple levels of information (i.e. multi-omic analysis) from the same single cells. In one instance, I will discuss how single cell methods can resolve cancer cell adaptive responses to therapy, and reveal that even isogenic cells can exhibit multiple, independent adaptive responses, each of which can be independently drugged. I will also discuss large library approaches designed for sampling and single cell characterization of antigen-specific T cell populations, with the goal of identifying matched antigen-TCRa/b pairs for T cells that are circulating in the blood, but are tumor-antigen (or neoantigen) experienced.

9:00 AM *SB09.04.02
Enhancing Chimeric Antigen Receptor (CAR) T Cell Cancer Immunotherapy through Lymph Node-Targeted CAR Ligands Darrell J. Irvine; Massachusetts Institute of Technology, United States

We recently developed a strategy to target peptide vaccines to lymph nodes, by linking peptide antigens to albumin-binding phospholipid-polymers. Small peptides are normally rapidly dispersed in the bloodstream following parenteral injection, but binding of amphiphile-peptides to endogenous albumin, which constitutively traffics from blood to lymph, retargeted these molecules to lymph nodes. However, these lipid-polymer conjugates bind to albumin with a relatively low affinity, and these molecules can also partition into cell membranes. We hypothesized that by attaching a small molecule, peptide, or protein ligand for a chimeric antigen receptor (CAR) to the same polymer-lipid tail (forming an “amph-vax” molecule), CAR ligands could be delivered efficiently to lymph nodes by albumin and subsequently partition into membranes of resident antigen presenting cells (APCs), thereby co-displaying a CAR T cell ligand from the cell surface together with native cytokine/receptor costimulation. In syngeneic mouse models of adoptive cell therapy, we demonstrated that this approach effectively concentrates CAR T ligands on the surfaces of dendritic cells in lymph nodes, leading to profound expansion of amph-vax-boosted CAR T cells in vivo. Amph-vax boosting safely increased the polyfunctionality of CAR T cells in parallel with T
cell expansion. In a syngeneic model of melanoma, this converted a CAR T treatment that had no impact on tumor progression to a therapy that strongly delayed tumor outgrowth and enhanced survival. We have reduced to practice three different strategies to generalize this approach to any CAR of interest. This concept provides a strategy to regulate the expansion and function of CAR T cells directly in vivo to enhance adoptive cell therapy of cancer.

High Throughput Microwell Assay for T Cell-Cancer Cell Interaction in Cancer Immunotherapy Qingxuan Li, Thibault Colombani, Sidi Bencherif and Ming Su; Northeastern University, United States

Cell-cell interaction is of fundamental importance for immune system to mediate abnormal stimuli and eliminate pathogens. Understanding the mechanism of cytotoxic T cells in eliminating cancer cells in tumor immunotherapy requires a quantitative analysis of the interaction between T cells and cancer cells. Given the heterogeneity of cancer cells, it is imperative to evaluate the killing efficiency at single cancer cell level. This project uses a microwell device as a high-throughput platform to assess co-cultured OT-1 cells (T cells) and OVA-expressing B16 cells (cancer cells) and evaluate the cytotoxic efficiency based on different T cell numbers. Each micro-well defines the interaction area, to the point where the same group of T cells with the specific single cancer cell are tracked continuously in each well. The cell activity during attacking process is quantified by fluorescence intensity, which indicates the cytotoxic efficiency is proportional to the number of T cells which have communication with cancer cells, and reversely proportional to the cancer cell size. This precise control, high-throughput method, longitudinal observation using micro-well platform can give a new idea to evaluate therapeutic dosage, reduce the cost and at the same time with the same efficacy of immunotherapy.

9:45 AM SB09.04.04
Biomimetic Molecular-Scale Devices for the Spatial Control and Study of Activating-Inhibitory Balance in Natural Killer Cells Esti Toledo, Guillaume Le Saux, Avichai Edri, Uzi Hadad, Angel Porgador and Mark Schwartzman; Ben-Gurion University of the Negev, Israel

The cytotoxic activity of lymphocytes is regulated by a gentle balance between activating and inhibitory signals. Understanding the molecular mechanism of this balance is of fundamental importance, and is essential for the rational design of the future based immunotherapies. For this purpose, the exact function of each receptor must be investigated individually and in combination with each other. In particular, to understand the mechanism of the spatial integration of activating and inhibitory receptors, individual receptors should be manipulated and controlled. Spatial control of receptor with molecular resolution has been possible by exposing cells to arrays of patterned nanodots functionalized with the ligands for the studied receptors\(^1\)\(^-\)\(^3\). Such state-of-the-art arrays, however, could only control receptors of one type, and therefore could not be used to study how different receptors with complementary function integrate their signals. An experimental platform that allows simultaneous spatial control of two or more different receptors within the cell membrane has not been demonstrate up to date. Here, we developed a novel nanochip approach that allows simultaneous spatial control of individual transmembrane receptors of two types. We applied this nanochip approach to reveal how the nanoscale segregation between NKG2D and KIRDL1, which are the activating and inhibitory receptors in Natural Killer (NK) cells, respectively, regulate the cytotoxicity of NK cells. Our nanochips are based on tunable arrays of paired 10 nm nanodots of different metals, which are selectively functionalized with activating and inhibitory ligands for NK cells. The functionalized arrays, in turn, are used as a stimulation platform for NK cells, which encodes the arrangement of the two receptors within the cell membrane, and allows to monitor the cytotoxic response of NK cells the variations in this arrangement. To realize the nanochips, we first fabricated heterogeneous arrays of Ti and Au nanodots by nanoimprint lithography, followed double angle evaporation of two metals, and liftoff. Here, the spacing between the nanodots, which was ranged from zero to a few tens of nm, is precisely controlled by the metal evaporation angle. We then selectively functionalized Ti and Au nanodots with (i) MHC class I polypeptide-related sequence A (MICA) – a ligand for NKG2D, and (ii) monoclonal antibody for KIR2DL1, using biotin-avidin and Nitriltriactice acid (NTA)-Histidine conjugations, respectively\(^4\). We stimulated NK cell on the chip surfaces, and assessed their degree of activation through the expression of CD107a – a commonly used degranulation marker. We found that KIR2DL1-regulated inhibition of NKG2D signaling indeed depends on the spacing between the two receptors, and is mostly effective when the two receptors are separated by 30 nm. Our results shed the light on the way by which the innate immune function is spatially regulated by the activating and inhibitory signaling crosstalk. Furthermore, our novel nanochip technology opens a general pathway to complex, multifunctional nanomaterials which can be used as experimental platforms for the nanoscale study of the function and structure of immunological synapse, as well as other interfaces between cells.

Final Program 1/13/2020 2767
and their environment.

10:30 AM *SB09.05.01
Platelet-Delivered Immunotherapeutics Zhen Gu; University of California, Los Angeles, United States

Platelets play a vital physiological role in hemostasis, inflammation and tissue regeneration, which are associated with wound healing as well as cancer development and metastasis. Inspired by this intrinsic ability of platelets and the clinical success of immune checkpoint inhibitors, we have demonstrated that conjugating anti-PDL-1 antibodies (aPDL-1) to the surface of platelets can reduce post-surgical tumor recurrence and metastasis. Using mice bearing partially removed primary melanomas (B16-F10) or triple-negative breast carcinomas (4T1), we found that anti-PDL1 was effectively released on platelet activation by platelet-derived microparticles, and that the administration of platelet-bound anti-PDL1 significantly prolonged overall mouse survival after surgery by reducing the risk of cancer regrowth and metastatic spread. Furthermore, we have shown that systemically delivered blood platelets decorated with anti-PD-1 antibodies (aPD-1) and conjugated to hematopoietic stem cells (HSCs) suppressed the growth and recurrence of leukemia in mice. This cellular conjugate also promoted resistance to re-challenge with leukemia cells. In addition, we genetically engineered platelets from megakaryocyte progenitor cells to express the programmed cell death protein 1 (PD-1). The PD-1 platelet and its derived microparticle could accumulate within the tumor surgical wound for eradication of residual tumor cells. Cyclophosphamide was further loaded into PD-1-expressing platelets to deplete regulatory T cells, enhancing inhibition of tumor recurrence after surgery.

11:00 AM *SB09.05.02
Proteases as Biological Bits for Programmable Medicine Gabe A. Kwong; Georgia Tech & Emory, United States

Biological systems endowed with engineered biocircuits have the capacity to augment and reprogram living functions. We create biological bits (bbits) using proteases – a family of pleiotropic, promiscuous enzymes – to construct the biological equivalent of Boolean logic gates, comparators and analog-to-digital converters. We use these modules to assemble a cell-free bioprogram that can combine with bacteria-infected blood, quantify infection burden, and then calculate and unlock a selective drug dose. Inspired by quantum computing, we leverage protease promiscicity as the biological analog of superposition to program three probabilistic bbits that solve all implementations of the two-bit oracle problem, Learning Parity with Noise. Treating a network of dysregulated proteases in a living animal as an oracle, we use this algorithm to resolve the probability distribution of complement and coagulation proteases in vivo, allowing diagnosis of pulmonary embolism with high sensitivity and specificity (AUROC = 0.92) in a mouse model of thrombosis. Our results demonstrate that proteases can be programmed in cell-free systems to carry out classical and probabilistic algorithms for programmable medicine.

11:30 AM SB09.05.03
Erythrocyte Leveraged Chemotherapy (ELeCt) for Lung Metastasis Treatment Zongmin Zhao, Anvay Ukidve, Yongsheng Gao, Jayoung Kim and Samir Mitragotri; Harvard University, United States
Due to its unique physiological features like high blood throughput and high density of narrow capillaries, lung is one of the major organs into which the evaded tumor cells from primary tumor sites can spread. In fact, 30-55% of advanced cancer patients have lung metastasis. In spite of being the mainstay of cancer treatment, chemotherapy has shown limited efficacy for the treatment of lung metastasis due to ineffective targeting and poor tumor accumulation. Here we report a highly effective Erythrocyte Leveraged Chemotherapy (ELeCt) platform, consisting of biodegradable drug nanoparticles assembled onto the surface of erythrocytes, to enable chemotherapy for lung metastasis treatment. The ELeCt platform significantly extended the circulation time of the drug nanoparticles and delivered 10-fold higher drug content to the lung compared to the free nanoparticles. In both the early- and late-stage melanoma lung metastasis models, the ELeCt platform enabled substantial inhibition of tumor growth that resulted in significant improvement of survival. Further, the ELeCt platform can be used to deliver numerous approved chemotherapeutic drugs. Altogether, the findings suggest that the ELeCt platform offers a versatile strategy to enable chemotherapy for effective lung metastasis treatment.

11:45 AM SB09.05.04
Biomimetic Membrane-Wrapped Nanoparticles for Targeted siRNA Delivery to Hematopoietic Stem Cells
Jenna Harris, Samik Das, E. Terry Papoutsakis and Emily Day; University of Delaware, United States

Delivery of therapeutic cargo to hematopoietic stem and progenitor cells (HSPCs) is a challenging problem whose solution would transform the treatment of a wide variety of diseases.[1] To target HSPCs, nanoparticles (NPs) must not only enter the bone marrow, but also specifically bind and deliver cargo to HSPCs, which are extremely difficult to transfect. To date, only a single NP formulation has achieved this goal.[2,3] It consisted of nucleic acid-loaded poly(lactic-co-glycolic acid) (PLGA) NPs, and while it represents a novel advance, the level of HSPC gene modification it achieved was <1%.[2] There exists a substantial need for a more potent delivery system that will overcome physiological barriers to efficiently deliver cargo to HSPCs. Here, we report the development of biomimetic membrane-wrapped PLGA NPs that meet this need. We show that PLGA NPs wrapped with megakaryocyte (Mk)-derived membranes and loaded with model cargo have preferential binding to, and can enter, HSPCs in vitro. Additionally, we show that these Mk membrane-wrapped NPs (MkNPs) can deliver functional siRNA cargo to HSPCs to elicit gene regulation.

DiD fluorophore-loaded PLGA NPs were prepared by a single-emulsion solvent evaporation process [4] and siRNA-loaded PLGA NPs were prepared following a double-emulsion solvent evaporation process. [5]. siCD34 and siNeg were used as proof-of-concept cargo to allow for measurable silencing of CD34 in early-stage HSPCs. For siRNA-loaded NPs, the encapsulation efficiency (EE) was measured by comparing the amount of siRNA remaining in the filtrate after purification to the total added. The EE was >99%, indicating the siRNA is contained in the NPs and not lost during fabrication.

To create Mk membrane-wrapped NPs (MkNPs), the PLGA NPs and Mk membranes extracted from Mk cells were co-extruded with an Avanti Mini Extruder. Membrane wrapping was confirmed by measuring NP size and zeta potential before and after wrapping with dynamic light scattering (DLS), nanoparticle tracking analysis (NTA), and transmission electron microscopy (TEM). These measurements showed that the NPs were monodisperse and spherical, with the wrapped NPs having a diameter 10-20 nm larger than bare NPs and a complete membrane coating. The preferential interaction of DiD-loaded MkNPs with HSPCs as compared to non-targeted HUVECs (human umbilical vein endothelial cells) and MSCs (mesenchymal stem cells) was evaluated by flow cytometry and confocal microscopy. HSPCs internalized DiD-loaded MkNPs within 24 hr of incubation at a much higher rate than the other two cell types, confirming the Mk membrane coating can facilitate HSPC-specific binding.

To evaluate gene silencing, siCD34-MkNPs and siNeg-MkNPs were cultured with early-stage HSPCs, which express CD34. After 24, 48, 72, and 96 hr incubation, CD34 expression was analyzed by exposing the samples to anti-CD34 antibodies and performing flow cytometry. Since HSPCs acquired from different donors have variable CD34 expression, the percent deviation from control was calculated by comparing CD34 expression in siCD34-MkNP and siNeg-MkNP treated cells to that of the untreated donor control cells in each trial. MkNPs containing siCD34 significantly decreased CD34 expression in HSPCs over a 96 hr time period by >15%, while MkNPs loaded with siNeg had no impact on CD34 expression. These data indicate MkNPs have substantial potential as tools for targeted gene regulation of HSPCs.

In conclusion, MkNPs can be successfully loaded with, and deliver, siRNA cargo to HSPCs in vitro, eliciting gene knockdown. This exciting advance paves the way for further optimization of the system to induce greater levels of HSPC gene regulation, as well as for further examination of their targeting specificity in vivo.

Antibody Nanocarriers for the Treatment of Triple-Negative Breast Cancer

Emily Day; University of Delaware, United States

Antibodies that antagonize cell signaling pathways specific to their targeted receptors are invaluable tools to treat cancer, but their utility is limited by high production costs and treatment dosages. We and other researchers have shown that antibodies conjugated to nanoparticles display increased affinity for their target relative to freely delivered antibodies due to multivalent binding. In this presentation, I will discuss how my group has exploited this capability to create antibody nanocarriers that are drastically more effective than freely delivered antibodies at suppressing oncogenic signaling. Specifically, we have developed nanoparticles coated with Frizzled7 antibodies and Notch-1 antibodies to suppress Wnt and Notch signaling, respectively, in triple-negative breast cancer cells. Wnt and Notch are developmental signaling pathways that are overactive in triple-negative breast cancer and drive its progression and metastasis. We have shown that our Wnt inhibitory and Notch inhibitory nanoparticles can reduce cell viability, invasion, and stem-like behavior \textit{in vitro} and hinder primary tumor growth and metastasis \textit{in vivo}. These exciting observations warrant further investigation of antibody nanocarriers to manage triple-negative breast cancer and other malignancies that suffer from lack of available targeted therapies.

Delivery of Monoclonal Antibodies to the Central Nervous System for Brain Tumor Therapy

Yunfeng Lu; University of California, Los Angeles, United States

As an essential component of immunotherapy, monoclonal antibodies (mAbs) have emerged as a class of powerful therapeutics for treatment of a broad range of diseases. For central nervous system (CNS) diseases, however, the efficacy remains limited due to their inability to enter the CNS. I'll discuss about a platform technology that enables effective delivery of mAbs to the CNS for brain tumor therapy (Advanced Materials, 1805697, Nature Biomedical Engineering, in press). This is achieved by encapsulating the mAbs within nanocapsules that contain choline and acetylcholine analogues; such analogues facilitate the penetration of the nanocapsules through the brain-blood barrier and the delivery of mAbs to tumor sites. This platform technology uncages the therapeutic power of mAbs for various CNS diseases that remain poorly treated.

Nanomedicines to Improve the Therapeutic Index of Precision Medicines

Daniel A. Heller\textsuperscript{1,2}; 1Memorial Sloan-Kettering Cancer Center, United States; 2Weill Cornell Medicine, United States

Therapy based on personalized medicine—the genomic context of a patient’s disease—has become a leading strategy to treat cancer. Small molecule drugs such as kinase inhibitors, which target key effectors of cancer signaling pathways, constitute a major component of this strategy. However, such drugs can affect the same signaling pathways in healthy tissues, which often leads to dose-limiting toxicities. Increasing the therapeutic index of targeted therapies would greatly improve their effectiveness. We are investigating new targets to localize precision drugs to the microenvironment of primary and metastatic tumors. We developed nanoparticle drug carrier platforms to localize targeted therapies in tumor-associated vasculature and away from healthy tissues to obviate dose-limiting toxicities and concomitantly improve therapeutic index. We targeted MEK and PI3K inhibitors, pan-kinase inhibitors, and sonic hedgehog pathway inhibitors to tumor sites in both primary and metastatic models, resulting in superior anti-tumor efficacy and the striking reduction of toxicities. Moreover, measurements of tumor tissue show prolonged inhibition of downstream effectors in the signaling pathways, constituting a significant modulation of drug pharmacokinetics.
Chiral Supraparticles for Controllable Nanomedicine Jihyeon Yeom¹, Pedro Guimaraes¹, Hyomin Ahn², Kevin McHugh¹, Michael Mitchell¹, Chae-Ok Yun², Ana Jaklenec¹ and Robert Langer¹; ¹Massachusetts Institute of Technology (MIT), United States; ²Hanyang University, Korea (the Republic of)

Chirality is ubiquitous in nature that is hard-wired into every living biological system. Despite the critical role, the nexus of chirality engineering on biomaterials has not been explored. Here we designed chiral supraparticles (SPs) that react distinctively to cells and proteins depending on their handedness. SPs coordinated with $D$-chirality showed at least three times more efficient cell membrane penetrations and anti-cancer properties. We carried out quartz crystal microbalance with dissipation (QCM-D) and isothermal titration calorimetry (ITC) measurements to understand the mechanism, which confirmed that $D$-SPs had more effective adhesion on lipid layers where most of the phospholipids in nature has $D$-chirality. The stronger affinity of $D$-SPs over $L$-SPs to lipids was because interactions between the same optical isomeric structures are thermodynamically more stable than that of opposites. When it comes to in vivo environments that contain a large, heterogeneous population of proteins, $D$-SPs showed superior stability and longer biological half-lives due to the incompatible chirality with endogenous proteins including proteases. This study shows that incorporating $D$-chirality into nanosystems enhances cellular uptake and in vivo stability in blood providing support for the importance of chirality in biomaterials. Chirality engineering will provide “smart” platforms for drug delivery systems, tumor detection markers, biosensors, and many other biomaterial devices.

Novel Nanolipogels for In Vivo Genome Editing of Triple Negative Breast Cancer Peng Guo¹, Jiang Yang¹, Jing Huang¹, Debra Auguste² and Marsha Moses¹; ¹Boston Children's Hospital, United States; ²Northeastern University, United States

Triple negative breast cancer (TNBC), which represents 15-20% of all breast cancers, is a devastating breast cancer subtype that occurs more frequently in women under 50 years of age, in African American women and in individuals carrying a breast cancer early onset (BRCA1) gene mutation. To date, TNBC holds the highest mortality rate among all breast cancer subtypes, and a central problem for TNBC therapy is the lack of effective therapeutics that can hinder the growth and spread of breast cancer cells. To address this challenge, here we report the development of a novel non-cationic, deformable and tumor-targeted nanolipogel system (tNLG) for CRISPR genome editing in TNBC tumors. CRISPR genome editing is a revolutionary biotechnology that may potentially provide a cure for many genetic diseases including TNBC. We have demonstrated that tNLGs can be used to encapsulate CRISPR genome editing plasmids in a highly facile and efficient manner. Then we showed that tNLGs mediate a potent CRISPR knockout of Lipocalin 2 (LCN2), a known breast cancer oncogene, in human TNBC cells in vitro and in vivo. The loss of Lcn2 significantly inhibits the migration and the mesenchymal phenotype of human TNBC cells and subsequently attenuates TNBC aggressiveness. Furthermore, we performed in vivo CRISPR genome editing of orthotopic TNBC tumors by systemically administering tNLGs, resulting in significant tumor growth suppression (>77%). Our proof-of-principle results provide the first experimental evidence that tNLGs can be used as a safe, precise and effective delivery approach for in vivo CRISPR genome editing in TNBC.

Genomic-DNA Coated 3D Printed Materials for Drug Capture Daryl Yee, Robert H. Grubbs and Julia R. Greer; California Institute of Technology, United States

Since the discovery of chemotherapy in the beginning of the 20th century, researchers around the world have been actively developing new and more effective chemotherapeutic agents to better treat cancer. Traditionally, chemotherapeutic agents work by interfering with cell division. However, by virtue of their mechanism of action, healthy normal cells can also be targeted and destroyed. As a result, while chemotherapy is an effective way of managing cancer, the resulting side effects limits its use. One approach currently taken to reduce these side effects is to deliver the chemotherapy drugs directly to the tumor via transarterial chemoembolization, or other similar procedures. While this has been effective in reducing systemic toxicity, more can be done to improve this. Ideally, a device that could sequester any unreacted chemotherapy agents could be installed "downstream" of the tumor prior to them entering systemic circulation. Such drug-capture materials have only just started to be realized due to the
difficulty in achieving materials that have the right surface chemistry and geometry for blood flow.

Working together with medical doctors, computational fluid dynamics experts, chemists, and materials scientists, we report the fabrication of DNA coated 3D printed porous materials that can be used to capture doxorubicin, a commonly used DNA-targeting chemotherapy agent. We discuss the concept behind the device, the use of 3D printed materials as an ideal substrate, and the chemistries considered in drug binding. To achieve scalability of these devices, we developed a method of attaching cheaply available genomic DNA to these materials, a departure from commonly used synthetic DNA. The efficacy of these functionalized materials were demonstrated, where we observed a >70% reduction in doxorubicin concentration over a period of 10 minutes, highlighting the viability of this as a method of drug capture.

Conductive Elastomer-Based Active Drug Delivery Platform for Targeted Chemotherapy in Glioblastoma Multiforme
Christopher Chapman, Estelle Cuttaz, Josef Goding and Rylie Green; Imperial College London, United Kingdom

Glioblastoma multiforme is an aggressive untreated brain cancer with a 14.6-month median survival time and a 2% 5-year survival rate after diagnosis. The current best practice for treatment is surgical resection followed by radiotherapy and systemic chemotherapy. However, many tumours cannot be removed surgically leaving only the nonspecific treatments of radiotherapy and systemic chemotherapy, further reducing survival rates. Currently the primary chemotherapeutic agent used to treat these tumours is the alkylating agent temozolomide (TMZ). The success of this drug stems from its limited ability to cross the blood brain barrier. Attempts to mechanically cross the blood brain barrier with an implanted device to deliver liquid drug cocktails directly to the tumour have seen limited efficacy due to increasing the intracranial pressure, which can produce oedema and additional brain damage. Recently, ionic drug delivery has been a subject of increased focus using both drug eluting electrodes or electronic ion pumps as the delivery vehicle. Because these devices can deliver drug molecules without a liquid carrier (termed ‘dry delivery’) they cause no increase in the volume to the surrounding tissue. Therefore, this mode of delivery is a strong candidate for the targeted delivery of high concentrations of chemotherapeutic agents deep in the brain, as the side effects associated with the liquid delivery are avoided.

Recently, fully polymeric conductive elastomers fabricated using dispersions of a doped conducting polymer poly(3,4-ethylenedioxythiophene):polystyrene-sulfonate (PEDOT:PSS) in polyurethane, have shown significant promise for applications in bioelectronic interfaces. These materials present a unique platform for the voltage controlled dry release of drug molecules as the elastomer enables the encapsulation of small molecule drugs, and the conductive polymer enables on-demand electronically controlled offloading of the drug. Here we demonstrate the ability for this system to actively release a model drug (fluorescein) in clinically relevant concentrations ranging from 1 µM to 1 mM through the application of a negative electrical potential. Similarly, a positive electrical potential can be applied to stop the release on-demand. Using the same method, we show that the common chemotherapeutic agent doxorubicin can also be released in the same concentrations ranges. Additionally, by tuning multiple material parameters such as the weight percent of PEDOT:PSS in the polyurethane as well as material thickness, further control of the drug release profiles can be achieved. Finally, the translatability of this technology is shown through the fabrication and implantation of a doxorubicin loaded device into an agar tissue phantom using traditional stereotactic methods.

Through the coupling of material parameters with applied electrical potential, we demonstrate a high degree of customizability for the device to be tuned toward patient specific needs. Moving forward, experiments are underway to confirm the active anti-cancer effect of the device in vitro through implantation of the doxorubicin loaded device into rat glioblastoma spheroids, actively releasing doxorubicin, and tracking of the toxic effects through spheroid size reduction over a period of weeks. Ultimately, this technology constitutes a significant step forward in biomaterials-based cancer treatments and shows promise for ease of translation into clinical use to improve the outcome of patients with non-operable glioblastoma multiforme.

Coaxially Electrospun Three-Dimensional Disc for Long-Term Local Therapy Against Brain Tumors

Daewoo Han¹, Riccardo Serra², Noah Gorelick², Henry Brem²,²,² Betty Tyler² and Andrew J. Steckl¹; ¹University of Cincinnati, United States; ²Johns Hopkins University School of Medicine, United States

Glioblastoma multiforme (GBM), the most aggressive brain cancer, has an incidence of ~3.2 cases/100,000 persons/year, with a recurrence rate > 90%, a 5-year survival rate of 5.1%, and a mean survival of < 15 months. GBM treatment relies mainly on the combination of maximally safe surgical resection followed by radiation therapy (RT) and concomitant chemotherapy with temozolomide (TMZ). Local chemotherapy for GBM treatments is the most attractive approaches by enhancing drug biodistribution to the tumor and avoiding systemic toxicities. GBM recurrence mostly within 2 cm of the original lesion makes it local therapy very attractive. Also, it overcomes the limitation posed by the blood-brain barrier. Gliadel®, a carmustine (bis-chloroethyl-nitrosourea (BCNU))-impregnated polyanhydride poly-(1,3 bis[p-carboxyphenoxy] propane-co-sebacic acid) 20:80 polymeric (p(CPP):SA) wafer, is currently the only FDA-approved local therapy device. Although Gliadel releases most of drugs within a week, the triple therapy paired with RT and systemic TMZ administration improved the median survival up to 21 months. Obviously, the use of local chemotherapy is very effective for GBM treatments. Therefore, the use of new polymer structures extending a release time period can further improve the survival and prevent the recurrence while minimizing side effects from cytotoxic agents.

We have developed discs formed from multi-layered core-sheath fiber membranes (‘NanoMesh’) to provide controlled and sustained drug release for long-term periods, leading to excellent in vivo performance in an animal model. Drug encapsulated core-sheath fibers have been fabricated using pCPP:SA / BCNU core and PCL sheath. SEM images show uniform fiber formation with average diameter of ~2.3 µm (sheath of ~0.46 µm). Three-dimensional discs were formed from coaxially electrospun fiber membranes by a simple fold-and-punch process and consistent long-term release with no initial burst release was observed in vitro for up to 160 days. NanoMesh discs provide fairly uniform diffusion lengths over time, because aqueous media gradually wets the disc from the outside due to the hydrophobic nature of fiber surfaces. Therefore, consistent long-term release of encapsulated drugs with minimized initial burst release is obtained. This benefit is significant when targeted to long-term release with hydrophilic drugs. NanoMesh reported here can provide long-term release kinetics regardless of the nature of the encapsulated drug.

In vivo survival was assessed following implantation of NanoMesh discs either concurrently with or five days after intracranial implantation of 9L gliosarcoma to F344 rats. Concurrent implantation of NanoMesh and 9L gliosarcoma resulted in statistically significant long-term survival (>150 days). Control (drug-free) NanoMesh confirmed the safety of these novel implants. Similarly, Day 5 studies showed significant median survival, and long-term survival rates of 50%. Brain histology shows no evidence of malignant cells even at Day 150. Animals in all control groups died very early (~12-14 days).

In addition, we have evaluated the release kinetics of multi-drug incorporated NanoMesh to mimic the current systemic ‘cocktail’ chemotherapy with multiple anti-cancer drugs. Different anti-cancer drugs can be incorporated into different layers within the NanoMesh to be released either in concurrent or sequential manner. Local chemotherapy using NanoMesh implants provides promising means for GBM treatment. Drug delivery with coaxial core-sheath structures benefits from high drug loading, controlled long-term release kinetics, and slow polymer degradation. This represents a promising evolution for the current treatment of GBM. Furthermore, controlled ‘cocktail’ local therapy may bring a new paradigm to the GBM therapy.

Harnessing Sustained Release Technologies to Produce Robust and Durable Immunity

Eric A. Appel; Stanford University, United States

Vaccines can take one of several forms, but those based on subunit antigens (representative subunits of the pathogen for which immunity is desired) offer the greatest safety profile and scalability, but elicit weaker, less durable immune responses. Failure to elicit a sufficiently strong response likely arises from inappropriate temporal control over antigen/adjuvant presentation and immune cell activation. Either short-term presentation of these signals, or misalignment of their presentation along different timelines, results in poor affinity maturation of antibodies and poor immune memory responses. When considering the iterative selection process occurring during somatic hypermutation and antibody affinity maturation in B lymphocytes, it is intuitive that prolonged lymphocyte activation and antigen exposure would lead to the generation of higher-affinity antibodies. In this work we exploit a
novel injectable hydrogel platform providing unique drug delivery capabilities for the long-term co-delivery of antigen and adjuvant in subunit vaccines and investigate impact of this altered delivery behavior on the humoral immune response and the development of ultra-high-affinity antibodies. We demonstrate that prolonged hydrogel-based immunizations greatly enhance the magnitude and duration of the primary antibody response, enhance and prolong germinal responses, and lead to 1000-fold enhancement in antibody affinity maturation when compared to the same vaccine delivered in bolus. These advanced materials technologies, therefore, have the potential to provide vastly superior vaccine performance through the precise and sustained delivery of subunit vaccines that take advantage of natural immune mechanisms for building long-lasting and potent immunity.

A Facile Approach to Augment DNA Vaccine Efficacy by Injectable Mesoporous Silica Microrods for Cancer Immunotherapy Thanh Loc Nguyen, Yue Yin, Youngjin Choi, Ji Hoon Jeong and Jaeyun Kim; Sungkyunkwan University, Korea (the Republic of)

DNA cancer vaccine is one of the potential strategies in cancer immunotherapy. In order to provoke robust antigen-specific adaptive immune response against tumor, DNAs coding tumor antigen are desired to be engulfed by host antigen-presenting cells (e.g. dendritic cells) which subsequently become antigen-activated for T cell priming. However, therapeutic efficacy of this approach is still restricted due to insufficient DNA transfection to host dendritic cells (DCs) and lack of immunogenicity. Herein, we introduce an injectable 3-demensional macroporous scaffold constructing of high aspect ratio mesoporous silica microrods (MSRs) and antigen-coded DNA complexes (designated as MSR-DNA vaccine) for augmenting the efficacy of DNA vaccine. Release of chemotactic and immune adjuvant from MSRs initiate the migration and maturation of huge amount of host DCs into MSRs scaffold where DNA complexes are present in the interparticle space, thus enhance cellular uptake of DNA complexes by recruited DCs. Subcutaneous immunization of MSR-DNA vaccine elicits more robust host DCs activation and maturation in comparison to the bolus DNA vaccine counterpart, consequently triggers antigen-specific CD8+ T cell response in draining lymph node. Interestingly, MSR-DNA vaccine induces Th1-biased immune response through significant secretion of TNF-α and IFN-γ by CD4+ and CD8+ T cells along with high production of anti-OVA IgG2a in blood serum. In prophylactic study, MSR-DNA vaccine significantly prevents melanoma growth by the generation of CD8+ effector memory T cells. Impressively, established lung metastasis can be inhibited with a single injection of MSR-DNA vaccine. Our findings suggest that MSRs could be a novel platform for delivering DNA vaccine to DCs for the effective cancer immunotherapy.

Solid-Phase Synthesis for Molecularly Imprinted Polymer Nanocomposites—Synthetic Antibody Mimics for Cell Targeting and Imaging, Diagnostics and Theranostics Alicia Alejandra Mier Gonzalez; Universite de Technologie de Compiegne, France

Abnormalities in the expression of cell surface proteins or receptors are promising biomarkers of human diseases, notably cancer. However, the detection and quantification of these biomarkers are often challenging. Molecularly imprinted polymers (MIPs) are tailor-made synthetic receptors (antibody mimics), able to specifically recognize target molecules. They are synthesized by copolymerization of functional and cross-linking monomers in the presence of a template molecule, resulting in the formation of binding sites with affinities and specificities comparable to those of antibodies.

In the present project, we demonstrate the targeting of a cancer protein biomarker with MIP nanoparticles. MIPs were synthesized using a solid-phase approach in which a fragment of the protein was selected as epitope and immobilized on glass beads (solid support) via click chemistry. This configuration allows an oriented immobilization of the template upon which thermoreponsive MIP nanoparticles are synthesized. The binding sites of the resulting MIPs all have the same orientation, thus MIPs synthesized by the solid-phase approach can be considered analogous to monoclonal antibodies.

MIPs were found to bind the epitope with high (nanomolar) affinity and selectivity as demonstrated by equilibrium binding assays with the peptide fluorescently labeled. Fluorescent MIPs were used for cell imaging to reveal the recognition of the target protein on cancer cells. When control cells not expressing the protein were used, the staining was dramatically decreased. In addition, very similar staining patterns were obtained at immunostaining with monoclonal antibodies. The application of MIPs as therapeutic agents is being studied.

Drug-Loaded Titanium Dioxide Nanoparticle Coated with Tumor Targeting Polymer as a Sonodynamic Chemotherapeutic Agent for Anti-Cancer Therapy Seonil Kim and Won Jong Kim; POSTECH, Korea (the Republic of)

Sonodynamic therapy utilizes ultrasound (US)-responsive generation of reactive oxygen species (ROS) from sonosensitizer, and it is a powerful strategy for anti-cancer treatment in combination with chemotherapy. Herein, we designed drug-loaded nanoparticle which could release drug by ultrasound-mediated ROS generation. Doxorubicin (DOX)-coordinated titanium dioxide nanoparticle (TNP) are encapsulated with polymerized phenyboronic acid (pPBA) via phenyl boronic ester coupling between pPBA and DOX. Phenylboronic ester bonding is cleavable by ROS generated from TNP under ultrasound stimulus. The size of nanoparticles is 200 nm, and DOX was released by generated ROS through ultrasound irradiation. In addition, this nanoparticle can target tumor by interaction between PBA and sialylated epitopes of tumor surface. Tumor targeting capability, intracellular ROS generation, and combined therapeutic effect against tumor cells were confirmed in vitro. Furthermore, this nanoparticle showed high tumor accumulation of and efficient tumor growth when treated by intravenous injection, which have potential as a multi-functional agent for sonodynamic chemotherapy. The nanoparticles have outstanding therapeutic effects owing to several advantages: 1) An appropriate size of the NP makes an effective cancer-specific accumulation through the EPR effect in vivo; 2) Negative charge of remaining carboxylic acid group can increase circulation time in vivo by preventing unnecessary interactions with serum proteins; 3) PBA moieties also have a high affinity to tumors; 4) Since DOX is released in response to US stimulation, it is possible to reduce the non-specific release of DOX and improve the delivery efficiency; and 5) The dual therapeutic effect of generated ROS and released anti-cancer drug by US can reveal combinatorial synergistic anti-cancer effect. In this study, we investigated the physicochemical properties of nanoparticles, tumor targeting ability, US-responsive behavior and its anti-cancer effect in vivo as well as in vitro.

SB09.07.03
In Vivo Fluorescence Imaging of Genetically Engineered Oncolytic Apoptin Nanoparticles for the Assessment of Targeted Cancer Therapy Dong-Eun Lee1 and Joong-jae Lee2; 1Korea Atomic Energy Research Institute, Korea (the Republic of); 2Kangwon National University, Korea (the Republic of)

Targeted delivery of pro-apoptotic proteins with tumor-selective properties, including oncolytic virus-derived proteins and other human tumor suppressors has been considered an ideal platform to achieve high therapeutic efficacy and negligible side effects in cancer therapy. Despite notable therapeutic efficacy, however, the facile production and combination of efficient targeted delivery system remain a challenge. Here, we present genetically engineered oncolytic protein nanoparticles comprising a tumor-selective protein and a targeting moiety as a direct protein delivery system for the targeted cancer therapy. Apoptin, which is a 13.6 kDa protein from the chicken anaemia virus (CAV), has attracted considerable attention as a promising anti-cancer therapeutic because it triggers tumour-selective cell death, while leaving normal cells unaffected. Interestingly activity of apoptin proceeds independently of tumor suppressor p53, and its biological function is stimulated by various intracellular oncoproteins. An EGFR-specific repebody, which is composed of LRR (Leucine-rich repeat) modules, was employed to play a dual role as a tumor-targeting moiety and a fusion partner for production of apoptin nanoparticles, respectively. The repebody was genetically fused to apoptin, and the resulting construct (repebody-apoptin, Rb-Apo) was shown to self-assemble into supramolecular apoptin nanoparticles (Rb-Apo-NP) with high homogeneity and stability as a soluble form in E. coli. We examined the whole-body distribution and EGFR specific uptake of the Rb-Apo-NPs, particularly after intravenous administration. Near-infrared fluorescence dye (Cy5.5) was conjugated to the Rb-Apo-NPs and MBP-Apo-NPs, and their distribution in vivo and ex vivo was analyzed
through optical imaging in xenograft mouse models with EGFR-overexpressing MDA-MB-468 cells. The Rb-Apo-NPs were shown to be preferentially localized around the tumor cells at 24 h after intravenous administration, and the tumour regions could be clearly distinguished from the normal surrounding tissue. On the other hand, relative low intensity was observed in EGFR-negative MCF7 xenografts. The Rb-Apo-NP showed a remarkable tumor regression in xenografts mice through a targeted delivery by the EGFR-specific repebody and tumor-selective apoptosis by apoptin.

SB09.07.04
Colloidal Motors for Autonomous Motion and Cargo Delivery in Extracellular Matrices

Shrishti Singh,
Delaram Dastan, Parag Chitnis, Remi Veneziano and Jeffrey L. Moran; George Mason University, United States

Most nanometer-size drug delivery systems fail to reach their target site (e.g. tumors), largely due to the action of the immune system or elimination by liver or kidney. Furthermore, the drug delivery nanosystems that do reach the tumor are inefficient at killing cells in the tumor neoplasm due to the formidable barrier posed by the tumor microenvironment. The tumor microenvironment limits diffusion of the nanocarriers' cargo (i.e. chemotherapeutics) due to high interstitial pressure and the presence of a dense stroma surrounding the cells. This extracellular environment (stroma) has a plethora of cells like fibroblasts, macrophages, T and B-cells embedded in a network of collagen, fibrin and other protein fibers. This network of fibers, known as the tumor extracellular matrix (ECM), can be remodeled by the tumor cells to their advantage, making it a dynamic obstacle for the drug delivery system to overcome. As a result, the overall delivery efficiency of nanoparticles to tumor cells is less than 1% on average.

Colloidal motors are synthetic particles roughly between 10 nm - 100 μm in size that can propel themselves in an aqueous environment by converting energy stored in their surroundings (chemical, electric/magnetic fields, sound, etc.) into propulsive forces. Steering these colloidal motors is challenging and requires clever engineering, but guidance systems based on magnetic fields have been developed and show promise for navigation in biological environments. Colloidal motors have been shown to carry and deliver cargo (including anticancer drugs) to targeted sites (including cancer cells). However, previous studies have demonstrated these feats in vitro, and successful drug towing and delivery in tumor ECM has yet to be demonstrated.

In this study, we experimentally demonstrate the movement of magnetic helical motors driven by rotating magnetic fields in two in vivo ECM mimics. The first ECM model/mimic used is Matrigel, a commercially available basement membrane commonly used for 2D and 3D cultures. The second is low-molecular weight PEG hydrogels modified with different molar ratios of DTT (dithiothreitol) for tunable pore-sizes. The pore size, shear and storage modulus are measured for both ECM models. The speed is dictated by the rotational frequency of the field and the orientation of the motors depends on the orientation of the field. Using glancing angle deposition (GLAD), helices 70 nm in diameter, 400 nm in length, and 120 nm wide can be fabricated. These are small enough to potentially be able to navigate between the openings in ECM. Fluorescent dyes and quantum dots enable external tracking of helices in both ECM models. The trajectory of the helices and their velocity is determined for different magnetic field properties and ECM parameters. Finally, we explore the viability of these colloidal motors to be tracked using photoacoustic imaging, which has the potential to image and track these particles in vivo. This work takes the first steps toward enabling targeted drug delivery by self-propelled nanocarriers a possibility.

SB09.07.05
Fabrication of Drug Loaded Poly (γ-glutamic acid)-Based Hydrogel and Its Application in Pancreatic Cancer Model

HyungHwan Kim¹, Jihyun Jang¹, Sukyung Ahn², Jin Hee Maeng², Eunhye Lee² and Hyesung Yoon¹;¹Samyang Biopharmaceuticals Corp, Korea (the Republic of); ²Utah-Inha DDS and Advanced Therapeutics Research Center, Korea (the Republic of)

Poly (γ-glutamic acid, PGA) is a poly (amino acid) naturally produced by Bacillus subtilis. It is made of glutamate units connected by amide linkages between α-amino and γ-carboxylic acid groups. As an FDA GRAS material, it is widely used in food and cosmetic industries. In the biomedical field, PGA has been widely studied due to its excellent muco-adhesion, biocompatibility, and biodegradability. In this study, a novel PGA-based hydrogel as a local anti-cancer drug delivery matrix for treatment of pancreatic cancer. It is important that drug loaded matrix is stably sufficiently retained on the surface of the tumor to be effective. To achieve this key property, an in situ forming adhesive hydrogel was designed by modifying the carboxyl group of PGA to NHS (N-hydroxysuccinimide) activated ester applying carbodiimide chemistry. Then the
NHS activated PGA was mixed with a multi-functional nucleophile (i.e. multi-arm PEG) to form the hydrogel. The hydrogel quickly formed a crosslinked 3-D network structure within 2 sec and showed good adhesive property as well as high burst pressure. Subsequently, anticancer drugs (e.g. paclitaxel, or gemcitabine, etc.) were loaded into the hydrogel (PTX: 0.97%(w/v), GEM: 5.18%(w/v)) and the anti-tumor efficacy was tested in vivo in murine orthotopic pancreatic tumor model. Briefly, the tumor growth was inhibited and the metastasis of pancreatic cancer cells was reduced, without bodyweight loss. Current results demonstrated that local delivery of anticancer drug enhanced an antitumor efficacy. We expect that this hydrogel system as a promising platform to enhance the efficacy of cancer drugs by increasing the therapeutic index.

Organic-Inorganic Bio-Hybrid Nanoparticle for Systemic Targeted siRNA Delivery for Simultaneous Treatment of Primary and Metastatic Melanoma Min Sang Lee and Ji Hoon Jeong; Sungkyunkwan University, Korea (the Republic of)

Although primary melanoma would be easily removed by surgical resection, it could be developed to metastatic melanoma spreading tumor cell from primary melanoma to other tissue, which leads to significant decrease of five-year survival rate of patient. In addition, detection of melanoma at an early stage is difficult due to lack of appropriate tumor markers and absence of symptoms, which causes that the majority of patients with melanoma experience metastasis. Therefore, considering therapeutic aspects of metastatic melanoma, simultaneous treatment of primary and metastatic melanoma would be suitable therapeutic strategies. To achieve desired therapeutic effect, delivery carrier encapsulating anticancer drug should be sufficiently accumulated not only in primary tumor but also in metastatic melanoma that was not detected in early stage of diagnosis, which could completely cure melanoma and increase overall survival rate for patient.

Small interfering RNA (siRNA) has attracted a lot of attention as an alternative anti-cancer drug reducing side effects of chemotherapy owing to their anti-cancer potency and selectivity via tumor-specific RNA interference. Despite their therapeutic potential, the application of siRNAs is limited due to their rapid enzymatic degradation, non-specific accumulation in tissue, and poor cellular uptake in vivo. Thus, successful tumor treatment via siRNA delivery requires the development of a systemic delivery carrier that provides efficient siRNA protection, tissue-targeting ability and enhanced intracellular uptake.

In this study, we prepared a targeted small interfering RNA (siRNA) delivery platform using organic-inorganic hybrid materials capable of specific tissue targeting and efficient target gene silencing. dopa-hyaluronic acid conjugate (d-HA) successfully formed stabilized calcium phosphate (CaP) nanoparticle, which effectively protect siRNA from enzymatic degradation, enhance colloidal stability and provide targeting ability for tumor cell overexpressing CD44. Cellular uptake of the nanoparticles was enhanced via HA receptor-mediated endocytosis in B16F10 melanoma cells, which leads to enhanced gene silencing efficiency. In vivo biodistribution and therapeutic effect demonstrated that the systemically injected nanoparticles formulated with VEGF siRNA was simultaneously accumulated in primary melanoma and metastatic lung tumor, resulting in an improved therapeutic effect by reducing VEGF expression. These results suggested that the systemic targeted nanoparticle formulated with therapeutic siRNA can be considered as a prospective candidate for simultaneous targeted therapy for primary and metastatic melanoma.

SB09.07.07
Membrane Wrapping Efficiency of Elastic Nanoparticles During Endocytosis—Size and Shape Matter Zhiqiang Shen and Ying Li; University of Connecticut, United States

Using coarse-grained molecular dynamics simulations, we systematically investigate the receptor-mediated endocytosis of elastic nanoparticles (NPs) with different sizes, ranging from 25 to 100 nm, and shapes, including sphere-like, oblate-like, and prolate-like. Simulation results provide clear evidence that the membrane wrapping efficiency of NPs during endocytosis is a result of competition between receptor diffusion kinetics and thermodynamic driving force. The receptor diffusion kinetics refer to the kinetics of receptor recruitment that are affected by the contact edge length between the NP and membrane. The thermodynamic driving force represents the amount of required free energy to drive NPs into a cell. Under the volume constraint of elastic NPs, the soft
spherical NPs are found to have similar contact edge lengths to rigid ones and to less efficiently be fully wrapped due to their elastic deformation. Moreover, the difference in wrapping efficiency between soft and rigid spherical NPs increases with their sizes, due to the increment of their elastic energy change. Furthermore, because of its prominent large contact edge length, the oblate ellipsoid is found to be the least sensitive geometry to the variation in NP’s elasticity among the spherical, prolate, and oblate shapes during the membrane wrapping. In addition, simulation results indicate that conflicting experimental observations on the efficiency of cellular uptake of elastic NPs could be caused by their different mechanical properties. Our simulations provide a detailed mechanistic understanding about the influence of NPs’ size, shape, and elasticity on their membrane wrapping efficiency, which serves as a rational guidance for the design of NP-based drug carriers.

SB09.07.09
Dual Probe Imaging of Tumors Using Cadmium-Free NIR-Emitting Quantum Dot
Alexander Saeboe, Keyi Han, Joshua Kays, Reyhaneh Toufanian, Matthew Finley and Allison M. Dennis; Boston University, United States

When nanoparticle-based imaging agents are used for targeted tumor contrast, only a fraction of the dose is specifically delivered; the remaining material circulates, passively accumulates in the tumor due to the enhanced permeation and retention (EPR) effect, or accumulates in off-target organs. When multiple contrast agents with near identical chemical and physical properties, yet distinct spectral emissions, are used, dual-probe imaging can be used to discern between the background and target signal. This can be achieved by removing the contribution of the untargeted probe from the image leaving only the signal from the targeted probe. NIR-emitting quantum dots (QDs) provide an excellent opportunity to improve targeted imaging of tumors in murine models for the study of cancer biology, as multiple QDs emitting discrete tissue-penetrating wavelengths can be prepared such that their size and surface properties are perfectly matched except for the presence or absence of a tumor-specific targeting ligand. We have synthesized multiple near infrared (NIR) emitting cadmium-free quantum dots (QDs) as bright and photostable contrast agents for multiplexed imaging in tissues. These indium phosphide-based QDs have tunable emission across most of the visible wavelength regime and the first near infrared (NIR) tissue imaging window. Our Inverted-Type I structure comprising InP shells on a ZnSe core, capped with ZnS for stability, exhibit extended tunability beyond that of a traditional InP Type-I QD. By controlling the thickness of the InP shell, we can tune the emission peak from 530 nm to 868 nm (2.34 – 1.43 eV). The full width half maximum (FWHM) of the emission peak remains constant as monolayers are added, indicating regular and high-quality shell growth. To confer water solubility, long circulation times, and chemical handles for bioconjugation, the QDs were encapsulated in PEGylated phospholipid micelles functionalized with terminal azido groups. The QDs retain their high quantum yield and monodispersity following encapsulation. Using click chemistry, the terminal azido groups are conjugated to tumor targeting ligands, including anti-HER2 or anti-CXCR4 peptides, as well as a clickable BCN-ethylenediamine modified folic acid. Dual probe imaging of tumors using targeted and untargeted fluorophores improves the imaging contrast of the specific cancer biomarker of interest.

For dual probe imaging to be successful, the signal contributions from each of the fluorophores has to be well resolved and the contribution from autofluorescence accounted for. To accomplish this, we evaluated multiple spectral unmixing algorithms to determine which generates the most accurate representation of true fluorophore concentration at tissue depth. This is done by covering well plates, where wells contain varying ratios of QDs, with skin-mimicking PDMS phantoms of varying thicknesses, and then imaging these well-phantoms using an IVIS sytem. This algorithm is then applied to the in vivo targeted tumor imaging experiments.

This method is being used to determine the biomarker status of two distinct biomarkers in tumor xenografts of BT-474 and MCF-7 cells in nude mice. Excitingly, the number of distinct biomarkers in a tumor that can be probed per imaging session is only limited by the full width half maximum of the emitters and the number of distinct emitters in the first optical tissue window.

Silica Coated Gold Nanorods for Target Tumor Specific Localization and Delivery of Therapeutic Molecules
Alexander M. Renner1, Shaista Ilyas1, Kerstin Wennhold2, Muhammad S. Hussain3, Hans A. Schlößer2 and Sanjay Mathur1; 1Institute of Inorganic Chemistry, Germany; 2Center for Molecular Medicine Cologne, Germany; 3Institute of Biochemistry I, Germany

With a size smaller than a living cell, nanoparticles became one of the most promising therapeutic tools in a variety of biomedical application fields. In particular, the new optical, physical and chemical properties of nanomaterials offer a new pathway of treating cancer without affecting healthy cells. Thereby, the hyperthermia properties of
magnetic or optical active nanoparticles can be used to induce specifically natural cell death. In this context, gold nanoparticles came into the main focus of cancer research over the last decades by showing high surface plasmonic resonance leading to optothermal behavior in the near infrared area. Furthermore, gold is chemical inert and nontoxic to the human body.

Nevertheless, an immense challenge for using nanoparticles in cancer therapy is to ensure a highly specific uptake of nanoparticles for cancer cells. Therefore, we present monodispersed and highly selective nanoconjugates for example iron oxide (Fe3O4 with a size of 5 nm) and gold nanorods (mSiO2@Au with a length of 40 nm and a width of 20 nm), which were vectorized by attaching estrogen molecules at their surface by chemo specific reactions. The as-vectorized nanoconjugates were also loaded with therapeutic agent to investigate its drug loading and drug release capacity. The nanoconjugates showed enhanced cellular uptake for MCF breast cancer cell lines, which was quantified by FACS analysis. The functionalized nanoprobes showed promising accumulation at the tumor side as compared to the healthy organs. Our data shows, that as-prepared nanoconjugates holed potential to be used as targeting specific drug delivery nanoprobes.

SB09.07.11
Regulate Hippo Signalling via Lipid-Raft-Targeted Molecular Assembly for Ovarian Cancer Treatment
Guanying Li, Xunwu Hu and Ye Zhang; Okinawa Institute of Science and Technology, Japan

Hippo signalling pathway controls multiple cellular functions that are central to tumorigenesis. Its importance in cancer cell proliferation and metastasis has been well recognized. Here we created polypyridyl ruthenium conjugated peptide complex for lipid-raft-targeted molecular assembly. Via hydrolyzation by ovarian cancer biomarker, glycosylphatidylinositol-anchored placental alkaline phosphatase (ALPP), molecules assemble into nanostructures adhere to lipid rafts restricting their dynamics and spatial distributions. Through actin cytoskeleton, the regulation of lipid rafts stimulates Hippo signalling pathway deactivating the core oncogene YAP in cancer cells suppressing cancer cell migration and inducing cancer cell apoptosis.

SB09.07.12
Harnessing Immunological Synapse Formation as Trigger for Highly Regulated Stimuli-Responsive Drug Delivery
Sooseok Im, Donghyun Jang and Won Jong Kim; Pohang University of Science and Technology, Korea (the Republic of)

Despite of an outstanding therapeutic effect, direct administration of chemotherapeutics still involves diverse side effects and lowers its efficacy. Although, nanoparticle-based drug delivery system (DDS) has been a promising strategy to resolve the problems, continuous controversies about the efficiency of EPR, active targeting, and stimuli-responsive delivery have been suggested. Therefore, rather than relying on man-made targeting system, we focused on natural and intrinsic tumor targeting system in our body, natural killer (NK) cells. The anti-cancer effect of NK cells are known to be innate, immediate and cancer specific, yet insufficient to induce complete regression of tumor. Once circulating NK cells approach to tumor tissue along chemokines from tumor microenvironment, a NK cell would encounter a target cell and initiate the formation of immunological synapse (IS). IS is a pivotal part where panels of activating and inhibitory receptors are binding whose the signals are integrated, thus NK cell decide whether to release its lytic granules. Inspired by the fact the acidic lytic granules are released toward the IS cleft, we hypothesized that the local acidification of the IS cleft would be a stimuli for controlled behavior of drug delivery. To reinforce the cytotoxic killing effect of NK cells as well as to deliver chemotherapeutics in highly regulated manner, IS formation-responsive drug delivery system was developed.

Herein we propose a NK cell decorated by functional nanoparticle with embedded therapeutic cargo. These nanoparticles are composed of acid degradable polymers in micellar formation which contains Doxorubicin. Micelle disassembly will only occur when local pH lowered by release of lytic granules from the NK cell towards cancer cell during immunological attack, therefore minimizing the non-specific release of cytotoxic DOX. Hence, the anti-cancer activity is enhanced through combination of NK-cell-induced tumor-specific homing and potent chemotherapeutic efficacy. The advantages in its therapeutic efficacy and targeting precision will benefit further trials in development and clinical translation of NK cell mediated immunotherapy of cancer.

SB09.07.13
Effect of Hollow Manganese Oxide and Surface Modification for T1 Relaxivity Enhancement
Byunghoon Kang1,2, Seungmin Han3, Moo-Kwang Shin2, Seungjoo Haam2 and Eun-Kyung Lim1; 1Korea Research Institute of
Magnetic resonance imaging (MRI) has attracted increasing interest because of its nonradiative and noninvasive character in addition to providing anatomic images with striking spatial resolution and depth. Positive contrast or proton MR images are produced by T1-based contrast agents such as gadolinium (Gd^{3+}) or manganese oxide (MnO) nanoparticles, which increase the signal from protons by reducing the spin-lattice relaxation time of nearby water leading to the brightening of the voxel. Through decades of research, various approaches have been developed for the synthesis of manganese oxide nanoparticles. Despite growing interest, T1-based MR imaging remains comparatively limited because of ratiometric complications and low signal intensities. Also, in order to impact their relaxation times, T1 contrast agent need to directly interact with the surrounding water protons. In case of nanospheres, only ions at the surface are effective. Decreasing the particle size could provide larger surface area. Also, by converting the particles to the hollow nanostructures, nanoparticle surface percentage could be increased which will in turn provide higher relaxivity. Hollow nanoparticles can provide a high specific area and, excellent penetration and permeation abilities. Hollow nanoparticles have significantly higher volumetric capacity to access water molecules, thereby, enhancing the MR contrast. Furthermore, ligand exchange can lead to added enhancement of contrast by making the surface hydrophilic as compared to the bilayer coated nanoparticles as, hydrophobic inner coating may inhibit water penetration leading to a lower spin effect. Until now, a few hollow MnO-based nanoparticles have been developed, including MnO nanoparticles loaded with iron oxide nanoparticles or drug molecules. Despite this, hollow MnO nanoparticles have not been optimized for low relaxivity and maximum contrast enhancement.

We have developed various solid and hollow manganese oxide (MnO) nanocubes for T1-weighted MR imaging (MnOEn, MnOEx, MnOEnHo and MnOExHo). The as-synthesized MnO nanocubes were rendered water soluble by ligand exchange and ligand encapsulation. Moreover, particles were further treated with phthalate buffer leading to formation of hollow MnO nanocubes. Further characterizations found that hollowed out-ligand exchanged nanostructures (MnOExHo) exhibit maximum enhancement of the longitudinal relaxation by allowing more exposure of Mn ions to water protons. We confirmed the T1 MRI contrast effect of the balb / c nude mice gastric orthotopic xenograft cancer model using MnOExHo nanocube. In this study, we suggested that these hollow ligands exchanged nanocubes (MnOExHo) could be used for biomedical research as effective T1 contrast agents.

SB09.07.14
Self-degradable Graphene Nanomedicine Operated by DNAzyme for Cancer Therapy and Clearance
Hyori Lee, Jinhwan J. Kim, Junseok Lee, Hyeongmok Park, Sungjin Jung and Won Jong Kim; Pohang University of Science and Technology, Korea (the Republic of)

DNA has been utilized as a building block for the formation of a specific structure as well as a fascinating biomaterial for delivery system due to high biocompatibility and the favorable interactions with several biomolecules. Moreover, recent studies have revealed that the DNA can transform the conformation dynamically depending on stimuli such as pH, ion, and biomolecules, suggesting the use of DNA as a functional domain as well. In particular, the G-quadruplex (G4), a guanine-rich sequence which forms the stacked G-quartets structure, can interact with hemin [iron (III)-protoporphyrin] with high specificity, and exhibits a remarkable catalytic property that mimics peroxidase. Owing to the high structural stability and easier handling, DNAzyme has been extensively studied for biosensing, DNA/RNA cleavage, and catalytic reactions.

Graphene oxide (GO) have attracted much attention in biomedical applications due to mechanical and chemical stability, abundant oxygen functional groups on large surface area, and photothermal effect. Although GO possesses many functionalities as itself, modification of GO with several polymers and/or protein is inevitable for the use of nanomedicine because of the fact that the modification increases physiological stability, decreases systemic toxicity, and improves gene/drug loading capability. However, such a modification severely prohibits the degradability of GO by catalytic enzymes including peroxidases due to the steric hindrance of modified materials on the surface of GO.

In this present study, we introduce the G4/hemin complex to take advantage of these modified GOs and induce degradation in the body after the therapy. By applying unique features of catalytic DNAzyme and GO, we propose an ingenious self-catalytic GO nanomedicine for cancer therapy operated by multifunctional DNAzyme and controlled by photo-switch. The surface of GO is decorated by DNA double strand of G4 and its complementary sequence with mucin1 (MUC1) aptamer for targeted delivery. An anticancer drug, doxorubicin (DOX), is loaded on the DNA double strand, while hemin is loaded on the surface of GO. After cellular internalization and turning on the
photoswitch, loaded DOX is released by the DNA melting triggered by the photothermal effect of GO. The remained single stranded G4 sequence conjugated on the GO surface forms quartet structure and subsequently the hemin on GO surface binds on the quartet, inducing catalytic peroxidase effect. Due to the high local concentration of H2O2 in cancer cells, G4-hemin generated efficient amount of strong oxidant, hypochlorous acid (HOCl), inducing the degradation of GO into the small fragments for potential clearance.

**SB09.07.15**

**Singlet Oxygen Generation in Graphitic Carbon Nitride Quantum Dots for Photodynamic Therapy of Cancer**

Pranjali Yadav¹, Nishanthi Thangaraj², Kamalakannan Kailasam¹ and Asifkhan Shanavas³; ¹INST Mohali, India; ²Central Electro Chemical Research Institute, India

Photodynamic therapy (PDT) is an anticancer therapy based on special drugs/ photosensitizers. The three basic elements of photodynamic therapy are the excitation laser, photosensitizer molecule, and oxygen in tissue. After irradiation, the photosensitizer responds to specific light thus generating reactive oxygen species (ROS) killing cancer cells. Being a potential photocatalyst, g-CNQDs are able to create more electron-hole pairs under visible light illumination thereby resulting in the production of large amount of ROS which is helpful to cause severe cellular damage. Graphitic carbon nitride (g-C₃N₄) has been used for various biomedical applications due to its small sheet size, high dispersity, hydrophilicity and non cytotoxicity. g-C₃N₄ also have the ability to generate ROS towards cancer killing under very low-intensity light irradiation. In this study, the g-CNQDs are synthesized by two step thermal polymerization of melamine and EDTA. The QDs are small in size ranging from 2-7nm and demonstrate no visible cytotoxicity against fibroblast cells (L929 cells) and HuVEC cells upto a concentration of 5mg/mL. The optical absorption lies in the UV region at ~250 nm which is due to π-π* electronic transitions. The CNQDs exhibit broad emission peaks shifting towards red region when excited at different wavelengths. The g-CNQDs show excellent singlet oxygen generation capacity that makes them a suitable photosensitizer. In vitro ROS studies reveal that CNQDs were able to generate 370% ROS as compared to control dark. The photocotoxicity of g-CNQDs was assessed using MTT assay and Lactate Dehydrogenase (LDH) assay. In presence of blue light, the g-CNQDs were able to kill almost 75% of C6 glioblastoma at a concentration of 1.25 mg/mL as revealed by MTT assay. This data was supported by LDH assay showed release of 582% of LDH with respect to control. The photosensitized cells were stained with Fluorescein Diacetate (FDA) and Propidium Iodide (PI) in order to determine the percentage of live and dead cells. The cells treated with CNQDs in presence of light exhibited almost 99%. Cell death via apoptotic pathway was observed from Annexin V/FITC PI assay confirming 93.6% of necrotic and apoptotic population. In addition, caspase 3/7 detection assay was performed to detect the caspase mediated apoptosis corresponding to 88% of apoptotic population in light sensitized cells. These data imply blue light irradiated CNQDs exhibited considerable photodynamic effect against cancer cells by caspase activation through the modulation of apoptosis.

**SB09.07.16**

**Thermoresponsive Polymeric Micelles with Enhanced Loading Efficiency Through a Co-Loading Approach**

Pooneh Soltantabar¹, Erika Calubaquib² and Mihaela C. Stefan²; ¹The university of Texas at Dallas, United States; ²The University of Texas at Dallas, United States

Chemotherapy is one of the most effective treatments for cancer, but it has always faced some challenges such as multi-drug resistant (MDR) effect, poor aqueous solubility, and cardiotoxicity of the drug. In the past few decades, micellar drug delivery systems were used to encapsulate anticancer drugs for better therapeutic effects, but they have poor drug loading content. To address this problem, we designed a micellar drug delivery system using benzyl-substituted poly(caprolactone) (PBnCL) as the hydrophobic block for better interaction with anticancer drug Doxorubicin (Dox). Another approach is the co-loading of Dox with other hydrophobic molecules. Quercetin (Que) is a polyphenolic plant-derived flavonoid which has cardioprotective and chemosensitizing properties. Thus, the co-loading of Dox and Que not only enhances the loading capacity of Dox in micelles but also decreases the adverse side effects of anticancer drug and overcomes the MDR effect. Our other approach to improve conventional chemotherapies is developing thermoresponsive micelles. Thermosensitive nanocarriers ideally will retain their load at physiological temperature and release the drug within a tumor once the external temperature is applied to induce local hyperthermia. Polymers exhibiting lower critical solution temperature (LCST) or upper critical solution temperature (UCST) are used as polymers for thermoresponsive drug delivery systems. Herein, we report the synthesis of thermoresponsive polycaprolactones (PCLs) having LCST close to physiological temperature with the advantage of biocompatibility and biodegradability.
Ring-opening polymerization of benzyl- and oligoethylene glycol-substituted ε-caprolactone monomers was performed using tin octanoate as a catalyst and benzyl alcohol as an initiator to generate amphiphilic block copolymers. The synthesized PME_n-CL-b-PnBL polymers were characterized by 1H NMR analysis. To make a comparison between amphiphilic copolymers, a 50:50 ratio of hydrophilic to hydrophobic block were synthesized. The critical micellar concentration (CMC) that evaluates the thermodynamic stability of micelles in the aqueous solution was measured using the fluorescent hydrophobic probe, pyrene. All polymers have CMC values in the order of 10^{-5} g L^{-1}, which indicates high thermodynamic stability of micelles. The particle size distribution of micelles in aqueous solution was measured by dynamic light scattering. All polymers formed micelles with sizes lower than 100 nm, which is the ideal size for passive targeting of tumor cells. LCST measurements will be performed using a temperature-controlled UV-Vis spectrometer. Que and Dox were loaded in micelles through solvent evaporation method, and the drug loading capacity and encapsulation efficiency were measured using UV-Vis spectroscopy. We are expecting that the co-loaded micelles will demonstrate higher drug loading for both drugs in comparison to individual loading of drugs in micelles due to hydrophobic interactions between drugs.

SB09.07.17
Iron-Catalyzed poly(methyl methacrylate) Oligomers for Vaccine Adjuvants Cordula Hege1,1, Amy Stimpson1,1, Kathy Belt2, Chris Fox2 and Derek Irvine1,1; 1University of Nottingham, United Kingdom; 2IDRI (Infectious Disease Research Institute), United States

Adjuvants increase the efficacy of vaccines and can reduce the number of needed immunizations to achieve protection. Mainly aluminium salts are the most used adjuvants, however their immune response is not broad enough (only Th2 response, not Th1 response). For example, aluminium adjuvants are not useable against influenza or malaria. Therefore, it is favourable to search alternative adjuvants. Poly(methyl methacrylate) is useable for medicine-related applications, for example hip replacements or bone cements. Therefore, it is attractive to analyse if it is a possible adjuvant. Previous studies showed that PMMA has good adjuvant activity.1 The previous works did not mention the molecular weight of the polymer. To allow renal clearance, adjuvants should have a molecular weight below 20 kg/mol. To achieve that, one needs to produce reproducible and controlled polymers with a low molecular weight, so oligomers.

Catalytic chain transfer polymerization (CCTP) is a valuable method to synthesize oligomers. However, mainly cobalt catalysts are used. This is disadvantageous for the use as adjuvant. To create a more biocompatible method, iron catalysts were analysed for CCTP. Four-coordinate (diimine)iron catalysts containing aryl substituents proved successful as CCTP catalysts.2 Related to that, four-coordinate iron-diimine complexes with disopropylphenyl (DIPP) and trimethylphenyl (TMP) as substituents were explored. Also we tried, to produce the catalyst in situ, so without additional synthesis of the catalyst. For that dimethyl glyoxime and diphenyl glyoxime were used as ligands. Iron(II)bromide and iron(II)chloride were used to generate the iron complexes.

The reactions were performed with conventional heating and microwave heating (MH), both in bulk and in solvent solution at a reaction temperature of 80°C.

Both methods display chain-transfer behaviour, noting that molecular weight of polymer products was lower than uncontrolled free radical polymerisations. In case of bulk polymerization one has to take care about the reaction conditions to avoid uncontrolled reactions and the Trommsdorff-Norrish effect. With the right conditions, it can lead to lower molecular weight than the solution polymerizations. Microwave heating proved rewarding for the iron-catalysed CCTP.

On the whole, iron catalysed CCTP is demonstrated to be a favourable way to produce MMA oligomers to be used as adjuvants.

SB09.07.18
Development of Near-Infrared Fluorescence Dye and Astaxanthin Loaded Hyaluronic Acid Micelle for
**Photothermal Therapy** Subin Kim¹, Myeong Ju Moon², Suchithra Poilil Surendran¹, In-Kyu Park¹ and Yong Yeon Jeong²; ¹Chonnam National University Medical School, Korea (the Republic of); ²Chonnam National University Hwasun Hospital, Korea (the Republic of)

Recently, researches on the relation between anti-oxidant activity and cancer have been much attracted. Astaxanthin (ATX) has been regarded as an strong anti-oxidant that is several hundred times stronger than vitamin C. Photothermal therapy (PTT) is the usage of heat produced by electromagnetic radiation for cancer treatment. PTT is utilized to maximize the synergistic effect of anticancer drug. Near-infrared fluorescent dye, IR780 iodide (IR), was utilized for performing PTT. In regarding to lipophilic property of both ATX and IR, there are limitation for bio-applications. Hyaluronic acid (HA) is widely used hydrophilic polymer to overcome the this limitation. HA based micelles are beneficial for cancer treatments owing to their biocompatibility and tumor targeting ability to CD44-overexpressing tumors.

In this study, we fabricated HA micelles by self-assembly method and co-loaded with IR and ATX (IR-ATX-HA) for selective tumor targeting in CD44 overexpressed mouse head and neck squamous carcinoma cell line (SCC7). The physicochemical characterization of IR-ATX-HA micelles showed that the IR and ATX were successfully co-loaded into HA micelles. Furthermore, IR-ATX-HA micelles were destabilized upon laser irradiation and were able to release ATX to be utilized for cancer therapy. Intracellular uptake analysis of IR-ATX-HA micelles in SCC7 demonstrated CD44-based targeting. Moreover, cytotoxicity studies proved the improved anti-tumor activity aided by both ATX and PTT therapies compared to without NIR laser irradiation. In conclusion, IR-ATX-HA based micelles were effective in targeting SCC7 cancer cell and able to elicit enhanced cancer therapy effect of ATX and PTT.

**SB09.07.19**

**Solid State Diffusion Controlled Dissolution of Iron-Doped Copper Oxide Nanoparticles Opens a Therapeutic Window for Cancer Therapy In Vitro and In Vivo** Hendrik Naatz¹,², Bella B. Manshian³,³, Suman Pokhrell¹,², Stefaan J. Soenen³,³ and Lutz Mädler¹,²; ¹University of Bremen, Germany; ²Leibniz Institute for Materials Engineering IWT, Germany; ³KU Leuven, Belgium

The therapeutic use of copper oxide nanoparticles (CuO NPs) as effective anti-cancer drug is a promising alternative to conventional treatments. In contrast to insoluble carrier nanoparticles, e.g. iron oxide, copper oxide readily dissolves in cellular nutrient-rich environments, even at physiological pH. Intracellular released Cu²⁺ leads to a redox imbalance and binds to available reaction partners such as amino acids, polypeptides or proteins. At the same time, lattice oxygen will result in the formation of reactive oxygen species causing oxidative stress. Regulatory mechanisms to maintain copper homeostasis involve transport and excretion of copper via Cu-ATPase. If the Cu²⁺ release kinetics are too fast for a regulation, elevated copper levels cause severe damage such as proteasome inhibition leading to apoptosis of cancer and peripheral cells.

Due to differences (i.e. metabolism and pH) between maleficent and peripheral cells determining the release kinetics, we postulated that finely tuned release kinetics of CuO NPs can open a therapeutic window for cancer treatment. To test our hypothesis, we synthesized a library of pure and iron-doped CuO NPs using our in-house flame spray pyrolysis process. The incorporation of iron resulted in a bond-length variation and a strong Jahn-Teller distortion with a decreasing release of copper in biotical environments¹. The Cu²⁺ release kinetics of pure and Fe-doped CuO NPs were investigated on the long-term (250 hours, in agreement with the cell and mice studies) in biological test media containing amino acids present in common growth media, e.g. RPMI or DMEM. In contrast to the fast burst-like release of pure CuO, the iron doping resulted in a two-step dissolution: (1) an initial release on the time scale of hours and (2) a long-term release on the time scale of weeks. Material characterization of the as-prepared particles and the remaining particles after long-term dissolution showed that only copper is released from the particle, while iron remains on the surface. Based on these findings, a release kinetic model was developed to explain the two-step dissolution. The model includes the release of copper until all surface available copper is released, followed by a solid state diffusion limited long-term release.

Three materials (pure, 6% and 10% Fe-doped CuO NPs) with a fast, an intermediate and a slow release kinetic, respectively, where chosen to investigate our hypothesis in-vitro and in-vivo. While the cell viability of tumor and peripheral cells was affected in case of pure CuO, 6% Fe-doped CuO NPs only reduced the cell viability of tumor cells, even for doxorubicin (conventional chemotherapy) resistant cell types. In a combined treatment with an immune activator (IDO1), the 6% Fe-doped CuO NPs were successfully tested in-vivo, resulting in complete tumor
remission in a syngeneic subcutaneous mouse model (KLN-205).

**Hollow Silica Capsules as Transporters for Sustained Delivery of Anticancer and Antimicrobial Drugs** *Eva Krakor*¹, *Isabel Gessner*¹, *Astrid Schauss*¹, *Silke H. Christiansen*², *Uwe Ruschewitz*¹ and *Sanjay Mathur*¹;

¹University of Cologne, Germany; ²Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

The field of nanoparticles for biomedical applications has become one of the most promising and most studied topics in the last years. In terms of therapeutic applications, especially drug delivery vehicles have been intensively studied. In this case, hollow mesoporous silica capsules (HMSC) have aroused tremendous interest due to their unique properties such as high biocompatibility and stability in biological milieu, large surface areas, low densities and high loading capacities due to a protected hollow core.

HMSC were synthesized through a hard template-based method. For that purpose, ellipsoidal hematite particles were synthesized in a solvothermal process, coated with silica in a sol gel process and subsequently the iron oxide core was etched resulting in HMSC. The porosity of as-prepared particles was analyzed using nitrogen adsorption-desorption method revealing a pore size of circa 4 nm and a high surface area of 308.8 m²/g. Cytotoxicity was determined using cell viability test (MTT) towards human kidney cells (HEK293) which clearly demonstrates that no reduction of cell viability was observed even at high concentrations of 100 µg/ml. Uptake studies using confocal microscopy were carried out using human cervical cancer cells (HeLa) which could show the successful internalization over a period of 24 hours. For testing their capability as drug delivery vehicle, a hydrophilic antibiotic (ciprofloxacin) and a hydrophobic anticancer (curcumin) compound were loaded and a pH dependent release under physiological conditions at 37°C was monitored via UV-Vis spectroscopy. Ciprofloxacin-loaded HMSC with a concentration of 10 µg/ml were also tested towards gram negative bacteria (E.coli) revealing a complete growth inhibition over 18 hours. This study demonstrates the suitability of as-prepared hollow silica capsules as drug delivery vehicles for a broad range of drugs.

**Adhesion of Gold Nanoparticles to Triple Negative Breast Cancer Cells** *Vanessa Uzonwanne*¹, *John Obayemi*¹, *Jingjie Hu*², *Arvand M. Navabi*¹, *Nima Rahbar*¹ and *Winston Soboyejo*¹; ¹Worcester Polytechnic Institute, United States; ²Mayo Clinic, United States

The need for the development of nanoparticles for the early detection and treatment of cancer provides the motivation for specific targeting of cancer. This paper presents results of an atomic force microscopy and molecular dynamics study of the adhesion between Triple Negative Breast Cancer Cells (TNBC) (MDA-MB-231 and MDA-MB-468) cells and biosynthesized gold nanoparticles (BGNP). The BGNPs are conjugated with Luteinizing Hormone Releasing Hormone (LHRH), which is known to target LHRH receptors that are over–expressed on the surfaces of breast cancer cells. The adhesion forces between the LHRH-conjugated gold nanoparticles and the breast cancer cells are found to be about 4-5 times greater than those between normal breast cells and LHRH-conjugated gold nanoparticles. The increase in the adhesion of LHRH to breast cancer cells is shown to be associated with an increase in the LHRH receptor density, which is revealed via confocal microscopy. The implications of the results are then discussed for the development of ligand-conjugated gold nanoparticles for the detection and treatment of cancer.

**SB09.07.22**

**FRα-Targeted Gold Nanobipyramids for Fluorescence-Enhanced Imaging and Multimodal Therapy of Triple Negative Breast Cancer Cells** *Ioannis G. Theodorou* and *Triantafyllos Stylianopoulos*; University of Cyprus, Cyprus

Despite significant advances in cancer therapeutics, breast cancer (BC) remains a leading cause of cancer-related death in women worldwide. This could be partly due to the lack of early detection required for improved prognosis, while treatment complications (*e.g.* high systemic toxicity of anticancer drugs or drug resistance) often lead to treatment failure. In particular, triple-negative breast cancers (TNBCs) are highly aggressive, lack validated
therapeutic targets and have high risk of metastasis, representing an urgent unmet clinical need for new treatment options [1]. Here, a novel multifunctional theranostic nanostructure for TNBC is presented, combining for the first time metal-enhanced fluorescence (MEF) imaging with multimodal cancer treatment, through hyperthermia and chemotherapeutic drug delivery.

This integrated theranostic platform comprises a gold (Au) nanobipyramid (AuNBP) core as the MEF amplification component. MEF is an optical process in which the near-field interaction of fluorophores with metallic nanoparticles (NPs) can, under specific conditions, produce large fluorescence enhancements [2]. Efforts are underway to exploit this light amplification to considerably increase detection sensitivity in fluorescence bioimaging, particularly in the biological near-infrared (NIR; wavelengths 650-900 nm) window [3], where bright and biocompatible fluorophores are lacking. In the present work, we focus on AuNBPs, a type of elongated Au nanoparticle (NP) with two sharp tips, equipped with several features that make them attractive candidates for MEF. For instance, their high monodispersity compared to other anisotropic NPs, affords lower inhomogeneous spectral broadening of their localized surface plasmon resonance (LSPR) peaks, while their sharp edges allow significant enhancements of the local electric fields. Here, AuNBPs with tunable sizes are synthesized, allowing LSPRs tunable in the NIR window. We show that NIR fluorophore conjugation to AuNBPs through a mesoporous silica (MS) spacer allows several times fluorescence enhancement in the NIR window. Using time-resolved fluorescence measurements to semi-quantitatively deconvolute excitation enhancement from emission enhancement, as well as electric field modeling, we provide important insights into the mechanism of MEF from AuNBPs.

We then explore the in vitro chemotherapeutic efficacy of doxorubicin, loaded within the pores of the MS layer as a strategy to facilitate local drug delivery to BC cells. In parallel, the AuNBP core is applied for photothermal therapy via NIR laser irradiation, as a synergistic treatment modality. Our results demonstrate that hyperthermia amplifies the potency of doxorubicin against BC cells. Finally, we use folate functionalization of the MS-coated AuNBPs for active targeting of the folate receptor alpha (FRα). FRα is a protein overexpressed in 86% of metastatic TNBC patients, and its expression is associated with poor clinical prognosis, making it a good candidate for TNBC targeting [4]. Using fluorescence imaging, we show that folate functionalization enables selective detection of TNBC cells over cells with low FRα expression. We also show that folate targeting enhances NP accumulation in TNBC cells and potentiates TNBC cell killing.

In summary, the insights gained through this work could guide further development of bright NIR-MEF nanoprobes. Our study also demonstrates the potential clinical utility of folate conjugation to enable selective detection and targeted treatment of aggressive BC subtypes.

Fabrication and Evaluation of High-Dispersive Gadolinium-Complexed Nanodiamond Particles for MR Lymphatic Imaging
Kosaku Yano1, Tomohiro Matsumoto1,2, Takako Nakamura3, Yutaka Okamoto1, Terumitsu Hasebe1,2 and Atsushi Hotta1; 1Keio University, Japan; 2Tokai University Hachioji Hospital, Japan; 3National Institute of Advanced Industrial Science and Technology, Japan

Nanodiamond (ND) particles are nano-scale materials that have recently been attracting major attention for biological purposes, owing to their high biocompatibility and chemical stability. ND particles, however, have their disadvantage to form micro-scale aggregates, which could lead to the loss of the advantageous properties of nanoparticles. An ND-based MRI contrast agent is an example of the material that holds such a problem as mentioned above. Nano-sized contrast agents were fabricated in our previous studies by the complexation of ND particles and gadolinium chelates (Gd-DTPA). The primary size of the gadolinium-complexed ND (Gd-DTPA-ND) particles was set at around 5 nm to achieve the selective imaging of the lymphatic system. This was because MRI contrast agents with a diameter of 3–10 nm could be selectively ingested through lymphatic vessels and filtered in...
Fabrication of Gadolinium-Complexed Carboxylated Nanodiamond Particles for MR Imaging of the Lymphatic System

Kosaku Yano1, Tomohiro Matsumoto1,2, Takako Nakamura1, Yutaka Okamoto1, Terumitsu Hasebe1,2 and Atsushi Hotta1; 1Keio University, Japan; 2Tokai University Hachioji Hospital, Japan; 3National Institute of Advanced Industrial Science and Technology, Japan

The structure and the role of the lymphatic system in the human body have not yet been fully explored in the medical field. This is mainly due to the microscopic diameter of lymphatic vessels, which makes it highly difficult to inject contrast agents directly into vessels. However, it has recently been reported that a macromolecular contrast agent can be uptaken selectively by lymphatic vessels through simple subcutaneous injection to perform high-resolution imaging of the lymphatic system. This is because particles larger than 3 nm in diameter can be drained by lymphatic vessels, but are difficult to penetrate through venular endothelia, resulting in selective lymphatic drainage. Particles smaller than 10 nm in diameter would be uptaken by vessels and filtrated in the kidney for the final excretion. Therefore, fabricating MRI contrast agents with 3–10 nm in size could be a major pathway to address this problem. Previously, we fabricated MRI contrast agents of a few nanometers in diameter with the condensation of gadolinium complexes and ND particles (Gd-DTPA-ND). The primary particles of these contrast agents possessed a diameter of approximately 5 nm, which was considered to be an adequate size for contrast agents to be selectively uptaken by the lymphatic vessels before the excretion in the kidney. However, these particles formed tight aggregations in water, resulting in micro-scale aggregates. The aggregates were too large to be well uptaken and excreted, and the agents could not be used for lymphatic imaging. In this work, the dispersity of the Gd-DTPA-ND particles was analyzed, which was improved by employing ND particles with abundant hydrophilic carboxyl groups on their surface by a pre-oxidation step (CND). The carboxyl groups introduced by oxidation induced hydrophilicity and hence negative charge to the ND surface, resulting in the high dispersity of the gadolinium-complexed CND particles. The dispersity of Gd-DTPA-CND particles in distilled water was evaluated by the dynamic light scattering, revealing higher dispersity for the fabricated particles than for the Gd-DTPA-ND particles. The MRI visibility of the Gd-DTPA-CND particles in distilled water was also evaluated by the 1.5T MRI. It was found that high contrast imaging could be established by the Gd-DTPA-CND particles, showing that the Gd-DTPA-CND particles possessed high MRI visibility in distilled water. Furthermore, the Gd-DTPA-CND particles also possessed high dispersity and MRI visibility even in human serum, suggesting that the particles could be used intravitally. Finally, Gd-DTPA-CND particle solution was injected in a tail vein of a rat to investigate the MRI visibility of the Gd-DTPA-CND particles in vivo. As a result, the injection of the Gd-DTPA-CND particles produced a strong contrast in the blood circulatory system. A bladder was eventually imaged, suggesting successful filtration of particles in the kidney and assembly in the bladder. The results revealed that Gd-DTPA-CND particles could realize high contrast imaging in living bodies and the particles could be filtered in the kidney for the final excretion in the bladder. It was, therefore, concluded that Gd-DTPA-CND particles could be promising MRI contrast agents for the imaging of the lymphatic system through subcutaneous injection.
Protein-Templated Raspberry Gold Nanostructures for Intracellular Plasmonic Imaging and Photothermal Therapy
Animesh Pan, Muzahidul Islam Anik and Geoffrey D. Bothun; University of Rhode Island, United States

Gold-based nanomaterials have shown outstanding physicochemical properties in biomedical applications due to their inherent low toxicity, and their tunable localized surface plasmon resonance (LSPR) wavelength from the visible to near-infrared (NIR) “biological window” region by simply adjusting the size and shape of the nanoparticles. This has enabled the building of fascinating gold-based nanostructures theranostic nanoplatforms for cellular imaging and photothermal therapy (PTT). Herein, we report the synthesis of raspberry gold nanostructures using a polyelectrolyte coated protein (albumin) nanoparticles templates. Albumin nanoparticles were synthesized by desolvation technique using conventional cross-linker (glutaraldehyde) for stable and uniform albumin nanoparticles and then were coated with positively charge poly-L-lysine to enrich the interface with gold anion, exposed to a reducing agent to form raspberry gold nanoshell. The protein templated nanostructures were characterized by dynamic light scattering, filed-emission scanning electron microscope, transmission electron microscopy and visible-near-infrared spectroscopy. The critical parameters for photothermal efficiency, including the concentration and irradiation time, were evaluated. Moreover, the good biocompatibility and the low cytotoxicity of raspberry nanostructures, together with their superior photothermal ablation effect on A549 cancer cells have also been confirmed. Furthermore, we also report the nanostructures for surface-enhanced Taman scattering (SERS) detection of cancer cells with the bioconjugation of different Raman tags. Our study indicates that the protein-templated gold nanoplatform could be a potential candidate PTT and plasmonic sensing in future.

SB09.07.26
Investigation of the Immunological Properties of Cationic Lipid Nanoparticles
Tianshu Li and Shinji Takeoka; Waseda University, Japan

Cationic lipid nanoparticles (LNPs) are well known as drug delivery system (DDS) of nucleic acids and proteins owing to their easy preparation and high cellular uptake efficiency. Many researches have shown various designs of the lipid component to enhance the cellular internalization in different types of cells and meanwhile reduce the cytotoxicity. However, there still lacks the investigation on whether or how cationic LNPs interact with the immune cells.

The NLRP3 inflammasome senses danger signals such as pathogens to alert the immune system by releasing interleukin (IL)-1β. Some cationic NPs and conventional adjuvant alum are reported to have the potential in stimulating the NLRP3 inflammasome. To study the rational of lipid structure in stimulating immune cells, we have investigated a series of cationic LNPs with lysine or arginine head groups but varied lengths of hydrophobic chains and spacers in between in terms of the NLRP3 inflammasomes activation. We found a preferable lipid backbone, ie, ditetradecyl fatty acids with propyl spacer, in either lysine- or arginine-based liposomes that showed high potency in the NLRP3 inflammasome activation in both human and murine macrophages. In addition, these liposomes also exhibited much enhanced antigen presentation in murine dendritic cells when they loaded the ovalbumin antigen on the surface in comparison with other liposomes. The antigen presentations were mediated by both major histocompatibility complex (MHC)-I and MHC-II molecules without interfering co-stimulatory molecules such as CD40, CD80 and CD86. Therefore, OT-I and OT-II lymphocytes (T cells) were sufficiently activated in vitro with significantly increased IL-2 secretion and cell division.

In summary, we have investigated the structure effect of cationic lipids in activating the innate immune cells and further verified their efficiency as antigen carriers in promoting antigen presentation.

Zinc Oxide as Enzyme Mimics for Nitric Oxide Delivery
Tao Yang1, Alexander N. Zelikin2 and Rona Chandrawati1; 1University of New South Wales (UNSW Sydney), Australia; 2Aarhus University, Denmark

Nitric oxide (NO) is a signalling molecule produced by endothelial cells that serves important biological functions in immune system, cardiovascular system, and central nervous system. However, radical NO species are short-lived.
For this reason, controlled delivery of precise amounts of NO with spatiotemporal resolution is highly challenging. Zinc oxide (ZnO) particles offer unique properties that make them excellent tools in biomedical diagnostic and therapeutic fields. In this study, we discovered enzyme-mimicking activities of ZnO and their ability to catalytically decompose endogenous NO prodrugs to generate NO (nM - µM) at physiological conditions. We report a simple approach to synthesize ZnO particles via a chemical precipitation method using poly(vinylpyrrolidone) as the directing agent to control ZnO morphology. We showed that NO can be locally synthesized and the amount generated can be up-/down-regulated simply by tuning the concentration of ZnO (enzyme mimics) and NO precursors. The catalytic approach enables NO delivery on demand, which can be initiated when needed by external administration of the precursors or prodrugs. ZnO preserved their catalytic activity for at least 6 months and enabled sustained delivery of NO. The present study offers opportunities to overcome current challenges of NO delivery in tissue engineering and regenerative medicine.

Cell Mimicking Microparticles to Tune the Immunity
Mohammad Mahdi Hasani-Sadrabadi1, Fatemeh Sadat Majedi1, Song Li1 and Manish Butte2; 1University of California, Los Angeles, United States; 2UCLA, United States

Diseases may arise if there is a physiological inability to make enough key protective factors when most needed. Nano-bio-manufacturing affords the opportunity to synthesize specific factors \textit{in situ} and deliver to cells while employing controls on timing and spatial delivery that cannot be achieved by biological systems. Our main objective here is to develop an on-demand production and release of therapeutic proteins at the site of immunological action. Here, we have developed a nano-bio-manufacturing platform that safely augments the immune response to cancers. As a proof of concept, we chose cytokine interleukin 2 (IL2) as our synthetic target which well known to help activate cytotoxic T cells to fight infections and cancer. Here, the microfluidic platform was used to make a library of monodisperse nanoliposomes of variable sizes that can encapsulate IL2 plasmid DNA and extracts of prokaryotic or eukaryotic cells with a high yield. DMPC and DOPC were used as lipid sources. Incorporation of fluorescent GreenLys or GFP-expressing plasmids were used to monitor protein production in real time. Activated caged ATP (DMNPE-caged ATP) was used to block the expression. UV exposure at 360–480 nm wavelength (OmniCure S2000) for 10 s and 80 mW/cm2 at pH 7.4, 37 °C uncaged the ATP, and IL2-GFP was successfully synthesized. We then first fabricate artificial cells that mimic the size, shape, and mechanics of lymphocytes like T cells. Then we contain the synthetic machinery for transcription and translation of functional IL2 protein and elements that allow for precisely controlled activation and release of the cytokine. The biosynthesis of proteins \textit{in vivo} from artificial cells allows for the production of cytokines with number of features not attainable by conventional biological systems: tunable initiation to eliminate basal expression and systemic toxicity; controlled release to locally focus the site of the cytokines’ activity; and targeting to attach the artificial cells to T cells or cancer sites. Here we optimize \textit{in vitro} synthesis of IL2 cytokine in order to tune T cell fate. First, we encapsulated cell-free protein biosynthesis systems into liposome nanoparticles to make IL2 cytokine. We have established a microfluidic platform to generate monodisperse nanoparticles of various sizes. By controlling the flow rates, we tuned the size of liposomes over a broad range of size (50 - 400 nm). These nanoparticles encapsulated the cell-free synthesis extract and desired plasmids with efficiency dependent on the DNA size of the cargo. 340 nm particles were selected as the optimized size of nanoliposomes and were loaded inside alginate-based microgels. Stimuli-responsive production and sustain release of IL2 showed improve activation and performance of CD4 and CD8 T cells both \textit{in vitro} and in B16 melanoma cancer model \textit{in vivo}. We have developed the \textit{de novo} design of synthetic immune cells to eliminate systemic toxicities through the local manufacture and sustained release of target cytokines (e.g. IL-2), and eliminating basal production by initiating the synthesis specifically upon an external stimulus.

Engineering T Cell Activation for Solid Tumor Immunotherapy
Fatemeh Sadat Majedi, Mohammad Mahdi Hasani-Sadrabadi, Manish Butte and Louis S. Bouchard; University of California, Los Angeles, United States
Despite the many promising results that adaptive T cell therapy has offered to cancer therapy the major hurdle that exists in its clinical translation is the difficulties associated with delivery of trained lymphocytes to tumor sites, along with lack of presence of a support for cells to allow their proper expansion in the immunosuppressive environment of tumor. To bring adaptive T cell therapy one step closer to clinical translation we seek to improve three aspects of current therapies. The first step is to improve capacity and efficiency of adaptive T cells. To tackle this here we have proposed a 3D biopolymer implant as an artificial niche that provides a support for better expansion of pre-trained T cells. We have developed biopolymer-based scaffolds based on the biocompatible Alginate and to further encourage cell trafficking within these structures we have decorated Alginate with RGD peptides. The porosity of scaffolds then modified to creates micro-pores within these implants that both allows for maximizing the loading capacity for delivering T cells and facilitates their expansion as well. To pursue proliferation which for that we have improved this artificial niche by embedding mesoporous silica microparticles within this scaffold to present cytokine (here IL-2) signal in order to improve T cell proliferation. Surface of these particles also decorated with anti-CD3/anti-CD28 to provide T cells with activation signals. One of the main reasons for immunosuppressive environment of tumors in the abundance of TGFβ signal that pursues formation of regulatory T cells (Tregs) which then results in suppression of T killer cells. To overcome this issue, we have empowered our artificial niche with PLGA nanoparticles that engulf TGFβ and suppresses formation of Tregs and gives the trained CD8 T cells a better chance to engage and fight cancer cells. Overall, these bioimplants can be most useful to treat inoperable tumors or in situation were it is near to impossible to remove the whole tumor.

Cell-Matrix Interactions in Cancer and Fibrosis—Multiscale Chemo-Mechanical Models Vivek Shenoy;
University of Pennsylvania, United States

Cell invasion into the surrounding matrix from non-vascularized primary tumors is the main mechanism by which cancer cells migrate to nearby blood vessels and metastasize to eventually form secondary tumors. This process is mediated by an intricate coupling between intracellular and extracellular forces that depend on the stiffness of the surrounding stroma and the alignment of matrix fibers. A multiscale model is used to elucidate the two-way feedback loop between stress-dependent cell contractility and matrix fiber realignment and strain stiffening, which enables the cells to polarize and enhance their contractility to break free from the tumor and invade into the matrix. Importantly, our model can be used to explain how morphological and structural changes in the tumor microenvironment, such as elevated rigidity and fiber alignment prior to cell invasion, are prognostic of the malignant phenotype. The model also predicts how the alignment of matrix fibers can recruit macrophages, which are among the first responders of the innate immune system following organ injury and are crucial for repair, resolution, and re-establishing homeostasis of damaged tissue. I will discuss how the deformation of the nucleus during migration can lead to changes in the spatial organization of chromosomes and their intermingling which can result in genetic mutations and genomic instability. I will also discuss how targeting extracellular matrix mechanics, by preventing or reversing tissue stiffening or interrupting the cellular response in cancer and fibrosis, is a therapeutic approach with clinical potential.

BIO: Vivek Shenoy is the Eduardo D. Glandt President’s Distinguished Professor in the School of Engineering and Applied Sciences at the University of Pennsylvania. Dr. Shenoy’s research focuses on developing theoretical concepts and numerical methods to understand the basic principles that control the behavior of both engineering and biological systems. He has used rigorous analytical methods and multiscale modeling techniques, ranging from atomistic density functional theory to continuum methods, to gain physical insight into a myriad of problems in materials science and biomechanics. Dr. Shenoy's honors include a National Science Foundation CAREER Award (2000), the Richard and Edna Solomon Assistant Professorship (2002-2005) and the Rosenbaum Visiting Fellowship from the Isaac Newton Institute of Mathematical Science, University of Cambridge and the Heilmeier award for excellence in faculty research (2019). He is the principal investigator and director of the NSF-funded
Science and Technology Center for Engineering Mechanobiology established in 2016. He also serves the editor of the Biophysical Journal and is a fellow of the American Institute for Medical and Biological Engineering.

Biomechanical Imaging of Cancer Cells and Tumor Development in 3D Ming Guo; Massachusetts Institute of Technology, United States

Sculpting of structure and function of three-dimensional multicellular tissues depend critically on the spatial and temporal coordination of cellular physical properties. Yet the organizational principles that govern these events, and their disruption in disease, remain poorly understood. Here, I will introduce our recent progress performing biomechanical imaging to quantify cell and extracellular matrix (ECM) mechanics, as well as their mechanical interaction. By integrating confocal microscopy with optical tweezers, we have developed a platform to map in three dimensions the spatial and temporal evolution of positions, motions, and physical characteristics of individual cells throughout a growing mammary cancer organoid model. Compared with cells in the organoid core, cells at the organoid periphery and the invasive front are found to be systematically softer, larger and more dynamic. These mechanical changes are shown to arise from supracellular fluid flow through gap junctions, suppression of which delays transition to an invasive phenotype. Together, these findings highlight the role of spatiotemporal coordination of cellular physical properties in tissue organization and disease progression.

3D Traction Force Microscopy of Multicellular Invasion in Biomimetic Silk-Collagen Hydrogels Susan E. Leggett¹, Mohak Patel¹, Thomas M. Valentin¹, Christian Franck² and Ian Y. Wong¹; ¹Brown University, United States; ²University of Wisconsin–Madison, United States

Epithelial tumors exhibit dysregulated cell-cell and cell-matrix adhesions as they invade into the surrounding extracellular matrix. In particular, the epithelial-mesenchymal transition (EMT) is associated with weakened cell-cell adhesions and strengthened cell-matrix adhesions, resulting in multicellular dissemination. Traction force microscopy enables new insights into the cell-generated forces that mediate these behaviors, but has primarily been applied to individual cells in 3D. Here, we elucidate the collective tractions of multicellular clusters in 3D matrix after induction of the EMT master regulator Snail. We find that multicellular clusters exhibit characteristic spatial signatures that can be used for mechanophenotypic profiling. In particular, EMT results in highly localized “hotspots” of strong cell-matrix adhesion, associated with high contractility and front / back polarization. We further show that chemotherapeutics and targeted inhibitors can perturb clusters towards more epithelial or mesenchymal-like mechanophenotype. We envision that this 3D culture assay will enable high content preclinical screening of targeted anticancer compounds as well as to predict the clinical response of human patient samples.

Unjamming and Collective Migration in MCF10A Series of Breast Cancer Cell Lines Jae Hun Kim and Jeffrey Fredberg; Harvard University, United States

Carcinoma cells tend to migrate in collective strands, ducts, sheets or clusters (Friedl, & Gilmour, Nat. Rev. Mol. Cell. Bio. 2009). To migrate collectively, the epithelial collective has been argued to overcome geometric constraints attributable to cell jamming (Atia et al., Nat. Phys. 2018). If so, then the greater is the degree of cellular jamming, then the more would be the extent to which each individual cell becomes caged by its neighbors, and therefore, the less rapidly it would be able to migrate (Park et al., Nat Mat. 2015). The jamming hypothesis, however, has never been tested in the context of cancer cell invasiveness. Using classical in vitro cultures of six breast cancer models, here we investigate structural signatures of jamming, dynamical signatures of jamming, and the relationship between them. In order of increasing invasiveness, the cell lines examined included MCF10A, MCF10A,vector; MCF10A.14-3-3z; MCF10.Erb2, MCF10AT; and MCF10CA1a. Across all models tested, cell shape and shape variability from cell-to-cell conformed well to structural signatures of cell layer jamming. In all cases but one, migratory dynamics changed roughly in concert with expectations based on structural signatures –as the strength of structural signatures of unjamming increased, the rapidity of migratory dynamics tended to progressively increased. The exception was the case of MCF10CA1a, wherein structure signified a moderately jammed state whereas migratory dynamics were excessively rapid and therefore discordant with structure. Closer
examination of migratory dynamics of MCF10CA1a showed anomalously large migratory persistence, but the mechanism of discordance in this case remains unclear. A hallmark of cancer is multiple dimension of heterogeneity. Nevertheless, each of the diverse cases examined here reveals that cell jamming imposes an overriding geometric constraint.

Mechanical Forces, the Microenvironment and Metastasis of 3D Microtumors Joe Tien¹, Celeste Nelson² and Bryan A. Nerger²; ¹Boston University, United States; ²Princeton University, United States

Progression to metastatic breast cancer requires cancer cells to invade from a solid tumor into the surrounding stroma and escape into a lymphatic or blood vessel. To understand the biophysical and biochemical parameters that define the kinetics of invasion and escape, we engineered a three-dimensional model of human breast microtumors embedded within native extracellular matrix. We previously found that interstitial fluid pressure (IFP) determines the invasive response of human breast microtumors: specifically, interstitial hypertension (i.e., elevated IFP) prevents invasion, whereas interstitial hypotension (i.e., lowered IFP) promotes invasion. We have now used this system to examine the effects of matrix density, proteolysis, proliferation, and IFP on the kinetics of tumor cell escape into an empty cavity. Our data suggest that the physical microenvironment of a tumor dictates the rates of two early steps in the metastatic cascade, namely, invasion of the surrounding interstitium and escape into an open space. These physical features dictate whether escape results from a ballistic or diffusive invasion process. Furthermore, acute changes in interstitial pressure can suppress tumor cell escape after invasion has already occurred. Our results point to the possibility of using physical therapies to delay or prevent metastatic progression in breast cancer.

11:00 AM *SB09.08.06/SB06.10.06
Engineered Microfluidic Environments to Study the Role of Nuclear Mechanobiology in Cancer Progression Jan Lammerding; Cornell University, United States

Cancer metastasis, i.e., the spreading of cells from the primary tumor to distant organs, is responsible for more than 80% of all cancer deaths. During cancer cell invasion and metastasis, tumor cells migrate through interstitial spaces and transendothelial openings substantially smaller than the diameter of the cell. Recent research has made it apparent that cells migrating in such confined three-dimensional (3D) environments face substantially physical challenges. In particular, the cell nucleus is the largest and stiffest organelle, making nuclear deformation a rate-limiting factor in the passage of cells through confined 3D environments. We have used micro- and nano-fabrication approaches to generate microfluidic devices that closely mimic the physical constraints of physiological interstitial environments, while providing precise control over the constriction geometry and enabling live-cell imaging at high spatial and temporal resolution. Using these devices, we demonstrated the importance of available pore size and nuclear deformability on the ability of cells to move through 3D environments. We combined these devices with fluorescent reporters for nuclear envelope rupture and DNA damage to assess the functional consequences of the physical forces exerted on the nucleus during confined migration. In addition, we developed a microfluidic micropipette aspiration device to rapidly measure nuclear stiffness in large numbers of cells. We found that highly metastatic breast cancer cells had decreased levels of the nuclear envelope proteins lamin A/C, which determine nuclear deformability, compared to less aggressive tumor cells, and that the increased nuclear deformability promoted migration through tight spaces. Increasing expression of lamin A in breast cancer cells with normally low levels of lamin A/C significantly impaired their invasive properties, while depletion of lamin A/C increased invasive potential through micron-scale microfluidic constrictions and dense collagen matrices. Importantly, analysis of human breast tumor tissue microarrays showed that low levels of lamin A/C correlated with reduced disease-free survival, demonstrating the clinical relevance of our findings. Taken together, these studies indicate that downregulation of lamin A/C could promote both cancer cell invasion and metastasis in breast cancer while highlighting the appeal of engineered materials and microenvironments to study tumor cell mechanobiology. Insights gained from this work could improve prognostic approaches; ultimately, targeting regulator pathways associated with altered lamin expression may offer novel therapeutic avenues to control metastatic disease in breast cancer.

The National Cancer Institute’s Support for the Interface of Bio/Nano Materials with Cancer Research

Nas Zahir; National Cancer Institute, United States

The U.S. National Cancer Institute (NCI) leads, conducts, and supports cancer research across the nation to advance scientific knowledge and help people live longer, healthier lives. Many advancements in cancer research in areas of progression, metastasis, and treatment response have been enabled by the development of innovative technologies, including novel biomaterials, microfluidics, and biomimetic engineered technologies. Several programs at the NCI have helped foster cancer technology development in these areas as well as the overall convergence of approaches and perspectives from the physical sciences and engineering into cancer research. Over the past decade, the NCI has supported the NCI Physical Sciences – Oncology Network (PS-ON), which is comprised of nearly 30 transdisciplinary teams that integrate physical sciences perspectives with cancer research to complement and expand on our current understanding of cancer across many biological length- and time-scales. Thematic areas under investigation in the PS-ON include transcriptional dynamics and genomic architecture, modeling evolutionary dynamics of treatment response, cancer mechanobiology and the physical microenvironment, and multi-scale computational modeling approaches to integrate data across length scales. PS-ON investigators and those in the affiliated Cancer Tissue Engineering Collaborative (TEC) research program are utilizing biomaterials and biofabrication for experimental model systems of cancer that recapitulate the tumor microenvironment and tumor-stromal interactions. There is also sophisticated incorporation of bioreactors and microfluidic culture to mimic perfusion, lymphatics, interstitial pressure, and molecular gradients. Other research initiatives supported by the NCI to promote convergent, cross-disciplinary research that include projects incorporating novel biomaterials are the Cancer Systems Biology Consortium (CSBC) and the Innovative Molecular Analysis Technologies (IMAT). The NCI demonstrates its interest in supporting materials science and engineering in cancer research by investment in these areas through investigator-initiated research and the targeted programs. The continued investigation of the physical dynamics of cancer and incorporation of novel biomaterials and biomimetic engineered technologies will be important, focusing on understanding the complex and dynamic multiscale interactions of the tumor, host, and immune system. Innovative technology development will continue to be critical for unprecedented measurements and discoveries in cancer research.

Nuclear Rupture at High Curvature and High Rates Upsets DNA Repair to Affect Cell Cycle, Differentiation and Genome Variation
Dennis E. Discher; University of Pennsylvania, United States

The nucleus links physically to cytoskeleton, adhesions, and extracellular matrix – all of which are subject to stresses and strains. We have taken various materials-intensive approaches to study nuclear rupture in tumors [1], embryonic organs [2], and various in vitro models, and we find rupture results from high nuclear curvature, leading to cytoplasmic mis-localization of multiple DNA repair factors and transcription factors that impact cell fate and function. Curvature is imposed by external probe [1], by migrating quickly (not slowly) through constricting micropores [3,4], or by cell attachment to either aligned matrix or stiff matrix [1], and theory indicates rupture pores from by a heterogeneous nucleation mechanism [5]. Mis-localization of nuclear factors is greatly enhanced by nucleoskeleton depletion (soft nuclei), requires many hours for nuclear re-entry, and correlates with pan-nucleoplasmic foci of DNA damage and with electrophoretic breaks. Excess DNA damage is rescued in ruptured nuclei by co-overexpression of multiple DNA repair factors as well as by soft matrix or inhibition of either actomyosin tension or oxidative stress – with combination treatments needed to rescue a cell cycle checkpoint [4]. Increased contractility has the opposite effect, and stiff tumors with softened nuclei indeed exhibit increased nuclear curvature, more frequent nuclear rupture, and excess DNA damage. Normal differentiation processes of myogenesis and osteogenesis are also affected by migration through constricting pores, suggesting general effects on cell fates [6]. Mis-repair of DNA is further suggested by two cancer lines that, after constricted migration, exhibit greater genome variation [1,3]. References: [1] Y Xia, … DE Discher. Nuclear rupture at sites of high curvature

2:00 PM *SB09.09.02/SB06.11.02
The Dynamic and Reciprocal Relationship between Tissue Tension and Pro Tumor Immunity Valerie Weaver; University of California, San Francisco, United States

Tumors show increased tissue level forces and a present with a chronically stiffened extracellular matrix (ECM), and transformed cells exhibit a perturbed oncogene-stimulated and ECM-tuned mechanophenotype. We have been studying how these aberrant cell and tissue level forces promote malignant transformation and drive tumor metastasis, and how they modulate tumor recurrence and treatment resistance in breast and pancreatic cancer and glioblastoma. We use two and three dimensional culture models with tuned extracellular matrix stiffness, as well as transgenic and syngeneic mouse models, human PDX models and human biospecimens, in which ECM crosslinking and stiffness and integrin mechanosignaling can be quantified and modified. Our studies have thus far revealed that the ECM in all tumors is progressively remodeled and stiffened by stromal fibroblasts and that this occurs prior to malignant transformation. We determined that ECM remodeling and stiffening is mediated very early during malignancy by stromal fibroblasts that are activated by factors including TGFβ that are secreted by infiltrating pro inflammatory macrophages. The stromal-fibroblast stiffened ECM disrupts tissue organization, promotes cell growth and survival and drives cell invasion. A chronically stiffened tissue stroma drives angiogenesis, and activates STAT3 to induce key cytokines and chemokines that promote pro-tumor immunity to foster tumor growth and dissemination and impede tumor treatment. The stiffened ECM also drives an epithelial to mesenchymal transition and primes the metastatic niche to foster metastasis. I will discuss the dynamic and reciprocal interplay between tissue tension and innate and acquired immunity and how this can not only force tumor aggression and metastasis but may also initiate tumor progression.

2:30 PM BREAK

3:30 PM *SB09.09.03/SB06.11.03
Biosynthetic Hydrogels for Islet Engraftment and Immune Acceptance Andres Garcia; Georgia Institute of Technology, United States

Hydrogels, highly hydrated cross-linked polymer networks, have emerged as powerful synthetic analogs of extracellular matrices for basic cell studies as well as promising biomaterials for regenerative medicine applications. A critical advantage of these synthetic matrices over natural networks is that the biophysical and biochemical properties of the material can be tuned with high control and precision. For example, bioactive functionalities, such as cell adhesive sequences and growth factors, can be incorporated in precise densities. We have engineered poly(ethylene glycol) [PEG]-maleimide hydrogels that support improved pancreatic islet engraftment, vascularization and function in diabetic models. Two biomaterial strategies will be discussed. We have developed proteolytically degradable synthetic hydrogels, functionalized with vasculogenic factors, engineered to deliver islet grafts to extrahepatic transplant sites via in situ gelation. These hydrogels induce differences in vascularization and innate immune responses among subcutaneous, small bowel mesentery, and epididymal fat pad transplant sites with improved vascularization and reduced inflammation at the epididymal fat pad site. This biomaterial-based strategy improves the survival, engraftment, and function of a single pancreatic donor islet mass graft compared to the current clinical intraportal delivery technique. In a second application, we have developed a localized immunomodulation strategy using hydrogels presenting an apoptotic form of Fas ligand (SA-FasL) that results in prolonged survival of allogeneic islet grafts in diabetic mice. A short course of rapamycin treatment boosts the immunomodulatory efficacy of SA-FasL-hydrogels, resulting in acceptance and function of allografts over 200 days. Survivors generate normal systemic responses to donor antigens, implying immune privilege of the graft, and have increased T-regulatory cells in the graft. Current studies focus on evaluating this immunomodulatory strategy in a large animal model of type 1 diabetes. This localized immunomodulatory biomaterial-enabled approach may provide an alternative to chronic immunosuppression for clinical islet transplantation.
4:00 PM *SB09.09.04/SB06.11.04
Viscoelasticity and Cancer David J. Mooney; Harvard University, United States

It has long been recognized that tissue mechanical properties are altered in cancer, and this can serve as the basis for early diagnosis. While the impact of changes in tissue stiffness has been the focus of research to date, the role of tissue viscoelasticity has not been widely explored. We have developed hydrogels which allow for independent control over elastic moduli and stress relaxation/creep, and can mimic the fibrillar architecture of native collagenous matrices. These material systems are being utilized in 3D cell culture models of cancer and immunotherapy, and demonstrate that the gene expression of various cell types present in tumors, including cancer cells, mesenchymal cells, and immune cells is profoundly impacted by the viscoelastic properties of their matrix.

4:30 PM SB09.09.05/SB06.11.05
Integrin-Specific Hydrogels Direct Mesenchymal Stem Cell Immunomodulation and Bone Regeneration
Karen E. Martin1, Amy Y. Clark1, José R. García1, Christopher T. Johnson1,2, Hannah S. Theriault1, Woojin M. Han1, Dennis W. Zhou1, Edward Botchwey1,2 and Andres Garcia1; 1Georgia Tech, United States; 2Emory University, United States

Mesenchymal stem cells (MSCs) are a promising cell source for regenerative medicine applications due to their ability to self-renew, capacity for multipotent differentiation and secretion of a diverse array of cytokines and growth factors (the MSC secretome). These cells are frequently utilized in conjunction with biomaterial scaffolds designed to encourage cellular retention and direct the cells’ regenerative properties. However, hydrogel carriers have not yet yielded significant results in the clinic in part due to a lack of understanding of how hydrogel biophysical and biochemical properties impact cellular function. Although many synthetic hydrogels incorporate short peptides (e.g. RGD) to support integrin-mediated cell adhesion, the impact of hydrogel adhesive properties on transplanted cell function remains unknown.

We engineered integrin-specific hydrogels for the delivery of MSCs by tethering either the ubiquitous RGD cell adhesion motif or the type-1 collagen derived GFOGER adhesion motif into synthetic poly(ethylene) glycol (PEG)-based hydrogels. Integrin-specificity was confirmed using blocking antibodies and a custom spinning disk platform in which cells attached to hydrogel disks are exposed to well-defined hydrodynamic shear forces allowing for sensitive measurements of the force required to detach the cell from the substrate. The effects of integrin-specific adhesive peptide presentation on MSC secretome and MSC-macrophage interactions were evaluated in vitro using Luminex multiplex technology. Finally, integrin-specific hydrogel directed MSC bone tissue regeneration was assessed over the course of 8 weeks in a critical size radial bone defect in an NSG mouse model.

Spinning disk analysis shows that cell adhesion to hydrogels presenting the adhesive peptides RGD and GFOGER are specific to αvβ3/β1 and α2 integrins respectively. Luminex data shows that the secretome of MSCs encapsulated in integrin-specific hydrogels cluster distinctly based on peptide and secretion of IL-6, IL-8, and VEGF is increased in GFOGER functionalized gels compared to RGD and non-adhesive controls. Further, in a co-culture assay, we show that macrophage cytokine secretion is differentially modulated by MSCs encapsulated in integrin-specific hydrogels, including an increase in IL-10 secretion by macrophages interacting with GFOGER encapsulated MSCs. Finally, MSCs delivered in GFOGER functionalized hydrogels significantly enhance repair of critical size bone defects in vivo compared to RGD and non-adhesive controls. Taken together, our results demonstrate that integrin specificity can be engineered into synthetic hydrogel systems resulting in modulation of the MSC secretome, differential MSC-macrophage interactions and improved tissue healing.

Designing Biomaterial Vaccines to Generate Tumor-Specific Immunotherapy
Nisarg Shah1,2, Alexander Najibi1, Angelo Mao1, Ting-Yu Shih1 and David J. Mooney1; 1Harvard University, United States; 2University of California, San Diego, United States

Acute myeloid leukemia (AML) is a malignancy of hematopoietic origin with limited therapeutic options. The standard-of-care cyto-reductive chemotherapy can rapidly induce an apparent remission but relapse occurs in the
majority of patients, highlighting the difficulty in eradicating all AML cells. A highly immunosuppressive AML microenvironment in the bone marrow and a paucity of suitable cell surface immunotherapy targets on AML cells precludes the induction of an effective endogenous adaptive immune response, which contributes to disease relapse. AML cells generally have a relatively low mutational load, are weak stimulators of host immune cells and often possess mechanisms that prevent induction of an effector T cell response. However, the anthracyclines used for treating AML induce cell death and promote dendritic cell (DC) cross-priming of tumor-associated antigens for T cell by the release of damage-associated molecular patterns. This effect is broadly associated with stimulating an antitumor T cell immune response and may partially contribute to the efficacy of the treatment. The susceptibility of AML to effector T cells is supported by the finding that AML, like many other types of cancer cells, displays tumor antigens that have the potential to trigger immune responses. Therefore, therapeutic vaccines have the potential of achieving a lasting AML-specific immune response capable of eradicating the residual disease that remains following chemotherapy. The development of cancer vaccines requires T cell activation resulting from effective presentation of one or more tumor antigens in the context of co-stimulation. To promote a robust and durable immune-response against AML, we developed a biomaterial-based vaccine which provided a sustained release of GM-CSF to concentrate dendritic cells (DCs), TLR agonist CpG-ODN and one or more leukemia antigens in the form of a peptide antigen, cell lysates or sourced from in vivo recruited AML cells. The vaccine induced local cell infiltration and activated DCs to evoke a potent anti-AML immune response. Prophylactic vaccination alone prevented the engraftment of AML cells. Moreover, mice were able to overcome a re-challenge, indicating the potential of these vaccines to establish a long-term immunity. Combining induction chemotherapy (iCt) and the biomaterial vaccine maximized efficacy to eradicate established disease, even without exogenous delivery of a defined vaccine antigen. We found that by recruiting DCs and sustaining their activation in an otherwise immunosuppressive AML environment, the biomaterial vaccine can harness a broad range of tumor antigens arising from chemotherapy-induced AML cell death, including those not delivered through the vaccine. Furthermore, iCt in combination with the biomaterial vaccine transiently decreased bone marrow FoxP3+CD25+ Tregs and enhanced tumor-specific T cells. The CD8+ T cell/Treg ratio was higher in the bone marrow of mice treated with iCt and the antigen-free vaccine, compared to the antigen-free vaccine alone. The combination treatment depleted AML cells and generated durable long-term effector T cell responses, and immunized transplanted mice against AML. The biomaterial vaccine treatment was well-tolerated and promoted AML rejection without the indication of pancytopenia or autoimmunity in the studies. Our findings suggest that induction of a potent anti-AML immune response in such a setting might prevent the life-threatening evolution of this disease. In contrast to neoantigen-based vaccination, a scaffold generating tumor specific immune responses in situ can be an off-the-shelf approach for treating patients post-iCt. The results from this experimental mouse model of AML demonstrate the capacity of a biomaterial-based vaccination approach to induce a potent immune response to deplete AML and prevent relapse.
SESSION SB10.01: Smart Textiles  
Session Chairs: Beatrice Fraboni, Alon Gorodetsky, Esma Ismailova and Martin Kaltenbrunner  
Monday Morning, December 2, 2019  
Hynes, Level 3, Room 300

8:30 AM *SB10.01.01  
Smart Textiles for Next-Generation User Interface Solutions Michael Haller¹, Martin Kaltenbrunner², Roland Aigner¹, Sara Mlakar¹, Patrick Parzer¹, Andreas Pointner¹, Thomas Preindl¹ and Reinhard Schwoediauer²; ¹Media Interaction Lab, Austria; ²Johannes Kepler Universität Linz, Austria

The beginning of the 1990s marked the dawn of research into smart textiles. At this time, Mark Weiser and his colleagues at Xerox PARC introduced their vision of a computational environment embedded seamlessly into our lives. The vision of Ubiquitous Computing proposed a world in which “computers disappear into our everyday environments and weave themselves into our daily lives without being noticed”. While smart textiles were initially mainly influenced by the military and existing wearable technologies, consumer and healthcare markets have since become major driving forces. Today, textiles make up an essential and indispensable part of our daily lives. Since they are generally lightweight and highly flexible, they are applicable in a wide range of applications. In combination with electronic components, textiles can be enhanced with several additional capabilities ranging from sensing and actuation to lighting and information display. This opens the door to many novel application areas. As stated by Ivan Poupyrev, the leader of the Project Jacquard team at Google, “if you can hide or weave interactivity and input devices into the materials, that will be the first step to making computers and computing invisibly integrated into objects, materials and clothing”.

Within the project TextileUX, we aim to take the next step in realizing Mark Weiser’s vision. We strongly believe that smart textiles can thoroughly augment any object and provide new and exciting features that are difficult or impossible to realize with other solutions. The goal is to create an interactive textile sensor capable of sensing touch gestures and deformation input in real-time. The underlying principle is similar to a Force Sensing Resistor (FSR) that has been used for over thirty years. A typical FSR device is a continuous electrical switch whose electric conductance gradually increases as external force is applied. In one common configuration, two conductors are placed into mutual contact via a semi-conductive material. Most of these sensors, though common, generally detect only a single touch. Resistive array-based multi-touch sensors have a flat form factor, are inherently inexpensive, use little power, and can continuously measure applied force. Researchers have transferred this basic principle into the field of pressure-sensitive fabrics in the form of textile materials that include an array of vertical and horizontal conductors separated by a semi-conductive layer. We reduce the layer stack to one single layer by transferring the same pressure-sensing principle right into the yarn itself. Our novel yarn comprises a conductive metallic thread with a resistive coating consisting of an organic polymer solution containing conductive carbon-based particles. Once an external force is applied to the resistive yarn, the coating gets compressed, which increases the density of conductive particles in the coating and corresponds to a change in resistance of the coating. In the case where two coated yarns overlap each other, the change in resistance can be measured by applying voltage to one yarn and measuring the voltage drop across the other one. The same principle can also be achieved by overlapping a resistive-coated yarn with an off-the-shelf conductive yarn. This simple principle opens up a wide array of possibilities for the design of interactive textiles.

9:00 AM SB10.01.02  
Flexible Magnetoelectronics for Interactive Wearables Gilbert Santiago Canon Bermudez and Denys Makarov; Helmholtz-Zentrum Dresden-Rossendorf e.V., Germany

The recent rapid advance and eagerness of portable consumer electronics stimulate the development of functional elements towards being lightweight, flexible, and wearable. Next generation flexible appliances aim to become fully autonomous and will require ultra-thin and flexible navigation modules, body tracking and relative position monitoring systems. Key building blocks of navigation and position tracking devices are magnetic field sensors. Although there is a remarkable progress in the field of shapeable magnetoelectronics [1], there is no technology available that can enable sensitivities to geomagnetic fields of 50 µT and, ultimately, magnetic fields of smaller than 1 µT in a mechanically compliant form factor. If available, these devices would contribute greatly to the realization of high-performance on-skin interactive electronics [2-5] and point of care applications [6,7]. Here, we will present technological platforms allowing to realize not only mechanically imperceptible electronic
skins, which enable perception of the geomagnetic field (e-skin compasses) [8], but also enable sensitivities down to ultra-small fields of sub-50 nT [9]. We demonstrate that e-skin compasses allow humans to orient with respect to earth’s magnetic field ubiquitously. Furthermore, biomagnetic orientation enables novel interactive devices for virtual and augmented reality applications. We showcase this by realizing touchless control of virtual units in a game engine using omnidirectional magneto-sensitive skins.

9:15 AM  SB10.01.03
Foundation for Textile Electronics—Self-Patterned Fibers Mehmet Kanik, Michael Tarkanian, Sirma Orguc, Anantha Chandrakasan and Polina Anikeeva; Massachusetts Institute of Technology, United States

Stable and reliable textile electronics require precise tools for the integration of active electronic components. Most printed circuit boards are manufactured using hard materials such as metals, glasses, and semiconductors, which often fail to provide a flexible foundation for textile applications. Polymer-based fibers, which exhibit flexible mechanical properties provide a promising alternative material choice for flexible electronics. Electronic textiles produced from multimaterial fibers could be designed to integrate multiple functionalities while providing the required mechanical stability owed to built-in packaging and insulation. Electronic fabrics based on such fibers can further be integrated into apparel or used for medical or situational monitoring.

As a flexible analog to a breadboard, we demonstrate self-patterned planar fiber structures with push-in electrical connectors. Self-patterned fibers contain 24 to 1000 electrodes (5 µm in thickness), for straightforward assembly of on-fiber electronics. While the thickness of these self-patterned fibers is < 50 µm, they can be drawn as long as 500 meters. The patterns along the fiber can be engineered prior to fiber drawing of the macroscopic preform using conventional machining. After deposition of the electrodes on the self-patterned preform, the fibers can be cut to various lengths and stacked to create complex electronic circuits or used as a continuous fiber-electronic board. In addition, the design allows the integration of on-chip connectors similar to USB ports. The electrodes on the self-patterned fiber can be thermally deposited metals (Au, Pt or TiN), and the impedance can be optimized by tuning the metal thickness. After surface mounted electronic components have been placed onto the fiber circuits, these devices can be encapsulated by depositing high-density dielectrics and parylene C or polymeric coatings. Such fibers are expected to find a broad range of applications in textile electronics, sensors, and structural health monitoring.

10:00 AM *SB10.01.04
Tailoring Multi-Scalar Material Behavior for Sensorimotor Movements and Social Interactions Sean Ahlquist; University of Michigan, United States

The design and control over bespoke means of advanced manufacturing has become ubiquitous within the field of architecture. A designer’s proficiency in orchestrating the means of production, through crafting design-specific fabrication techniques, links directly to the level of technical specificity that is possible for the assembly, form and responsivity of an architectural system. In the most experimental cases, this approach is deployed in order to finely tailor the ambient relationships between the architectural system and its environment – embedding responsivity to atmospheric factors such as light, temperature and humidity. The on-going research discussed here, titled Social Sensory Architectures, looks to further such access to advanced manufacturing by exploring the influences of architectural environment on human behavior. Particularly, the research addresses architecture’s imposition on social function for individuals with the neurodevelopmental disorder of autism, where a sensorial hyper-awareness can commonly drive anxiety and maladaptive behavior.
In this research, novel uses of industrial knit manufacturing are leveraged to create sensorially-reactive architectural environments intended to access an individual’s beneficial spectrum of hyper-awareness towards sensory stimuli. The common immutability of an architectural environment poses a diminished capacity for an individual’s development due to their lack of adaptability towards stressful scenarios – typical for those with autism. Alternatively, proffering an environmental adaptability, particularly towards the tactual modes of stimulation, creates the potential for enhancement of learning, motor and social outcomes. This is done so through tailoring degrees of elasticity across the entire hierarchy of constitutive properties for a manufactured knit textile – fiber, stitch, pattern, interface and structure. As part of a tent-like assembly, which affords a macro-scale degree of deformation and elasticity, the textile serves as a reactive tensile interface. Its operative nature utilizes (i) elastic filaments and the ability to straighten coiled inelastic fibers tailored for responsiveness at the scale of the hand, (ii) the conformable nature of varying stitch types to produce areas of differential pre-stress, and (iii) 3D geometry through which volumetric spatial organizations emerge and manage loading at the scale of the body.

Two key capacities were exhibited: (i) the adaptiveness of the responsive environment towards a diversity of sensorial interests across the neurodiverse population that was observed, and (ii) a sustained interest in the exploration, practice and mastery of new movement behaviors allowing for generalization beyond the specific site in which it was mastered. This unfurls the overarching potential for the research, in providing a template for exploration, practice and mastery of new movement behaviors allowing for generalization beyond the specific site in scales of movement patterns taking place across the entirety of the environment.

For those with autism, the development of motor skills is commonly delayed and the ability to engage in physical activities increasingly limited with age. The acquisition of motor skills on the same timetable as with peers is critical to social engagement, particularly when centered around play. This linkage between sensorimotor and social behaviors is core to this research, enabling individuals to shape patterns of tactile, proprioceptive and vestibular movement. Through field studies with the sensory-responsive environments, in venues with elementary-age children such as schools, science museums and specialized therapy centers, observational data showed such variability in scales of movement patterns taking place across the entirety of the environment.

Two key capacities were exhibited: (i) the adaptiveness of the responsive environment towards a diversity of sensorial interests across the neurodiverse population that was observed, and (ii) a sustained interest in the exploration, practice and mastery of new movement behaviors allowing for generalization beyond the specific site in which it was mastered. This unfurls the overarching potential for the research, in providing a template for sensorimotor accommodations necessary within more normative architectural conditions. To afford social opportunity within the responsive environment enables the acquisition of the critical adaptive behaviors that allow for more successful engagement in adjacent environments and activities – ones that pose more inflexible sensory and social demands.

10:30 AM SB10.01.05
Wearable Textile Platform for Selective Sensing in Healthcare Luca Possanzini, Isacco Gualandi, Marta Tessarolo, Federica Mariani, Erika Scavetta, Francesco Decataldo and Beatrice Fraboni; Bologna University, Italy

Nowadays, the ubiquity of smart technologies and wireless communication networks is stimulating the development of sensing systems able to continuously monitor the human health state and physiological parameters. Local point-of-care medical units or monitoring systems for athletic training performance are two possible examples that would directly profit from such a technology. The crucial bottleneck to establish robust wireless biological sensor networks is the development of new transducer materials capable to effectively convert the biological event (for example concentration changes of chemical markers or a bioelectronic current) into the electronic domain. Semiconducting polymers, such as PEDOT:PSS (poly(3,4-ethylenedioxythiophene) poly(styrene sulfonate)) are widely employed in bioelectronic and biosensing applications as they combine two main advantages: (i) they offer electronic as well as ionic conductivity; (ii) they exhibit excellent bio-compatibility and good mechanical properties.

Here, we report a new fully textile biosensing platform that can be directly integrated into fabric, for continuous monitoring of ion chloride concentration and the pH value in biofluids, such as sweat, thus limiting the invasiveness for the wearer. Human sweat contains abundant information about a person’s health status and representing an excellent biofluid for portable, non-invasive chemo-sensing. For instance, chloride content is a precious index for hydration status as well as a consolidated hallmark in newborns diagnosis of cystic fibrosis, while sweat pH is related to hormonal unbalance and lactic acid secretion during physical activity. Our platform consists of PEDOT:PSS-coated threads whose functionalization determines their selective sensing. The ion chloride thread sensor exploits Ag/AgCl nanoparticles that act as a gate electrode embedded into the conductive polymer channel, thus combining an intrinsically amplified response with a simple two terminal electrical connection [1]. The sensor is validated in standard electrolytes and in artificial sweat showing high sensitivity and selectivity demonstrating the reliability of our device.

On the other hand, we synthesize a pH-sensitive composite of PEDOT doped with pH dye Bromothymol Blue to convert pH variation into an electrical signal. The simple two terminal thread sensor gives results similar to the one
observed for the devices fabricated onto planar substrates, providing the proof of principle for a wire-shaped sensor that can be easily sewed on clothes for monitoring pH level in sweat.

In conclusion, we demonstrate selective and real-time monitoring of bioanalytes in artificial sweat, validating the implementation of our biosensors in a fully textile electronic device. This approach paves the way for a new generation of smart wearable sensors for medical point of care, effectively fabricated onto non-conventional substrates, such as textiles or single fibres.

10:45 AM SB10.01.06
Advanced Textile-Based Hybrid Energy Harvesting/Storage System Lu Yin, Jian Lyu and Joseph Wang; University of California, San Diego, United States

Next generation wearable electronics hinges on the development and integration of emerging technologies that can further advance the functionality, user comfort and runtime of devices. Flexibility, conformity and stretchability are commonly addressed in individual textile-based electrochemical devices such as sensors, supercapacitors and batteries, but few works has been reported on the device-level integration of electrochemical energy harvesters and energy storage units. Addressing this issue, we report for the first time of a device-level energy-harvesting and energy-storage hybrid system based on textile-based flexible and stretchable wearable biofuel cells and supercapacitors. The reported all-in-one epidermal device can harvest energy from enzymatic reaction fueled by the abundant lactate from human perspiration. Furthermore, the energy is directly stored into capacitive/pseudocapacitive materials to deliver enhanced and stable output over long period of time. Simple, low-cost and high-throughput screen-printing fabrication is used to deposit customized, screen-printable and stretchable ink composites that exhibit outstanding stability under rigorous mechanical deformations. The continued development of such integrated wearable energy system represents a vital step towards self-powered wearable electronics for healthcare, fitness, security and environmental monitoring applications.

11:00 AM *SB10.01.07
Rubbery Electronics - Electronics Fully Made out of Rubber Materials Cunjiang Yu; University of Houston, United States

Owing to the merits of mechanical softness and stretchability, stretchable electronics holds promise in many applications including health monitors, medical implants, artificial skins and human-machine interfaces. In general, electronic materials, especially semiconductors, are non-stretchable. Structural designs with special mechanical architectures have been widely adopted to enable the stretchability in those materials. An alternative route to eliminating the burden of constructing dedicated architectures and the associated sophisticated fabrication processes is to build stretchable electronics from rubbery electronic materials, which have potential toward scalable manufacturing, coherent material and device integration, and large-strain tolerance. Here, I would like to present our recent progress on developing rubbery electronics fully made out from intrinsically stretchable, rubbery composite materials of semiconductors and conductors, which can be scalably manufactured from common and commercial available materials without dedicated and complicated synthesis. Specifically, we build nanofibril organic semiconductor and metallic nanowires percolated in the elastomeric polymer matrix in a composite format for the rubbery semiconductors and conductors, respectively. Employing these rubbery electronic materials, we have achieved fully rubber format devices, including transistors and sensors, logic gates, active matrices, and elastic sensory skin systems etc. The rubbery stretchable electronics holds a wide range of applications, such as artificial skins, biomedical implants, and wearable applications.
1:30 PM *SB10.02.01
Materials and Processing in E-Textiles: Challenges to Marketplace Jesse S. Jur, Amanda C. Myers, Inhwan Kim, Braden M. Li, Elizabeth Cobarrubias, Caitlin Knowles and Boemjun Ju; North Carolina State University, United States

Strategies for the selection of materials and manufacturing overwhelmingly dictate e-textile product cost and acceptance into a specific marketplace. Challenges are presented due to the uncertainty in materials selection and then the subsequent need to matching that material within a process to manufacture, which often results in delays in the product development cycle. The goal of this presentation is to outline current best practices and future advancements in materials and manufacturing of e-textiles. From a materials perspective, particular focus will be made on yarn-level design and use of printing strategies, which allow for ‘in process’ formation of e-textile systems. The implication on materials selection and the impact on fabric formation processes will be made based on traditional cut and sew strategies and the evolving whole garment as well as flatbed knitting techniques. Finally, testing strategies will be reviewed for understanding the e-textile at the component and system levels. The future prospective toward more complex e-textile systems will be presented.

2:00 PM SB10.02.02
Coaxial Electrospinning of Core-Shell PEDOT:PSS – PVP Nanofibers Doped with Different Solvents and PbS Quantum Dots for Optoelectronic Applications Domingo Ixcoatl Garcia Gutierrez, Maria I. Mendoza-Diaz and Diana F. Garcia-Gutierrez; Universidad Autonoma de Nuevo Leon, Mexico

Conductive polymers (CPs) display an exceptional set of electrical and optical properties, which in many cases can be tuned to mimic those of inorganic semiconductors and/or metals. Therefore, they have found numerous applications in different technological arenas, such as transparent and flexible conductors in optoelectronics, and as biomaterials, biosensors and tissue engineering substrates in biomedical applications. The fabrication of CPs nanostructures has been investigated comprehensively in recent years, in particular the synthesis of CPs in the form of nanofibers. Unfortunately, producing nanofibers of such CPs has been a challenge faced by several research groups due to the rigid backbone they display. Coaxial electrospinning has been reported as one of the possible approaches that allow the formation of CPs nanofibers. Additionally, recent studies have reported that doping the CPs with certain solvents can improve their charge carriers transport properties; moreover, recent reports have indicated that the addition of metallic and semiconductor nanoparticles into CPs thin films and nanofibers not only improves the electrical charge transport properties of the composite nanofibers, but also bestows on them the property of photocurrent generation when illuminated with the proper light source. In the present study core-shell PEDOT:PSS – PVP nanofibers were synthesized by coaxial electrospinning. These fibers were doped with different solvents (dimethylsulphoxide, isopropyl alcohol, and ethylene glycol) and PbS nanoparticles at different concentrations; additionally, the coaxial electrospinning setup process was inverted in order to exchange the phases comprising the core-shell morphology. The synthesized samples displayed an increment in the conductance of the composite nanofibers, based on a more conjugated structure of the PEDOT:PSS phase, and a better dispersion of the PbS nanoparticles within the nanofibers; this increment was, under certain synthesis conditions, up to three orders of magnitude higher than in the case of the nanofibers with no solvent, nor nanoparticles, added. Photoresponse also showed a clear increment in the value of the photogenerated current as the concentration of the nanoparticles increased. Inverting the arrangement of the core-shell phases in the nanofibers increased the conductance and the photogenerated current in the cases analyzed. These results show novel evidence on the capability of tuning the conductance and photoresponse of composite core-shell nanofibers, based on the doping of the PEDOT:PSS phase with different solvents and PbS nanoparticles, and the arrangement of the core-shell phases.

2:15 PM SB10.02.03
A Cephalopod-Inspired Thermoregulatory Material for Clothing Erica Leung; University of California, Irvine, United States

Abstract not available.

2:30 PM *SB10.02.04
Highly Durable Elastic Conductors for Electronic Textiles Tomovuki Yokota, Hanbit Jin and Takao Someya; The University of Tokyo, Japan
In this talk, we will report recent progress of elastic conductors for electronic textile. First, we have fabricated a metal–elastomer composite with a nanofiber reinforcement. By embedding randomly aligned polymer nanofibers into a silver–fluoroelastomer composite, the elastomer matrix was reinforced and the stress was dissipated by the nanofiber scaffolds. Moreover, combined with the buckled structure, high cyclic durability against repeated stretching was achieved. As a result, a stretchable electrode made from nanofiber-reinforced elastic conductors and wrinkled structures has both excellent cyclic durability and high conductivity, and is stretchable up to 800%. The cyclic degradation (ΔR/R0) remains at 0.56 after 5000 stretching cycles (50% strain), while initial conductivity and sheet resistance are 9903 Scm$^{-1}$ and 0.047 Ωsq$^{-1}$, respectively. Finally, we demonstrated a skin-tight multimodal physiological sensing suit using a highly conductive and durable elastic conductor as electrodes and wirings. By wearing the suits, we successfully demonstrated continuous long-term monitoring of electrocardiogram, electromyogram, and motions during weight-lifting exercises without significant degradation of signal quality.

3:30 PM *SB10.02.05
Flexible Elastomeric Materials and Sensors via 3D Printing Rigoberto C. Advincula; Case Western Reserve University, United States

Flexible electronics and wearable textiles are of high interest for functional devices including health monitoring and other display applications. Haptics technology enables the appreciation of functional surfaces for interfacing with the human sensory function. The use of 3D printing to create prototypes and devices from elastomeric and polymeric materials has appended the design functionality for new materials including uses in biomedical devices enabling rapid development. New opportunities for multi-materials and composites are possible. The processability and functionality of thermosets and elastomers make it a challenge to employ using most 3D printing methods for polymer additive manufacturing. This is more evident with the choices of 3D printing methodologies (fused deposition modeling - FDM, stereolithographic apparatus - SLA, selective laser sintering- SLS, and viscous solution printing - VSP) which can make use of blended or formulated compositions. We have demonstrated the 3D printing of biomedical grade thermoplastic polyurethanes (TPU), epoxy, silicones, and rubberized epoxies to demonstrate flexible and wearable objects and devices. 4D printing allows the design of new materials and applications based on integrating the chemistry of conversion with the printing mode. In this talk, we will demonstrate the fabrication of multi-materials including thermosets and thermoset elastomers with concept objects and elastomeric actuators. This is based on the use of biomedical grade TPU melts and extruded viscous solutions. Other works based on the use of SLA, SLS, FDM, towards high strength epoxy, silicones, and nanocomposite materials will be discussed.

4:00 PM SB10.02.06
Thermal Drawing of Stretchable Triboelectric Fibers for Efficient Energy Harvesting Chaoqun Dong, Andreas Leber, Tapajyoti Dasgupta, Qu Yunpeng, Tung Nguyen, Wei Yan and Fabien Sorin; École Polytechnique Fédérale de Lausanne, Switzerland

Fibers that are capable of harvesting various mechanical energy via triboelectric effect are excellent power units for wearable electronics, especially for smart textiles. However, the fabrication of highly stretchable and soft fibers for the realization of truly conformal, elastic and durable textiles with high triboelectric outputs remains still challenging. Here, a large-scale fabrication of inherently stretchable and soft triboelectric fibers with engineered architectures, for a dual function of energy harvesting and self-powered mechanical sensing, is demonstrated. We take advantage of the rheological behavior of the selected thermoplastic elastomer and employ the one-step thermal drawing process for the large-scale production of uniform triboelectric fibers (Advanced Materials 2018, 30, 1707251). The resulting fibers can sustain large strains of up to around 560% and maintain high electrical outputs, regardless of long-term extreme deformations and extended environmental exposure. By exploiting the particular attributes of the thermal drawing process, we optimized the outputs by introducing textured pattern to the triboelectric fiber surface (Advanced Functional Materials 2017, 27, 1605935). The versatility of this unique fiber enables its facile integration into a soft, elastic and machine-washable triboelectric textile with excellent electrical outputs of ~490 V (triggered by hand tapping), which are even higher than two-dimensional planar triboelectric nanogenerators with similar dimensions. With the drawing process being simple and scalable, it opens the possibilities for the practical implementation of self-powered multi-functional smart fibers and large-area textiles.
Photo-Actuated Fiber-Based Artificial Muscles

Mehmet Kanik, Sirma Orguc, Anantha Chandrakasan, Yoel Fink and Polina Anikeeva; Massachusetts Institute of Technology, United States

Advances in artificial muscles have demonstrated high power-to-mass ratio, work capacity, energy density, and work efficiency, challenging traditional actuators. Recently, thermally actuated fiber-based artificial muscles, capable of lifting more than 650 times their weight, have demonstrated strain programmability and the ability to transduce electrical signals in response to contraction and relaxation, similar to biological muscles. Expanding the palette of the suitable driving stimuli to include electrical, thermal, photonic, hydraulic, and pneumatic will pave way for applications of these fiber-based devices in smart textiles, implantable sensors, wearable electronics, and prosthetics.

Here, we report on a class of fiber-based artificial muscles that can be actuated by a broadband illumination with wavelengths spanning 10-400 nm. These photo-actuated artificial muscles are manufactured using thermal-drawing process, and consist of polymer bimorph structures of cyclic olefin copolymer elastomer (COCe) and carbon loaded polyethylene (CPE) as the low and high thermal expansion materials, respectively. CPE further serves as a UV absorbing material. To amplify the actuation capacity of the thermally drawn fibers, we transformed them into coiled structures via cold drawing, arriving at cross-sectional dimensions of 300×470 µm². We demonstrate the weight lifting capacity of the photo-actuated fibers using a 324 nm light emitting diode with an energy density of 1 mW/mm². Photo-actuated fiber muscles can be actuated using a single LED, potentially enabling the remotely controlled operation and further expanding the domain of utility of these miniature devices.

A Dynamic Stretchable and Self-Healable Composite Conductor Enabled Electrical Self-Boosting

Hyunseon Seo¹, Zhenan Bao² and Donghee Son¹; ¹Korea Institute of Science and Technology, Korea (the Republic of); ²Stanford University, United States

The phenomenon of self-healing, an intrinsic nature of human skin, has inspired those who focus on interdisciplinary field of biomimetics, robotics, and wearable electronics to pursue humanlike electronic skin systems that offer the opportunity to realize future healthcare and wearable robotics. Specifically, developments of intrinsically stretchable and self-healable conductors are significantly desirable for interfacing with active electronic modules with taking advantages of reliable reuse and low power consumption even after mechanical damages. However, it is still difficult to simultaneously achieve high stretchability and high conductivity and autonomous self-healability, due to limited materials strategies.

Here, we describe electrically and mechanically self-healable composite conductor with ultra-stretchability, fabricated by simply mixing conducting nano-/micro-materials (Ag flakes) with a tough self-healing polymer (SHP, PDMS-4,4’-methylenbis(phenyl urea) (MPU)_0.4-isophorone bisurea units (IU)0.6). The conductivity of our self-healable composite conductor is as high as 1137 S cm⁻¹ even under 3500% tensile strain, and more interestingly, it gradually increased to 3086 S cm⁻¹ over 60 hrs under 3500% strain. Such unprecedented phenomenon, termed “electrical self-boosting”, result from a synergy effect: an efficient strain energy dissipation of SHP and self-alignment and rearrangement of Ag flakes with spontaneously assembled AgNPs in response to dynamic nature of the strained polymer matrix. This dynamic behaviors of Ag flakes-AgNPs in a stretch mode is confirmed by using micro computed tomography (μ-CT), in-situ scanning electron microscope (SEM), and transmission electron microscope (TEM).

Furthermore, we found that a double-layered conducting structure formed using a self-bonding process shows extremely reliable stretching endurance performances over 1000 cycles at 50% strain owing to its homogeneous conducting interface located on the neutral mechanical plane. Finally, we successfully demonstrated that electromyogram (EMG) signals can be measured in real-time by a flexible wireless bio-integrated system using our conductor and transmitted to a prosthetic robot hand to control various hand motions after making a complete cut and self-healing. Our dynamic stretchable and self-healable composite conductor is highly applicable to the robust interactive human-machine interfaces.

Highly Elastic Conductive Polyamide/Lycra Fabric Treated with PEDOT:PSS and Polyurethane

Desalegn Alemu Mengistie¹,², Melkie G. Tadesse³,⁴, Yan Chen⁵, Lichuan Wang⁶, Carmen Loghin⁷ and Vincent Nierstrasz²; ¹Chalmers University of Technology, Sweden; ²California Polytechnic State University, San Luis Obispo, United States

4:45 PM SB10.02.09

Highly Elastic Conductive Polyamide/Lycra Fabric Treated with PEDOT:PSS and Polyurethane

Desalegn Alemu Mengistie¹,², Melkie G. Tadesse³,⁴, Yan Chen⁵, Lichuan Wang⁶, Carmen Loghin⁷ and Vincent Nierstrasz²; ¹Chalmers University of Technology, Sweden; ²California Polytechnic State University, San Luis Obispo, United States
Conductive elastic fabrics are desirable in wearable electronics and related applications. Here, we report a highly elastic conductive polyamide/lycra knitted fabric using intrinsically conductive polymer poly (3, 4-ethylenedioxythiophene) (PEDOT) blended with polyelectrolyte poly (styrene sulfonate) (PSS) by easily scalable coating and immersion methods. We investigated the effects of these two methods of treatments on uniformity, electromechanical property, stretchability, and durability. Different grades of waterborne polyurethanes (PU) were employed in different concentrations to improve the coating and adhesion of the PEDOT:PSS on the fabric. The immersion method gave better uniform treatment, higher conductivity, and durability against stretching and cyclic stretching than the coating method. The surface resistance increased from ~1.7 and ~6.4 Ω/sq at 0% PU to ~3.7 and ~12.6 Ω/sq at 50% PU for immersion and coating methods, respectively. The treatment methods as well as the acidic PEDOT:PSS did not affect the mechanical properties of the fabric and the fabric showed high strain at break of ~650% and remain conductive until break. The resistance increased only by a small amount when samples were stretched for 10 cycles at 100% strain and the samples show good durability against 10 domestic laundry washing cycles.

SESSION SB10.03: Poster Session I: Electronic Textiles I
Monday Afternoon, December 2, 2019

3D Braided Textile Structures as Low Cost Microfluidic Platforms for Electrophoretic Separation of Chemical and Biological Analytes Jawairia U. Khan1,2,3, Sepidar Sayyar1,2, Brett Paull4,2 and Peter Innis1,2;
1University of Wollongong, Australia; 2ACES, ARC Centre of Excellence in Electromaterials Science, Australia; 3University of Agriculture, Pakistan; 4University of Tasmania, Australia

In recent decades, microfluidics has emerged as a game changer in the field of clinical diagnostics. These in-situ, on-site microfluidic portable devices have a great potential to substitute traditional analytical labs. However, the complex fabrication techniques (photolithography, etching and printing) used to make microchannels, as well as complex pumping system to drive fluids, are a potential barrier for the development of practical microfluidic devices. In a simpler approach, textile substrates (in the form of fibres, yarns or fabric) which have an inherent ability to create microchannels and wicking properties that facilitate fluid movement provides the potential for a far simpler approach than the microfluidic chip. In this work multi-yarn textile assemblies, that are either knitted or braided, have been investigated as a potential electrofluidics separation platforms. These provide an open surface accessible separation platform, which contrast conventional closed glass capillaries or chips, where direct access to sample zone during separation is nearly impossible. In this work, braided structures made from a range of commercially available fibers have been investigated for; the electrophoretic separation of different analytes through capillary zone electrophoresis; the preconcentration of analyte through Isotachophoresis and selective delivery of analyte through their transport and separation in bifurcated and trifurcated braided structures. This channelled textile platform can be successfully used for the separation of complex mixtures of chemical and biological samples. The developed technology will provide significant new inverted-microfluidic capabilities in bioanalysis, proteomics and rapid clinical diagnostics.

All Textile-Based Tactile Pressure Sensor Array Kuni Takei1,2, Satoko Honda1, Takayuki Arie1 and Seiji Akita1;
1Osaka Prefecture University, Japan; 2JST PRESTO, Japan

Macroscale, flexible electronics are now of great interests in the human-interactive application. In fact, low-cost device fabrications such as printing technique have been proposed. For the practical applications as human-interaction devices, reliability and washability as well as economic fabrication method are key parameters. However,
most of reports have not covered all important requirements due to difficulties to fabricate the devices. To address this challenge, we demonstrate textile-based tactile pressure sensor sheet with high reliability and washability as well as the sensitivity and threshold pressure analyses. To simplify the fabrication method and structure, Ag threads or printed conductive polymer (PEDOT:PSS) are used for the resistive sensing materials.

Ag thread and standard thread were sewn in the two linen textiles by using a commercial sewing machine. After sewing the threads, a mesh sheet was sandwiched by the linen sheets. For the electrical connection between the textile sensors and measurement equipment, Ag coated Velcro strap was used. One side of the Velcro strap was sewn on the linen sheets using the Ag thread continued with the sensor area. Another side of Velcro strap was sewn on a PET film, where Ag electrodes were screen-printed. Using this Velcro strap, textile sensor sheet and read-out circuit can be readily connected and disconnected, which allows it to wash the sensor sheets without having special water-proof coating over the equipment. For the sensing mechanism, by applying tactile pressure, Ag threads are contacted through the mesh holes. After contacting the electrodes, then contact resistance changes as a function of applied pressure due to rough surface of Ag thread.

Mesh thickness and diameter size dependences for the pressure sensor were characterized to control the detectable tactile pressure range. Detectable threshold pressure was varied from 1 kPa to 1 MPa depending on the number of mesh sheets (i.e. thickness: 1 – 5 sheets) and diameter (0.5 – 3.0 mm) of mesh. This indicates that this can detect the pressure difference by monitoring the resistance change, and the threshold pressure can be tuned by mesh sheet thickness and diameter of mesh size. It is also confirmed that real-time pressure can be measured with relative fast response less than 0.5 s.

Next, reliability and washability were analyzed. The results indicate the limitation of repeatable measurement cycles. Depending on the applied pressure, this limitation is varied. However, it is found that the limitation can be estimated with line fitting of the results. For human body pressure monitoring on a bed, the pressure distribution is ~5 kPa. For this body pressure monitoring, the sensor sheet shows high reliability >250,000 cycles. Without using any water-proof coating or packaging, this sensor sheet can be washable using a standard washing machine with detergent. Output resistance does not change even after 2 times washing processes.

Finally, as proof-of-concepts, real-time monitoring of derriere and foot pressure distributions and respiration were conducted by placing the sheet under body. Based on the results, this simple device structure can be used for the tactile pressure sensor sheet with high reliability and washability.

This study proposes the high reliable and washable tactile pressure sensor textiles. We confirmed that this platform can be used for the pressure distribution monitoring including respiration.
Textile electronics are increasingly becoming an important field of research. One of the key features of smart textiles is the ability to control core body temperature in different weather conditions. Particularly, the idea of battling cold weather conditions using self-heated textile is intriguing. It can be done in for various applications like in jackets for military personnel who fight in cold climate conditions, in hand gloves for skiers [1], for heat therapy for certain medical conditions and so on. A power supply, bus bars for sending the currents, heating elements and a carrier to assist the heating elements are needed for such heated wearable textiles [2]. Another important aspect is that the heating element needs to be flexible and stretchable since it is used in textiles. This work presents the idea of using space-filling fractal curves based heating elements in textiles. Because heating elements are based on metal coils, they are the most large-area and expensive component of a self-heating wearable. However, decreasing metal spacing or metal length in coils leads to non-uniform temperature distribution. Hence, a cost-effective and efficient heater should have uniform temperature distribution while having minimum metal consumption. The geometry of the heater plays a crucial role in its uniformity and average temperature ($T_{av}$). We modelled space-filling fractal curves as geometries for heaters and observed that they are on par with the typical double-spiral heat-pad in terms of temperature uniformity, while being cost-effective due to optimal distribution of metal. This work presents modelling of fractal curves based on Peano curve, Hilbert curve and Moore curve of different orders, as micro-heaters. To make the metal coil designs stretchable, sharp edges in the geometries were modified into smooth arcs. Further, to compare them in an efficient way, a constant power of 2 W was maintained across all the geometries and the heating elements were restricted to an area of 30 mm x 30 mm. Finite element analysis (FEA) results showed that heating elements based on Hilbert & Moore curves of order-4 and Peano curve of order-3 outperformed double-spiral heating element in terms of temperature uniformity while being cost-effective, i.e., using lesser metal coil length (all the curves were assumed to have the same metal width and thickness). Heaters based on Hilbert & Moore curves of order-4, Peano curve of order -3 were observed to have a temperature non-uniformity (%) of 4.4%, 4.3% and 2.2% respectively, whereas double-spiral had non-uniformity of 5.8%. The average temperature was lower by 10 K for Hilbert and Moore order -4 and 50 K for Peano order -3. Further, heaters one fractal order lower than these, i.e., Hilbert & Moore of order -3 and Peano of order -2, gave the same average temperature as double spiral heaters, while using only half the length of the double-spiral, thus promising significant reduction in metal consumption. Hilbert and Moore order -3, Peano order-2 were observed to have a non-uniformity of 11.7%, 11.6% and 7.24%, respectively, which makes them slightly more non-uniform compared to the double-spiral heater, but with only half the metal consumption. With many fractal patterns to choose from, space-filling fractal curves can provide very good performance heating elements for smart, self-heating textile applications.

Flexible Photodetector Based on Reduced Graphene Oxide Electronic Yarns Hee Yeon Yang, Hyun Joo Lee and Yong Ju Yun; Kunkuk University, Korea (the Republic of)

Graphene-based electronic textiles have recently been recognized as a promising flexible materials and devices for smart fabrics and next-generation wearable electronics due to their many advantages such as good electrical conductivity, mechanical strength, chemical stability, softness, light weight. In addition, they can be produced at low cost, easily cut, and assembled into diverse flexible substrates in various form by simple approaches such as sewing and weaving. In these reasons, a variety of wearable devices have been developed including textiles transistors, thread like solar cells, fabric type nanogenerators, yarn like chemical and physical sensors, etc. Among these devices, threat and fabric type photodetectors have gained importance for applications in biomedical imaging, environmental sensing, fire monitoring, etc. However, processing challenges for improving their poor performances and complicated fabrication process have so far precluded the realization of diverse wearable electronic devices. Here we report a facile solution strategies to fabricate the high performance graphene electronic textiles composed of reduced graphene oxide (RGO) and commercial cotton yarns by simple dipping and chemical reduction and investigate the broadest photoresponses from the ultraviolet upto the infrared in various deformations such as bending and stretching. The as-prepared RGO yarns showed good basic properties including including electrical conductivity (~1.0 S/cm) and mechanical stability (1,000 cycles), as well as a UV photoresponsivity of 1.31 mA/W.
(flat) and 1.0 mA/W (bent) and response times of 5 s/6 s (flat) and 6 s/7 s (bent). Using our high-performance RGO textiles, we successfully fabricate wearable optoelectronic systems that can be integrated with garments for continuous ultraviolet radiation.

SB10.03.06
**Stretchable Micro-Wavy Structured Cu Interconnects Fabricated by Using a Micro-Corrugation Machine and a Pre-Stretched Rubber Substrate** Shinji Okuda, Michitaka Yamamoto, Ryu Karasawa, Seiichi Takamatsu and Toshihiro Itoh; The University of Tokyo, Japan

Wearable IoT devices and sensors have been featured recently, therefore stretchable interconnects and devices are required to develop. In this research, we have developed an advanced fabrication method of stretchable interconnects that corrugated copper (Cu) foil attaches to a pre-stretched elastomer substrate. Fabricated interconnects applying our method showed >200% stretchability stably. We also applied our method to stretchable electrical circuits.

There are two types of methods to fabricate stretchable interconnects: using conducting inks such as a mixture of metal nanowires or carbon nanotubes with thermoplastic polyurethane resin (TPU) or fluorine rubber, and processing metal film into a wavy shape (vertical or horizontal wavy structure). Stretchable vertical-wavy-shaped metal interconnects are getting attractive because the conductivity is smaller by one order of magnitude to that of the above mentioned inks. Wagner et al. (2004) made stretchable thin-film conductors by metallizing a pre-stretched elastomer membrane with Au, and reported that fabricated conductors showed 10-100% stretchability. But the stretchability was unstable, that is, it varied widely in the fabricated samples. Although vertical-wavy interconnects are preferred since they can achieve high density wiring and electrical stability, vertical-wavy-structured interconnects are hard to fabricate in terms of manufacturing stability.

Thus, we propose a new method of bending a Cu film by corrugate process in advance and then attaching it on a pre-stretched substrate in order to shrink corrugated Cu foil further. The proposal method is as follows:

1. Corrugating a strip of copper (Cu) foil by a pair of gears to create vertical-wavy structure
2. Adhering the above processed Cu foil on a pre-stretched Polydimethylsiloxane (PDMS) substrate
3. Relaxing the pre-stretched PDMS substrate into its initial length to compress the vertical wavy structure
4. Covering the whole interconnect with PDMS and peeling it off

The elongation rate of a pre-stretch substrate was changed to 0, 25, 50 and 75%, and each sample was prepared. The thickness of Cu foil was 5um. The fabricated samples showed 220% stretchability in the case where pre-stretch rate was 75%, while 102% stretchability in the case where a PDMS substrate was not stretched in advance. The resistances of all samples were <1 ohm/cm and these fluctuations during stretching were ±0.1 ohm/cm.

In order to consider possibility of higher stretchability if Cu foil thickness is different from 5um, an effect of Cu foil thickness on stretchability was investigated when a PDMS substrate is not stretched beforehand. Cu foil thickness was varied from 2um to 40um. Stretchability of vertical-wavy interconnects can be predicted by measuring a wavy shape (pitch, height and angle) of corrugated Cu foil. The actual shapes of fabricated samples were measured and stretchability was predicted from prediction equations. It was assumed that the thinner Cu foil is, the larger stretchability gets because height of waves also is getting high. On the other hand, as the result of the break tests of fabricated samples, the stretchability became the highest (73%) when the thickness was 10um. The reason is considered that thinner Cu foil has not enough strength so it broke before it gets flat.

In this study, higher stretchability and lower resistivity than those of previous studies were achieved, so our fabricated interconnects can be useful as stretchable interconnects with high conductivity. Finally, we demonstrated stretchable LED circuits with our proposal technique. LEDs can be lit in the manufactured circuit with about 50% stretch. Therefore, it is assumed that our proposal technique can be applied to stretchable circuits.

SB10.03.07
**Impact of Fabric Properties on Textile Pressure Sensors Performance** Luca Possanzini, Marta Tessarolo, Enrico Campari, Laura Mazzocchetti and Beatrice Fraboni; Bologna University, Italy
In recent years, the field of wearable technology and Internet-of-Things has attracted a great attention and a large variety of sensors has been developed. Wearable electronics sensors are becoming extremely attractive for several application fields such as medical, healthcare, wellness, sport, entertainment and safety. A very promising platform to realize fully wearable and imperceptible sensors is the “smart textile” one, as fully textile physical or chemical sensors offer unique features in terms of comfort and fitting features.

In this framework, we focused our attention on developing wearable textile pressure sensors operating in a wide linear pressure range. Pressure sensors with high sensitivity in the low pressure range (<10kPa) allow touch detection, very relevant for human-computer interaction and for the development of artificial hands for handling object. Conversely, pressure sensors that operate in high pressure range (up to 100 kPa), can be used to monitor the foot pressure distribution, the hand stress during the movement of heavy weights or to evaluate the cyclist’s pressure pattern on a bicycle saddle.

In this presentation, we report on a new promising class of fully textile pressure sensors based PEDOT:PSS (poly(3,4-ethylenedioxythiophene) poly(styrene sulfonate)) [1]. The sensor can be easily fabricated directly on textile fabric by processing from solution and sewing. We report and discuss the sensor working principles, investigated by comparing the effects of macroscopic to nanoscopic variation in the sensor performance [2]. We quantitatively discuss (by analyzing static and dynamic operation mode) how the mechanical properties of several fabrics and the piezoresistive properties of different ink formulations impact on the sensor response. Our results highlight the complexity of the whole system, due to the active role of multiple parameters (e.g. the fabric composition, structure, the polymer formulation, the targeted pressure range, etc.) and suggest a protocol to optimize and tune textile pressure sensors to every kind of application.

Electrically Conductive Silver/Polyimide Fabric Composites Fabricated by O2 Plasma Pretreatment and Spray-Assisted Electroless Plating

Fangbing Lin, Jinhua Jiang and Nanliang Chen; Donghua University, China

Functional flexible fabrics with both excellent electrical conductivity and high-performances are increasingly attractive in modern industries. In this study, we report a silver/polyimide fabric (Ag/PIF) composite with high conductivity, heat-resistance, mechanical and fastness properties, which is fabricated by combining an O2 plasma pretreatment and a spray-assisted electroless plating (SAELP) technique. The O2 plasma pretreatment can firstly roughen the surface of PIF, induce the oxygen functional groups on PIF and rearrange the imide groups in PIF, which results in a great improvement in the wettability of PIF. The silver nanoparticles (Ag NPs) are deposited on the plasma-treated PIF by the SAELP technique to obtain the Ag/PIF composites. The effects of O2 plasma treatment and SAELP duration on the Ag/PIF composites are investigated and discussed. The results demonstrate that the Ag NPs are coated on PIF uniformly and densely with surface resistance of 0.1 Ω/sq. The first decomposition temperature of Ag/PIF composites is up to 600 °C, indicating the excellent thermal stability of Ag/PIF composites. This work gives a new strategy for fabricating electrically conductive functional fabrics with high-performance properties.

Textile-Fiber-Array-Embedded, Stretchable Alternating-current Electroluminescent Device—Utilization of In-Plane Electric Field

Seongkyu Song and Soon Moon Jeong; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

To date, although there has been significant progress in the development of new techniques for emerging EL devices, enabling soft robots, actuators, flexible/stretchable/wearable electronics, and self-healable devices, most of these reported devices require planar electrodes with high transmittance and mechanically durable characteristics as well as stable electrical conductivity, even in the deformed state. Here, we present a textile-fiber-array–embedded flexible composite system capable of producing multiluminescence (electroluminescence (EL) and mechanoluminescence (ML)) on the application of electromechanical stimulus [1]. In our work, we embed a conducting fiber array into a mixture of PDMS and ZnS EL phosphors with parallel orientation, to act as electrodes. Because the EL is generated by the in-plane field, there is no requirement for the light to be transmitted to the electrode, thereby eliminating the requirement of high transmittance. We also found radially distributed electric/optical fields arising from the unique fiber-array configuration, which are beneficial for applications as a uniform plane light source. Furthermore, a patterned device was realized by controlling the embedding depths of fibers, utilizing the vertical and in-plane electric fields simultaneously. We believe that these results can provide a basis for the development of emerging soft display systems.

Textile Strain Sensor Knitted with Conductive Aluminum Coated Yarn, for Wearable Electronics

Junhyeok Jang, Kangmin Lee and Mijung Lee; Kookmin Univ., Korea (the Republic of)

E-textile is a representative technology used in smart clothing, which is an integrated type of fabrics with electronic components to realize wearable computers. In early stage, it was realized by attaching various kinds of electronic devices on clothes. Recently, research is active on inherently textile-like devices such as fiber transistors, piezoelectric temperature sensors, and fiber displays based on yarn-type conductive fibers.[ref] In our previous research on e-textile using conducting yarns, we have succeeded to develop the resistance switching memory devices with normal yarn, coated with aluminum using solution process, and carbon fiber.[ref] This study focuses on change of resistance at the contact between fibers along the strain, and a strain sensor was developed that can be used in smart clothing. The contacts between different yarns for the resistance change were achieved with all in one yarn, comprising aluminum coated yarns, carbon fibers and normal yarns. In this knitted textile, the resistance switching characteristics was shown as confirmed in previous studies. Then, the samples were stretched in both the horizontal and vertical directions to demonstrate a change of on / off resistance ratio. This variation of on/off ratio was verified by the physical and chemical mechanism and a dependence on the contact area was also investigated. On / off resistance ratio decreased when stretched, and restored to the ratio before stretch when the sample was recovered. This characteristic is maintained when stretching and recovery are repeated along the cyclic test. We
expect that the textile-type resistance strain sensor developed in this study can be used as a strain sensor/motion sensor by applying to the joint part of clothing.

SB10.03.12
A Textile Design Study Informed by the Exploration of New Surface Materials—Is 'Calm' Technology the Future of Wearables? Raymond Oliver and Jacob B. Goff; Northumbria University, United Kingdom

The concept of wearable technology is currently concerned with products that are more 'attachable' than truly wearable. Over the past decade the world’s biggest consumer-product focused corporations have found varying levels of success from their experiments within the industry. These devices generally exist to quantify, socialise or record. They are ‘outward facing’ and share data that contributes to ‘The Internet of Things’. Intuitive interfaces, further development of responsive materials and a deeper understanding of unobtrusive human-centred design or ‘calm’ technology (Weiser, 1993) are all central to the concept of an authentically wearable device.

Using practice-led 2D and 3D design:STEM activities, this research explores the triangular relationship between the user, the device and the environment it exists in, on both a physical and emotional level. Key to this exploration is the understanding that human bodies are kinetic and their needs therefore differ from that of static entities. As identified, these three factors contribute to the development of effective ‘wearable’ materials used in, on or around the human body. Although the study of ergonomics, anthropometrics and human-centeredness are well explored, challenging them within the context of materials that possess intrinsically responsive behaviours reveals new areas of research. This work describes results of research undertaken at Northumbria’s bio-design STEM Lab to investigate interactive materials with intrinsically responsive behaviours that can be applied to soft stretchable fabrics potentially resulting in artefacts that work in harmony with its user and/or surrounding space to benefit living. The basis for this work and the results of the sensing and response to external stimuli will be highlighted including progress with Weiser’s concept of ‘calm technology’ which is not a burden on the user.

SB10.03.13
Piezo-Enhanced Triboelectric Generator Using Carbon Fiber Yarns Raquel Barras, Andreia dos Santos, Elvira Fortunato, Rodrigo Martins, Rui Igreja, Pedro Barquinha and Luis Pereira; Universidade NOVA de Lisboa, Portugal

With a forecasted market value higher than 27 billion dollars by 2022, the amount of wearable devices sales will double by that time and obviously continuing to grow. As consumers interest pursues more and more portable electronic devices such as wearables, batteries dimensions and capacity of such devices is a common limitation of their size, weight and life time between charging cycles. Off the grid standalone power harvesting systems that can convert kinetic energy from human motion through piezoelectric and triboelectric effects will soon be a reality capable to meet the requirements of such low power electronics.

In this work, carbon fiber stretch-broken yarn is used as inner electrode for a piezo enhanced triboelectric generator (PETG). The carbon yarn was functionalized with nanostructured ZnO rods grown by a simple solvothermal method and covered with a layer of Polydimethylsiloxane rubber (PDMS) by a novel method that was, to the extent of the authors knowledge, not ever reported in literature and named “in-situ PDMS curing”. The use of a fiber-shaped system and the selection of such materials and methods intends to meet a lightweight, bendable, ecological and sustainable power converter for the widely available and unused energy from body motion, in which the enhancement of power output, as well as the energy conversion mechanisms, were subject of study.

SB10.03.14
A New Device Architecture with Double-Stranded Assembly of Electrode Microfibers for High-Performance Fibrous Organic Transistors in Electronic Textile Applications Jung Ah Lim1, Soo Jin Kim1,2 and Hyoung Jun Kim1; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

With the increasing importance of electronic textiles as an ideal platform for wearable electronic devices, organic thin-film transistors (OTFTs) comprised of organic or polymeric electronic components have been shown to be a promising component for e-textile applications on account of their flexibility, light weight, and ease of implementation. While the realization of fibrous OTFTs have been demonstrated so far, several critical issues including a low drain current, unstable contact between the semiconductor and source/drain electrodes, and a high operation voltage remains to be addressed. We report herein is a demonstration of high performance fibrous organic transistors with a new device architecture that exceeds the current limitations of fiber OTFTs. A key feature of this
work is that the semiconductor channel of the fiber transistor comprises a twist assembly of the source and drain electrode microfibers that are coated by an organic semiconductor. This architecture allows us to not only facilely control the channel dimension of the device by varying the thickness of the semiconductor layer and the twisted length of the two electrode microfibers, but also passivate the device without affecting interconnections with other electrical components. The resulting fibrous organic transistors based on the twist assembly of the microfibers showed a high output current of over -5 mA at a low voltage of -1.3 V and a good on/off current ratio of 10^5. The electrical properties of the device were maintained even after repeated bending deformation and washing with a strong detergent solution. In this presentation, discussions on a holistic process for the fabrication of this fiber OTFTs and the correlation between the nano-crystalline structure of semiconductor films and the device performance will be included.

SB10.03.15
Mechanical Modeling of Stretchable Conductive Paste Kazuki Hiraoka, Seiichi Takamatsu and Toshihiro Itoh; University of Tokyo, Japan

To fabricate stretchable electronics devices, wiring parts to connect power supply and devices such as sensors and IC chips is important. There are two types of stretchable wiring: metal thin film and electrically conductive paste. Electrically conductive paste made by dispersing conductive fillers such as silver particles and CNTs into insulating polymer matrices are widely used because it can be fabricated by simple printing method. The recent papers reported a successful strategy to effectively improve electrical conductivity by using multiple CNTs with different shape. On the other hand, research and development of stretchable conductive paste have mainly been conducted based on discovery and empirical rules. If the modeling of stretchable paste is developed, further research and development of new stretchable can be expected to be promoted.

In this study, to develop a modeling method of mixing multiple types of conductive particles, a mechanical and electrical model to calculate the conductivity of the stretched silver paste mixing micro-flake particles and nano-spherical particles at different blending ratios was suggested. Here, micro-flake particles and nano-spherical particles are treated as multi-sphere and hypothetical sphere models, respectively.

The calculation steps are described below.

(1) Generate multi-sphere and hypothetical sphere models in a cubic area. In this paper, volume fraction of silver particles, blending ratio of micro-flake particles and nano-spherical particles, and dimensions of area can be changed. In case of three-dimensional model, the three-dimensional particle distribution was generated by stacking the two-dimensional particle distribution in the normal direction. Moreover, in order to avoid the calculation of the distance between silver particles, the region is divided into small regions to be able to determine the particle distribution without volume intersection.

(2) Update the position of particle distribution following the stretch force to the silver paste, which was calculated by using the finite element method (COMSOL).

(3) Calculate the electrical resistance between each particle: If the spherical particles obtained by the finite element method are adjacent to each other, it is 1Ω, otherwise ∞Ω.

(4) Calculate the electrical resistance of the entire composite between two parallel plate electrodes by inverse matrix calculation.

In this paper, volume fraction of silver particles was set to 50%, and three-dimensional model was selected. Blending ratio of micro-flake particles and nano-spherical particles was varied from 0 % to 100 % every 10 %. In calculation, the size of the particles in model was set to Φ 3.5 to 5.5 μm for micro-flake particles and 200 nm for nano silver particles, which was determined from measurement result of real silver particles.

From the above calculation of conductivity, the optimum blending ratio of small particles and large particles when stretch force was applied to silver paste was estimated. As a result of blending large and small particles, the volume resistivity became lower than the result of small or large single silver particle, and the lowest result was obtained when the blending ratio of nano-particles was 50%. The contact between the particles is classified two types: contact in the conduction direction and contact in the normal direction of the flake particles. In this model, the resistance of contact in the conduction direction was calculated as the same electrical resistance regardless of the particle shape. Therefore, the increase in the volume resistivity of the nano-spherical particles was considered to be caused by the increase in the number of contact points in the conduction direction between the flat plate electrodes sandwiching the particle distribution. On the other hand, the high resistivity in case of using only flake particles seems to be caused by the high resistance value...
in the normal direction of the flake particles.

SB10.03.16
Silver Nanowire Modified Fabrics for Wearable Triboelectric Nanogenerators Doga Doganay, Mete Batuhan Durukan, Melih Ogeday Cicek, Merve N. Guven and Husnu E. Unalan; Middle East Technical University, Turkey

Functional textiles received considerable attention both in scientific field and in the market since late 2000s. Thanks to the developments in nanotechnology, functional textiles have been evolving into smart textiles. In addition to powering the smart textiles, improvement of their washing stability has utmost importance. Currently, batteries are used as the energy sources of smart textiles. However, there are cases where batteries do not fulfill the consumer needs. Moreover, integration of batteries onto the conventional clothes without reducing the consumer comfort is almost impossible. As a consequence, self-powered systems using triboelectric nanogenerators (TENGs) are evolved as strong alternatives to battery powered smart textiles. Silver nanowires are known to impart antibacterial activity [1] and heatability [2] to the textiles. In this study, silver nanowire (Ag NW) decorated fabrics are used as current collectors for the realization of wearable TENGs. Thermoplastic polyurethane (TPU) was deposited onto Ag NW decorated textiles and used as both the dielectric and protection layer. Simple dip and drying method was used for the deposition of both Ag NWs and TPU. The overall structure was used as a single electrode for wearable TENGs, where an open circuit voltage and short circuit current of 30 V and 4 µA were measured, respectively. TENGs were connected in series to further improve the output power. TPU overcoating was also demonstrated to enhance the washing stability of the Ag NW decorated fabrics. While the fabrics without TPU coating lost their conductivity after 10 washing cycles, TPU overcoated fabrics kept their conductivity up to 20 washing cycles.

SB10.03.17
Channel-Dimension Controllable Fibriform Organic Field-Effect Transistors by Hydrogel-Supported Transferring of Printed CNT Microelectrodes Hyoung Jun Kim, Tae-Hyung Kang, Hyunjung Yi and Jung Ah Lim; Korea Institute of Science and Technology, Korea (the Republic of)

With the extensive research of electronic textiles for wearable devices, fibriform organic field-effect transistor is a one of the key components for organizing the electronic circuit into the fabric by weaving the fiber. However, fiber type field-effect transistors have disadvantage of channel dimension since the resolution of printing or deposition techniques on microfibers is primarily restricted by the dimension of the microfibers. Here, we report a new strategy to improve the performance of fibriform OFET where the channel dimension can be readily controllable. Key technology of this work is that single-walled carbon nanotube source and drain (S/D) electrodes with desirable geometry are printed at hydrogel substrate first, then directly transferred to the semiconductor-insulator layer coated Au microfiber. Fine geometry of CNT electrodes was successfully transferred to the microfiber by special rolling process and resulting transistors with wrapped CNT S/D electrodes exhibited a high on/off ratio of ~ 10^5 and good field effect mobility of 0.73 cm^2 V^-1 s^-1. It was confirmed that the fibriform transistors demonstrated on the flexible polyurethane thread also exhibited good electrical performance which was maintained even after bending deformation at different bending radius.

SB10.03.18
The Optical and Structural Properties of Melt-Spinning Nanocomposite Fibers of UHMWPE/HDPE Blended Fibers Yassine Ait-El-Aoud1, Richard Pang1, Elizabeth A. Welsh1, Ihsan Uluturk1, Sean Dinneen1, Stephen A. Giardini1, Peter Stenhouse1, Michael Okamoto1, Luis M. Lozano2,3, Yi Huang2, Seongdong Hong4, Alkim Akyurtlu5, Svetlana V. Boriskina2 and Richard M. Osgood1; 1US Army CCDC-SC, United States; 2Massachusetts Institute of Technology, United States; 3Tecnologico de Monterrey, Mexico; 4Defense Agent for Technology and Quality, Korea (the Republic of); 5University of Massachusetts Lowell, United States

Recently, some forms of polyethylene compounded with nano-particles/micro-particles promise to absorb less infrared radiation by enhancing the forward scattering in the long-wave infrared. By developing such as fibers containing special materials that are infrared transparent and visibly opaque, textiles could be made for clothing which actively cool the body and provide thermal comfort. This technology could have potential in civilian and
In this study, the nanocomposite fibers comprised of blended ultrahigh molecular weight polyethylene (UHMWPE) and high density polyethylene (HDPE) with different mass ratios were successfully prepared using a microcompounder/twin-screw extruder via a two-step process. The first step involved melt-blending UHMWPE powder with TiO2 nanoparticles at 250°C for a residence time of 3 minutes; then HDPE pellets were added and mixed with the melt blended TiO2/UHMWPE at 220°C for a residence time of 5 minutes. The fibers were produced via melt-spinning through a controllable diameter spinneret and collected on a motorized spool at various speeds. The morphology and thermal properties of the samples were characterized by scanning electron microscopy (SEM) and differential scanning calorimetry (DSC) techniques. The total reflection and transmission of the blended fibers were measured using the FTIR coupled to an IR integrating sphere. This study showed that the crystallinity and melting temperature of nanocomposites of the blended fibers were found to be significantly increased by decreasing the blended fiber diameter and the IR-transparency of samples was remarkably improved by increasing the draw ratios.

**Simultaneous Submicron IR+Raman Analysis of Inkjet Printed Flexible Electronic Textiles** Curtis Marcott¹, Frank Weston², Eoghan Dillon², Debra Cook², Jay Anderson², Inhwan Kim³, Ying Zhou³ and Jesse S. Jur³; ¹Light Light Solutions, United States; ²Photothermal Spectroscopy Corp, United States; ³North Carolina State University, United States

Inkjet printing of functional inks on textiles to embed passive electronics devices and sensors is a novel approach in the space of wearable electronic textiles. Achieving functionality such as conductivity by inkjet printing on textiles is challenged by the porosity and surface roughness of textiles. A novel reliable and conformal inkjet printing process is demonstrated for printing particle-free reactive silver ink on uncoated polyester textile knit, woven, and nonwoven fabrics. The particle-free functional ink can conformally coat individual fibers to create a conductive network within the textile structure without changing the feel, texture, durability, and mechanical behavior of the textile. It is noteworthy that the electrical conductivity of the inkjet-printed conductive coating on pristine polyethylene terephthalate fibers is improved by an order of magnitude by in situ heat-curing of the textile surface during printing as the in situ heat-curing process minimizes the wicking of the ink into the textile structures. A new approach which combines simultaneous collection of submicron spatial resolution infrared (IR) and Raman spectra was used to help characterize the structures produced. These two complimentary vibrational spectroscopy techniques provide key insights into the identification and distribution of chemical entities on the surface of these textile fibers as a function of deposition and heat curing conditions.

**Design of Highly Durable and Flexible Electrodes for Wearable Supercapacitors** Nasim Anjum, Jun Li and Caiwei Shen; University of Massachusetts Dartmouth, United States

Flexible supercapacitors have been intensively studied as promising power sources for next-generation flexible electronics in many consumer, medical, and military applications, because they are safe, mechanically stable and durable compared with current batteries. However, flexible supercapacitor devices reported so far have not demonstrated mechanical properties that can withstand critical deformations including folding, twisting, and machine washing, which are required for real-world applications. Multifunctional materials that can provide not only mechanical flexibility and strength, but also energy storage capability are desired for practical flexible supercapacitors.

Here we present the design of composite electrodes with exceptional mechanical properties for foldable, twistable, and machine-washable supercapacitors. The composite materials consist of polymer electrolyte as matrix and carbon-based materials as fillers. The polymer electrolyte acts as both ion conductor and binder. The combination of activated carbon fibers and particles serves as both high-surface-area electrodes and reinforcement materials. Calculations and simulations show that proper volume ratio of the polymer, fibers, and particles results in optimized flexibility, strength, as well as high areal capacitance. The use of carbon fiber with proper length also enables the composite to survive critical mechanical deformations which particle-based electrodes cannot.

The supercapacitor prototypes are constructed using thin composite electrodes and ion-conducting separators. The separator is composed of randomly distributed glass fibers in polymer electrolyte matrix. The electrochemical and
mechanical tests demonstrate that the activation of the carbon fiber surface has not only improved the mechanical properties of the laminates, but also greatly increased the surface area of electrodes, which leads to two orders of increase in their electrical double-layer capacitance. The prototypes show adjustable areal capacitances of over 10 mF/cm² with thickness and flexibility (flexural rigidity) comparable to wearable fabrics. The electrochemical performance has remained unchanged after repeated folding and twisting tests. Moreover, we sewed the devices onto fabrics and washed them in a washing machine, after which we observed no mechanical damage or capacitance degradation.

In conclusion, we believe that the excellent electrochemical performance, flexibility and mechanical durability make the composite-based flexible supercapacitors promising to power various flexible and wearable electronics. The design rules and results are also applicable to developing other multifunctional devices that require high performance without sacrificing mechanical properties.

SB10.03.21
Electrically Conducting and Mechanically Strong Fibers for Flexible Electronics and for Joule Heating
Mingxuan Lu1, Jiawei Xu1, Prabhakar V. Gulgunje1, Kishor Gupta1, Pedro J. Arias-Monje1, Narayan Shirolkar1, Adam Maffe1, Edward DiLoreto1, Yudhisthira Sahoo2, Sandip Agarwal2 and Satish Kumar1; 1Georgia Institute of Technology, United States; 2Vuronyx Technologies, Inc, United States

Polyacrylonitrile (PAN)/carbon nanotube (CNT) composite fibers have been processed by gel spinning with combined good tensile properties and electrical conductivity. These fibers can potentially be used for smart textiles, electromagnetic interference (EMI) shielding, electrical heating of fabrics, and for making stabilized fibers and carbon fibers via Joule heating. High CNT loading leads to high materials cost. To address this issue, further studies have been done to reduce CNT content in the fiber while also achieving good electrical conductivity and mechanical properties.

Bi-component spinning has been successfully conducted to produce fibers with 100% PAN in the core and 90:10 PAN:CNT weight ratio in the sheath. The overall CNT content in the fiber is about 5 wt%. The processing steps, structure and properties of the fibers will be presented. One important application for these composites fiber is to make carbon fibers. Polyacrylonitrile (PAN)/carbon nanotube (CNT) fibers can be stabilized by applying electric current (Joule heating process), rather than by external heating. Thus, stabilization of PAN/CNT fibers by application of electric current provides a pathway for making carbon fibers with reduced energy consumption. The innovation, opportunity, as well as the scale up challenge for Joule heating, and for flexible electronic applications of this PAN/CNT bi-component fiber technology will be presented and discussed.

SB10.03.22
Reel-to-Reel Production of Sub-Micron Diameter Metallic Wires over Meter Scale Lengths through Contactless Electroplating onto Electrospun Nanofibers
Heena K. Mutha1, Alex Couch1, Aykut Aydin2, David Adler1, Ernest Kim1, Peter H. Lewis1, Vinh Nguyen1, Terrell Williams1, Didier Rusangiza1, Roy Gordon1, David J. Carter1 and Kasey J. Russell1; 1The Charles Stark Draper Laboratory, United States; 2Harvard University, United States

Sub-micron diameter metallic wires of long lengths would enable a wide range of applications including electronic textiles, woven batteries to power wearables, sensitive neural electrodes, and low-loss conductors for microwave electronics, among many others. Existing synthesis methods for developing nanowires are often limited to sub-millimeter lengths, or long length fine wires are extruded at high cost. Instead, we use a low-cost, scalable, bottoms-up approach to fabricate small wires by metallizing long lengths of electrospun polymer (PMIA) nanofibers. While we have demonstrated that a wide variety of metals can be deposited onto the PMIA nanofibers by sputter or vapor deposition, electroplating would provide a more cost-effective and scalable deposition approach. Traditional reel-to-reel electroplating is done by connecting electrical leads to the drum that a metalized wire sits on and driving it through a plating solution that has a platinum electrode immersed in it also connected to electrical leads, thus closing the circuit. However, polymer nanofibers in air can easily be disturbed by forces exerted by convection and electrostatic charging, and can also break under low tensile loads, which can make handling the fibers challenging and prevent making an electrical connection through physical contact. Therefore, we developed a contactless electroplating method comprised of at least two isolated fluid streams of plating solution and conductive salt solution which are used to tension and guide the nanofiber. A potential drop across electrodes immersed in the fluids drives current to flow through the bridging conductive nanofiber allowing for contactless electroplating. Using a
commercial gold electroplating bath, we demonstrate metallized wires with lengths that are $10^3$ to $10^6$ times greater than the core diameter. This work was sponsored by the Air Force Research Laboratory (AFRL) and the Defense Advanced Research Agency (DARPA).

**SB10.03.23**

**Electrospun Microfibers with Embedded Thermochromic Material for Textile and Energy Storage Applications**
Sharan K. Indrakar$^1$, Keon Sahebkar$^3$, Sylvia Thomas$^1$, Sessa Srinivasan$^2$ and Elias Stefanakos$^1$; $^1$University of South Florida, United States; $^2$Florida Polytechnic University, United States

Electrospinning is an inexpensive and versatile technique for fabricating micro and nano scaled fibers for varied applications. There have been limited attempts to employ it for the fabrication of a thermochromic device however, and the fabrication for a three component (dye, developer, and solvent) thermochromic system has required the use of a more complicated coaxial electrospinning technique. Herein, we will employ a simple and novel method for creating thermochromic fibers by electrospinning single strands of poly(methyl methacrylate) (PMMA) with embedded thermochromic powder of polymer encapsulated three-component system. Unlike past thermochromic fibers, an unmodified syringe tip can be used for the spinning process and only one flow rate needs to be determined. A solution of solvent (either N-dimethylformamide or chloroform), PMMA, and commercially available black thermochromic powder was created and spun using a custom-made electrospinning apparatus. The effects of solvents, polymer concentration, and thermochromic powder concentration on morphology and thermochromic performance were also investigated to determine the composition for an electrospinning solution with the most consistent structure and most visible color change from black to translucent. These as-developed micro- or nano-fibers will be characterized by scanning electron microscope (SEM) and transmission electron microscope (TEM) imagery to determine surface/interface morphology, energy dispersive X-ray (EDS) spectroscopy to determine the elemental composition, differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) to analyze thermal properties and Fourier Transform Infrared Spectroscopy (FTIR) to determining the chemical environment. The thermochromic color change behavior with respect to temperature of these electrospun fibers will be observed by modified Ocean Optics’s UV-Vis/CIE spectrophotometer.

**SB10.03.24**

**Wearable Sensor Enabled by Carbon Nanoink**
Changyu Wang and Ming Su; Northeastern University, United States

Wearable sensors with various sensing functions and lower costs are necessary for practical application. Sensors based on carbon materials with unique physical and chemical properties can be considered alternatives to relatively expensive electronic devices. This project uses a quick and effective dip-dry method to make carbon nanoparticle wearable sensors on cotton fabric, silk, and sponge. The sensors are responsive to various physical stimuli like relative humidity, temperature, strain, and pressure. The sensor can be properly designed to isolate each stimulus from others, allowing precise determination of each property through resistance measurement. The composites formed by carbon nanoparticles and sponge are found to have high sensibility and fast response to pressure and strain, showing potential for wearable sensors.

**SB10.03.25**

**Silver Nanowire–Cobalt Hydroxide Textile Electrodes for Flexible and Wearable Energy Storage**
Mete Batuhan Durukan, Farzaneh Hekmat, Doga Doganay and Husnu E. Unalan; Middle East Technical University, Turkey

While the future developments are emphasized towards thinner, lighter and cheaper solutions, flexible electronics are highly promising and expanding the areas of use almost daily. In this manner, smart textiles are considered to be the next generation of textiles with added functions like sensing, controlling, computation etc [1]. Regarding the key role of energy storage systems for wearable electronics, the actual interest of the researchers will be allocated for developing high performance wearable energy storage systems—receiving benefit from foldability and flexibility. In this work, polyol synthesized silver nanowires are used as conductive additives to fabricate conducting textiles via a simple dip and dry method [2]. Cobalt hydroxide (Co(OH)$_2$) is decorated onto conducting textiles via electrodeposition [3]. A detailed morphological, structural and chemical analysis was performed on the fabricated textile-based electrodes. Electrochemical characteristics of the fabricated textile-based electrodes were investigated through cyclic voltammetry, chronopotentiometry and electrochemical impedance spectroscopy. During
electrochemical measurements, 3 M KOH aqueous electrolyte was used. Preliminary results showed that the fabricated Co(OH)₂ decorated Ag NW smart textiles have a capacity of 33.7 C.cm⁻² at a current density of 3 mA.cm⁻² within a potential range of -0.2 - 0.6 V. Moreover, an energy efficiency of 65% and a Coulombic efficiency of 87% was obtained. Improved electrochemical stability of the Ag NWs was also noteworthy. Numerous bending cycles were used to determine the mechanical stability of the fabricated textile-based electrodes. Gravimetric analysis is underway to determine the gravimetric capacity of the electrodes.

SB10.03.26
CuS/Au-Coated Velour Fabric Composite Electrodes—A New Architecture for Stretchable and WearableEnergy Storage Yunyun Wu and Tricia B. Carmichael; University of Windsor, Canada

The future of textiles is electronic, with new wearable devices integrated into "smart clothing" systems that will incorporate sensors to detect biometric data, light-emitting devices to display data, and integrated wiring. Powering this next generation of smart clothing is of key importance, making the development of flexible and stretchable energy storage devices that are compatible with textiles particularly urgent. Lithium-ion batteries (LIBs) are one of the most promising power sources because of their high energy density and long cycle life. As a core component, the battery electrode largely dictates the mechanical properties of the entire battery. The electrodes of conventional LIBs are typically fabricated by depositing brittle composite materials on metal foils. These electrodes are vulnerable to mechanical strain, which can cause the delamination and cracking of active materials, and ultimately device failure. Previous work has relied elastomeric materials to improve the mechanical properties of these active materials. Depositing active materials onto a prestrained elastomer to form wavy electrodes, coating 3D porous elastomers, or mixing active materials with elastomers to form stretchable composites are all leading approaches. However, active materials in these systems still experience strain to some extent, which can be problematic for practical use. There is therefore an urgent need to explore new ways to fabricate electrodes with good mechanical properties and that retain functionality under strain for use in stretchable LIBs. In this presentation, we report a new approach that uses textile structures to protect the active materials from strain and subsequent damage. We use a warp-knitted velour fabric structure, which consists of a warp-knitted trellis and a cut pile. Metallizing the fabric using solution-based electroless nickel-immersion gold plating renders it conductive, preparing it for use as a current collector. We then electrolessly deposit copper selectively on the cut pile fibers, and convert the resulting copper film into CuS by reaction with elemental sulfur. This unique preparation method integrates the active material and the current collector into a single piece of velour fabric in a way that protects the CuS from strain when the fabric electrode is elongated. The CuS/Au-coated velour fabric electrode shows stable conductivity to 130% strain, and the conductivity also remains stable through 1000 cycles of 50% strain. We demonstrate its application in LIBs. The electrode exhibited a specific capacity of ~400 mAh/g at 0.5 C with no obvious sign of capacity decay for at least 300 cycles. After 1000 cycles of 50% strain, the electrode still exhibited stable electrochemical performance.

SB10.03.27
Analysis of Heat Releasing Engineered Fibers and Films for Thermal Comfort via a Simulated SkinTemperature Device Michael Okamoto¹, Yassine Ait-El-Aoud¹, Ihsan Uluturk¹, Elizabeth A. Welsh¹, Svetlana V. Boriskina², Luis M. Lozano², Yi Huang² and Richard M. Osgood¹; ¹US Army Combat Capabilities DevelopmentCommand - Soldier Center, United States; ²Massachusetts Institute of Technology, United States

Radiative cooling and heating can play a role in influencing and controlling the temperature of things like shelters, solar cells, and the human body. Personal thermal comfort is an important consideration for helping to maintain optimum physical and cognitive performance in an individual. It has been shown that thermally transparent polymeric films and fibers can theoretically transmit metabolically-generated heat from the body to the environment via passive radiative cooling [1].

In order to compare the heat-trapping or heat-releasing properties of engineered films and fiber swatches, a
simulated device for skin temperature was designed. The device consists of a heater operating at constant power output to mimic the heat produced by human skin which is at roughly 34°C. High density polyethylene (HDPE) fibers and/or films will be compared to commercially available ones. The fabric and/or film of interest is placed over the “skin” and the temperature differential, delta-T, across the elemental material or monolayer fiber array or film/membrane is measured. This unique capability can directly measure two test samples simultaneously thus allowing for direct comparison under identical environmental conditions to control for changes in factors like air temperature, wind, and humidity. Finally this device can be operated in a vacuum thus removing conduction and convection as cooling or heating pathways.

While the textile industry community employs standardized test methods and instruments for measuring larger end-item textile products, this measurement capability will enable better analysis of early-stage research materials instead of just finished textiles thus allowing for better control, prediction, and understanding of inherent material properties.

**SB10.03.28**  
**Textile-Based Capacitive Pressure Sensors** Saki Tamura¹², Justin K. Wyss¹¹, Mirza S. Sarwar¹, Addie Bahi¹, John D. Madden¹ and Frank K. Ko¹; ¹University of British Columbia, Canada; ²Kyoto Institute of Technology, Japan

Capacitive pressure sensors (CPS) have long been recognized to be an effective component for interaction with electronic devices. The growing interest in the development of flexible and wearable electronics has prompted the interest in flexible sensors. A number of sensor arrays have been demonstrated on bendable and stretchable substrates. In order to enhance design flexibility and scalability in the manufacture of the CPS, we demonstrate orthogonally woven CPS integrated into elastomer substrates. A further advantage of using a combined elastomer and textile structure is the ability to shape the elastomer to maximize change in capacitance in response to proximity, pressure, touch and shear. In this work we focus on proximity and pressure detection. Specifically, 4x4 cross array woven structure consisting of Ag coated Nylon yarns (diameter 0.54 mm, 0.438 Ω/cm) have been developed that cover an area of 5.5 x 5.5 cm. The woven structure was embedded into Ecoflex™. Each electrode is composed of 5 parallel Ag coated Nylon yarns, with 4 electrodes interlaced in each direction to form an array of 16 intersection, each sensitive to pressure and proximity. The woven composite assemblies were subjected to light touch and pressure loads. The corresponding capacitances were measured and are similar in response to those of the orthogonal non-interlaced/non-textile structure, including good proximity detection (> 1 cm), pressure detection (0.23 %/kPa) and spatial resolution ~1 cm). The devices operate in bending and during stretch. Next steps include integration in clothing and bedding to enable health monitoring.
speech, ambulatory gait, body orientation and others, of wide applicability in health monitoring and clinical care. Demonstrations include comparisons to clinical gold standards for various individual indications, and to full-night polysomnography (PSG) results captured in a hospital sleep lab.

Washable ECG Electrodes from Sewn High Performance Carbon Nanotube Fibers Lauren W. Taylor1, Steven M. Williams1, J S. Yan1, E A. Bengio1, Oliver S. Dewey1, Flavia Vitale2 and Matteo Pasquali1,1,1; 1Rice University, United States; 2University of Pennsylvania, United States

Commercially available electrocardiogram (ECG) electrodes are rigid and require a gel electrolyte to obtain a clear signal. This electrolyte can dry over time leading to a degradation in signal to noise ratio. Furthermore, the lack of airflow to the skin and adhesive can be irritating to the user. This can pose issues for individuals that require continuous monitoring. Here, we present ECG electrodes made with high performance carbon nanotube (CNT) fiber that are suitable for long-term use. The high conductivity of the fiber and low contact impedance between the fiber and skin allow for good transmission of the ECG signal without the use of a gel. Additionally, the CNT fiber has excellent tensile strength and flexibility so it can be sewn into fabric with a standard sewing machine. The woven structure and softness minimizes the irritation caused by recording ECGs. Furthermore, the CNT fiber is robust and chemically inert so that it can be machine washed without losing performance.

9:15 AM SB10.04.03
Sensing Human Behavior with Smart Garments Trisha L. Andrew; University of Massachusetts Amherst, United States

Smart apparel with embedded self-powered sensors can revolutionize human behavior monitoring by leveraging everyday clothing as the sensing substrate. The key is to inconspicuously integrate sensing elements and portable power sources into garments while maintaining the weight, feel, comfort, function and ruggedness of familiar clothes and fabrics. We use reactive vapor coating to transform commonly-available, mass-produced fabrics, threads or premade garments into a plethora of comfortably-wearable electronic devices by directly coating them with uniform and conformal films of electronically-active conjugated polymers. By carefully choosing the repeat unit structure of the polymer coating, we access a number of fiber- or fabric-based circuit components, including resistors, depletion-mode transistors, diodes, thermistors, and pseudocapacitors. Further, vapor-deposited electronic polymer films are notably wash- and wear-stable and withstand mechanically-demanding textile manufacturing routines, enabling us to use sewing, weaving, knitting or embroidery procedures to create self-powered garment sensors. We will describe our efforts in monitoring heartrate, breathing, joint motion/flexibility, gait and sleep posture using loose electronic garments and highlight collaborative endeavors to combine signal processing, machine leaning and human factor integration to predict behavior in selected at-risk populations.

Smart Textiles for Personalized Health Care Jun Chen; University of California, Los Angeles, United States

There is nothing more personal than healthcare. Health care must move from its current reactive and disease-centric system to a personalized, predictive, preventative and participatory model with a focus on disease prevention and health promotion. As the world marches into the era of Internet of Things (IoT) and 5G wireless, technology renovation enables industry to offer a more individually tailored approach to healthcare with more successful health outcomes, higher quality and lower costs. However, empowering the utility of IoT enabled technology in personalized health care is still significantly challenged by the shortage of cost-effective and wearable biomedical devices to continuously provide real-time, patient-generated health data. Textiles have been concomitant and playing a vital role in the long history of human civilization. In this talk, I will introduce my research on smart textiles for biomedical monitoring and personalized diagnosis, textile for therapy, and textile power generation as an energy solution for the future wearable medical devices. Lastly, I will briefly introduce an autonomous self-powered textile body area network that seamlessly integrates wearable power sources, self-powered sensors, microcontrollers, and internet connection for revolutionary applications in the future personalized health care and body computing.

References (* Equal contribution author; * Corresponding author)
Integration of smart devices into textiles is a key challenge for tomorrow-wearable technologies. On one hand, the electronics should perform diversified computational operations, such as data processing and transmission, with high performances for responsive smart systems. These conditions are only met today by rigid silicone-based systems. On the other hand, clothes are soft, closely fit to the skin and adapt to the human body. The mismatch in mechanical properties between soft substrates and rigid components induces specific reliability issues, especially for wearable systems, as they are subjected to wearing and washing.

In this work, we present a fabrication process of soft and ultra-thin circuit for imperceptible systems, integrating microelectronic silicon-based components. We use a customized stack of thin decorative copper leaf on polymer, which can be assembled and connected through vias for multilayered systems. We consider and study the aforementioned aspects of imperceptibility (wearability), and mechanical robustness through specifically designed bending tests. We investigated the optimization of electrical connection between ultra-soft substrates and rigid components, and the influence of the stack composition in multilayer electronic systems on the overall reliability of the device.

The combination of optimized stack layout and compliant interconnections allow the fabrication of robust and ultra-conformable, imperceptible devices.

An Ultrasoft Graphene Network-Based Stretchable Sensor for Full-Range of Human Bodily Motions Detection

Zijun He1,2, Ling Qiu3,1 and Dan Li2,1; 1Monash University, Australia; 2The University of Melbourne, Australia; 3Tsinghua-Berkeley Shenzhen Institute, China

Human bodily activities are complex that consists of dynamic motions of different body parts with broad frequency ranges. Despite it has been widely exploited in human bodily motion detections, the possibility of using soft rubber-based stretchable sensors in the detection of full-range of bodily motions from muscle functions up to mass movements have not been well explored. Here, we demonstrate that controlled interfacing of an ultralow modulus graphene network with rubber can lead to a stretchable hybrid elastomer with performance combinations of high sensitivity, large stretchability, similar modulus compliance to the skin and good durability. The resultant sensor allows resistive detection of subtle dynamic skin stretches induced by muscles and large deformation caused by joints motions, which fills the gap for sensing the whole spectrum of human bodily motions via soft flexible electronics.

Wearable and More—Biopotential Recording by Ultraconformable Devices

Piero Cosseddu, Danilo Pani, Andrea Spanu and Annalisa Bonfiglio; Università di Cagliari - UniCa, Italy

The recent rise of the so-called flexible electronics has paved the way for the development of flexible systems that can be easily integrated and also directly fabricated onto textiles, and be employed for the monitoring of a different
bio/physical parameters. In this presentation we will introduce different technological solutions for the realization of smart wearable systems specifically engineered for biopotential recordings and on-skin sensing applications. The first proposed approach is based on screen printed PEDOT:PSS electrodes which are seamlessly integrated directly onto commercial garments, for the measurement of the ECG signal, coupled with respiration. These 2 measurements allow evaluating the physiological status of patients and subjects as athletes and workers under stressful conditions, in several applications ranging from rehabilitation to the monitoring of athletes performance or subjects at work.

Moreover, we will also show the employments of similar electrodes for EMG applications. These recordings can be used to evaluate muscle performance and fatigue, by means of simple commercial garments where recording electrodes have been seamlessly integrated. Examples of applications in rehabilitation and gesture recognition will be shown.

Textile sensing systems are part of a broader area of devices that, thanks to their mechanical conformability, can be successfully used for the human body monitoring. Also tattoo electronics can offer interesting solutions for this kind of applications. In this presentation, we will discuss comparatively their advantages and drawbacks for the recording of biopotentials and/or different physiological parameters.

New Generation of Flexible Energy Storage Devices and Humidity Sensors on Reinforced Carbon Fiber Textile
Karen R. Pearson¹, Kasra Sardashti¹, Shi Fu² and Vladimir Samuilov²; ¹Fashion Institute of New York, United States; ²State University of New York at Stony Brook, United States

Carbon fiber textile has been utilized as flexible supercapacitor electrodes with cost-effective graphene nanoplatelete (GNP) composite as model material for coating the electrodes. This composite is considered to be a new class of carbon nanomaterial with very high intrinsic electrical conductivity in plane and accessible surface area. Carbon nanotubes (CNT) at the concentration 50:50 of CNT to GNP were added to take advantage of the high surface area of the composite of these two carbon nano-materials. Perfect shape of the voltammetric curves indicates excellent ion transport behavior, good charge propagation and low losses in supercapacitors with GNP/CNT coated electrodes. The first experimental results without optimization showed promising supercapacitor behavior of the carbon fiber textile with bare pads, better than in the state-of-the art reference [1]. Graphene nanoplatelete – carbon nanotube (50:50) electrode material has improved the capacitance density approximately 10 times. Carbon fiber textile is promising material for fabrication of electrodes for high-capacitance high-energy density flexible supercapacitors [2].

We have also developed flexible carbon nanotube sensor for applications of moisture detection. A cost-effective sensor that could detect and measure humidity/moisture levels has been developed. Prototype sensor have demonstrated an extremely high sensitivity to water.

1:30 PM *SB10.05.01
Textile-Based Wearable Robots Conor Walsh; Harvard School of Engineering, United States

The rapidly emerging field of soft robotics presents a new opportunity to develop wearable assistive technology optimized for the needs of individuals with residual capacity as well as for augmenting human performance. Unlike their rigid counterparts, soft wearable robots are lightweight, intimately conformal to the body and can more easily
fit a range of sizes. The hierarchical structure and flexible/conformal nature of textiles provide an ideal platform to construct these wearable robotic systems. The ability to tune mechanical properties for use in inflatable actuation profiles or to anchor to the body and distribute and route forces through attachment points in cable driven systems. Looking forward, additional functionalities will be embedded into the textile beyond structural needs including sensing, and flexible electronic routing.

2:00 PM SB10.05.02
Electromagnetic Textiles with Novel Thermal and Reconfigurable Properties Richard M. Osgood1, Michael Okamoto1, Yassine Ait-El-Aoud1, Ihsan Uluturk1, Elizabeth A. Welsh1, Sean Dinneen1, Justin Murphy1, Danielle Froio-Blumsack1, Svetlana V. Boriskina2, Luis M. Lozano2, Alkim Akyurtlu3, Guinevere Strack3, Leila Deravi4, Amrita Kumar4 and Camille Martin4; 1US Army Combat Capabilities Development Command - Soldier Center, United States; 2Massachusetts Institute of Technology, United States; 3University of Massachusetts Lowell, United States; 4Northeastern University, United States

The field of electronic textiles (“e-textiles”) is currently growing rapidly, impacting by research and development activities in multiple fields, from physics and mathematics to textiles and power engineering to health, safety, and social sciences. Combining multiple functionalities – from basic warmth and comfort to harvesting power to more focused monitoring and/or protection – is of great interest, but has so far found only limited success. We report on our research to analyze and experimentally demonstrate both heat-releasing and heat-trapping polymer films and simple 1-d arrays of fibers, and discuss enabling both functionalities in different scenarios for both heating and cooling applications, such as for the human body. We discuss the use of a thermally transparent film in some hot weather applications, when it is critical to release heat, and also where it is essential, for cold weather applications, to trap heat at an extremity. We build on earlier results that highlighted the importance of polyethylene, especially high- and ultra-high –weight polyethylene, for heat release and improved thermal conductivity [1] and light-scattering bio-particles in melt-extruded polymer fibers [2]. Using our thermally transparent materials, we observe small decreases (few degrees C) in the temperature of artificial ‘skin’ when constant power density, emulating an exercising person, is applied to a novel system for characterizing both power density and artificial skin temperature, compared to control samples of standard, commercial polymers. Similarly, we report on heat-trapping experiments when the outside temperature is much lower than the temperature of the artificial skin. We discuss how such ‘electromagnetic textiles’ – purely passive but electromagnetically responsive materials – can be controlled actively, using 1) electrical voltage with conductive particles in the fibers 2) magnetic fields using magnetic particles and 3) thermoelectric materials that generate a voltage in response to an engineered thermal differential 4) light-activated scattering. These active controls will enable the fiber’s or film’s heat-trapping or heat-transmitting states to be reconfigured actively (voltage control) or passively (due to temperature or electromagnetic field alone). We predict how future textiles, containing polymer materials with particles similar to those we have studies, will perform, and discuss new applications for electromagnetically-responsive polymers, including protection and color.

2:15 PM SB10.05.03
Stretchable Ultrasheer Fabrics as Transparent Electrodes—A Textile-Centric Approach to Wearable Light-Emitting e-Textiles with Changeable Display Patterns Yunyun Wu, Sara Mechael, Cecilia Perez-Lerma, R. Stephen Carmichael and Tricia B. Carmichael; Univ of Windsor, Canada

Research on smart clothing aspires to seamlessly integrate electronic devices with textiles to add exciting new functionality without losing softness and wearability. In particular, light-emitting e-textiles are an emerging technology with applications in fashion design, interior design, visual merchandizing, and healthcare. At present, light-emitting textiles are mainly realized by sewing discrete, rigid elements like light-emitting diodes (LEDs) or optical fibers into clothing, which reduces softness, stretchability, and wearability. Better integration of device functionality into clothing requires the incorporation of intrinsically stretchable functional materials into the textile structure; however, this fabrication is challenging due to the porous, 3D structures of textiles that present a non-planar surface for fabrication and readily absorb and wick solutions of functional inks. In this presentation, we show...
that textile structures can instead be exploited to form the basis for a new, textile-centric design approach. We use the open structure of a low-denier nylon and spandex ultrasheer fabric as the framework for a highly stretchable transparent electrode in wearable and stretchable light-emitting devices. We coat the fibers of the ultrasheer fabric with a conformal gold coating using solution-based electroless nickel immersion gold plating, producing a semitransparent, conductive, and highly stretchable textile electrode. Adhering these new textile-based electrodes to a stretchable emissive material produces lightweight, wearable, and washable light-emitting e-textiles that function to 200% strain. Combining the metallization of the ultrasheer textile with low-cost stencil printing of a wax resist provides patterned electrodes to create patterned light-emitting displays; furthermore, incorporating soft-contact lamination in the device fabrication produces light-emitting textiles that exhibit, for the first time, readily changeable patterns of illumination.

2:30 PM SB10.05.04
Towards the Smart Fabrics—Rollable Metamaterial as a New Paradigm Chun-Che Wang, Yang-Fang Chen and Hung-I Lin; National Taiwan University, Taiwan

Since the development of photonics, towards optoelectronic devices of flexible, rollable, wearable, user-friendly, and robust to improve human-machine interfaces have been progressed rapidly. To integrate these devices onto human body, they are designed to be biocompatible and can withstand mechanical deformation. A large number of demonstrations have been proven for the promising market of wearable photonics and optoelectronics such as flexible photodetectors, stretchable laser systems, artificial electronic skins, and paper-based memory devices. Biocompatibility, high sensitivity, low energy loss, and long-term endurance, are the features to successfully integrate with wearable photonic systems, the flexible and rollable optoelectronic devices. Certainly, there remains a great challenges to achieve the above mentioned benefits with considering the practical applications.

On the other hand, photonic metamaterials provide a large number of potential functionalities that can be used for wearable optoelectronic devices. Metamaterials are designed with sub-wavelength geometries for controlling or tailoring the electromagnetic waves for a variety of functionalities. A distinct class of metamaterials is hyperbolic metamaterial (HMM), which is defined by its hyperbolic iso-frequency curve in momentum space. For light-matter interactions, HMMs have been proven to boost the transition rates for both of the spontaneous and stimulated emission dynamics. Owing to the increased transition rate of the optical gain media, stimulated emission (e.g., laser action) comes along with a strong output power and a reduced lasing threshold. However, these demonstrations have primarily been done on rigid substrates. To fully explore the excellent functionalities of HMM, large degree of flexibility and even rollability are highly desirable, which remains as a challenge issue.

To realize the usefulness of our new design, we demonstrate that the flexible and rollable HMM is able to enhance random laser action, in which light suffers from multiple scattering in between disordered media, thereby strongly enhancing its optical gain. We choose low-dimensional organic-inorganic perovskite nanocrystals (PNCs) as the gain material, which is composed of methyl-ammonium lead bromide (MAPbBr3) with a bandgap of ~2.3 eV that can achieve a high quantum efficiency up to ~90.5%. Interestingly, the enhanced laser action based on our flexible and rollable HMM maintains superior stable performance even under cyclic bending to curvatures below 1mm. The intensity of laser action is enhanced by 2.5 times as compared to the flat surface. By tuning the thickness of the HMM structure, we have achieved a large enhancement of the density of states and the scattering efficiency. Simulation results based on the scattering efficiency and the dipole-like dynamics confirm an efficient out-coupling. We anticipate that this flexible and rollable HMM structure can serve as a diverse platform for flexible photonics technologies, such as light-emitting devices, wearable optoelectronics, and optical communication.

Multifunctional Triboelectric-Nanogenerator Fabric for Universally Harvesting Energy from Rain Drops, Winds and Human-Motions, and as Self-Powered Sensors Ying-Chih Lai, Yung-Chi Hsiao and Hsing-Mei Wu; National Chung Hsing University, Taiwan
Developing nimble, shape-adaptable, conformable and widely-implementable energy harvesters with the capability to scavenge multiple renewable and ambient energy sources is highly demanded for distributed, remote, and wearable energy uses to meet the needs of internet of things. Here, we present the first multifunctional and waterproof triboelectric-nanogenerator fabric that can produce electricity from both natural tiny impacts (rains and winds) and body movements, which can not only serve as a flexible, adaptive, wearable, and universal energy collector but also act as a fabric-based self-powered active sensor. The working principle comes from a conjunction of contact triboelectrification and electrostatic induction during contact/separation of internal soft fabrics. The structural/material designs of the smart textile are systematically studied to optimize its performance, and its outputs under different conditions of rains, winds and various body movements are comprehensively investigated. Its applicability is practically demonstrated in various objects and working situations to gather ambient energy. Lastly, a self-powered human-system interface is demonstrated on a garment for remotely controlling a music-player system. The multifunctional yet nimble energy fabric can not only address the long-lasting challenge of waterproof, adaptive, deformable, and universal energy devices for locally accessible energy but also bring a new class for wearable energy and smart articles.

Engineering Flexible Multi-Scale Materials for Sustainable Multi-Functional Clothes and Wearables Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

The ever-growing demand for lightweight portable high-tech devices is evolving into an even more challenging demand for fully wearable devices integrated into clothes. To meet this demand, the emerging wearable optical technologies must combine multiple functionalities, including visual effects, communications features, thermoregulation to maintain personal comfort level, and even self-cleaning and microbial treatment by sunlight. These technologies often require portable or renewable power sources to operate—and the lack of cheap, long-lasting and lightweight sources has proved a big hurdle to wider adoption. Finally, new technologies must meet the global demand for tighter environmental standards to reduce energy and water use and waste during the fabrication process as well as throughout the garments life cycle. They must also provide a clear pathway for recycling and re-using the materials into new fabrics and wearables. We develop multi-functional materials for wearable technologies, which combine a variety of optical, thermal, mechanical, and biological functionalities, and meet high standards for energy and water saving and sustainability. I will discuss the engineering approaches used in designing and fabricating woven and knitted fabrics out of polyethylene fibers to achieve either passive cooling without breaking a sweat or passive heating without the use of uncomfortable metal films. I will then show how the fiber micro-structuring can be combined with nano-scale engineering via embedding a variety of nano-inclusions to combine thermoregulation-by-radiation-control functionality with structural coloring, unique lateral heat conduction properties, and anti-microbial resistance of new textiles. We embed colorants and anti-microbial agents into fibers and films during their fabrication, which does not require significant water usage, in stark contrast with the standard industrial processes that use 200 liters of water to produce 1 kg of textile, and create large amounts of wastewater contaminating the environment. The new textiles also offer excellent water wicking, dirt-resistant, and fast drying functionalities, offering significant energy and water savings for their maintenance, and can be easily recycled at the end of their lifetime. Finally, I will discuss how the new fabrics can be further enhanced by incorporating other functional wearable elements, including fibers for optical communication, photo-detectors, and flexible, lightweight, round-the-clock energy harvesters capable of operating in the self-powered regime.

Two-Dimensional Field-Effect Heterostructures for Wearable and Textile Electronics Tian Carey1, Stefania Cacovich1, Giorgio Divitini1, Jiesheng Ren2, Jong Min Kim1, Chaoxia Wang2, Roman Sordan3 and Felice Torrisi1,4; 1Cambridge Univ, United Kingdom; 2Jiangnan University, China; 3Politecnico di Milano, Italy; 4Imperial College London, United Kingdom

Solution processing of graphite and other layered materials provides low-cost stretchable inks enabling electronic textile devices [1]. However, the limited quality of the two-dimensional (2d) material inks, the complexity of the layered arrangement, and the lack of a suitable dielectric 2d material ink [2] has impeded the fabrication of active field effect devices on fabric based on fully-printed 2d heterostructures. In this work we demonstrate fully inkjet printed 2d material active heterostructures with graphene, MoS2 and hexagonal-boron nitride (h-BN) inks, and use them to fabricate all inkjet printed flexible and washable ambipolar, n- and p-type field effect transistors (FETs) on textile, reaching a field effect mobility of μ ~ 105 ± 29 cm2 V-1 s-1 on polyester fabric, at low operating voltages (< 5 V). The devices maintained their performance even under ~ 4% tensile strain and showed stable operation for periods up to 2 years, indicating the two-fold role of the h-BN layer as a flexible dielectric and encapsulant. Our 2d material textile FETs are washable up to 20 cycles, which is ideal for textile electronics. The viability of our process for printed and textile electronics is demonstrated by fully inkjet printed electronic circuits, such as reprogrammable volatile memory cells, complementary inverters, and OR logic gates with graphene/h-BN FETs.

Superelastic Sputtered TiNiCuCo Thin-Film Serpentine Interconnects for Wearable Electronics Sabrina M. Curtis1,2, Lars Bumke1, Prasanth Velvaluri1, Ohuwaamilola Ajibuwa1 and Eckhard Quandt1; 1Kiel University, Germany; 2University of Maryland, United States

The next generation of wearable sensors, actuators, and power microsystems must maintain a large area density while recovering reversible elastic deformation of at least 30 - 100% macroscopic strain, to match the elasticity of human skin. To achieve this, wearable devices are often fabricated through the “island-plus-bridge” method where an array of active rigid device micro-islands are separated by stretchable serpentine metal interconnects. Serpentines are advantageous for integration into textiles as interconnect structures since they can undergo geometrical reconfigurations to relieve stress under applied strain. Traditional metals with low intrinsic tensile strains (i.e Cu) configured into serpentine with a large amplitude and narrow wavelength are able to achieve large macroscopic strains of tens to hundreds of percent. Replacing these traditional metals with materials that have a larger elastic intrinsic strain may offer a route to create higher area density devices by requiring less serpentine interconnect material to achieve the same macroscopic strains.

Freestanding magnetron sputtered Nickel – Titanium (NiTi) based shape memory alloys (SMA) are attractive for
textile and wearable interconnect technologies. They can reversibly recover from unusually large elastic strains (up to 6%) through a temperature induced solid-to-solid phase transformation, compared to 1% for traditional metals like Cu. When a SMA’s transition temperature is below room temperature, the material is considered to be superelastic, where elastic strain recovery occurs purely upon unloading. Previously, superelastic TiNiCuCo thin-films were demonstrated to be ultra-low fatigue, reversibly deforming through 10 million cycles at a 2% strain [1]. Additionally, superelastic and SMA materials exhibit exceptional mechanical strength and efficient electrical conductivity, making them ideal stretchable electrode material candidates for active serpentine interconnects in various wearable devices.

Here, we present a MEMS compatible fabrication process to fabricate and characterize the stretchable mechanical performance of novel superelastic TiNiCuCo serpentines [2]. Fabricated devices have a serpentine amplitude of 1 mm, wavelength of 1 mm, width (w) between 25 – 75 μm, and film thickness (t) between 20 – 80 μm. We evaluate different mechanical deformation modes for our serpentines where < 1 results in buckling deformation and > 1 results in scissoring deformation [3]. We demonstrate large single strain-to-rupture testing of all devices ranging between 97 - 156% macroscopic strains, superior than those modeled for a Cu system of the same geometry. Preliminary cyclic fatigue testing has demonstrated these serpentine interconnects can survive up to 8000 cycles at a 100% macroscopic strain, with minimal structural and functional fatigue. Future fatigue testing will explore electropolishing of the serpentine structure to exclude any residual defects which is likely to improve the fatigue resistance even further. Overall, our results show superelastic metals may offer a route to increase the stretchability of wearable devices while simultaneously reducing the size and cost of device production.

4:30 PM SB10.05.09

Graphene Nanoplatelets-Based Membranes for Thermal Comfort Enhancement in Textiles Lorenzo Bonetti1, Andrea Fiorati1,2, Andrea Serafini1, Francesca Tana1, Agnese D'Agostino1, Guido Masotti1,3, Lorenza Draghi1,2, Roberto Chiesa1,2, Silvia Farè1,2, Massimiliano Bianchi1, Laura Giorgia Rizzi1 and Luigi De Nardo1,2; 1Politecnico di Milano, Italy; 2National Interuniversity Consortium of Materials Science and Technology (INSTM), Italy; 3DIRECTA PLUS S.p.A. c/o ComoNExT - Science and Technology Park, Italy

Composite materials incorporating carbon allotropes are emerging as a powerful technology to manufacture membranes able to impart advanced functions to textiles [1,2]. Body temperature increases under physical effort, and an excessive body warming negatively affects the comfort feeling and the physiological performances [3]. Here, we report an innovative family of advanced nanocomposite membranes for thermal comfort enhancement in functional textiles, based on a thermosetting aliphatic polyurethane (PU) and graphene nanoplatelets (GNPs).

A thorough chemico-physical characterization of GNPs was performed to provide an insight of the thermal properties obtained for the composite materials. The highly crystallographic quality of GNPs, obtained via physical-mechanical processes, was revealed by Raman spectroscopy (ID/IG = 0.127) [4]. TEM and AFM analyses assessed that about 85% of the analyzed GNPs possessed a thickness lower than 10 graphene planes. These results confirmed the suitability of the produced GNPs for the fabrication of highly performant membranes in terms of thermal conductivity.

The GNPs were then loaded into the PU matrix (5 and 10% w/w) by conventional industrial mixing process. The obtained composites were characterised after coupling with cotton fabrics, via hot-melt process. SEM micrographs showed that graphene nanoplatelets were homogeneously distributed in the PU matrix, with a preferential alignment parallel to the matrix plane, maintaining the original dimensions. Crystalline phases present in the composites were evaluated by X-ray diffraction: two peaks around 2θ = 26.48° and 54.78°, corresponding to the characteristic peaks of GNPs, were clearly present in the diffraction patterns of PU-GNPs composites. Moreover, the intensity of these peaks increased by increasing the GNPs loading [5].

Thermal characterization was performed on the composite membranes as a function of the filler percentage. In-plane thermal conductivity of the pristine PU membranes and PU-GNPs membranes was measured, showing that thermal...
conductivity improved (up to 471 %) by increasing the percentage of GNPs. An appropriate designed forearm manikin device was used as phantom to evaluate the thermal conductivity and thermal dissipation of the developed membranes, mimicking the possible in vivo condition [6]. PU-GNPs membranes were demonstrated to improve the thermal dissipation, lowering the internal temperature of the phantom compared to pristine PU membranes (-1.2 °C for 10% GNPs-loaded membranes).

This study provides a new approach for the design of innovative membranes suitable for sport and technical textiles, with significant performance improvement in thermal comfort.

Monitoring Joint Motion Using Knitted Fabric Strain Sensors S. Zohreh Homayounfar, Hannah Meeran, Alfred J. Crosby and Trisha L. Andrew; University of Massachusetts Amherst, United States

Smart apparels capable of tracking the wearer’s gait and motion have the potential to revolutionize human behavior sensing and personalized health monitoring by transforming everyday clothing into sensors. The ability to measure motion at individual joints can enable many applications. For example, the knee and ankle joints are important to monitor gait disorders that can occur due to neurological causes like Dementia and Parkinson’s, as well as non-neurological causes such as Osteoarthritis, intoxication, and medications (e.g. sedatives). However, existing sensing techniques typically rely on sewing or inserting traditional hard sensors (such as inertial measurement units and piezoelectric buttons) into tight-fitting garments to obtain sufficient signal to noise, making it uncomfortable to wear and limiting the technology to niche applications in lab settings.

Here, we describe an approach to leverage the unique properties of textiles and garments themselves to enable entirely new ways to sense motion using clothing. Specifically, a garment folds, compresses, twists, and stretches as a wearer moves, and, by conformally applying an imperceptible electronic polymer coating directly onto the textile surface, we demonstrate the ability to transduce these mechanical deformations into an electrical signal. We use a solvent-free vapor coating technique developed in our lab to conformally deposit an electronic polymer film followed by an insulating polymer encapsulant onto mass-produced fabrics or garments. Vapor coated samples retain the weight, feel and flexibility of the starting fabrics and garments. Our polymer coatings simply impart electronic functionality to a previously insulating substrate, thus providing a handle to detect changes as the fabrics/garments bend, compress or twist during movement. Notably, vapor deposited polymer coatings are sweat repellent and stable to machine washing, ironing, and mechanical abrasion.

Vapor coated compression socks and elbow sleeves, in particular, serve as resistive strain sensors that produce a unique signal pattern (resistance change) for each specific joint motion. The special knitting pattern of these garments imparts multiaxial strain sensitivity to the sensor, and their tight fitting design maintains constant body contact during motion, limiting spurious noise. The high stretchability of the commercial fabric used in compression socks and elbow sleeves allows for a large range of dynamic motions (axial, bending and torsional strain) to be captured without the need for adaptive circuitry or sophisticated signal processing routines. Because vapor-deposited electronic polymer films are conformal and pinhole-free, a linear resistance change is created while a subject is wearing the compression sock or elbow sleeve, even at large strains (>100%), which is a notable advance over reported movement sensors. Moreover, since vapor deposited coatings are automatically grafted onto the surface of the fabric, repeated and varied mechanical deformations do not deadhere, delaminate or realign the electronic polymer coating over time, meaning that signal hysteresis and stretching fatigue are not observed. Lastly, due to the direct and tight-fitting contact of the vapor coated compression sock with skin, this structure also boasts the ability to record ECG data, which can be correlated with joint motion. All these prominent properties empower wide-spread applications in gait detection and human performance monitoring.
Developing new textile devices is a sequence of trial and error. This iterative process is largely due to a lack of modeling tools that are paramount for predicting properties like electronic conductivity and mechanical performance. In comparison, other industries, such as automotive and aerospace, rely on a digital design environment before fabrication to study the effects of geometry and architecture on device performance. As this kind of engineering system does not exist for textiles, studying the effects of these parameters, including knit architecture, geometry, and loop pattern, on device performance has been underexplored.

We have developed a novel bicontinuous helicoid lattice system for modeling yarn pathways within the knit structure that can begin to address this challenge. This lattice is based on established principles, with the surfaces of the lattice mathematically defined. This allows the path of the yarn to be known at each distinct point throughout the structure, defined by its relationship to the lattice surface, providing an understanding of the complex three dimensionality of the knit textile structure. With the helicoid lattice, we can model how stitch pattern changes lead to loop deformations in the resulting fabric structures. This includes the effects of knit and purl stitch combinations and the deformations these patterns can create, leading to variable surface geometries. The model was originally developed to understand the deformation mechanisms that occur within the knit structure and produce a self-folding effect. Through this understanding, we can see how loop architecture informs device performance in a variety of textile applications, including electronic textiles, where design of non-planar structures can be used to enhance functionality.

Specifically, in the design of textile supercapacitors we explored the effect of knit structure on device performance. Recent literature on the development of fiber and yarn supercapacitors demonstrate high capacitance and energy density at short lengths only (<4 cm), with reduced performance at longer lengths due to high resistance. For this reason, knitted electrodes are a promising new architecture of textile energy storage devices; yarn electrodes are manipulated into interconnected loop structures, providing multiple pathways for electron transport. One of the inherent challenges of knit supercapacitors is that the spacing between electrodes is significantly larger than that of planar microsupercapacitors, and it is well known that the narrower the spacing between electrodes, the better the rate capability, power response, and energy density of a device.

In this work, methods to minimize the electrode spacing were explored by exploiting the fundamental loop structure of knitted textiles. Using the bicontinuous helicoid lattice model to inform design decisions, specific loop structures were chosen to control the device geometry and optimize electrochemical performance. By tuning the knit structure, the spacing between electrodes decreased by more than a factor of 4 and the capacitance increased by almost a factor of 2 at low scan rates.

Photolithographic defined films play an important role in modern optoelectronics and are crucial for the development of advanced organic thin-film transistors (OTFTs). Here, we explore a facile photosist-free photopatterning method for natural carbohydrates and their use as OTFT gate dielectrics and passive for flexible transistors. The effect of the cross-linkable unit chemical structure on the crosslinking chemistry and dielectric strength of the corresponding films was explored by investigating cinnamate-functionalized carbohydrates from monomeric (glucose) to dimeric (sucrose) to polymeric (cellulose) backbones. UV-illumination of cinnamate ester of these carbohydrates leads to [2+2] cycloaddition and thus the formation of robust crosslinked dielectric films in the irradiated areas. Using propylene glycol monomethyl ether acetate as solvent/developer, patterned dielectric films with micrometer size features can be fabricated. P- and N-type OTFTs were successfully demonstrated using unpatterned/patterned crosslinked films as the gate dielectric and pentacene and N,N'-1H, 1H-perfluorobutyl

Fiber-Based Highly Efficient Phosphorescent Organic Light-Emitting Diodes and Addressable Structure for Textile Displays Yong Ha Hwang, Seon Il Kwon, Jeong Bin Shin, Hyun Cheol Kim and Kyung Cheol Choi; KAIST, Korea (the Republic of)

Textile-based light-emitting devices, one of the more promising approaches for cutting-edge wearable electronics, have been developed in a variety forms. They can be fabricated directly on fabric, or on individual strands of the fiber itself. Among these approaches, fiber-based light-emitting devices possess many structural advantages including flexibility, breathability and light weight, that make them promising candidates for future wearable displays.[1-2]

So far, most fiber-based light-emitting device studies have focused on fabricating a single device. However, it is essential that light-emitting devices are capable of displaying composite information. High efficiency is also a very important characteristic for functional textile displays. Here, we introduce fiber-based phosphorescent organic light-emitting diodes (fiber phOLEDs) which exhibit the impressive current efficiency (CE) of over 20 cd/A, the highest CE value ever reported. This work also proposes an addressable structure which allows multiple emitting-cells to emit light from a strand of fiber.

The fiber phOLEDs are based on a dip-coating process strategy developed in our previous work proposing organic light-emitting fibers.[2] First, to obtain a higher CE than achieved in our previous work [2], we used a phosphorescent dopant material, tris(2-phenylpyridine)-iridium(III) (Ir(ppy)3), which can achieve 100% internal quantum efficiency (IQE). However, Sophisticated structures to control the excitons were needed to take advantage of the 100% IQE because the exciton lifetime is so long. The Ir(ppy)3 based emitting layer (EML) was therefore designed to not only take charge balance into consideration, using co-host materials, but also the appropriate concentration for avoiding aggregation of the solution. Also, a high triplet energy hole transport layer (HTL) was inserted between the EML and Al anode layer for exciton confinement. These sophisticated structures on the thin fiber resulted in the outstanding CE value of over 20 cd/A, along with a sufficient level of luminance, over 3000 cd/m². Next, to make them addressable, an array structure composed of the fiber phOLEDs and Al-deposited fibers was prepared. The layer next to the dip-coated EML was deposited by vacuum thermal evaporation as a series of striped patterns on one side of the fiber, to form multiple emitting–cells on a strand of fiber. Then, each Al-deposited fiber was contacted to the patterned layer. Initially, when we simply placed the fibers on this array structure, there were problems with short circuits and instability. To solve these problems, we introduced contact regions that were inserted between the EML and the patterned layers. No incidental damage was observed in this array structure. As a result, each emitting-cell of the high efficiency fiber phOLED can be reliably addressed.

The resulting fiber phOLED is addressable and highly efficient and exhibits the characteristics required for textile displays, including flexibility, weavability and a reasonable level of brightness. We expect that these strategies will take us a step closer to functional textile displays that can provide visual information.

Merging the Lines between Fashion, Material Science and Engineering Galina Mihaleva; Nanyang Technological University, Singapore

Leaving in the era of the Fourth Industrial Revolution provides the opportunities of taking wearable technology and
design to a whole new level. The increase in reliance on creativity across industries and interdisciplinary creative work in fields such as fashion, science and technology, sets the balance and the boundaries, used as a metaphor to describe "creativity in terms of crossing or pushing out a ..." Bogartz (1994). The fusion of smart textile materials and wearable computing technology are introducing a shift in textile, from a passive to a dynamic behaviour: active smart textiles and ultra-smart textiles. The ultra-smart textiles perform similarly to a human brain, with reasoning, cognition, and activating capabilities or a second smart skin.

The recent urge in the design and development of biosensors for health care and wellness engineering is pushing the boundaries of material and technological processes for new kinds of material modification and manipulation, with emphasis on sustainability. The aim of this research is to propose and to open up new opportunities and challenges of the next-generation e-healthy monitoring, in collaboration with one of the most forward moving field: Fashion. Also to push the boundaries of what makes smart fabric technology revolutionary based not only on its ability to communicate, transform, but also to grow or naturally fabricate. Proposing another fold of opportunities - one where technology meets craft and craft meets science and art, while sustainable materials are also a key factor. To propose the next generation of wearables by implementing electrophysiology interfaces by mechanically Interlocking of conducting polymer and silk fibroin to develop new applications for monitoring, diagnosing, displaying and preventing.

Textiles of today are materials with applications in almost all everyday activities. Fibres, yarns, and other structures with added-value functionality have been developed for a range of applications textile materials and the textile has become an important platform for high-tech innovations. The projects developed and introduced in this paper followed a design approach by fusing technology, science and nature, introducing new innovative hybrid fabrics explorations that requires the understanding of: the what (the purpose of the concept); the how (the used bio and tech); the where (the context in which the product is used) and finally the wearability issues connected to the role of trans materials and technology in human body, changing and perception.

A Yarn-Based Microbial Fuel Cell Yang Gao and Seokheun Choi; State University of New York at Binghamton, United States

We demonstrated an innovative, flexible yarn-based biobattery that generates green electricity from bacterial respiration. The battery can be easily scaled up by controlling the length of the yarn of a single battery or connecting multiple yarns in series. Bacterial cells in the yarn break down the organic fuels (e.g. glucose and lactic acid) and transfer the produced electrons to the electrode, providing power for external applications. The yarn-based biobattery was knotted into a bracelet by connecting three battery units in series, generating the current density of 0.33mA/cm². Furthermore, this proposed biobattery can be woven or embroidered into a large smart fabric, potentially providing hundreds of milliampere for powering actual wearable electronics. The ever-increasing worldwide efforts in developing renewable energy sources and reducing environmental footprint are among the greatest challenges faced by mankind. Although there are great potential and innovations in large-scale alternative energy technologies (e.g., wind and solar), the small-scale applications are still powered by batteries that may cause environmental and economic burdens with their recycling and replacement. In addition, electronic products such as wearable devices are becoming more powerful and smaller in size, and work in closer contact with the human body. The conventional energy storage and harvesting devices (e.g., lithium-ion batteries and photovoltaic cells) fail to meet flexible and environmental requirements for the next generation of electronics and micro-/nanosystems (MNSs). Hence, various emerging energy-harvesting techniques have been proposed as a power source by using organic-photovoltaic, thermoelectric, electromagnetic, and piezoelectric/triboelectric principles. The biochemical energy harvesting devices (or biobatteries), notwithstanding being the least explored, have three major advantages. First, the biofuels that can be utilized for electricity generation are readily available in sweat, saliva, urine, and even in common beverages. Second, they are capable of continuously generating electricity independent from lights or motions. Last, the devices are easily disposable and cost-effective. However, significant challenges remain in the making of flexible, green and scalable biobattery for the energy conversion. The biobattery developed here can not only be readily integrated into wearable electronics or smart textiles, but also be scaled up to revolutionize the power performance for real-world applications. The proposed battery was made by wrapping the functionalized yarns onto
a non-conductive cord. Both the anodic and cathodic yarns were treated with the poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS), making its own yarn conductive while retaining its porosity and hydrophilicity. Furthermore, the cathodic yarn was loaded with a low-overpotential Ag2O solid electron acceptor and coated with Nafion as a proton exchange membrane (PEM).

10:45 AM SB10.06.06

The goal of this research was to realize a textile display that could sustain 3 dimensional deformation such as bending, wrinkling, and stretching. We developed a multifunctional next-generation display technology with commercial-level driving voltage, brightness and efficiency characteristics, and a new form factor. There were three fundamental technical components used to fulfill the goal of the research, a Platform, the Display and Encapsulation layer.

(1) Platform: A study of an elastic clothing platform with a flat surface and a stress lowering structure
[Planarization] A planarization study was conducted to form a flat surface on a textile. A sacrificial layer, a planarization layer, an adhesive layer and the textile were formed on the glass, and then the sacrificial layer was simply removed by deionized water. Previous studies have performed planarization by attaching a plastic film to the textile, and used a very thick planarization layer of several tens of, hundreds of micrometers.[1, 2] However, the planarization layer in this work was only 0.5 micrometers.
[Stress-lowering structure] Flexible and stretchable features of textiles produce very high strain and stress as well. Accordingly, this work studied a platform between the planarization layer and the textile by introducing a ‘stress–buffer’ layer. The stress–buffer also functioned as the adhesive layer, and significantly reduced mechanical strain and stress, and had the advantage of enhancing durability.
[Improvement of applicability] A stress–buffer that was capable of hardening at room temperature was used to prevent any deformation and distortion by heating. This research developed a fabrication process that can be applied to any textile including cotton, linen, wool, leather, etc.

(2) Display: Low temperature process (below 150 degrees Celsius) OLED display
[Textile-based OLED] To realize the clothing-shaped full-color display, red, green and blue OLEDs were fabricated on the textile platform. The textile–based R, G, B OLEDs had almost the same luminance and efficacy as glass-based OLEDs.
[Low temperature processed display backplane] Thin film transistors (TFTs) typically require a high temperature heating. This causes serious damage to the textile such as twisting and burning. Since a heat treatment is necessary to repair interface damage on the insulator produced by plasma during sputtering, a TFT fabrication method was investigated to avoid plasma damage and chemical deposition of the insulator.

(3) Encapsulation: Washable encapsulation with water-blocking ability and flexibility
[Nano-stratified and washable encapsulation] A study using a nano-stratified structure was performed to improve the gas barrier property and mechanical flexibility of the encapsulation. The nano-stratified encapsulation was composed of ultra-thin sub-layers (less than 3nm) fabricated using the ALD(atomic layer deposition) process. The multi-interface system blocked the growth of defects, and as a result, WVTR(water vapor transmission rate) was lowered. The porous structure also contributed to improved flexibility. In addition, the encapsulation layers were formed on a passivation film to block liquids, and then it was integrated with the textile display.[3]

(4) Practical application study of the textile display
[Smart fashion] The developed textile display combines aesthetic elements with smart functions, which means that it not only has functional capability, but can be attractive in the fashion industry. The proposed approach permits OLED displays on shirts, hats, shoes etc.

References
After more than 20 years of development, e-textiles for various applications are gaining increasing attention worldwide. Industry driven application oriented developments are superseding the research oriented projects. This leads to changes in the technological approaches. Manufacturability becomes a more important aspect which leads automatically to a simplification of components and processes. On the other hand the overall systems reach a new complexity in order to be useful in a real life environment.

In order to enable industrial manufacturing of wearable e-textiles it is necessary to develop modular concepts as well as integration processes suitable for high volume production. Only with modules dedicated for textile integration with standardized interfaces it will be possible to realize new systems in short development cycles. These smart modules have to be compatible to allow fast design of new functionalities and even flexible adaptation.

Approaches to integrate electronics on textile ribbons with conductive bus structures instead of aiming to assemble the modules directly on large area textiles are very promising. They reduce complexity and footprint of the assembly equipment while simultaneously reducing the process time. New interconnection processes like thermoplastic non conductive adhesive bonding and ultrasonic welding will allow to reduce cycle times additionally.

From the early stages of smart textile development the monitoring of physiological parameters plays the most important role. Smart textiles for medical applications can cover various aspects: prevention, diagnosis, therapy and rehabilitation. Derived from rehabilitation concepts a new generation of wearable systems which will support patients but also healthy subjects are now aiming at combining the monitoring of movement, muscle activity and other parameters with actuators for active assistance. For most applications sensors can be textile or polymer based but also miniaturized conventional sensors can be required. A broad range of measurement principles can be realized and integrated. In most cases only the combination leads to the data required for optimum control.

The scope of the presentation is the overview and evaluation of technologies for conductor-, electronics-, sensor- and actuator-integration in textiles to meet the requirements of different wearable applications together with manufacturing and reliability aspects.

The development of new composite materials exhibiting both high infrared (IR) emission and good electrical conduction represents a challenging task for those applications where efficient radiative properties and electrical conduction are simultaneously needed as for instance for heat dissipation in conductive yarns and conductive textiles or for the realization of IR thermal detectors.

To this aim, a set of polymeric fibers composed of randomly oriented carbon nanotubes (CNTs) dispersed into a poly(ethylene terephthalate) (PET) matrix host was prepared and investigated [1]. Among the different carbon materials, CNTs were chosen for the uniqueness of their emissive properties in the IR wavelength range. Besides electrical conductivity, in fact, the inclusion of CNTs offer the possibility to increase of the IR emissivity which is usually not straightforward.

The amount of CNTs in the investigated set of samples ranges between 1 and 10 wt%. The effects of the inclusions on electrical and morphological properties were studied by means of electric conductance, scanning electron microscopy and white light interferometry investigations, respectively. Finally, the IR emissivity was characterized in the 3.5-5.1 micron spectral range by using the infrared thermography technique under heating regime [2]. The electrical conductivity showed a percolation-like behavior with increasing CNTs content. In particular, an exponential conductivity growth from the pure PET value (~ 10^-18 S/cm) to about 2×10^-3 S/cm was obtained by dispersing 1 wt% of CNTs as the percolation threshold is passed while an almost linear increase was observed in the samples with a larger CNTs concentration. Concerning with IR characterization, experimental results show that emissivity is gradually growing with the amount of dispersed CNTs.

In order to analyze the obtained experimental results, a model based on the Maxwell Garnett mixing rules was
adopted to calculate the dielectric permittivity of the polymeric matrix with randomly oriented inclusions. The effective medium data have then been employed to retrieve the absorption cross section for infinitely long cylinders by means of the Mie scattering theory. The experimental data show higher emissivity values with respect to numerical ones, particularly for larger CNTs concentrations. The large values of the experimental emissivity has been ascribed to the emerging of surface roughness when CNTs are included, as evidenced by SEM images and mean surface roughness measurements carried out by WLI analysis. Indeed, the emerging of surface roughness may lead to an increase in the specific surface and, consequently, gives rise to an increase of the IR emissivity due to the larger value of the radiating sample surface.

Concerning with mechanical properties, in order to preserve the flexibility of the bare PET fibers along with the ability to use these fibers to form textures or fabrics, CNTs values should be kept lower than 4-5 wt%. However, experimental results demonstrate that limiting the CNTs content to 5% still allows good electrical conductivity ($1.5 \times 10^{-3}$ S/cm) along with IR high emissivity (>0.90).

In conclusions, this study highlights the possibility to get high electrical conductivity values associated to high values of IR emissivity. Such unconventional properties encourage their use for the realization of conductive yarns displaying both high IR emissivity/absorbance and good electrical conduction.

SESSION SB10.07: Textile Devices and Smart Systems

1:30 PM *SB10.07.01
Microsystem Packaging and Integration Technologies for Electronic Textiles Toshihiro Itoh; The University of Tokyo, Japan

Electronic textiles (e-textiles) are fabrics that are integrated with electronic elements including sensors, actuators and microcontrollers, and are expected to be applied to not only wearables but also smart sheets, for instance. In order to realize high function e-textiles, we have been developing integration and packaging technologies to integrate silicon or compound semiconductors based microdevices into textiles, such as stretchable interconnect, flexible interposer and spring contact technologies. Continuous manufacturing processes for these have been developed. Stretchability is frequently required for e-textiles. For instance, since human skin around the elbow or knee joints can be stretched to more than 30%, interconnects of wearable devices need stretchability of 30% or above. Although stretchable interconnects on textile substrates are often realized by printing horseshoe-patterns with use of “stretchable” inks, printing patterns cannot cover stretch as large as 30% and require large surface areas. To realize fine interconnects with stretchability of 30% or above, we have developed vertical wavy Cu stretchable interconnects utilizing micro-corrugation process of Cu foils and embedding in silicon rubber. When Cu foils are shriveled to -30% by micro-corrugation, the interconnects should be stretched to 30% without electric resistance change. The micro-corrugation process is based on the metal foil forming technique where a flat Cu foil is continuously deformed into wavy shape of interconnects between the upper and lower gears. After the process, the wavy machined Cu foils are embedded in silicone rubber to protect them and improve the interconnects’ elasticity. The fabricated wavy Cu interconnects showed stretchability of more than 40%. Using the 0.5-mm-wide interconnects, FPC(flexible printed circuit)-compatible stretchable electric circuit integrated with LEDs was successfully demonstrated.

It could be difficult to integrate “hard” devices such as ICs, optical devices, MEMS sensors and passive elements as they are into “soft” textile substrates. In addition, inflexibility of hard devices causes breaks of e-textiles during use including washing. To overcome the problems, we have developed an interposer of miniature FPC board on which hard devices are mounted. The flexible interposer can be easily integrated on soft textiles. Using the interposer
technology, we prototyped large area (1.2 m x 1.2 m) LED array fabric. The interposers with LED and passives can be continuously mounted and soldered on ribbon textiles woven with polyester fibers copper wires. The large area fabric is realized by weaving the LED integrated ribbons and polyester fibers together. These interposers are necessary for re-distribution of interconnects, because it is often difficult to form fine interconnects and bonding pads on textile substrates.

Even though both interconnects and devices are flexible, solid electrical contacts between them may cause breaks of breaks of e-textiles during use. We have developed reel-to-reel continuous fabrication process of flexible contact structures on fibers (cables). The contact structures are hemisphere or bell shaped elastomers coated with PEDOT:PSS. The fabrication process consists of dispensing suitable silicon elastomer and both hydrophilic and hydrophobic PEDOT:PSS coating. It was found that the structure has life time of more than a million deformation cycles. Although the contact structure was developed for the contact between the fibers (cables), it could be effective that this type of flexible spring structure is introduced into joints between interconnects and devices on textile substrates.

Compressible and Electrically Conducting Fibers for Large-Area Mapping of Pressures Andreas Leber, Alexis Page, Dong Yan, Qu Yunpeng, Shahrazad Shadman Yazdi, Pedro Reis and Fabien Sorin; École Polytechnique Fédérale de Lausanne, Switzerland

The integration of conductive elements in soft material constructs provides attractive opportunities for the realization of diverse electromechanical devices. Flexible pressure sensors, in particular, offer a wide application range in health monitoring and human-machine interaction. However, their implementation in functional textiles is limited because existing devices are usually small, 0-dimensional elements, and pressure mapping is only achieved through arrays of sensors that are difficult to integrate and include many failure-susceptible connections. Here, we demonstrate compressible and electrically conducting fibers for the detection, quantification, and localization of kPa-scale pressures over m²-size surfaces.[1, 2] The scalable thermal drawing technique is employed to co-process polymer composite electrodes within a soft thermoplastic elastomer support into long fibers with customizable architectures. Exerting pressures on the fibers results in the selective and reversible contacting of the electrodes within the fully enclosed structure, thereby generating electrical signals at distinct pressure levels. Moreover, resistance measures can be directly related to pressure positions along the fibers, enabling pressure localization. The fibers act as accurate and robust 1-dimensional pressure sensors, functional over large cycle numbers, variable frequencies of mechanical stimulation, and in humid environments. Their potential in health care is demonstrated by mapping pressures on a gymnastic mat for the monitoring of body posture and motion. The fibers represent a simple, cost-effective, and reliable strategy towards the functionalization of large, flexible surfaces.

Making Soft Optical Sensors More Wearable Cindy K. Harnett; University of Louisville, United States

This presentation will discuss new materials and components that enable our intrinsically stretchable optical fibers [1] to measure strain while meeting the power and washability requirements of wearables. These threadlike sensors work with high-throughput fabrication methods designed for textiles. However, for wearables, practical requirements must be taken into account.

Coated [1], molded [2], and extruded [3] elastomeric optical fibers are a new low-cost, all-polymer sensor material for measuring wearer activity. They can be applied to fabrics by sewing or adhesives. After their light intensity signals are transformed into electronic signals using optoelectronic sensors, the activity data can be sent over a wireless link for analysis. Because washable, battery-free radios are still under development, a battery/processor/radio communication module that separates from the textile is a popular approach that lets the communication module skip the laundry. Resistive strain sensors and conductive-fiber electrodes for sensing the electrical activity of skeletal muscles (electromyography or EMG) rely on conductive connections to the communication module. For reversibly connecting the communication module to these electrical signal sources, a common solution is a metal snap fastener. Fabric-integrated optical fibers need a similar rugged, quick-connect
solution for practical applications. This presentation will cover our approach to making reversible optical
counters specifically for wearables using all-polymer components.
All-polymer optical sensors are heat-bondable to synthetic fabrics and do not corrode during washing, in contrast to
conductive fibers that corrode in water. However, power consumption for light emitting diode (LED)-driven optical
fiber strain sensors is significantly higher (~10 mW) than for resistive strain sensors made from conductive fibers
(~0.1 mW). Because the power resources for wearables are so limited, both optical and resistive sensors are turned
off when not in use. Even so, the peak power requirements of optical sensors may still prevent their use in
lightweight, battery-free energy-harvesting wearables.
Differential absorption in a mismatched fiber pair removes the effect of changing light conditions for optical strain
sensors, making it possible to drive them with unknown-intensity ambient light. We have previously investigated
process-based methods for modifying the light attenuation coefficient of fibers [4]. Control over optical transmission
means one can compare the signal intensity from two parallel fibers with known optical transmission differences and
thus subtract out the unknown source light that leaked into the fibers along their path over a surface. This approach
will be discussed in the presentation. When sufficient external light is available to make measurements, the LED can
be turned off, cutting out the main power-consuming component. The optoelectronic sensor brings power
consumption to the resistive sensor level. Unlike resistive sensors, no signal return path is required for textile-
embedded fiber pairs that use ambient light. Since textiles increasingly form the skins of soft robots in addition to
wearables, new developments here will lead to sensorized surfaces in a wide range of applications.

2:30 PM BREAK

3:30 PM *SB10.07.04
Design and Development of Wearable Textile Materials on an Industrial Scale Arnaldo Usai; Let's Web-earable
Solutions, Italy

The development of objects of sensorized clothing in the previous years has been the subject of experiences of
affixing sensors extraneous to the textile nature of the fabric, maintaining as a principle of stability of the sensors on
the skin the containing effect of the pressure of the fabric on the body; compromising the effective wearability,
comfort and usability of the sensorized clothin'objects.
In this framework we present a new method of developing a range of fully textile sensorized clothing items,
completely wearable, washable and usable in different contexts: work, sport, defense and health.
The use of a new method and the new materials for the production of fully wearable sensorized clothing items
changes the scope of application of the monitoring materials of bio-vital parameters in use, from a purely episodic
and professional use, to a continuous widely use.
The industrialization of this technology makes it possible to apply these materials to different sectors of clothing:
technical, formal and specialist, expanding the concept of clothing from a need for purpose and function, creating a
new and different awareness of users with respect to clothing materials and individual well-being.
The classic prerogatives of clothing materials in covering, decorating, protecting and distinguishing the human body
and its social function are changed by the use of these materials, in which the functions of the body's purpose (its
own performances) are measured and evaluated, analyzing the basic parameters of organized action no longer on
time shifts but by introducing indicators of safeguard and individual well-being.

In the framework we will present concrete cases of the application of these materials and wearable technologies in
the industrial, health and sport fields.
We developed 5 μm thick ultrathin film MEMS piezoresistive strain sensor for wearable human motion sensors. We made the 5 μm thick ultrathin film MEMS sensor on polyurethane film and detected human finger motion. Thin microelectromechanical systems (MEMS) sensors which is made of very thin (< 5 μm thick) have been expected for the application to healthcare monitoring, infrastructure monitoring, structural health monitoring of infrastructure, automotive, aircrafts, and other transportation equipment. The advantages of thin (<5 μm thick) MEMS devices are highly flexible, long-term stability, high sensor sensitivity and mass productivity because thin film exhibits smaller bending strain than conventional thick MEMS films and silicon-based devices have not be affected by the atomosher without packaging in compared with organic semiconductor devices.

Thin MEMS sensor assembly of releasing thin MEMS film and transferring thin film onto flexible substrate has been, however, difficult. Previous studies on thin MEMS sensor assembly report the surface machining MEMS structure as a thin MEMS film releasing structure with PDMS stamp. But the adhesive force of PDMS is not stable or applicable to industrial use because vacuum suction type chip mounter is commonly used.

In this paper, we developed the mechanical model of ultrathin MEMS sensor separation and optimize the design of MEMS sensors and connection parts to achieve high yield of thin MEMS sensor chip mounting with commercially available chip mounter. In detail, we analyze plastic-scale-model-like assembly of ultrathin MEMS piezo-resistive strain sensor theoretically and experimentally in order to find an optimal design of MEMS sensor chip for high yield assembly. In the plastic-scale-model-like assembly of ultrathin MEMS sensor, MEMS sensor chip consists of ultrathin piezo-resistive sensor parts, disconnect part, and outer frame and its structure is similar to the plastic scale model. The plastic-scale-model like MEMS sensor chip is fabricated through conventional MEMS process. By using commercially available chip mounter, the MEMS sensor is cut and picked up from the outer frame in the similar manner of plastic-scale-model assembly. Then, the MEMS sensor film was placed and released on the desired area of substrate.

In the chip-mounting mechanical model analysis and experiment, if the number and the width of the disconnection parts are decreased to four and 20 μm, the successful rate of the chip mounting increased to 100 % because the shear stress on those parts are concentrated for ease of cutting and the resultant small load on sensor body reduces bending stress on sensor body for avoiding crack of sensor body. Therefore, in case of 1 mm x 5 mm sensor film, the four connecting parts with 20 μm width are optimal design for high successful plastic-model like MEMS sensor assembly.

Finally, we made human finger motion sensor by ultrathin MEMS sensors. The stretchable silver paste is patterned on the Polyurethane film (PUfilm) to make electrode. Then, ultrathin MEMS sensor is placed on the electrode and the edge of the MEMS sensor and electrode is connected by silver paste. Then the hot-melt PU film covers the MEMS sensor for avoiding the break of the sensors. The fabricated MEMS sensor on PU film is attached on the glove and the bending of the human finger was detected.

Recently, emerging technologies like 3D-printing has doped the development of flexible electronics to design foldable displays, bioprosthesis, wearable devices, etc.1,2 Particularly, stretchable microelectronics able to adopt easily complex shapes like emulating the human body have attracted attention for smart textiles3,4. To achieve the fabrication of such devices, innovative technologies and new designs involving the use of materials with advanced mechanical properties are required5. In this work, the fabrication of lithium nickel manganese oxide (LNMO) micropillar electrodes on Al serpentine interconnects that can be stretched up to 70% without structural damaging has been achieved by laser patterning technique6. Unlike compact and continuous electrode thin-films, we show that under mechanical strains, arrays of vertical micropillar supported on serpentines are carrying empty spaces that can prevent the formation of cracks and the electrode delamination.

This innovative approach has been used to fabricate a flexible micro-battery for powering a smart contact lens7 and garments. The innovative micro battery approach relies on two flexible substrates assembling consisting of polydimethylsiloxane (PDMS) supporting 1 cm² surface area disk of LNMO and LTO serpentine electrodes separated by a gel polymer electrolyte.
Interestingly, the micro battery shows in the first reversible cycle a charge and discharge areal capacities of 1.22 mAh cm\(^{-2}\) and 1.196 mAh cm\(^{-2}\), respectively. The coulombic efficiency for the first reversible cycle corresponds to 96.17%. Regarding the cycling performance, the LTO/polymer/LNMO micro battery has been assessed at fast kinetics for 30 cycles. The micro battery delivers 73.5 µAh cm\(^{-2}\) at 6C, 47 µAh cm\(^{-2}\) at 12C and 32 µAh cm\(^{-2}\) at 20C with a remarkable stability.

**REFERENCE**

monitoring of health conditions. The sensing part is typically made into a thin film that guarantees high flexibility with different sensing materials as functional units at different locations. However, a thin-film sensor easily breaks during use because it cannot adapt to the soft or irregular body surfaces, and, moreover, it is not breathable or comfortable for the wearable application. Herein, a new and general strategy of making electrochemical fabric from sensing fiber units is reported. These units efficiently detect a variety of physiological signals such as glucose, Na⁺, K⁺, Ca²⁺, and pH. The electrochemical fabric is highly flexible and maintains structural integrity and detection ability under repeated deformations, including bending and twisting. They demonstrate the capacity to monitor health conditions of human body in real time with high efficacy.

SB10.08.02
Development of Solution-Processed Polymer Light-Emitting Diodes on a Plastic Fiber and Its TFT-Driven Operation for Textile Displays

Hyungsoo Yoon, Taehoon Kim, Sujin Jeong and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Electronic textiles have integrated life of human being with highly developed electronic devices in an innovative way, enabling wearable electronics for displaying bio-medical information and illuminative textiles for smart fabric or internet-of-things applications. Light-emitting devices on textiles can display bio-medical signals immediately via integrating with health-monitoring devices or notify information using a luminous carpet. Although, in order to realize “real” textile displays, flexibility, lightweight, and breathability are necessary for skin-conformal electronic devices, various prototypes of commercial products still have been focused on rigid silicone-based devices. Recently, many research groups have reported flexible light-emitting devices directly implemented on the fabric or fiber. The alternating current electroluminescent (EL) devices on fiber substrate have been reported, whose device configuration is quite simple compared to other EL devices, however, low power efficiency demands high driving voltage up to hundreds volts, which limits practical use. Organic light-emitting diodes on fabric substrate showed good mechanical properties based on its ultra-thinness, but they have low breathability because of additional planarization layers for evaporation process. In addition, high process temperature in the fabrication causes inevitable deformation in the textile substrate. While, polymer light-emitting diodes (PLEDs) has good advantages of low-voltage operation and low temperature process available. And, since the light-emitting polymer is compatible with solution processes, fiber-shaped PLEDs and the corresponding woven structure can be developed without any breathability loss. Although some papers have already reported fiber-shaped PLEDs, a practical integration with thin-film transistor (TFT) has not been reported yet. Some technical challenges such as low device performances should be also addressed.

In this work, we report development of solution-processed PLEDs on a plastic fiber substrate and its TFT-driven operation for textile displays. Specifically, we fabricated the fiber PLEDs on polyethylene terephthalate (PET) fiber, which is flexible and weavable for textiles. By controlling the condition of dip coating of PET fibers, such as withdrawal speed and coating number, we can obtain poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) anode, which has resistance of 200 ohm/mm for 5 times dip coating. Then, PEDOT:PSS hole-injection layer and SPG-01T emissive layer are successively dip coated. After then, lithium fluoride and aluminum are thermally evaporated for an electron-injection layer and cathode, respectively. The device shows a turn-on voltage of 4.8 V at 1 cd/m², a current efficiency of 4.58 cd/A at 1000 cd/m², and luminance of ~4000 cd/m² at 10 V, enabling low-voltage operation for highly luminous display applications. Finally, we integrated fiber PLEDs with fiber TFTs that are also fabricated by a solution process on a PET fiber, showing the feasibility of our devices in textile displays. The detailed fabrication process and experimental results will be discussed at the conference.

This research was supported by Samsung Research Funding & Incubation Center of Samsung Electronics under Project Number SRFC-IT1801-07. This work was also supported by the OLED (Organic Light-Emitting Diodes) center of Samsung Display Corporation and ISRC (Inter-University Semiconductor Research Center) of Seoul National University.

SB10.08.03
Investigation of Thermo-Regulating Properties of Textiles with Incorporated Microencapsulated Phase Change Materials

Maria Cristina Larciprete¹, Stefano Paoloni², Concita Sibilia³, Vitalija Rubeziene³ and Audrone Sankauskaitė³; ¹SBAI Sapienza, Italy; ²Università degli Studi di Roma Tor Vergata, Italy; ³State research institute, Lithuania

Thermal regulating textiles play a very important role in providing thermal comfort for human beings in temperature
changing environments. The level of thermal comfort depends on the heat exchange between the human body and the surrounding environment. The thermoregulatory effect can be achieved by dispersing microcapsulated phase change materials (PCMs) into the textiles. As these materials have ability to lower the temperature of the body, besides wearing comfort they can improve thermal concealment properties of nowadays defence personnel military camouflage clothing.

Various types of phase change materials (PCM) are currently used in the production of smart materials capable to actively control the temperature of the body. Studying the thermoregulatory effects of PCM treated textiles and their multi-layer assemblies is fundamental for the effective use of such smart thermal functional textiles [1, 2].

In the present work two types of commercially available microcapsules of organic phase change materials were investigated in order to improve the thermo-regulating properties of textile fabric. The first type of PCMs, namely type PCM-A (PCM microcapsules –Mikrathermic P, developed by DEVAN® Chemicals NV, Belgium), demonstrates chemical activity to all kinds of fibres without the use of a binder. The second type of PCMs, type PCM-B (Ito finish PCM microcapsules, LJ Specialities LTD, UK) was embedded into the textile by means of an acrylic binder as cross linking resin.

For samples preparation, the knitted fabric, produced from cotton/PES, intended for contacting layer near the skin, were treated by PCM microcapsules using pad-dry-cure method. After sample preparation, melting point and latent heat storage capacities (enthalpy ΔH, J/g) of PCM microcapsules and the corresponding treated knitted fabrics were characterized, using differential scanning calorimeter equipped with a nitrogen-based refrigerated cooling system.

The IR emissivity of the PCM-based textiles has been characterized by means of Infrared Thermography according to the ASTM E1933-99a standard method [3] in the contact-free configuration. In the adopted method, a small portion of sample is covered with a thin layer of a reference paint with known emissivity. The textiles samples were placed onto a heating stage, which is also equipped with a Peltier modulus in order to set their temperature below and above phase transition temperature of PCMs. During measurements samples and reference paint were simultaneously imaged by the IR camera, operating in the 3.5-5.1 μm range, and from the resulting thermographic images the infrared (IR) emissivity was characterized before and after PCMs phase transition. Experimentally obtained data show an emissivity increase with increasing temperature, as a consequence of additives’ phase transition. Furthermore, the emissivity dynamic range (εhot-εcold) for the three samples containing type-A additives show anti-correlation with melting enthalpy values, i.e. the higher enthalpy corresponds to lower emissivity variation, along the phase transition. The observed features open the way to potential applications such as tunable emissivity smart textiles and pave the way to the design of customized IR shielding textiles, by proper selection of the suitable additives type and amount.

The Adaptive Design of an Image Pre-Processing Step for Classifying Materials Design Experiments Paul Clegg; University of Edinburgh, United Kingdom

Ideally, the outcome of materials design experiments would be determined automatically based on a limited quantity of readily obtainable data. This task is often possible for an experienced practitioner. Here we automate this classification step for the case of soft materials design. We want to know whether a particular attempt to create a bijel has been successful or not based on a single confocal micrograph. Our most effective classification approach is based on shape descriptors of the co-continuous fluid domains in the image. Here, I will show how adaptive design can be used to optimize the pre-processing of the confocal image to improve our classification performance.

9:00 AM SB11.01.02
Active Liquid Colloids and Their Application as Transducers in Liquid-Sensing Applications Lukas Zeininger1,2, Markus Antonietti1 and Timothy M. Swager2; 1Max Planck Institute of Colloids and Interfaces, Germany; 2Massachusetts Institute of Technology, United States

Dynamic multiphase complex emulsions formed from two or more immiscible solvents offer a unique platform for the generation of new triggerable materials. In designing our methods, we make use of solvent combinations that are immiscible at room temperature but exhibit a lower (LCST) or upper critical solution temperature (UCST). Emulsification of the mixture below LCST or above UCST enables a simple one-step fabrication of complex multicomponent emulsions as well as structured soft-matter particles with highly uniform morphology via temperature-induced phase separation. The morphology of these dynamic liquid colloids is exclusively controlled by interfacial tensions and the droplet geometries can be controllably altered after emulsification. Dynamic liquid colloids can selectively invert morphology in response to external stimuli such as the presence of specific analytes, small pH changes, light or high energy irradiation, and the presence of an electric or magnetic field and thus provide a new active element for novel and existing applications of emulsions including chemotaxis, the fabrication of optical metamaterials, and chemical/biological sensing.

We explore the potential of our dynamic micro-colloids to manipulate the pathway of light in response to chemically triggered morphology changes. Dynamic morphological reconfiguration of microscale refractive components in combination with the potential to incorporate a variety of active optical media as well as stimuli-responsive elements enables the application of these purely liquid-based or solidified micro-colloids as new transduction materials for chemo- and bio-sensing. Here, we will demonstrate a series of optical transduction methods that are based on having control over the total internal reflection of light from outside and inside multicomponent colloids. An associated understanding of the unique chemical-morphological-optical coupling inside chemically functionalized active soft matter colloids creates a solid foundation for the development of sensing paradigms targeting a series of chemical and biological analytes, including a rapid and sensitive method for the detection of common foodborne pathogens Escherichia Coli and Salmonella enterica bacteria.

How Wettability Controls Nanoprinting Joel De Coninck; University of Mons, Belgium

Using large scale molecular dynamics we study in detail the impact of nanometer droplets of low viscosity on at substrates and the effect of the wettability between the liquid and the plate. We show the maximal contact diameter during the nanodroplet impact (Dmax) as well as the time required to reach it (tmax) are in agreement with experimental data at the macroscale showing similarities between droplet impacts at the nano and the macro scales. The comparison between the MD simulations and different models reveals that most of these models do not take into
account all the effects we observe at the nanoscale. Moreover, most of their predictions for the impact at the nanoscale do not correspond to the simulation results. Because of this, we have developed a simple model for Dmax which is in agreement not only with the simulation data but also the experimental observations and it also takes into account the effects of the liquid-solid wettability. We also propose a new scaling for tmax with respect to the impact velocity which is also in agreement with the experimental observations. With the new model for Dmax plus the scaling found for tmax, we present a new way to collapse in a master curve the evolution of the micro to nanometer drop contact diameter during impact for different wettabilities and different impact velocities. We believe our results may help to design better nanoprinters since they provide an estimation of the maximum impact velocities required to obtain a smooth and homogenous coverage of the surfaces without dry spots.

9:30 AM *SB11.01.04  
Bicontinuity is Easy with Fumed Silica—A Morphology-Composition Map for Particle-Filled Blends of Immiscible Polymers  
Derrick Amoabeng1, Andrew Tempalski2, Brian Young2; Bernard Binks3 and Sachin Velankar1; 1University of Pittsburgh, United States; 2The Pennsylvania State University, United States; 3University of Hull, United Kingdom

In ternary mixtures of two immiscible liquids and one particulate species, capillary forces are a strong driving force for particle aggregation. In such mixtures, a rich variety of microstructures appears from a coupling between interfacial tension, particle wetting phenomena, and viscous forces of mixing. For the simplest case of spherical particles, it is possible to construct a non-equilibrium state diagram based on rational considerations of the various phenomena. This talk will discuss the situation with a far more complex type of particle: fumed silica.

We examine melt-blended mixtures of two molten plastics, polyisobutylene (PIB) and polyethylene oxide (PEO), and fumed silica particles which have strong affinity for the PEO. The unusual structure of fumed silica – which comprises 15-30 nm primary particles permanently bonded together into highly porous, fractal-like aggregates – strongly influences the morphology at all compositions. At relatively low PEO loadings, the PEO is absorbed into the pores within the fumed silica aggregates. The morphology consists of a network of interlocked particle aggregates bonded together by PEO. At higher PEO loadings, the PEO and the particles form a combined phase that is solid-like even at low fumed silica loadings. The morphology somewhat resembles a conventional co-continuous morphology where one phase is PIB and the other is a fumed silica-filled PEO. What is most interesting and potentially useful is that morphologies with two percolating phases appear across almost the entire composition range examined. We construct a composition-microstructure map for mixtures containing fumed silica and contrast against the simpler case of spherical particles.

Epoxy-Based Bicontinuous Nanocomposite Monoliths  
Molla Hasan and Jonathan P. Singer; Rutgers University, United States

Epoxy-phenolic resins, valued for their ease of processing into various shapes and coating thicknesses, have been widely used as base materials for a wide variety of applications, such as integrated circuit packages, laminating resins, adhesives, binders, surface coatings, and impregnants. Here we report a simple method to make bicontinuous epoxy-based porous nanocomposite monoliths. We begin with a bijel comprised of immiscible mixtures of two fluids: epoxy and vegetable oil, stabilized by epoxidized soybean oil (ESO) as a surfactant and a means to improve the interfacial bonding between the epoxy resin and vegetable oil. By adding nanofillers and mixing at high shear, interfacial jamming occurs, which arrests the fluids in a bicontinuous configuration. During the evolution of the emulsion, the configuration maintains, creating an interconnected porous structure, which length scale is determined by the selection of particle. Our rheology results reveal the role of ESO in this process, with low quantities not participating in the epoxy curing due to interfacial segregation and high loadings modifying the curing kinetics and mechanical properties as a plasticizer. Through this fabrication method, we can produce porous monoliths at a wide range of feature length scales that shrink less than 2% after curing and removal of the oil porogen, and due to the non-volatile nature of the oil, have uniform porosity through the bulk of the structures. In addition, the surface of the porous monolith can be functionalized by selectively altering the nanofillers.

10:45 AM SB11.01.06
3D Printed Porous Structures of 2D Materials Using Capillary Suspensions Hui Ding, Suelen Barg and Brian Derby; University of Manchester, United Kingdom

Capillary suspensions of particles in immiscible fluid mixtures are stabilised by pendular drops of the minor liquid phases forming bridges between the solid particulate phase, a structure distinctly different from that of a Pickering emulsion.[1] This behaviour requires two immiscible fluids one of which strongly wets the solid phase (the secondary liquid which is usually a relatively small volume fraction of the suspension), while the other shows a relatively high contact angle. Capillary suspensions have a distinct rheology with a transition from a rigid gel to a fluid emulsion occurring above a yield stress and the gel reforming if the fluid strain rate drops below a critical value. This rheological behaviour is similar to that found with particle suspensions in tri-block copolymer solutions (e.g. Pluronics) but can be achieved with immiscible small molecules, e.g. water and octanol. The rheology of capillary suspensions is ideal for 3D printing by direct write extrusion and has the advantage over current methods by not requiring large quantities of polymers that may need removal by secondary post-processing.

Here we demonstrate a printable graphene ink produced by adding a small amount (1-2 vol%) of the secondary liquid, in this case octanol, to an aqueous graphene suspension (GS). Octanol is immiscible with the primary liquid, water, and strongly wets the graphene flakes in the suspension, forming the graphene capillary suspension (GCS). Rheological studies show that the storage modulus of GCS is three orders of magnitude larger than that of the original GS with a yield stress of 95 Pa. Beyond the yield stress the GCS shows shear thinning behaviour with the viscosity decreasing as the shear rate increases. The GCS materials were used as inks for Robot-assisted direct writing to fabricated simple graphene structures. These show a relatively high porosity of 81% and a corresponding bulk density of 426 kgm⁻³. The printed structures show a crushing strength of 1.4 MPa and high electrical conductivity of 2370 Sm⁻¹ after heat treatment. Computed X-Ray tomography and SEM are used to explore the internal structure of the extruded filaments. Comparing the X-Ray tomography images of GCS and GS filaments, it shows a shear aligned graphene plate structure with the GS ink and a more disordered flake distribution with the GCS ink. This is consistent with the flake alignment in the GCS occurring after extrusion has arrested and the capillary suspension gels. Similar behaviour is found using BN as the 2D particulate material but not with MoS₂, despite both materials showing similar surface energetics when dispersed in water and octanol. Reasons for this discrepancy are explored.

Electrohydrodynamic Bridging for Scalable Thermal Oscillators Tianxing Ma¹, Matthew Signorelli¹, Darrel Dsouza¹, Kyrsten M. Ryerson², Yang Zhao³, Chinedum Osuji³ and Jonathan P. Singer¹; ¹Rutgers, The State University of New Jersey, United States; ²Biola University, United States; ³University of Pennsylvania, United States

Pyroelectric materials are emerging as an alternate to thermoelectrics for waste heat harvesting due to their potential for higher efficiency. The desire to maximize scenarios compatible with pyroelectric waste heat harvesting introduces the challenge of inducing temperature oscillations in a pyroelectric material based on near-constant temperature, or constant flux, heat sources. Prior efforts in this area have utilized electrowetting on dielectric (EWOD) and microelectronic mechanical systems (MEMSs) to fabricate compact waste-heat harvesting devices for testing. However, for large-scale applications, a compromise must be made between device efficiency, cost, and device miniaturization. In this presentation, we demonstrate a method using electrohydrodynamic (EHD) force to actuate a capillary bridge from a liquid droplet between a heat source and heat sink which serves as a proxy for a pyroelectric material. Enhancement of heat transfer is derived from the capillary bridge. Through EHD thermal experiments with different thermal fluids, we found the enhancement of heat transfer is achieved by different dominant mechanisms depending on the viscosity of the formulation, with high viscosity formulations relying on thermal conductivity and lower viscosity relying more on the convection induced by the EHD and Marangoni flow. Through periodically forming and breaking the capillary bridge, temperature oscillations were successfully established due to the resulting differences in the heat transfer rate. Employing this approach, a laminate device is built to turn a steady thermal field to an oscillating thermal field, showing a scalable method compatible with the roll-to-roll fabrication of sheet devices.
Multiphase fluid systems are strongly influenced by gravitational phenomena that affect everything from transport dynamics to the self-assembly of ordered systems. Buoyancy-driven convection drives heat and mass transport, providing a source of mixing. Density-driven segregation leads to inhomogeneities and phase separation including sedimentation. One byproduct of the sedimentation is the occurrence of stratification phenomena in self-assembled multiphase fluid systems such as foams and emulsions. The removal of gravity as a force provides opportunities for the investigation of discrete phenomena such as diffusion or viscosity in isolation. For example, in a persistent microgravity environment, the interfacial energies in self-assembled structures can be studied in isolation from sedimentation and stratification effects.

The International Space Station (ISS) U.S. National Laboratory offers a unique environment in persistent microgravity that enables the decoupling of physical phenomena such as buoyancy-driven convection from diffusion. Areas of investigation onboard the ISS have included droplet formation, colloid interactions (emulsions, nanoparticles, biomolecules, etc.), foam formation and stability, gel formation (aerogels, hydrogels, etc.), and self-assembled structures. For example, microgravity provides the opportunity to study “wet” foams in the absence of drainage—a result that is difficult to replicate terrestrially.

We will introduce the underlying physical phenomena of multiphase liquids in microgravity. We will present case studies of multiphase liquid system investigations conducted onboard the ISS, including studies of droplet formation, gel and foam stability, and the self-assembly of hydrogels and aerogels, and compare results with those from terrestrial experiments. We will also discuss translational lessons learned from microgravity experiments that inform and direct terrestrial research and manufacturing. Finally, we will present opportunities for future microgravity experiments and access to ISS facilities through the ISS U.S. National Laboratory.
the production of structured hydrogels whose conformation changes over 10s of micrometer length scales. This is achieved using drops with well-defined sizes and compositions that are produced with microfluidics. I will demonstrate microfluidic devices that offer a tight control over the arrangement of the drops. These assembled drops are subsequently converted into macroscopic structured hydrogels possessing compositions with well-defined, locally varying compositions. I will show how the local composition of hydrogels influences their macroscopic mechanical properties.

Self-Ejection of Crystal Structures from Evaporating Droplets on Superhydrophobic Surfaces Samantha McBride, Henri-Louis Girard and Kripa Varanasi; Massachusetts Institute of Technology, United States

Crystal fouling due to saline spray leads to corrosion and degradation of many materials, including metals, stones, and organics. This degradation is visible in many coastal cities, where buildings and other structures degrade faster than their non-coastal counterparts due to salty ocean spray. Implementation of superhydrophobic surfaces is one strategy that may help prevent crystal fouling, but is only successful when no crystals are able to form at the surface, as any amount of nucleation will seed additional crystal formation at that surface and degrade the hydrophobicity. In this work, we demonstrate an unusual phenomenon in which sodium chloride crystals grown from a drop placed on a heated superhydrophobic surface self-eject from that surface. This phenomenon is related to the plastron (a thin film of air) layer within the texture of the superhydrophobic surface, which creates a channel for water vapor to escape from the evaporating drop. A large temperature gradient across the drop leads to enhanced vaporization at the surface, and escaping vapor creates crystalline micro-tubules which continue to grow as salt crystallizes at the tips. These tubules grow into "legs," causing the entire salt structure to lift off from the surface. We find that the self-removal of the crystals keeps the surface clean, and observe no degradation of the anti-fouling performance over extended use. This phenomenon could be useful in cooling towers using water spray heat exchange, where water typically must be very pure to avoid salt corrosion. By implementing substrates that cause self-ejection of crystals, it may be possible to use salt water rather than ultra pure water, and thus preserve fresh water resources while also cutting down on costs associated with water treatment.

2:30 PM SB11.02.04

Jammed Films of 2D Materials Assembled at Liquid/Liquid Interfaces Joe Neilson and Brian Derby; The University of Manchester, United Kingdom

2D materials are being widely explored for use in the fabrication of large area flexible, transparent electronic devices such as: field-effect transistors (FETs), sensors, and light emission devices. The assembly of large area films from a 2D material dispersion is a key step in the manufacture of electronic devices. Close packing and edge to edge contact is believed to be crucial in order to ensure high carrier mobilities through the 2D material film. However, widely used film assembly methods such as spin coating and spray coating result in low transfer efficiency, flake restacking and loose random packing of flakes in the film. Here, we present a thin film assembly method which overcomes these issues using a molecularly flat assembly plane; the interface of two immiscible liquids.

In this work, dispersions of exfoliated 2D material are deposited at the liquid/liquid interface and are compressed laterally by an interfacial tension gradient away from the point of injection. The resulting thin film is a 2D jammed monolayer of flakes which has minimal overlap and predominantly edge to edge contact between flakes. The packing density of the resulting film is high (87 %) and the transfer efficiency is over 100 m² per gram of exfoliated 2D material. The method described has the additional benefit that the bulk liquid phases help to wash contaminants from the thin film. We demonstrate how the resulting large area films, which can coat the entire surface of a 4 inch wafer, are highly pristine and simple to produce.

FETs were manufactured using the aforementioned film deposition method with a dispersion of electrochemically exfoliated MoS₂. The mobility and on/off current ratio of the back gate and bottom contact FETs were 7 cm² V⁻¹ s⁻¹ and 10⁵ respectively; comparable to chemical vapour deposition grown MoS₂ FETs. This work demonstrates the use of liquid/liquid interfaces as a tool for self-assembly of high performance monolayer thin film devices made from dispersions of ultrathin 2D material.

Cellulose-Based Membranes for Effective Capture of Oil Microdroplets in Water

Ana C. Trindade¹, Ana P. Almeida², João Oliveira², João Canejo², Susete Fernandes², Jon O. Fossum¹ and Maria Helena Godinho²; ¹Norwegian University of Science and Technology, Norway; ²Faculty of Science and Technology, Universidade NOVA de Lisboa, Portugal

Disasters are sometimes associated with the transportation of oil across big distances using oil tankers. When an accident occurs large volumes of oil are spilled into the ocean and have to be collected from the water. However, the traditional oil-removing methods fail to collect the micro-sized droplets of oil originated by the mechanical action of the waves.[1] Oil/water separation is an important field, not only for scientific research but also for practical applications aiming to resolve industrial oily wastewater and oil-spill pollution, as well as environmental protection[2,3].

This work focusses on the recovery of oil microdroplets suspended in water, using a manufactured cellulose acetate (AC) non-woven electrospun membrane coated with different patterns of cellulose nanocrystals (CNCs). Efficiency tests show that these membranes can remove up to 80% of the oil microdroplets present in a water emulsion. The imprint the different designs of the CNCs layer was performed using screen-printing and the adhesion of the CNCs with the fibers of AC was promoted by a thermal treatment. The removal of the oily micro droplets is achieved when a water/oil emulsion flows through the membranes, due to the hydrophilic character of the AC fibers, and the CNC-coated regions collect micro droplets of oil, due to its oleophilic character.

This work demonstrates that it is possible to produce efficient all-cellulosic composite membranes for the capture of micro-oil droplets dispersed in water, with easy tailoring of the ratio AC membrane and annealed NCC allowing to maximize the micro-droplet oil collection and at the same time the water flow. More, the combination of annealed NCC with non-woven electrospun membranes opens the door to a low-cost environment-friendly method of treating polluted ocean and waste-oily waters.

Large-Scale Production of Microfluidic Emulsions and Particles via Parallelization Daeyeon Lee; University of Pennsylvania, United States

The advent of microfluidics has led to remarkable advances in the synthesis of functional particles and microcapsules for a variety of applications. The ability to precisely manipulate the flow of multiphase fluids in microchannels enable production of highly uniform liquid droplets and gas bubbles with complex morphology. Despite these exciting developments, there remains some key challenges that must be addressed to enable successful commercialization of these technologies. In this talk, I will discuss our recent contributions in producing “designer” microparticles for drug delivery, diagnostics and regenerative medicine applications. The importance of understanding and harnessing the fundamental interfacial phenomena to engineer the structure and functionality of these particles will be described. I will also discuss our recent efforts to scale-up the production of particles via parallelization in solvent-resistant microfluidic devices.

Lipid Droplet Microarrays Steven Lenhert, Troy Lowry and Aubrey Kusi-Appiah; Florida State University,
United States

If micro-wells were the size of biological vesicles, there would be room for $10^{17}$ compartments in one cubic centimeter. In contrast, the state of the art in high-throughput screening uses 1536 well plates and about 3 ml of solution per plate. Motivated by a desire to understand biological compartmentalization and to use it for biotechnology, this presentation will describe the fabrication and applications of arrays of micrometer and nanometer scale lipid droplet microarrays. Arrays are fabricated by nanointaglio, which involves the transfer of fluid inks from the recesses of a microstructured stamp onto a substrate.[1] Thousands of different materials can be integrated into the droplets using pin spotting technology. Lipophilic small molecules can be encapsulated into the oil droplet, and cell cultured over the arrays for phenotypic screening with pharmaceutical applications.[2] Furthermore, exposure of these droplet arrays to lipid binding analytes such as proteins while observing scattered light from the arrays allows label free detection of remodeling events in the lipid droplet nanostructure.[3] Droplet size, shape, and composition are central to these applications. Recent progress in the use of these multiphase fluids to investigate and control biological systems will be presented.

Emulsions and Heterogeneous Materials for Fabricating Oscillatory Chemo-Mechanical Networks Seth Fraden; Brandeis University, United States

A simplified theoretical model treats neurons as non-linear oscillators that when coupled together through excitatory and inhibitory connections give rise to complex spatio-temporal patterns. When organized, these patterns are capable of processing and storing sensory information, and actuating musculature. Extrapolating from this general definition of a neuronal network, we posit these dynamics can be captured on an abiologic reaction-diffusion platform. We reported advances in soft lithography that allow the engineering of synthetic reaction-diffusion networks capable of producing the same spatiotemporal dynamics of the eel’s CPG². The network is natural in the sense that the oscillators and couplings are physical-chemical processes that, once initiated, proceed without any external intervention. Our experimental model system uses the oscillatory Belousov-Zhabotinsky (BZ) reaction with which we created diffusively coupled networks over which we designed (i) the topology of the network, the (ii) boundary and (iii) initial conditions, (iv) the volume of each reactor, (v) the coupling strength, and (vi) whether the coupling is of an inhibitory or excitatory nature. In particular, Central Pattern Generators have been modeled theoretically as being networks of identical oscillators²-⁴. With this BZ experimental system we will probe a number of fundamental questions addressing the suitability of chemical oscillators networked into CPGs for control of soft robotics. It is important to note that the engineering principles we identified are general and can be applied to other oscillatory reaction-diffusion systems besides BZ.

Network symmetry imposes constraints on dynamics in both expected and surprising ways²-⁴. First, the impact of network symmetry is completely independent on the underlying chemical nature of the oscillator. When wiring together identical oscillators, symmetry imposes significant constraints on the dynamics. These constraints create invariant manifolds, privileged subspaces in phase space that are impenetrable to the dynamical flow of the system. Invariably, real systems are not strictly symmetric. Oscillators and their connections have heterogeneities. How much variability does a system need in order to break the rules arising from symmetry?

A related question arises in regards to control of a network. Optimal control theory asks what is the minimum effort required to move as system from one stable attractor to another. Because dynamics is constrained to move on invariant manifolds, symmetries influence control protocols. We can test the theoretical role of symmetry and the protocols of optimal control theory in an experimental system. As specific examples of the role symmetry plays in network dynamics, we consider the simple cases of a ring of 3 and 4 identical oscillators and study how the dynamics changes as we break symmetry by changing the natural frequency of oscillation. The ring of 3 oscillators has two stable attractors. Moving to a ring of 4 oscillators leads to richer dynamics corresponding to the gaits of quadrupeds²-⁴. The general questions we ask are: How to optimally switch from one gait to another? Can one control the entire network by manipulating a subset? How robust is the stability of the attractors to noise?

Porous Liquid Infused Surfaces in Microfluidics for Fluid Delivery—Pressure and Heat Transfer Measurements
Reginald Goodwin, Bolaji Sadiku and Jeffrey R. Alston; North Carolina A&T State University, United States

Porous liquid infused surfaces, commonly referred to as SLIPS (slippery liquid infused surfaces), can be fabricated from any nano/microstructured porous solid material with a lubricating liquid film used to create surfaces that exhibit liquid repellency, self-healing, optical transparency, pressure stability, and self-cleaning. If designed properly these surfaces can repel many fouling challenges including bacteria, ice, water, oil, dust, barnacles, or other contaminants, and have been proposed as coatings on industrial and medical surfaces. These surfaces are robust even under high temperature and pressure conditions which also positions them as a viable treatment for the walls of microelectronic cooling channels or on fuel lines to reduce coking in high-temperature fuel delivery. To establish this use case, we present the development of a microfluidic device incorporating a porous liquid infused surface, and we measure the pressure drop and heat transfer across this surface while tailoring the chemistry, porosity and infusing liquid on the surface.

Are Contact Angle Measurements Useful for Oxide-Coated Liquid Metals?
Ishan D. Joshipura1,2, K. A. Persson2, Hong Zhao3 and Michael Dickey2; 1Lawrence Livermore National Laboratory, United States; 2North Carolina State University, United States; 3Virginia Commonwealth University, United States

Liquid metals are useful soft and fluidic conductors for electronics, composites, and microfluidics. In the presence of oxygen, these metals form a thin (~3 nm) surface oxide that acts as a deformable solid shell and adheres to many surfaces. The first portion of the talk will address the unusual wetting behavior of oxide-coated liquid metals (in comparison to water) on smooth, non-reactive substrates using conventional tools for measurement contact angles. These experiments demonstrate the unusual contact angle hysteresis behavior due to pinning of the oxide. Next, this talk will discuss the effect of surface roughness and surface chemistry on oxide adhesion, including strategies to prevent oxide adhesion. Overall, we find that the contact angle can be manipulated mechanically to be any value from 0° to >140° depending on the hysteresis. Thus, for oxide-coated liquid metals, conventional wetting measurements may be relatively uninformative and subject to different interpretations. Accordingly, the results provide fundamental insights on the adhesion of the oxide to substrates, which is important for additive manufacturing of metals, soft and biocompatible electrodes and interconnects, and reconfigurable electronics.

Liquid-Based Resistive-Switching Memory with Synaptic Functions Using Ion Dynamics in Liquid Dongshin Kim, Min-Kyu Kim, Youngjun Park and Jang-Sik Lee; POSTECH, Korea (the Republic of)

Liquid materials have emerged as a promising material in neuromorphic devices and energy storage devices because of the high ionic mobility of the liquid. We report liquid-based resistive-switching memory (LRSM) devices, exploiting the formation and rupture of silver filaments in the solution [1]. The devices are designed to have a metal-solution-metal structure, consisting of an Ag electrode and an inert electrode that together sandwich a solution. The switching behaviors of the LRSM devices occur at a very low operating voltage, similar to the action potential in biological synapses because the movement of silver ions does not need much energy to migrate under the electric field in the AgNO₃ solution. Furthermore, we also evaluate the potential use of LRSM devices in neuromorphic devices. The LRSM devices have neuromorphic characteristics including potentiation, depression, excitatory postsynaptic current (EPSC), and paired-pulse facilitation (PPF). Silver filaments that are formed in solution lead to changes in the conductivity of the device and provide neuromorphic characteristics. Also, LRSM devices have flexibility due to using a liquid as the main component. This study will offer the potential for the development of flexible and highly energy-efficient brain-mimicking devices. In this presentation, liquid-based resistive-switching memory characteristics will be presented in detail.

SB11.03.04
Microfluidic Patterning of Liquid-Mediated Materials through Liquid Foam Control Juyeol Bae and Taesung Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Appropriate external forces or physicochemical constraints can reshape liquid into desired morphologies. Historically, early strategic techniques for shaping liquid (e.g., brushing and printing presses) have significantly affected civilization. Recently, numerous micro- and nanofluidics has substantially enriched applicable micro- and nanodevices made of functional liquid-processible materials (i.e., liquid-mediated materials) by enabling spatiotemporal manipulation of fluids at the micro- and nanoscale, simultaneously offering cost-effectiveness, simplicity, flexibility in choice of materials and substrates, and scalability. In the micro- and nanofluidic liquid-mediated patterning (MNLP), nanowires particularly have been studied to meet increasing demands for transparent and wearable electronics. However, the state-of-the-art methods have required expensive preparation steps for nanostructured templates, otherwise they have shown low-resolution spatial control of liquid. Though nanoscale liquid-air interface control by microstructured templates have been a compromise between the cost and resolution issues in the nanopatterning, it is limited to unidirectional wire patterns. To this end, liquid foam pervasive in nature can be useful in comparison to the reported approaches for patterning networked high-resolution nanowires, though it involves certain challenges such as their unmanageable drying, complex topological changes, and dynamic fluidity.

Herein, we report a MNLP technique to engineer 2D liquid foam, motivated by its potentials in micro- and nanoscale material patterning. The main idea is the design of micropost and microhole arrays in a hexahedral liquid space. The evaporative microholes allow the fast generation of discretized liquid–air interfaces and directed receding of the interfaces toward micropost. Then the microposts pin the generated interfaces in predefined locations to make them form networked-line pattern of liquid. The generated liquid pattern could be used as molds for evaporatively structuring of the target materials in liquid, enabling material patterns of several micrometers or hundreds of nanometer width, showing results that cannot be easily achieved by using conventional patterning technologies. First, multiple heterogeneous materials could be self-aligned respectively into multiple different patterns precisely without cumbersome high-resolution alignment. Second, conventional photolithography technique could be combined with our MNLP method. From the demonstration of microscale UV writing on the bottom-up nanoscale prepatterned uv-curable poly(ethylene glycol) diacrylate (PEGDA), we can do mask-less nanopatterning in a low-
cost and high-through manner. Third, our suspended nanowire was made in a single step without any conventional fabrication process, otherwise the 3D structure is made commonly using relatively laborious multi-step top-down fabrication techniques. Furthermore, it is no doubt that other useful materials like organic-inorganic hybrid perovskite, functional nanocrystals, graphene will be patternable. Therefore, our foam-based MNLP technique shows high potential in field of micro-/nanopatterning for various applications such as micro-/nanofluidic, optoelectronics, and multi-functional electronic devices.

SB11.03.05
The Strange Case of Coexisting Isotropic Phases in Liquid Crystal Solvent Mixtures Catherine G. Reyes¹, Jörg Baller¹, Takeki Araki² and Jan P. Lagerwall¹; ¹University of Luxembourg, Luxembourg; ²Kyoto University, Japan

Though the dynamics of phase transition in many multi-phase liquid mixtures have been thoroughly investigated, there is still more to explore with mixtures containing common liquid crystalline (LC) compounds and low molar mass solvents. Especially now that much LC research has been devoted to the development of soft devices and composites [1-3], where the preparation of LC-solvent emulsions may be necessary for processing using microfluidics [4-5] or ink-jet printing [6], for instance, it is essential that experimentalists consider the phase equilibria of LCs in solvents. While numerous studies already exist on 4-cyano-4′-pentylbiphenyl (5CB), a low molar mass room temperature nematic, we now experimentally find that binary mixtures between this LC and anhydrous ethanol show a broad miscibility gap that leads to phase separation between two distinct isotropic phases. More surprisingly, contaminating the ethanol-5CB mixtures with water (3 vol.% suffices) dramatically raises the temperature range of the miscibility gap and the critical temperature at which phase separation by spinodal decomposition occurs to higher than 50°C. The phase diagrams presented here describing these phenomena, experimentally analyzed using temperature-controlled polarized optical microscopy and differential scanning calorimetry (DSC), corroborated by theory and numerical simulations, emphasize the often overlooked practical consequences that mixing LCs with common laboratory solvents can have in the formation and stabilization of future LC-composites.

In Situ Templating for Faster Protein Crystal Nucleation Caroline McCue, Henri-Louis Girard and Kripa Varanasi; Massachusetts Institute of Technology, United States

Slow protein crystal nucleation is a major barrier to using crystallization as a separation and purification strategy in protein drug manufacturing. This work demonstrates the use of functionalized nanoparticles in solution to act as in situ templates for initiating crystal nucleation. We used lysozyme, a protein with well-characterized crystallization conditions, to evaluate the nucleation rates of crystals grown on the functionalized particles. On a microfluidic chip, a supersaturated solution of lysozyme is mixed with a stream containing precipitants and functionalized nanoparticles. The nucleation rates are measured using an emulsion based technique. Nanoparticles functionalized with groups that covalently bind with proteins demonstrate up to four times faster crystal nucleation than controls, and faster nucleation than bare nanoparticles or nanoparticles with other types of functionalizations. Surface adsorption measurements on larger flat surfaces with the same functional groups are used to examine the mechanism by which the functional groups enhance crystal nucleation.

SB11.03.07
A Dry Bacterial Cellulose-Carboxymethyl Cellulose Formulation as Stabilizer for Pickering Oil-in-Water Emulsions Daniela Martins, Fernando Dourado and Miguel Gama; Centre of Biological Engineering - University of Minho, Portugal
Hydrocolloidal microcrystalline cellulose (MCC) from plant sources, is already widely used in industry to regulate the stability, texture, rheology and organoleptic properties of many food and cosmetic formulations. Bacterial cellulose (BC) is produced biotechnologically by different microorganisms, but most efficiently by acetic acid bacteria from the genera *Komagataeibacter*. This biomaterial is a prominent alternative to the already marketed celluloses, being more pure, crystalline, and having nanoscale fibres with high aspect ratio which account for excellent mechanical properties. BC has already been used in its hydrated form for the stabilization of oil-in-water (o/w) Pickering emulsions (particle-stabilized systems, as an alternative for the conventional surfactant-stabilized). For the sake of storage, economy and practicality, additives for industries are preferentially provided in a dry or powder form. Co-drying cellulose fibres or crystals with water soluble polysaccharides helps maintaining the rheologic and structuring properties after rehydration.

The main objective of this study was to assess the stabilizing properties of BC in Pickering o/w emulsions. For this, an equimassic formulation of BC and 90 kDa carboxymethyl cellulose (BC:CMC) was prepared and spray dried. Isohexadecane-in-water emulsions (10:90) were prepared in the presence of 0.10%, 0.25% and 0.50% of the BC:CMC formulation. Visual and microscopic aspect of the emulsions was registered over time. Samples were also visualized in Cryo-SEM. Rheological tests were performed to assess the emulsion’s viscosity profile, storage and loss moduli. Interfacial tension between the immiscible phases was measured with the Pendant Drop and Du Noüy Ring methods. For benchmarking purposes, the same emulsion preparation and analysis protocol was made with several different commercial cellulose products and xanthan gum.

Microscopic analyses showed large oil droplets, but stable over time. Despite a visible creaming in the emulsions with lower BC:CMC concentrations, there was no evident separation of the oil phase; with 0.50% BC:CMC, the emulsions were effectively stabilized against agglomeration, coalescence and creaming for up to 90 days without the need of any other emulsifying agents. The same did not happen for the commercial celluloses at the same concentration. Cryo-SEM images showed the entangled and disordered three-dimensional networks formed by BC fibres structuring the water phase and surrounding the dispersed oil droplets. The BC:CMC emulsions showed a characteristic viscoelastic and shear-thinning behaviour. An increase in BC:CMC concentration results in higher emulsion viscosity, higher than the emulsions prepared with other cellulose products. IFT measurements showed that the presence of the BC:CMC formulation actually diminishes the interfacial energy between the immiscible phases, more than the other cellulose products. The results of our dry BC:CMC formulation were only comparable to the ones with xanthan gum.

In short, BC:CMC showed formation of a three-dimensional network and viscosity increasing (thickening) properties, crucial characteristics for emulsion stabilizing formulations. BC has technically superior properties that will allow it to compete with, or even replace, plant celluloses in industry.

**Acoustic Bubble Suppression by Constructing a Hydrophilic Coating on HDPE Surface**

Junjie Niu; University of Wisconsin--Milwaukee, United States

Due to the serious reflection/scattering of sound waves, the acoustic bubbles on the surface that are generated during the sonication are posing a critically detrimental effect on the signal resolution of sonochemical devices such as various sensors for water-based liquid detection and sonobuoys for underwater acoustic study and anti-submarine warfare applications (*Adv. Mater. 2011, 1922*). In parallel, a large variety of high-density polyethylene (HDPE) polymers are extensively used in different devices particularly with sensors due to the high chemical and mechanical stability (*Polym. Degrad. Stab. 2007, 1219*). This outstanding stability also poses a challenge on modifying the surface with designed functional groups. The original HDPE surface shows a contact angle large than 60°, which generates plenty of bubbles when it suffers the ultrasound agitation. Even though there are a few reports about the hydrophilic coating created using versatile nanoparticles and polymers, forming a controllable hydrophilic coating on HDPE surface is not studied yet.

The ultrasonic bubbles on the solid surface of various sonochemical devices largely affect the signal resolution due to the serious reflection/scattering of sound waves. The Laplace pressure of the cavitation bubble can be tuned by constructing an ultra-thin hydrophilic layer, which leads to the solvation or pinching off of the bubbles from the surface. In this talk, we will introduce a polydopamine polymer layer coated on the HDPE surface (*Ye et al.* *ACS*...
The formed hydrophilic layer with contact angle less than 45 degree almost completely eliminates the bubbles in both water and 32.5 vol% diesel exhaust fluid (DEF) solutions upon sonication, which results in the operation of the piezoelectric sensor over 500 hours while the sensor with pure HDPE only ran less than 2 hours. Further, the coated sensors showed a high stability under the temperatures of 60-80 °C. An improved mechanical property was confirmed via abrasion test, enabling a long-term stability in harsh environments including acidic urine and ultrasonic agitation. The acoustic bubble suppression via the hydrophilic polymer coating on HDPE surface displays broad applications particularly with acoustic sensors, sonobuoys and non-destructive surface detection in sonochemistry.

**Multicomponent Phase Separation During Thin Film Formation** Eleni P. Hughes and Edward Van Keuren; Georgetown University, United States

Recently, phase separations in multicomponent solutions have attracted attention due in part to their potential usefulness in understanding biological systems. Living cells possess membrane-less organelles, formed by liquid-liquid phase separations with the cell. Multicomponent phase separations of polymers in solution may occur under certain thermodynamic conditions of temperature and concentration. Here we present studies of the phase separation of two immiscible polymers during film formation. By taking real-time optical microscopy video of the blade coating process, we are able to observe the multicomponent polymer system as it transforms from solution to thin film. Additionally, we use Raman mapping to confirm localized regions of polymer components. Finally, we present results showing the effect of additional components on the system.

**Droplet-Based Magnetofluidic Platforms for Detection and Analytics** Larysa Baraban¹ and Denys Makarov²; ¹Dresden University of Technology, Germany; ²Helmholtz-Zentrum Dresden-Rossendorf, Germany

The development of next-generation biosensing technologies has picked up momentum in the past decade. Particularly, among a variety of biosensing principles, magnetic biosensing technologies based on magnetic particles and magnetic field sensors have attracted growing attention due to the unprecedented advantages brought by this unique sensing format. Our contribution to this exciting field of research and technology includes the development of a compact droplet-based magnetofluidic platform encompassing integrated novel functionalities, e.g. analytics in a flow cytometry format [1-3], magnetic barcoding [4] and sorting of magnetically encoded emulsion droplets [5,6]. We put forth a novel high-capacity indexing scheme based on multiphase microfluidic networks for large-scale screening applications [5,6] and realized flexible microfluidic platform with integrated magnetoresistive sensors [4]. The technology on how to integrate high-performance magnetic field sensors into multi-functional self-assembled tubular architectures [7-9] for lab-in-a-tube concept [10] will be discussed. These features are crucial to address the needs of modern medical research, e.g. drug discovery [11].

In recent years, numerous innovative methods have been developed to meet the increasing demand for high throughput production of monodisperse droplets. These methods can be either passive, such as dripping, or active, such as acoustophoretic printing. However, both often require elaborate fine-tuning or cost-heavy equipment, which inhibits the field’s growth as it poses an entrance barrier for new researchers.

As a cheap and simple alternative to these methods, we have explored the use of commercial inkjet printers for the production of picoliter droplets; thereby, benefitting from decades of optimization in their speed, precision, and miniaturization. Nowadays, a 300$ office printer can produce >10k droplets per second from nozzles spaced 80 µm apart and a size down to 1.5 picoliter. In addition, many modern inkjet printers allow for variation of the droplet size, which makes their versatility even more pronounced. Despite the clear advantages, challenges related to backlash induced printing repeatability and printer-roller introduced sample contamination have limited the exploration of the many possibilities.

Through simple hardware adjustments to the office printer, we have made it possible to print multiple times without smearing and improved the between-print positioning repeatability from millimeter range to below 50 µm. This improvement enables a manifold of new utilities for the inkjet system. The low-cost inkjet printer has six ink lines; thereby, immediately allowing for droplet production with six different liquids. We demonstrate simultaneous printing with both polar and non-polar liquids containing fluorescent dyes, drugs, bacteria, and colloids. In particular, we have focused on using the inkjet printer to load drugs into microcontainers for targeted delivery and personalized treatment. This new loading method is superior to its predecessor due to its possibility of easily customizable drug content.

Hacking Office Printer for Multipurpose Droplet Production Nikolaj K. Mandsberg, Jesper Højgaard, Shreya S. Joshi, Line H. Nielsen, Anja Boisen and En T. Hwu; DTU Health Tech, Denmark

With the emergence of additive manufacturing technologies, such as “in-air microfluidics”, compound drops are attracting an increasing attention. One of the critical challenges 3D printing applications is to control the deposition process of the impacting drop and therefore its spreading, potential rebound and splashing. By studying the dynamics of compound drops consisting of immiscible liquids, we identified the mechanism of self-lubrication of water-in-oil compound drops impacting on a solid surface. The presence of an oil shell encapsulating a core water drop acts as a lubricating layer promoting water rebound even on a hydrophilic substrate, on which water deposition is typically expected. We define the mechanisms and the conditions that lead to deposition or rebound of the inner water drop, as such providing design guidelines for the printing of compound drops to be used in additive manufacturing.

A New Paradigm on Minimal Adhesion at Solid-Bio/Species Interface Bahareh Eslami, Peyman Irajizad and Hadi Ghasemi; University of Houston, United States
Interfacial characteristics of a material play a key role in its interaction with foreign species. Low adhesion of the deposited materials provides the advantage of their easy removal from the surface. Different approaches have been developed to reduce solid-bio/species adhesion by modifying chemical and physical atomic forces, tailoring polymer chains, micro/nano structuring of a surface and so on. Here, we developed the underlying physics of the stress-localization concept to minimize adhesion of a solid on a surface. The fundamental underpinnings of this concept are elucidated and a simple formulation that could be used to characterize solid adhesion on various surfaces is derived. Using this concept, we developed a new bio-polymer material system with superior characteristics while exhibiting long-term mechanical, chemical and environmental durability. This polymeric material contains dispersed organogels in a high shear modulus matrix. In this study, we focused on the interaction of bio-species including both soft and hard organisms with this biopolymer material. Interfacial cavitation induced at the interface of bio-species and organogels particles lead to stress-localization and detachment of bio-species from these surfaces with minimal shear stress. In a comprehensive study, the performance of these surfaces is assessed for both soft and hard-biofouling including Ulva, bacteria, diatoms, barnacles, and mussels and is compared with state-of-the-art surfaces. These surfaces show Ulva accumulation of less than 1%, minimal bacteria biofilm growth, diatom attachment of 2%, barnacle adhesion of 0.02 MPa and mussel adhesion of 7.5 N. These surfaces promise a new physics-based route to address the biofouling problem and avoid adverse effect of biofouling on environment and relevant technologies.

Temperature Effect on Fluid Behavior for Crystal Growth and Material Assembly Yan Li, Yitan Li, Yuguang Chen and Hao Wang; Peking University, China

The behaviors of fluid have shown great importance in crystal growth and material assembly on various substrates. Herein, we studied the temperature dependence of the fluidic behavior of several organic solutions on both solid and liquid substrates. On solid substrates, we focused on the liquid wedge near the air-liquid-solid contact line. The temperature gradient of the liquid wedge was manipulated by using a top-heating-bottom-cooling (THBC) setup. A steady Marangoni flow with a single vortex was created in the thin liquid film which benefits the material patterning. We also studied the behavior of volatile organic droplets on the water surface. The liquid-liquid-air contact lines are tunable by varying the temperature. A spontaneous self-division process of the droplets was observed. By thus tuning the fluid behaviors, the crystal growth and material assembly processes were manipulated and CH$_3$NH$_3$PbI$_3$ crystal arrays and dumbbell-shape C$_{60}$ aggregates were prepared.

The World’s Largest ‘Ink Jet Printer’—From the Lab to Full-Scale Implementation Raymond Oliver$^1$ and Robert Munro$^2$; $^1$Northumbria University, United Kingdom; $^2$Institute for Manufacturing, United Kingdom

Laminar flow cylindrical inviscid and viscous jet break-up by capillary instability has been observed, measured and modelled many times since Lord Rayleigh’s initial physical insights, from Rutland and Jameson to Lafrance using both analytical and numerical solutions to predict linear and non-linear jet break-up. The driver has been the prediction of droplet size, satellite formation and overall size distribution as these provide printing quality or , in our case, allow us to investigate new opportunities from solutions to suspensions to melts for the creation of near monodisperse particulates. In our work, we had the additional challenge to create an environmentally beneficial industrial process for the creation of agrochemical products that had to have an extremely narrow size distribution in order to generate monodispersions. These would then undergo multiple phase transitions that resulted stable particulates for agricultural use on a grand scale of approx. 1 Te/ min or in excess of 1000tes/day! The work carried out will describe in detail the experimental and numerical work carried out over a two year period from single jet studies, through bench-scale investigation to pilot plant optimisation and finally full-scale production. In carrying out this work, we will describe a novel means of perturbing cylindrical liquid jet break—up allowed us to simultaneously control 2800 jets, the evolution of which was modelled using a 3rd order perturbation method considering amplitude effects to predict and validate the final size distribution outcome.
Gait Engineering—Studies of Small Synthetic Neural Networks
Ian Hunter, Michael M. Norton, Chris Simonetti, Bolun Chen and Seth Fraden; Brandeis University, United States

Living beings have evolved to use coupled neurons to perform autonomous functions, from breathing to walking. Local, often small, clusters of neurons known as central pattern generators (CPGs) perform these essential functions in the absence of constant guiding input from the brain. This modular method of control of whole organisms may present advantages over centralized, computational robotic control. An experimental platform, composed of diffusively-coupled PDMS microreactors each containing the oscillatory, light sensitive Belousov-Zhabotinsky (BZ) chemical reaction forming CPG-like patterns has been studied. Understanding experimental observations of quadruped gaits, and an explanation of a systematic method making synthetic CPGs with desired steady state gaits will be the focus of the presentation.

Microfluidic Biochip Platform Incorporating Hydrogel-Based Differential Coulter Counting Technology for Rapid, Multiplexed Detection of Biomolecules
Thomas Cowell, Enrique Valera, Aaron Jackelow, Joonhyuck Park, Alex Schrader, Ruihua Ding, Rashid Bashir and Hee-Sun Han; University of Illinois at Urbana Champaign, United States

Rapid, multiplexed quantification of biomarkers in patient samples is a critical step for effective diagnosis and prognosis. Recently, we have developed a new microfluidic biochip platform integrating a differential coulter counter and an immuno capturing chamber. This platform enables rapid quantification of a specific cell type and plasma proteins without involving expensive apparatus. Despite their immense potential as a cheap, simple, point-of-care diagnostic device, the current platform suffers from its inefficiency in simultaneous quantification of multiple targets. This limitation is due to the non-optimal properties of solid microparticles used for biomolecule capture. Using droplet microfluidics, we have created multiple monodisperse populations of magnetic hydrogel beads (MHBs), which address all the limitations presented by solid microparticles. In particular, each MHB population exhibits distinct electrical signal while having similar sizes and densities, a key requirement to achieve uniform capture efficiencies across different MHB populations at a given flow condition. The magnetic properties of our new hydrogel beads enable facile manipulation and separation of the beads from a complex mixture. The additional advantages of the new MHBs include easily tunable surface chemistry, highly monodisperse size, and density close to dispersing aqueous solutions. Using a differential counting microfluidic device and the newly synthesized MHBs, we confirmed the simultaneous and selective detection of target DNA molecules. The dependence of capture efficiency on the concentration of target molecules is also demonstrated. The size of our newly synthesized MHBs is similar to the size of cells, thereby enables researchers to use the same chip to analyze both cell counts and biomarker concentrations. We aim to use this technology for rapid quantification of multiple biomarkers from fluid samples in a point-of-care device.

Wrapping of Drops and Nanoparticles in Clay Nanosheets
Osvaldo Trigueiro Neto¹, Ville Liljeström², Koiti Araki³, Lina Mayr³, Josef Breu³, Jon O. Fossum¹ and Paul Dommersnes⁵; ¹Norwegian University of Science and Technology, Norway; ²Universidade de São Paulo, Brazil; ³University of Bayreuth, Germany

We have investigated synthetic clay mineral nanosheets of different lateral sizes. The clay nanosheets have mechanical properties similar to graphene oxide or graphene sheets, which already have been proven to be capable of wrapping at different lateral length-scales. It is known that clays (e.g. mica) can also wrap magnetic nanoparticles, which might lead to improved control of magnetic particle transportation in porous media, e.g. for medical, or for oil-reservoir diagnostic purposes.

To achieve wrapping of liquid droplets, very dilute oil-in-water emulsions (0.01–1%) and exfoliated clay colloidal suspensions have been prepared separately and subsequently mixed. The oil drops have diameter 10-25 μm, and the exfoliated clay (synthetic sodium fluorohectorite) have thickness 1 nm, and lateral dimensions 10-100 μm. Our results demonstrate wrapping of droplets by the clay nanosheets.
Furthermore, we have probed clay sheet deformation characteristics by depositing exfoliated clay particles on solid substrates with various curvatures. This forms the base for ongoing work of establishing protocols for nanosheet clay wrapping of magnetic nanoparticles.

Reduction in Contact Time of Bouncing Droplets on Dense Nanostructured Superhydrophobic Surfaces Lin Wang and Tak-Sing Wong; The Pennsylvania State University, University Park, United States

Many plants and insects have developed intriguing wetting properties that enable them to thrive in their natural habitats [1, 2]. Lotus leaf, which is one of the most well-known biomimetic examples, has served as the blueprint for designing superhydrophobic surfaces for over two decades. Specifically, the water repellency of lotus leaves mainly stems from the hydrophobic epicuticular wax coating and low fraction of solid surface (Φs) that is in direct contact with water [2]. As shown by the classical Cassie-Baxter equation (1944), superhydrophobicity can be achieved by a surface with solid fraction (Φs) less than 0.05 [3]. However, some insect surfaces exhibit exceptional water repellent characteristics at solid fractions (Φs) much greater than 0.05. For example, superhydrophobic mosquito eyes, springtails, and cicada wings possess solid fractions (Φs) as high as 0.25 – 0.64 [4 – 6]. In addition, the texture size on these insect surfaces is typically on the order of 100 – 300 nm. To understand why both high solid fraction and nanoscale textures are important on these superhydrophobic insect surfaces, we systematically designed and fabricated a series of synthetic textured surfaces with feature size ranging from 100 nm to 30 µm with solid fractions (Φs) of 0.25 and 0.44, and investigated their static and dynamic wetting behaviors. We discover that nanoscopic textures (i.e., ~100 nm) at high solid fraction (i.e., Φs ~ 0.44) enable reduced droplet contact time (the duration that an impacting droplet is in contact with the solid) by as much as ~2.6 ms, which is ~14% of contact time reduction as compared to those of microscopic counterparts. The amount of contact time reduction is significant, as it is comparable to the timescale for a mosquito to escape from a lethal raindrop collision [7]. Detailed analysis of the results will be presented in the meeting. Our discovery may provide a new physical insight to the design of new superhydrophobic materials for highly dynamic environments.

Microfluidic Device for Optical Screening of Droplets Kouta Taniuchi1,2, Takasi Nisisako3 and Satoru Shoji1,2; 1The University of Electro-Communications, Japan; 2Japan Science and Technology Agency, Japan; 3Tokyo Institute of Technology, Japan

The sorting and separation techniques of microscopic droplets have been progressed with the aid of microfluidic
device. At present, various methods had been reported for the manipulation of droplets based on electric, acoustic, magnetic, hydrodynamic control[1]. In this presentation, we introduce a method utilizing optical radiation pressure. The magnitude of the optical radiation pressure depends upon the optical property (refractive index, scattering cross section and absorbance) of the materials. Therefore, the method will be able to distinguish the droplets by not only size-dependence but also color-dependence. We developed a micro fluidic device for screening droplets by optical radiation pressure. The device we developed is simple construction only irradiating laser beam to micro fluidic channel. Micro fluidic channel we designed contains inlet, main and outlet channels. The inlet section consists of three 50µm-width and 20µm-height channels crossing by 90 degree. The main channel has its width of 150µm and height of 20µm along 10mm. The main channel is branched out into two 75µm-width and 20µm-height outlet channels. The channel was made of poly(dimethylsiloxane) and fabricated by soft lithography. In our experiment, oil in water emulsion was infused to a center inlet channel. Aqueous solution without droplets was infused to the two side branched channels as sheath flow. The structure of three crossing channels caused hydrodynamic focusing, hence a line of flowing droplets was created at the main channel. A line shaped focused laser beam with 532 nm wavelength was irradiated to the main channel orthogonally. Flowing droplets in the main channel were irradiated by the laser beam. Depending on their optical property, only the droplets experienced strong optical radiation pressure were changed their flowing position. Eventually, they were introduced to one of outlet channels, however, the rest flew into the others. In the presentation, we will show experimental results showing screening droplets by their size and color.

Chemically Patterned Surfaces and Their Use as a Component in Liquid Molding Processes Takamichi Shimosaka and Thomas J. McCarthy; University of Massachusetts Amherst, United States

Wetting-controlled surfaces are typically hydrophobic/hydrophilic patterned surfaces that can be wet rapidly to create a matrix of precisely aligned and shaped sessile liquid droplets. 2D wetting controlled surfaces have attracted much interest for both fundamental issues and applications that include the creation of small droplet arrays of proteins and cells for analysis and screening purposes. Wetting controlled surfaces are also applicable to generate effective solution separating walls for precise ink deposition or conductive layer deposition in producing electronic devices. A potentially beneficial attribute of this process is that the two-dimensional patterned surfaces create, along with the liquid, three-dimensional shaped features. These features can be used in molding processes that are versatile because of the flexibility of the 2D pattern, the liquid identity and the liquid volume (contact angle).

We present a novel 3D structure fabrication technique using 2D hydrophilic / hydrophobic patterned wetting surfaces. The preparation of controlled wetting surfaces and the subsequent liquid coating processes create reproducible sessile droplet arrays. The patterned surfaces show sufficient liquid trapping capability with a wide range of liquids with surface tension values ranging from 72.8 (water) to 18.8 mN/m (octamethylcyclotetrasiloxane). These droplet arrays can be covered with controlled thickness silicone prepolymers which are cured catalytically. The array serves as a mold, and the liquid is retained in the more hydrophilic regions due to a hydrophilic / hydrophobic confinement effect. The velocity of liquid application using a flow coating system affects the volume of coated liquid yielding molds with varying feature height while maintaining the width of droplets. Several types of liquid, including ionic liquids, glycerol, and water were studied to confirm the versatility of this molding process. Immiscibility between the silicone and certain ionic liquids permitted precise molding. A molded silicone resin showed light scattering behavior that was predicted by the 2D droplet array structure, indicating the successful replication of the array to the silicone resin. The shape of resulting molded silicones when water was used was a function of relative humidity, because of the significant water vapor permeability of silicones. Due to the finite vapor pressure of glycerol, we could control the height (and shape) of features using controlled condensation/evaporation after flow coating. In this presentation, we will present our work on the preparation of wetting controlled surfaces, the creation and effect of the liquid droplet as a mold, and subsequent molding processes.

Wettability at Picodrop Levels—Analysis of Ink and Substrate Surface Properties under Inkjet Conditions Paul Simutis1, Peter Oberschachtsiek2, Martin Gruesser2 and Michaela Laupheimer2; 1DataPhysics Instruments USA Corp., United States; 2DataPhysics Instruments GmbH, Germany
Compatibility of ink and substrate is crucial for an optimal printed image. Currently in inkjet printing, the ink must be adjusted to each printer head and then precisely formulated for the printing process. Consequently, the only degree of freedom for desired print image lies in the properties of the substrate’s surface. By choosing a proper substrate or modifying it, according to its surface free energy, the required wettability and adhesion properties can be obtained; sometimes even without any primer or additional sealing process, which reduces production costs. In addition to wetting and adhesion, the absorption process on absorbent substrates has an influence on the final image quality. Using a goniometer capable of delivering ink droplets to a volume as low as 30 picoliters, the wettability of different raw and modified substrates was determined by contact angle measurements and the surface free energy of the substrates was calculated. With this knowledge it becomes possible to estimate wetting and adhesion behavior of inks. Using picodrop-level dosing with the goniometer, the ink-substrate interaction directly under inkjet drop dispensing conditions is observed. Contact angle changes due to absorption and wetting can be determined with a speed of up to 1 ms. This picodrop delivery technique can be used for early-stage printing tests of newly developed ink formulations with conditions similar to the inkjet process without the risk of printer head blockage. These measurements enable fast and reliable determination of the surface properties of substrates and inks which simplifies the choice of substrate-ink combination for ideal image printing. Selected examples will be presented.

SB11.03.24
New Force Tensiometer Development for Adhesion Force Measurement of Liquids on Solid Surfaces

Paul Simutis¹, Daniel Scholz² and Michaela Laupheimer²; ¹DataPhysics Instruments USA Corp., United States; ²DataPhysics Instruments GmbH, Germany

The measurement of contact angles and surface free energy is a well-known method to study and understand adhesion properties of liquids to solid surfaces. Work of adhesion between liquid and substrate can be estimated by determination of surface energy of a substrate, measurement of surface tension of a liquid and calculation of adhesion work between them using Young-Dupre equation. This methodology is therefore commonly used in the development of coatings, paints and varnishes, for example, as well as to characterize surfaces and the effects of surface treatments. In this lecture a new, more direct approach to measurement of adhesion using a tensiometer will be presented. This new method uses small platinum ring to hold a droplet of the test liquid, software-controlled movement of the substrate to attach the droplet to the test substrate and measure the force between the liquid and the substrate while the droplet is being pulled off from the substrate. An integrated camera records the process of the drop detachment and allows calculation of the contact area as well as contact angle between the drop and the substrate. With this novel technique it is now possible to directly observe and measure the liquid’s behavior when in contact with a solid surface. Several examples will be presented including biosurfaces and membranes to test the adhesion of water droplets to them. The droplets are brought in contact with, pressed onto and then pulled off the biosurfaces and various membranes. During this process force distance curves were recorded and later compared to each other. An analysis of the maximum adhesion force shows good correlation to contact angles which can also be analyzed combining the tensiometer with this video system.

Furthermore liquid transfer to or into the material can be analyzed and different compression rates can be used to simulate different drop behavior.

Correlating the Structure of Ferrocene-Loaded Microemulsions near Surfaces to Their Electrochemistry

Luke Heroux¹,², Brian Barth¹, McKensie Nelms¹, Nelly Cantillo¹, Jing Peng¹, Thomas Zawodzinski¹,², Douglas Hayes¹ and Mark Dadmun¹,²; ¹University of Tennessee, United States; ²Oak Ridge National Laboratory, United States

Structured liquids are of interest as possible electrolytes for energy storage and other electrochemical applications, where one focus is the electrochemical behavior of oil-in-water microemulsions. Stable microemulsion systems consisting of water (plus salt), toluene (oil phase) and a Polysorbate 20/butanol surfactant/cosurfactant system with ferrocene, a model redox active agent, loaded into the toluene phase is the focus of our studies. Electrochemical results indicate remarkably reversible (fast) electrochemical kinetics in the region in which oil-in-water droplets or bicontinuous microemulsions are present. To understand this process further, we have examined the structure of the microemulsion in the bulk with x-ray and neutron scattering and near a surface with neutron reflectivity. The near surface studies will provide insight into the interaction and ordering of the microemulsion at an electrode surface.
This talk will focus on the structure of this microemulsion near surfaces with well controlled hydrophobicity using neutron scattering, where initial results indicate a layering of the components near these surfaces.

SB11.03.26  
**Fabrication of Electromagnetic Interference Shielding Sheet with Stretchable Using Ga Based Liquid Metal Powder**  
Chan-Geun Song, Hyeunseok Choi, Sungbok Kang and Jongseok Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Gallium based liquid metal (LM), Eutectic gallium indium (EGaIn) exists in liquid form at room temperature. EGaIn has high electrical conductivity and thermal conductivity in liquid phase. Many kinds of way to make stretchable electrode pattern with LM and study of its properties have been published in research papers. These researches show several applications such as microfluidic systems, soft electronics and wearable devices. In the recently, micro-nano sized LM droplet or powders have received significant focus in fabrication methods, applications and its natural material properties. LM powders are a type of biphasic materials which have an inner core in liquid state and an outer shell of Ga oxide, is reported to be a 30-50A thickness. LM powder has been of interest as this is able to show high interesting characteristics coming from the difference material properties (electrical, mechanical) between core and shell. The shell is electric insulation material, and the core is conductive. In this study, we propose a fabrication process of micro-nano size liquid metal (LM) powder. For showing application example, we implemented a stretchable EMI shielding sheet using LM powder and silicone resin. This sheet has electric insulation that reason why the shell of LM powder is the insulating oxide layer, and it has enough EMI shield property because the core of LM powder in the sheet is conductive metal.

At first step, we make ethanolic micro-nano scale LM colloids using sonication, ultrasonic homogenizer make high oscillating shear forces in vial with LM and to form LM particles. The LM is a eutectic gallium–indium (Ga 74.5% and In 25.5%, Melting point 16°C). During the sonication process, LM particle is exposed to oxygen. Gallium oxide continuously forms on LM particles. We can control size of the LM particle by sonication time. The longer time of sonication, the smaller size of LM particle is. When sonication time is 15min, we can produce LM particle size 100nm~150nm. After sonication, Precipitation makes LM particle separation in vial by its size. We extract the LM particles from vial using a syringe. Finally evaporating the ethanol, we can get dried LM powder.

The sheet of EMI shield is made by silicone resin (Dragon skin™ 10NV) and fabricated LM powder. We mix the LM powder with the silicone resin, and add the hardening agent. After curing 2hours, we fill off the EMI shield sheet applied LM powder from a substrate (Si wafer)

Generally, EMI shielding materials use conductive materials and there is a risk of electric short circuits. We have confirmed the possibility of liquid metal powder as EMI shielding materials with non-conductive properties. This study used LM powder as EMI shielding material while preventing electric short circuits on the surface. Silicone resin is easy to form and have a stretch, which is advantageous for applying a composite sheet to various fields. We measured the electromagnetic shielding using a network analyzer and measured the insulation performance using an insulation resistance tester withstand voltage insulation resistance tester. The EMI shielding performance of LM powder, insulation was evaluated via experiment results of developed the LM powder shield sheet. In the future work, we will study the theoretical relationship between the size of LM powder and the EMI shielding performance. We expect the performance of the sheet depending on the volume ratio of silicone resin and LM powder.

SB11.03.27  
**Controlling the Jet-Mode Break-Up of Multiphase Emulsions for High-Throughput Fabrication of Structured Microparticles Using Microfluidic Devices**  
Seung-Kon Lee and Jin-Hee Kim; KAERI, Korea (the Republic of)

There has been intense and longstanding interest in the use of biocompatible microparticles for a variety of applications such as bio-imaging, drug delivery, medical diagnostics, photonics, optical data storage, and display pigment. Batch synthesis has been the method of choice for preparing polymer particles due to practical advantages in productivity and accessibility, despite disadvantages in controllability and efficiency. In batch synthesis, multiple separated steps of synthesis, purification, loading and washing are required to prepare the particles. During this process, the amount and size of loadable materials is limited. Furthermore, an excessive portion of loading materials is wasted, which is especially problematic when expensive loading materials are used (ex. Quantum dots, biomaterials, drugs and etc.).

Compared to the batch processes, the microfluidic drop breakup scheme allows predominant production of uniform
emulsions with highly controlled size in continuous manner. Combined with photopolymerization scheme, those emulsions can be instantly converted into crosslinked particles containing various functional materials. Even infinitesimal amount of precious materials can be handled without any loss, since the emulsions are prepared from shear induced breakup of one phase into another immiscible fluid. In this scheme, there is no additional washing step or development step which causes material dissipation. Furthermore, this scheme allows easy loading of relatively large dispersion materials up to several micrometers. Most of the microfluidic particle synthesis is operated in a dripping mode regime which allows precise size distribution control. However, dripping mode operation has limited production rate since the breakup occurs one by one, with relatively low frequency. In addition, the controllable size range is limited because the emulsion sizes are more dependent on the nozzle diameter and interfacial properties rather than the flow conditions. To get smaller emulsion sizes, dimensions of the microfluidic channels around the breakup junction must be decreased, causing unstable flow and significant pressure build up in the system. Viscous monomers used for the particle preparation creates even larger pressure accumulation and can lead to device failure. By applying multiphase flow in the microfluidic system, structural emulsions, such as janus or eyeballs, snowman and hemispheres can be fabricated.

In this study, we presented production of highly uniform emulsions with various structures using harmonic breakup of co-flowing jet with high Weber number system. In jet mode breakup, axisymmetric laminar jet of inner fluid is broken into a train of uniform tiny emulsions. Ideal harmonic fluctuation formed by a well-defined microchannel leads to series of disconnection with regular interval from the periodic modal points. Since the jet diameter is relatively small and widely variable for given nozzle diameter, the jet mode allows low pressure drop, high production rate and wide range of controllability, simultaneously. Here, biocompatible microspheres with various shapes were synthesized throughout a controllable size range of 10 ~ 100 μm and 3% of uniform size distribution using jet breakup. The production speed can be ranged from 400 Hz to 100,000 Hz, according to the microfluidic chip material.

Advective Flow in Nanostructured Bijels via Electroosmosis Martin F. Haase; University of Utrecht, Netherlands

Particle stabilized bicontinuous emulsions (bijels) have been introduced over 10 years ago.[1] Soon after their discovery, their future use as continuously operated crossflow reactors for chemical reactions between immiscible reactants was proposed. This potential yet remains to be demonstrated. Here, we take a significant step towards realizing this vision by introducing advective flow in bijels via electroosmosis. Recently, we have introduced Solvent Transfer Induced Phase Separation (STrIPS), a straightforward technique for generating bijel fibers with asymmetric oil/water channels of micrometer dimensions.[2] Our current work has advanced STrIPS to generate bijel fibers with submicron sized oil/water channels of high uniformity. Surface tension and contact angle measurements are employed to rationalize the structure formation mechanisms. The uniform channels are found to enhance the mechanical strength and elasticity of STrIPS bijels, as determined by microfluidic in-situ mechanical testing.[3] Last, we investigate electroosmotic flow by monitoring dye propagation within the bijel fibers. Electroosmotic flow with speeds of up to 1 cm per minute is observed in the bijels by increasing the voltage and the nanoparticle surface charge. We report our research as a major step towards employing bijels as media for multiphasic processes with potential applications in Pickering interfacial catalysis and as cross-flow microreactors.

Optical Sorting of Droplets and Particles by Optical Radiation Pressure Runa Sugimoto1,2 and Satoru Shoji1,2;
Recently, centrifugation and chromatography are commonly used to sort micro/nano particles. These methods allow us to sort particles by mass difference or size difference. In this presentation, we propose another particle separation method, in which particles are sorted by the difference of optical properties. For this purpose, we use optical radiation pressure. When laser light is launched onto small particles, the particles scatter the light, the particles are received impulse exerted as reaction. This optical force is usually very small, in the order of a few pN, and this force is called optical radiation pressure. Since the cause of the pressure is scattering of light, the magnitude of optical radiation pressure depends on optical scattering efficiency of particles. To utilize this dependence to sort particles, we built a simple optical system, consisting of a glass microcapillary and laser. First, we filled the glass capillary with an aqueous suspension of particles. Then we focused laser light from the tip end. The laser light traveled into the tube by waveguide mode toward the opposite end. The particles floating in the capillary were pushed by optical radiation pressure. The particles moved in the capillary with different speed. In the experiment, we used Nd:YVO4 laser light emitting at 1064 nm. The inner and outer diameter of the capillary are 20 µm and 25 µm, respectively. To prevent temperature rising, we used heavy water for the dispersant. The motion of these materials was observed by a bright field optical microscope from the side of the capillary. We investigated 3 types of micro/nano particles, milk fat/water emulsions, polystyrene microspheres, and multi-walled carbon nanotubes. We observed the transport speed varied in material. We also show experimental results of sorting milk fat/water emulsions and polystyrene sphere.

Sequential Bottom-Up Assembly of Synthetic Cells Joachim P. Spatz and Oskar Stauffer; Max Planck Institute for Medical Research, Germany

The evolution of cellular compartments for spatially and temporally controlled assembly of biological processes was an essential step in developing life by evolution. Synthetic approaches to cellular-like compartments are still lacking well-controlled functionalities, as would be needed for more complex synthetic cells. With the ultimate aim to construct life-like materials such as a living cell, matter-to-life strives to reconstitute cellular phenomena \textit{in vitro} – disentangled from the complex environment of a cell. In recent years, working towards this ambitious goal gave new insights into the mechanisms governing life. With the fast-growing library of functional modules assembled for synthetic cells, their classification and integration become increasingly important. We will discuss strategies to reverse-engineer and recombine functional parts for synthetic eukaryotes, mimicking the characteristics of nature’s own prototype. Particularly, we will focus on large outer compartments, complex endomembrane systems with organelles and versatile cytoskeletons as hallmarks of eukaryotic life. Moreover, we identify microfluidics and DNA nanotechnology as two highly promising technologies which can achieve the integration of these functional modules into sophisticated multifunctional synthetic cells.

From Long-Term Stability to Ultrafast Dynamics of Pickering Bubbles Valeria Garbin; Imperial College London, United Kingdom

Solid particles can adsorb at fluid-fluid interfaces, much like molecular surfactants. Unlike molecular surfactants, however, the adsorption of solid particles can be considered to be irreversible, due to a large capillary energy associated with adsorption. As a result, solid particles can be used to stabilise drops and bubbles. Remarkably, particle-stabilised bubbles (Pickering bubbles) are found to be indefinitely stable, because the particle monolayer can arrest bubble dissolution, which is otherwise driven by the Laplace pressure. I will present two phenomena, discovered in our laboratory, which occur when particle-stabilised bubbles are subjected to changes in temperature or pressure. We found that a decrease in temperature destabilises particle-coated microbubbles in water beyond dissolution arrest. A simple model describing the effect of the change in temperature on mass transfer suggests that the dominant mechanism of destabilization is the increased solubility of the gas in the liquid. We can also drive particle-stabilised bubbles into periodic compression-expansion at 10-100 kHz by ultrasound forcing. This causes ultrafast deformation and microstructural changes in the particle monolayer. For large-amplitude forcing, the compression of the interface leads to particle expulsion, and we have uncovered different expulsion scenarios depending on the mode of bubble deformation, including highly directional patterns of particle release during non-spherical oscillations. For small-amplitude driving, we have observed the formation of a transient microstructure -- a
network of strings -- which is consistent with anisotropic interparticle interactions. By comparing the experimental results with the predictions of particle-based simulations, we have found evidence of dynamic capillary interactions resulting from the deformation of the interface due to the non-negligible inertia of the colloidal particles at the extreme accelerations caused by ultrasonic forcing.

10:45 AM SB11.04.05
The Vibration Behavior of Submicron Gas Vesicles in Response to Acoustic Excitation as Determined via Laser Doppler Vibrometry An Huang¹, Shuai Zhang¹, Avinoam Bar-Zion², Jiaying Wang¹, Oscar Mena¹, Mikhail Shapiro² and James Friend¹; ¹University of California San Diego, United States; ²California Institute of Technology, United States

Gas vesicles (GVs) are remarkably stable nano-sized gas-filled protein shells proven effective in ultrasonic imaging, especially in traditionally difficult, small-scale vasculature and interstitial spaces around tumors. The many potential benefits of GVs arise from their strong gas equilibrium at a submicron size as produced by bacteria or algae from a known genome, producing significant contrast in ultrasound imaging. The actual vibration behavior of GVs, including buckling and collapse, is poorly understood since the GVs are too small for observation methods of sufficient speed to produce details of the GV deformation during exposure to ultrasound. Traditional optical or acoustic microscopy methods are, in any case, not useful, and ex-situ transmission electron microscopy produces useful images but without sufficient time resolution.

We propose to instead use laser Doppler vibrometry (LDV) to observe the vibration behavior of GVs. Employing interferometry, LDV offers a far better spatiotemporal resolution, in our case up to 2.4 GHz in frequency and as little as 200 fm in surface displacement over a spot size of 1 µm. While the typical GV is smaller than 1 µm, an agglomeration of GVs may be used with the LDV to produce a measurable displacement response from a controlled, acoustically-delivered pressure. In this talk, we report the fundamental and first harmonic resonance frequencies of GVs at 1.02 GHz and 1.70 GHz, interparticle resonances at ~300 MHz, and vibration to buckling and collapse at the clinically relevant frequency of 6.5 MHz. We also compare these results with predictions from classic theories of bubble and particle oscillations and finite difference-based computations.

Closed Cellular Structure from Monodispersed Graphene Bubbles for Ultralight, Strong and Superelastic Materials Min Jun Oh¹, Seon Ju Yeo², Hyun Min Jun¹, Minhwan Lee³, Jung Gun Bae³, Yeseul Kim¹, Kyung Jin Park⁴, Seungwoo Lee⁵, Daeyeon Lee⁶, Byung Mook Weon¹, Won Bo Lee¹, Seok Joon Kwon⁷ and Piljin Yoo¹; ¹Sungkyunkwan University, Korea (the Republic of); ²North Carolina State University, United States; ³Seoul National University, Korea (the Republic of); ⁴Kyung Hee University, Korea (the Republic of); ⁵Korea University, Korea (the Republic of); ⁶University of Pennsylvania, United States; ⁷Korea Institute of Science and Technology, Korea (the Republic of)

The design of well-controlled three-dimensional (3D) structures from individual building blocks such as graphene nanosheet or carbon nanotube has technological and scientific importance since it can provide advanced physical properties compared to their bulk counterparts. In particular, for a number of practical applications including electrode, supercapacitor, sensor, fluid absorber, energy damping, thermal insulator and catalysis, it is essential to fabricate well-defined 3D graphene structures with high surface area. While progress toward creation 3D porous graphene materials, previous efforts have placed severe restrictions on their wide-spread utilization because it is hard to create regularized and ordered structures with controlled dimensions, shapes, and morphologies. To overcome these challenges, we investigated multiphasic fluid mixtures such as emulsions droplets as alternative templates for generating well-defined 3D structures. This study uses a hierarchical design approach starting from the functionalized graphene oxide nanoplatelets at the molecular- and nanoscale, leading to the microfluidic fabrication of solid bubbles at the microscale. Then, generated graphene microbubbles are assembled into centimeter-scale 3D structures. Importantly, these assembled structures are self-interconnected into completely space-filled and reinforced closed-cellular structure. The 3D graphene structure exhibits the Young’s modulus above 177 kPa with a light density of 4.67 mg cm⁻³ and structurally stable up to 87% of the compressive strain benefiting from systematic stress dissipation through the complete space-filled closed-cellular structure. The method opens a new horizon for designing lightweight, strong, and superelastic properties.

11:15 AM SB11.04.07
Tuning the Properties of Infrared-Absorbing Nanofluids for Microfluidic Applications Urice Tohgha¹,² and
The transport and actuation of droplets in microfluidic-based devices strongly relies on the properties of the fluids. Nanofluids (fluid-containing nanomaterials) offer an appealing approach to modulate key fluid properties such as conductivity, viscosity and interfacial tension which directly impact the wettability on various surfaces. This approach also has the added advantage of utilizing the optical properties of the nanomaterial for microfluidic-based optoelectronic applications such as reflective displays as well as photodetectors. Nanofluids comprising IR-absorbing nanofluids have been less explored and also pose colloidal stability challenges. We will present our results on the engineered properties of nanofluids comprising Ag$_2$Se, PbS and SnTe semiconductor nanoparticles in different solvent systems. The study highlights the synthesis of nanoparticles with surface ligands capable of significantly altering the conductivity and interfacial tension of nanofluids. This work uses electrowetting (droplet actuation through voltage application) in a biphasic system to probe the wettability of the different nanofluids by evaluating the changes in droplet contact angle on a dielectric surface. We show unique spreading characteristics of nanofluids in non-aqueous (Dimethyl sulfoxide and Dimethylformamide) and aqueous dispersion media. The work presented will certainly shed more light on the use of nanofluids in microfluidic-based devices and the properties of nanoparticles in aqueous and non-aqueous media.
phase behaviors and mechanical properties. We demonstrate that this gelation platform is general and robust over a wide range of composition, colloid size and component chemistry. By carefully characterizing the colloids and obtaining a mechanistic understanding of their response, we construct the interparticle potential and explain trends in material behaviors. This stimulus-responsive gelation platform is general and offers new strategies to engineer complex viscoelastic soft materials.

2:15 PM SB11.05.03
Connecting the Viscoelastic Response of Nanosheet Gels to the Elastic Properties of the Particles  
Sebastian Barwich and Matthias Möbius; Trinity College Dublin, Ireland

Micron-sized nanosheets such as graphene or MoS₂ platelets can be used to make conducting inks or as fillers in composites to enhance their mechanical properties. At high concentrations beyond rigidity percolation, nanosheet suspensions become yield stress fluids with a finite storage modulus. In this regime the elastic response of nanosheet suspensions appears to be universal. The storage modulus plateau of few-layer graphene in NMP solvent [1] and aqueous graphene oxide gels [2] exhibit a power law exponent close to 3 as a function of packing fraction.

We present a new analytical model that explains this behaviour and connects the bulk response to the elastic properties of single nanosheets and their size. We infer the bending stiffness of single nano-sheets from our rheological data which agrees well with previous AFM experiments on single sheets and simulations. This model opens up the possibility to infer elastic properties of different nanosheets from rheological data of the suspension rather than performing AFM experiments on single nano-sheets. Furthermore, this model may explain the mechanical enhancement of nanosheet composites where a similar exponent can be observed [3].

Anomalous Compliance of Structured Liquids  
Yu Chai¹,²,³, Alysia Lukito³, Jaffar Hasnain³, Anju Toor³, Wenqian Feng¹,², Yufeng Jiang¹,³, Joe Forth², Yanhui Tang¹, Honghao Hou², Teresa Williams¹, Ravi C. Chintala¹, Dong Li¹, Philip Geissler³, Brett A. Helms¹,², Thomas Russell²,⁴,⁵ and Paul Ashby¹,²; ¹Lawrence Berkeley National Lab, United States; ²Lawrence Berkeley National Laboratory, United States; ³University of California, Berkeley, United States; ⁴University of Massachusetts Amherst, United States; ⁵Beijing University of Chemical Technology, China

The jamming of nanoparticle surfactant assemblies at liquid-liquid interfaces enables the generation of persistent liquid in liquid structures or Structured Liquids. In general, increasing the binding strength of the individual nanoparticles to the interface leads to an increase in the stiffness of the assemblies. However, we observe a region of anomalously low compressive stiffness as nanoparticle binding energy is increased. We use a combination of tensiometry and in-situ AFM to reveal that the mechanism of anomalous stiffness is surfactant molecules surrounding nanoparticles at the interface without phase transfer which facilitates nanoparticle-nanoparticle interactions normal to the plane of the interface leading to facile multilayer formation. This region of anomalous stiffness expands the parameter space for the creation of complex shapes of structured liquids.

3:30 PM SB11.05.06
Smart Microcapsules with Molecular-Polarity-Selective and Temperature-Dependent Permeability  
Ji-Won Kim¹, Sang Seok Lee², Jinho Park³, Minhee Ku³, Jaemoon Yang³ and Shin-Hyun Kim¹; ¹Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); ²Korea Institute of Science and Technology, Korea (the Republic of); ³Yonsei University, Korea (the Republic of)

Cells, the building blocks of life, are enclosed with semi-permeable membranes. The membranes protect important genetic materials from surroundings while selectively allowing the transmembrane transport of molecules. This
molecule-specific permeation is of great importance in cell growth and cell-to-cell communications. Inspired from the cell membrane, microcapsules with molecular size- or charge-dependent permeability have been developed using the membranes with consistent pore sizes and surface charges. Beyond these simple regulations of transmembrane transport, here, we suggest a new microcapsule with molecular polarity-selective permeation whose rate is further adjustable with temperature. Highly monodisperse microcapsules are produced using a microfluidically-prepared template of water-in-oil-in-water (W/O/W) double-emulsion drops. As the middle oil phase of the double-emulsion drops, we use a ternary mixture of photocurable triacrylate monomer, phase change material (PCM), and molecular compatibilizer. Upon UV irradiation on the drops, the monomer forms a polymeric shell and the liquid PCM fills the voids of the polymeric framework. The molecular compatibilizer, composed of acrylate group and PCM-like moiety, prevents the macrophase separation between the polymer and PCM, maintaining a homogenous shell at sub-10 nm scale. As the PCM forms the continuous nanochannels across the shell, the molecules that are soluble in the liquid PCM can diffuse through the channels above the melting point of PCM. By contrast, the molecules insoluble in the PCM are rejected from the microcapsules. The rate of permeation through the shell depends on the partition coefficient of the molecules in the PCM relative to water. As a less polar molecule has a higher partition coefficient, it shows faster permeation. The rate of permeation can be further adjusted by temperature. When the temperature drops below the melting point of PCM, the solubility dramatically decreases, resulting in the significant retardation of permeation. Therefore, the microcapsules provide molecular polarity-selective and temperature-dependent permeability whose threshold values are adjustable by the selection of PCM. As the polymeric framework and PCM form a homogeneous shell in the presence of molecular compatibilizer, PCM is preserved in the shell during temperature swing below and above the melting point, enabling the reversible change of permeability. This advanced transmembrane regulation provides a new opportunity for microcapsules as drug carriers, microsensors, and microreactors. For example, the microcapsules can be used as an injectable and implantable drug carrier that releases relatively hydrophobic drugs in a sustained fashion when the body temperature rises above the melting point of PCM as we verified through in-vitro and in-vivo experiments.

New Materials for Spatiotemporal Control of Jamming via Photo-Actuation Nicholas Vishnosky and Rachel Steinhardt; Syracuse University, United States

Many materials consist of soft particles at or below the jamming transition. However, we incomplete understanding of the relationship between material properties—such as rheology— and microstructure. To aid in this study of soft materials, we have created an experimental tool that enables spatiotemoral control over jammed microstructure. The composite has a photo- triggered jamming transitions, so we can direct what micro-regions of the materials are jammed. We have characterized the properties of this material on multiple length scales. This tool assists in the quantitative assessment of individual microstructural elements to the bulk material rheology, and may aid in the design of new soft materials.

4:00 PM SB11.05.08
Structural Coloration from Multiple Total Internal Reflections at Complex Emulsion Concave Interfaces Amy Goodling1, Sara Nagelberg2, Bryan Kaehr3, Caleb Meredith1, Seongik Cheon1, Ashley Saunders1, Mathias Kölle2 and Lauren D. Zarzar1; 1The Pennsylvania State University, United States; 2Massachusetts Institute of Technology, United States; 3Sandia National Laboratories, United States

Structural color is created by the interaction of light with physical structures and is most commonly seen in hard materials with high refractive index contrast and nanoscale periodicity such as diffraction gratings or photonic crystals. Developing methods to harness structural color in soft materials at larger length scales, such as in droplets, would enable use of such coloration mechanism for more diverse applications such as sensors, camouflage, or displays. Recently, we have observed tunable structural coloration from microscale concave interfaces of oil-oil complex droplets suspended in an aqueous surfactant solution. We were able to model the observed color and found that this effect was from light propagating by TIR along the interface can have different numbers of reflections and thus different path lengths which leads to interference and iridescent color. The requirements to achieve this effect include a transition from a high to low refractive index and a microscale geometry to support multiple TIR, allowing generation of structural color in a multitude of different materials and geometries and by diverse fabrication methods. For example, we have generated this effect in complex liquid droplets, solid particles, water drops condensed on substrates with low wettability, and solid elastic surfaces. With a light responsive surfactant, we were able to pattern reflective colored images in complex emulsions by stabilizing droplets of varying shape. These
simple geometric requirements provide new opportunities for fabricating, designing, and controlling structural color, enabling use of such structural coloration in materials where it previously would have not been possible.

SESSION SB11.06: Active Matter

Anisotropy in Action—Harnessing Emergent Dynamics in Flowing Anisotropic Matter Anupam Sengupta;
University of Luxembourg, Dept. of Physics and Materials Science, Luxembourg

Anisotropy, the ability of partially ordered materials to respond directionally to a stimulus, is key to the dynamics and functions in living systems. From transporting signalling molecules within cells to transmitting mechanical stresses within growing bacterial colonies, anisotropy underpins the physics of living matter. Outside biological systems, liquid crystals (LCs) – formed typically by locally oriented low-molecular-weight rod-like molecules – offer an experimentally tractable system within which the fundamentals of anisotropic interactions can be precisely tuned and studied. In my lab, we harness this setting to, on the one hand, understand the fundamentals of anisotropic cross-talks between bio-relevant fluids and cues, and on the other hand, apply this knowledge to uncover the dynamics of real living systems. During this talk, I will allude to this iterative learn-apply-n-learn strategy to showcase how topological defects emerge within biological systems, regulate their micro-environment, and thereby tune the local material, transport, and mechanical attributes. Analysing living matter as emergent systems where anisotropy mediate evolutionarily well-timed biological functions, introduces a novel, yet general, mechanistic framework applicable for disparate biological systems. I will conclude by discussing how our ability to harness anisotropy – in action across disparate material fields – could have meaningful implications, from designing novel materials to exploring open questions in biology and translational medicine.

9:00 AM SB11.06.02
Nonreciprocal Chasing Interactions in Active Emulsions Caleb Meredith1, Pepijn Moerman2,2, Yu-Jen Chiu1, Jan Groenewold2, Willem Kegel2, Alfons van Blaaderen2 and Lauren D. Zarzar1; 1The Pennsylvania State University, United States; 2University of Utrecht, Netherlands

Emulsions stabilized with surfactants above the critical micelle concentration undergo solubilization as oil from droplets is transferred into the micellar phase. Concentration gradients of solubilize species can create interfacial tension differences across droplets leading to their movement via the Marangoni effect. We explore how long-ranged interactions between solubilizing oil droplets occur due to the overlap of their continually maintained solute profiles to generate active behavior. Mixing droplets of different oils under various surfactant conditions we observe unique nonreciprocal interactions which lead to chasing between droplets and drive their self-assembly into clusters with dynamic but predictable motions. We show how the underlying interactions are caused in part by oil exchange between droplets via oil-filled micelles. Control over droplet interactions and the directional exchange of chemical components can be utilized in the design of tunable active multiphase fluid systems with the ability to self-organize, adapt to environmental stimuli, or carry out self-regulated reactions.

9:15 AM SB11.06.03
Self-Propulsion of Small Droplets on Thin Oil Films Victor Leon and Kripa Varanasi; Massachusetts Institute of Technology, United States

Surfaces that prevent the adhesion of and remove droplets have received significant attention in the context of self-cleaning, anti-icing, and anti-fouling surfaces. Superhydrophobic surfaces offer a passive solution; however, they are susceptible to Cassie-to-Wenzel transition and depend on gravity to move the droplets. Active droplet manipulation has also been explored using electric, magnetic, and vibrational fields, but such technologies have difficulties with surface pinning and viscous liquids. In this context, systems in which droplets self-propel are promising avenues to remove contaminants from surfaces.
Here, we investigate the self-propulsion of small droplets of radii at and below the capillary length on heated thin oil films. At film temperatures above the boiling point of the droplet and low film viscosities, we observe that droplets can propel at velocities up to 16cm/s. The propulsion of the droplet originates from the asymmetric release of vapor from beneath the boiling droplet, propelling the droplet towards the edges of the substrate. Studies of film parameters, such as film oil, temperature, viscosity, and thickness, were conducted. Additionally, the effects of surface geometry and texture were explored. The droplet velocity was found to have the greatest dependence on film oil, temperature, and viscosity. We predict the droplet velocities using a model that balances the viscous dissipation in the oil film with the momentum of the vapor ejected from beneath the boiling droplet. Within our experimental range, the simple model accurately predicts droplet velocities at a variety of oil film thicknesses, oil viscosities, oil temperatures, and droplet radii.

9:30 AM *SB11.06.04
Understanding Sperm Navigational Mechanisms to Improve Assisted Reproductive Technologies Alireza Abbaspourrad; Cornell University, United States

The fertilization process in mammals as sperm traverse towards the fertilization site where the oocyte has been released. In the case of marine animals and plants, which release gametes into the sea, the motion of sperm occurs in a vast aquatic environment. In contrast, the fertilization process of mammals happens inside a complex environment known as the “female reproductive tract”. The intriguing, multifaceted question is, how do healthy sperm naturally navigate the correct path towards the fertilization site? And concurrently, how does the female reproductive tract select for the best sperm while they move towards the oocyte. Since performing in vivo studies to answer these questions is difficult and faces many technical and ethical issues, designing in vitro environments that mimic at least one facet of female reproductive tract is vital.

In the last two decades, “microfluidics”, with its high and unprecedented precision of preforming studies on microswimmers and active matters in microenvironments, has enabled us to study the navigation strategies of mammalian sperm. Although the journey of mammalian sperm is many-sided and includes complex biological and chemical processes, studying the motion of sperm in microfluidic geometries, and under fluid flows that mimic the biophysical aspects of the sperm swimming channel in vivo, is critical. These studies will reveal new insight about the physical and fluid-mechanical clues provided by the female reproductive tract to facilitate sperm navigation towards the fertilization site.

The fluid-mechanical clues that enable mammalian sperm to swim along a correct path towards the fertilization site include the upstream swimming of the sperm in a simple, shear flow known as “rheotaxis”. Furthermore, the hydrodynamic interactions of sperm with nearby rigid boundaries is another navigation mechanism that is referred to as “boundary-dependent navigation”. We have performed studies on the fluid-mechanical navigation of the mammalian sperm as well as the influence of specific, geometrical features on the sperm locomotion. To study the sperm navigation in a geometry that mimics the shape of “uterotubal junction”, which is a narrow junction at the beginning of fallopian tube, we designed a microfluidic stricture and studied the sperm locomotion under a simple shear flow. We discovered that such junctions select for highly motile sperm that can pass through the stricture while the slower sperm accumulate before the stricture. Therefore, a microfluidic stricture functions as a fluid-mechanical gate. The accumulation before stricture occurs in a hierarchical manner so that the competition is fiercest among sperm with the highest motility. To study the role of flagellar beating pattern on the sperm navigation, we first studied the flagellar beating pattern of sperm discovering a zeroth harmonic in the spatially asymmetric beating of the flagellum. This asymmetric beating creates a net torque and, thus, rotational components in the motion of sperm. We discovered that this zeroth harmonic, and asymmetric beating, impairs the boundary-dependent navigation while rheotaxis is less dependent on flagellar beating pattern.

To use our basic understanding of the sperm locomotion for such medical applications, we also have designed a microfluidic, rheotaxis-based sperm separation method. The microfluidic sperm separation techniques are sought-after for assisted reproductive technologies and infertility treatment as they are passive and operate without exertion of external forces. These efficient methods, accordingly, provide sperm with less DNA fragmentation. Our “microfluidic corral system” is a passive technique that only isolates progressively motile sperm with motilities higher than a tunable cut-off value.

10:00 AM BREAK
We will present a number of strategies for using multiphasic liquid-liquid-polymer systems to make a rich variety of colloidal structures and materials. The capillary forces originating at the liquid/liquid interfaces can serve for reconfigurable binding in soft matter systems, including Pickering emulsions, novel responsive capillary gels, and compositions for 3D printing. We will first present responsive structures made of filaments from lipid-coated magnetic nanoparticles suspended in water-oil systems. The nanocapillary binding results in ultra-high filament flexibility. As an example of the application of such structures, we will discuss the development of new 3D printing inks consisting of water, crosslinked PDMS microbeads and liquid PDMS phase. These Homocomposite Thixotropic Pastes (HTPs) can be directly extruded and shaped on a 3D printer. The curing of the PDMS bridges yields remarkably elastic, flexible and biocompatible structures. The HTP-3DP inks enable the 3D printing of “active” and magnetically reconfigurable structures. In alternative materials synthesis approach the liquid/liquid droplet interfaces can template the formation of a variety of polymer nanomaterials, including nanoparticles, nanofibers, nanoribbons, microrods, and microsheets. This allowed us to introduce a new class of soft dendritic polymer microparticles (“dendricolloids”) with hierarchical morphology similar to molecular-scale polymer dendrimers, but two orders of magnitude larger in scale. The polymer particles with branched and fractal morphology are fabricated by a simple and scalable process of interfacial polymer precipitation in turbulently sheared liquid media. The dendricolloids combine the properties of two of the most fascinating and studied soft matter systems – the freely-suspended dendritic particles have very large excluded volume, while in contact their nanofiber corona possesses the highly adhesive abilities of the nanofiber-padded gecko legs. The fractal branching and contact splitting phenomena of the dendricolloids enable a range of highly unusual properties – gelation at very low volume fractions, strong adhesion to surfaces and to each other, and ability to bind strongly and form coatings, nonwoven sheets, and ultrasoft membranes.

Visible light driven nano/micro swimmers are promising candidates for potential biomedical and environmental applications. However, the previously reported mean squared displacement (MSD) values are low, typically in the range of up to 200 µm² (when measured over 10 s), even under the favourable UV light illumination.[1,2] This is a severe drawback for the applications where the efficient transport of micromotors within a vessel is demanded.

Here, we demonstrate Ag/AgCl-based spherical Janus micromotors that reveal an efficient propulsion under visible blue light illumination.[3] The proper design of an Ag/AgCl-based micromotor can boost the MSD to a remarkable value of 3000 µm² (over 10 s) in pure H₂O, even when activated with blue light (excitation λ = 450-490 nm). The revealed propulsion of micromotors owns a dependence of the intensity of visible light, which is contributed by the couple plasmonic light absorption of Ag/AgCl and the efficient photochemical decomposition of AgCl. With the motion comparisons of individual Janus particle, small cluster, and large cluster, the effect of suppressed rotational diffusion has been revealed experimentally and in numerical simulations. Furthermore, we show that Ag/AgCl-based Janus micromotors reveal efficient exclusion effect to their surrounding passive polystyrene (PS) beads in pure H₂O.[4] The exclusion efficiency is controlled by the number of single Janus PS/Ag/AgCl particles that compose a cluster. Using numerical simulations of the Langevin equations, we gain a fundamental understanding not only the diffusion constants, but also the system-specific interaction parameter between Janus motors and passive beads.
Tuning Synthetic Active Matter—From Living Clusters to Liquid Swarms Paul Dommersnes and Jon O. Fossum 1,2; 1Norwegian University of Science and Technology, Norway; 2Institut Pierre-Gilles de Gennes (IPGG), ESPCI, France

Biological active matter, such as populations of cells and animals, often change between different swarming states. One example is shoaling, milling and schooling fish. Synthetic active matter consist of self-propelled inanimate units and emulates biological active matter. We combine electric field induced attraction with electro-rolling propulsion [1] in a population of granular beads. A variety of swarming regimes is realized: living crystals and clusters, a stripe phase of clusters, and polar liquid swarms, reminiscent of transitions in active matter simulations [2,3,4]. Remarkably, the crystal to liquid transition occurs at a different velocity threshold than the local to global polar order transition. The stripe phase is reminiscent of those in quasi two-dimensional matter with competing interactions. The system links universal patterns in biological and synthetic active matter, and can open new routes for tuning self-assembly in soft matter technologies.

controlled topologies, as vesicle templates. In particular, we show the utility of water-in-oil-in-water (W/O/W) double emulsion drops with ultrathin middle oil layers as templates to fabricate vesicles exhibiting either phase separations in the vesicle cores or domains in the vesicle membranes [1,2]. We also show the utility of W/O/O/W triple emulsion drops with two ultrathin middle oil layers as templates to fabricate vesicles with asymmetric membranes [3]. Both approaches have high encapsulation efficiency and yield vesicles with monodisperse sizes, owing to the size monodispersity of the emulsion drops used as templates. Furthermore, coupling microfluidic vesicle production techniques to confocal fluorescence microscopy observations enables the accurate determination of both the composition of phase-separated compartments in the vesicle cores and the degree of asymmetry in the vesicle membranes.

Engineering Compartments in Cells Using Complex Coacervation of Supercharged Proteins Jouwen Wang, Vivian Yeong and Allie Obermeyer; Columbia University, United States

Complex coacervation is a well-studied liquid-liquid phase separation phenomenon between oppositely charged polyelectrolytes. Recently, it has been appreciated that complex coacervation likely plays a role in the formation and function of membraneless organelles in eukaryotic cells. For example, polyanionic RNA can condense with cationic intrinsically disordered regions of proteins to form membraneless organelles such as nuclear bodies. Here we investigate how liquid-liquid phase separation via complex coacervation can be engineered from the ground up. Using protein engineering the overall charge and charge distribution on model fluorescent proteins was systematically varied. In particular, this study explores the impact of GFPs with different supercharged tags on the formation of protein complex coacervates in vivo. GFP variants with the same net charge but different charge distributions were expressed and their intracellular localization was monitored by optical microscopy. We found that GFP variants with positively charged tags can form a condensed phase in E. coli, and this condensed phase has many of the properties of a complex coacervate. In summary, we have identified several supercharged amino acid tags that can promote liquid-liquid phase separation of proteins of interest intracellularly. This finding can be applied to engineer intracellular complex coacervation to form artificial membraneless organelles.

3:45 PM SB11.07.04
Marangoni Flows Drive the Alignment of Cell-Laden Collagen Hydrogels During Self-Assembly Bryan A. Nerger, Pierre-Thomas Brun and Celeste Nelson; Princeton University, United States

Type I collagen is a self-assembling protein that generates fibrous viscoelastic networks. In the body, cell-laden networks of collagen are remodeled to generate anisotropic fiber networks that can impact biological processes as diverse as cancer cell invasion and vascular network formation. Despite this ubiquity, fabricating cell-laden networks of aligned collagen fibers ex vivo remains challenging. Here, we use Marangoni flows in evaporating sessile droplets of monomeric collagen to fabricate cell-laden networks of aligned type I collagen fibers. Using time-lapse confocal reflection microscopy, we find that Marangoni flows give rise to radial flow in the evaporating droplet, which orients collagen fibers radially over mm-scale areas. Our data suggest that the resulting collagen fiber alignment depends on the relative humidity and the rate of collagen fiber self-assembly. Moreover, we found that the pattern of collagen fiber alignment can be tuned by changing the geometry of the droplet. By incorporating mammalian cells into evaporating droplets, we generate cell-laden collagen hydrogels that can be used for cell culture. We observe that cells collectively orient in the direction of collagen fiber alignment. Marangoni flow is a simple, rapid, and scalable approach that can be used to generate fibrillar cell-laden collagen hydrogels with broad applicability.
Molecular Communication between Synthetic Cells Friedrich Simmel; TU Munich, Germany

Exchange of molecular signals is essential for the coordination of cell behaviors in cellular consortia and tissues. This, in turn, enables the development and organization of large multicellular structures of higher complexity than typical single-celled organisms.

In recent years, a variety of attempts have therefore been made to emulate such communication processes in the context of artificial cells – e.g., to divide tasks between specialized synthetic organelles or for the creation of artificial tissue-like materials.

In this talk, we will present several examples, in which compartments containing chemical reaction systems and gene circuits communicate with each other via the exchange of molecular signals – e.g., on-chip gene expression, gel-based organelles that exchange RNA molecules, or emulsion droplets that communicate via small molecules.

SB11.08.01
Electrochemical Generation of Supercooled Microdroplets Nian Liu and Po-Wei Huang; Georgia Institute of Technology, United States

Since the first discovery of supercooling in 1724, the study of supercooled matter has been mainly limited to varying temperature or pressure. Early this year we have demonstrated an electrochemical approach to generate supercooled sulfur and observe the dynamic process in situ (see Publication 1 below). Our methodology combines dark-field optical microscopy, a transparent electrochemical cell, and a fast camera to visualize the process at single microdroplet with millisecond time resolution. This platform may open up opportunities for studying supercooled liquids as the droplets approach either homogeneous nucleation to the crystalline state or enter into the glass transition. The sulfur droplets remain liquid at 155 °C below sulfur’s melting point (Tm = 115 °C), with fractional supercooling change (Tm − Tsc)/Tm larger than 0.40. In operando light microscopy captured the rapid merging and shape relaxation of sulfur droplets, indicating their liquid nature. Micropatterned electrode and electrochemical current allow precise control of the location and size of supercooled microdroplets, respectively. Using this platform, we initiated and observed the rapid solidification of supercooled sulfur microdroplets upon crystalline sulfur touching, which confirms supercooled sulfur’s metastability at room temperature.

In a follow-up work (see Publication 2 below), we expanded the above methodology to generate polybromide droplets, which is the charge product in zinc-bromine flow batteries, a promising technology for stationary energy storage. The liquid behavior was also confirmed by rapid merging and shape relaxation. The results provide insights into the future design of zinc-bromine flow batteries.

This presentation is based on the following two recent publications from my lab:

Controlling Shape Changes and Interactions within Nanogel Arrays at Liquid-Liquid Interfaces Vaibhav A. Palkar, Chandan K. Choudhury and Olga Kuksenok; Clemson University, United States

Nanogels at liquid-liquid interfaces are used for applications ranging from emulsion stabilization to interfacial catalysis and enhanced oil recovery. We present herein a dissipative particle dynamics (DPD) approach to model dynamics of polyacrylamide (PAAm) hydrogels at the oil/water interface. To develop the model, we first compare hydrogel swelling dynamics to continuum theory. We compare the distribution of end to end distances of polymer
chains within a swollen hydrogel network to the Gaussian model predicted for polymers in a theta solvent. Next, we compare equilibrium swelling volume fraction of gels measured from the DPD simulations to continuum Flory-Rehner theory. Using this equilibrium swelling volume fraction, we estimate the elastic moduli of our model hydrogels to be within the range observed in experiments. Having established these comparisons, we next focus on the shape changes of the hydrogel as it adsorbs from the aqueous phase onto the oil/water interface. The nanogel undergoes reshaping and adopts several morphologies from spherical to pancake. We highlight the competition between interfacial energy (which tends to deform the gel) and the gel’s elastic energy (which opposes this deformation). We also investigate spreading dynamics and interactions of nanogel arrays initially placed in the aqueous phase. We investigate conditions at which saturation of the interface with these gels forces protrusion of gels into the aqueous phase. These findings provide data for optimizing the design of PAAm-based nanogels for various applications.

Droplet Manipulation for the Synthesis of Anisotropic Nanoparticles with Controlled Morphology Abhiteja Konda1,1, Ryan Dohn2, Rebecca Back2, Tijana Rajh1 and Anindita Basu2,1; 1Argonne National Laboratory, United States; 2The University of Chicago, United States

Anisotropic nanoparticles have gained significant interest in the past decade due to their enhanced properties (both physical and chemical). These properties can be tuned and are dependent not only on their size and morphology, but also on their composition. The use of anisotropic nanoparticles for enhanced surface plasmon resonance (SPR) effect is widely studied. In the present work we use droplet-based microfluidics for the synthesis of anisotropic gold nanoparticles (a-AuNPs) for applications in biology based on its SPR effect. Specifically, we use the Pico injection (a technique of introducing picolitre volume reagents into droplets by the application of electric field that destabilizes the surfactant in the droplets and thereby allowing the addition of the new solution) for the controlled synthesis of a-AuNPs. While there are several other potential applications for these a-AuNPs, we are interested in using these for the lysis of microbial cells in single-cell sequencing experiments. The current single-cell techniques predominantly focus on multicellular organisms and cannot be readily transferred to unicellular organisms due to the differences in their size and composition. The microbial cells are small (~1 μm) with concomitantly small amount of RNA and have a tough, adaptive cell wall that permits their survival in harsh environments (extreme pH or temperatures, anti-microbials, etc.); these characteristic features of the microbes together make their lysis challenging. Here, we use the a-AuNPs and their SPR effect (induced by laser irradiation) to achieve micron-scale heating when attached to the cell wall and thereby its lysis by disrupting the cell wall. Once lysed, the single-cell lysates will be sent for high-throughput single-cell RNA sequencing. Single-cell sequencing of microbial cells is critical in addressing some of the challenges in medicine and other environmental engineering applications.

Temperature-Dependent Pattern Formation in Drying Aqueous Drops of Lysozyme Anusuya Pal1, Amalesh Gope2 and Germano Iannacchione1; 1Worcester Polytechnic Institute, United States; 2Tezpur University, India

Drying bio-colloidal drops have a wide range of applications from medical diagnostics to industries as the patterns at the dried state can be linked to the nature of the constituent particles. The drying process and the resulting patterns are found to be affected by the atmospheric conditions including temperature, humidity, and so on. It, therefore, demands a detailed investigation to understand the nature of atmospheric conditions on the drying states. Lysozyme is a well-known globular protein, and preparations of lysozyme in de-ionized water make the simplest bio-colloid which could be used to explore the atmospheric effects on the drying states. During the drying process, a drop containing lysozyme particles gets pinned to the substrate and undergoes a convective flow. In the next stage, a fluid front recedes in a stick-slip manner and deposits particles from the periphery to the central region of the drop. The particles get redistributed during the fluid front movement; form a "coffee-ring", and finally result in crack patterns like other bio-colloids. A mound-like structure which forms in the central region is believed to be the leftover lysozyme particles flowed along with the fluid front. It is considered as a fingerprint for any aqueous lysozyme drop. In this experimental work, the time evolution and the resulting morphology during the drying process at different initial concentrations (1-20 wt%) and temperatures (25-55 °C) are investigated using bright-field optical microscopy. The captured images are then analyzed by various image processing techniques in ImageJ. The initial concentrations of lysozyme solutions are divided into three regimes, diluted (1 wt%), concentrated (5-13 wt%) and ultra-concentrated (17-20 wt%) regimes. During the drying process, initially, the fluid front moves slowly and linearly and then shows a fast, non-linear movement in both dilute and concentrated regimes. With the increase of...
Initial lysozyme concentration, this movement in the non-linear region slows down as the front carries and deposits more particles at each step. However, in the ultra-concentrated regime, the fluid front moves linearly throughout the drying process. The deposition of particles by the fluid front creates the “coffee-ring” and is found to increase with every initial concentration. A dimple is observed in the existing mound-structure, and both structures grow with the increase of the initial concentration. The width of the ring also increases monotonically with the concentration. The cracks which are only observed in the ring at dilute regime, are spread throughout the drop at concentrated and ultra-concentrated regimes. Besides these concentration effects, the temperature increases the drying rate at every regime. It provides almost no time for the convective flow of the particles during the early stage of the drying process. The dimple in the mound structure changes to an inflamed spot in the diluted and concentrated regimes, whereas, it diminishes in the ultra-concentrated regime when the temperature rises. Both concentration and temperature gradient within the drop leads to a surface tension gradient, affecting the drop morphology. Due to the presence of a large number of particles in the ultra-concentrated regime, the drop forms thickest film and experiences high mechanical stress resulting in smaller and delaminated crack domains. This study sets an example to the diverse assays of biocolloidal drops and has the versatility and applicability for machine learning algorithms.

**Evaporation of SiO2 Colloidal Droplets on a Hydrophobic Surface in the Presence of Saturated Wax-Esters**

Rudra Dev Mandal and Saumendra Bajpai; Indian Institute of Technology Madras, India

Differential evaporation of a sessile droplet containing small particles leaves a ring-like deposit, called the coffee ring effect (CRE). However, an inward flow, also known as the Marangoni flow, can also occur due to a surface tension gradient. In this investigation, we study the evaporation of a 1 ul droplet of a suspension containing low molecular weight Wax Esters (WEs, about 0.48 KDa) and silicon dioxide nanoparticles (NPs, about 15 nm) of varying concentrations (null to 5 mg/ml) and wettability (unmodified silica or PDMS-coated silica NPs) on a hydrophobic glass substrate (modified using FOTS) at room temperature (about 25 C). We observe that for hydrophobic NPs/WE droplet, the residual pattern after complete evaporation shows a single ring exhibited in all conditions and that the ring-thickness increases with increase in the WEs concentration. In contrast, the residual pattern for hydrophilic NPs/WE droplets showed a transition from ring-like deposits to uniform deposits, as we increase the WEs concentration. Concurrently, measurement of surface tension (pendant-drop method) reveals a bipartite change in surface-tension with varying NP: WE ratio under all conditions. In the light of these results, we propose that polar attractions between hydrophobic NPs and WEs ensure localization of WEs at the periphery of the droplet, thereby increasing the local surface tension and giving rise to inverse Marangoni flow. This results in a thicker ring as observed before. On the other hand, hydrophilic NPs and WEs do not exhibit a strong polar attraction, thus forming a Marangoni eddy and subsequently suppressing the ring-formation. Together, these results provide us with a closer insight into the evaporation of volatile solvents while spiked with oils and NPs. Finally, these findings can be used in applications that require a uniform particle deposition, such as printed electronics and ink-jet printing.

**Ghost in the Machine—Translating New Technologies into Next Generation Neurodevices**  
Brian Litt; University of Pennsylvania, United States

Modern neurodevices are rapidly expanding their footprint in research and clinical care. As science and technology advance, so is device complexity: hardware, software, and the systems that unite them. In this lecture I review the current state of neuro and bioelectronic devices, and provide a vision for how new materials and hardware will seamlessly integrate with state of the art algorithms and systems to improve quality of life. Cost, complexity, robustness and “plasticity” are themes we will discuss, as we envision devices of the future and their role in modern healthcare.

**Biography:**
Brian Litt, M.D., is Professor of Neurology, Neurosurgery and Bioengineering at the University of Pennsylvania. A clinician and scientist, he divides his time equally between Penn’s Schools of Medicine and Engineering, Directing the Penn Epilepsy Center, Penn’s Center for Neuroengineering and Therapeutics and a new cross campus medical technology initiative called Penn Health-Tech. Dr. Litt has an A.B in Engineering from Harvard, completed an M.D and Neurology training at Johns Hopkins, and has held faculty appointments at Johns Hopkins, Emory, Georgia Tech and for the past 20 years, Penn. His research translates NeuroEngineering - hardware, algorithms, machine learning, and high speed computing for implantable devices into clinical systems and devices, with a focus on improving the lives of people with Epilepsy. Dr. Litt has received many awards, created over 20 patents, contributed to or co-founded several device med-tech companies including Blackfynn, NeuroPace, MC10, NeuroVista, EpilepsyCo and the Rothberg family of companies.

**Nanoengineered Materials for Advanced Energy and Water Technologies**  
Evelyn N. Wang; Massachusetts Institute of Technology, United States

Nanoengineered materials have exciting, untapped potential to improve energy and water technologies. In this talk, I provide a few examples of how we leverage nanoscale manipulation capabilities to develop advanced thermal management, solar thermal energy conversion and water harvesting devices. First, I discuss our recent work that harnesses novel surface designs to control and manipulate wettability and liquid-vapor phase-change processes. We demonstrated high flux evaporation from ultra-thin nanoporous membranes and nanostructured surfaces that can repel liquids even during condensation. Next, I discuss how nanoengineered materials can also be used to increase the efficiency of solar thermal devices. Specifically, I share our work on nanophotonic solar thermophotovoltaics and optically transparent thermally insulating aerogel solar receivers. Finally, I present a water harvesting device that leverages the unique properties of metal organic frameworks and other adsorbents to address water scarcity.
challenges in arid climates.

**Biography:**
Evelyn N. Wang is the Gail E. Kendall Professor and Department Head in the Mechanical Engineering Department at MIT. She received her BS from MIT, and MS and PhD from Stanford University in Mechanical Engineering. From 2006-2007, she was a postdoctoral researcher at Bell Laboratories. Her research interests include fundamental studies of micro/nanoscale heat and mass transport and the development of efficient thermal management, solar thermal energy conversion, and water harvesting systems. Her work has been honored with awards including 2008 DARPA Young Faculty Award, the 2011 Air Force Office of Scientific Research Young Investigator Award, the 2012 Office of Naval Research Research Young Investigator Award, the 2012 ASME Bergles-Rohsenow Young Investigator Award, the 2016 ASME EPPD Women Engineer Award, and the 2017 ASME Gustus L. Larson Award. She was recognized as one of Foreign Policy’s Global Re-Thinkers in 2017. She is an ASME Fellow.

Using Materials Science Concepts to Design New Drugs  
Francesco Stellacci; Ecole Polytechnique Fédérale de Lausanne, Switzerland

Viral diseases kill millions of people every year, mostly in developing countries. We need efficient drugs to fight them when vaccines fail. To date, only a handful of antivirals have been developed. I will show that it is possible to use Materials Science concepts to design a whole new class of antiviral drugs. Viruses can be viewed as the self-assembly of many biological components. It is possible to design nanoparticles, macromolecules, and simple molecules that target specific parts of the viruses (the viral attachment ligands). I will show that, in these materials, the presence of long hydrophobic, flexible arms induces irreversible damages to the self-assembled virions upon binding, rendering them non-infective permanently. The design principle underlying this effect is the hydrophobic contact between the drugs and the virions that results in a locally applied pressure. Results in vitro, ex-, and in-vivo against a number of viruses will be discussed.

**Biography:**
Francesco Stellacci is a full professor in the Institute of Materials and in the Bioengineering Institute at EPFL where he also founded and heads the Integrative Food and Nutrition Center. Stellacci graduated in Materials Engineering at the Politecnico di Milano, in Italy, where he studied photochromic polymers. He moved to the Chemistry Department of the University of Arizona as a post-doc and worked on two-photon microfabrication techniques to produce three-dimensional metallic structures embedded in polymeric matrices. He was an assistant and associate professor in the Department of Materials Science and Engineering at the Massachusetts Institute of Technology. There he worked on the characterization of the ligand shell of nanoparticles, on DNA-based microfabrication techniques, and invented the concept of super-hydrophobic materials that remove oil from water. He is a fellow of the Royal Society of Chemistry, the European Academy of Sciences, and the Academia Europaea.

Engineering 2D Heterostructures with a Twist  
Alessandra Lanzara1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States
The past few years have seen exciting new opportunities emerging from simply stacking and/or twisting together atom tick layers of same or different materials. The lattice mismatch or rotational misalignment introduced by such stacking give rise to long range Moire patterns that leads to modification of the electronic band structure. This leads to the appearance of unexpected properties, such as Mott like behavior and superconductivity, even in weakly interacting systems such as graphene. In this talk I will present some recent efforts in my group on twisted and strained graphene and TMD heterostructures as a function of twisting angle and gating. By using angle resolved photoemission spectroscopy I will discuss the effect of such misalignments on their electronic structure and discuss what are the key parameters that lead to the onset of strong correlation and novel behavior in these materials.

Biography:
Alessandra Lanzara is the Charles Kittel Professor of Physics at the University of California Berkeley since 2002. She is the Elected Chair of the American Physical Society (APS) Far West Section, and the Director of the International School of Non-Equilibrium Phenomena at the Majorana Institute in Italy. She is the founder of QuAD - Quantum Advanced Detection, a company that enables breakthrough research in quantum computing. Lanzara has made groundbreaking contributions in quantum materials from discovery of spin momentum locking and electron-phonon interaction in high-temperature superconductors, symmetry breaking in graphene, to optical control of spin photocurrents in topological insulators. She has received several prizes such as Fibonacci Prize, Goepert Award, and Elected Fellow of APS. Lanzara received a Bachelor in Physics in 1995 from University of Rome La Sapienza, a Ph.D. in Physics and Materials Science from the same university in 1999 and was a post-doctoral fellow at Stanford University.
