SiC and W-SiC functionally-graded coatings have been fabricated and exposed to deuterium (D) plasma bombardment at different surface temperatures and ion impact energies in the PISCES-E radio frequency (RF) plasma source [1] to assess their viability as a plasma-facing material (PFM) in a magnetic confinement nuclear fusion device. In situ optical emission spectroscopy (OES) revealed that CD emission, which approximates C chemical erosion, increased with ion impact energy up to 80 eV. Chemical erosion of Si was not observed spectroscopically via the SiD molecular band. Post-mortem Auger electron spectroscopy (AES) measured a <15% increase in relative Si content within the first few hundred nm of the surface. Si enrichment was likely due to preferential erosion of C atoms, as indicated by the asymmetric spectroscopic emission mentioned above. Erosion due to physical sputtering may have also been higher for C than for Si, as shown in [2]. The amount of D retained in samples due to implantation increased by a factor of ~5 between 20 eV and 50 eV, likely due to the onset of ion-induced, extrinsic trap formation. Overall retention was 1.7-2.5× higher in SiC than in W exposed to identical plasma irradiation. The pure W surface of the W-SiC functionally-graded coatings survived plasma exposure at a fluence of $10^{25}$ m$^{-2}$, as confirmed by AES measurements. Overall erosion of the W-SiC coating was around 2.3× higher than that of pure, crystalline W samples exposed to the same conditions. D retention in the W-SiC coatings exhibited combined trap behavior of both W and SiC samples, and was >10× higher than retention in SiC and W samples. High erosion and retention values may have been an artifact of the coating process, resulting in increased intrinsic trap density and reduced lattice displacement and surface binding energies.

SiC has been considered for use as a PFM in future magnetic fusion devices due to its excellent mechanical strength under neutron irradiation, high thermal strength, and low hydrogenic diffusivity. Tungsten is currently the leading PFM candidate, due to favorable thermal and mechanical properties and low erosion. However, concerns regarding its strength under intense neutron irradiation and its detrimental effect on plasma performance when eroded have led to research on other material candidates, such as SiC. Recent experiments in DIII-D showed that SiC exhibited lower levels of chemical sputtering than that of graphite (a common PFM) [3]. These results motivated further characterization of fundamental plasma-material properties in a dedicated plasma source. SiC samples (coating thickness = 100-200 µm) and W-SiC samples (coating thickness = 10 µm) were fabricated in-house via chemical vapor deposition (CVD) and RF magnetron sputtering, respectively, on ATJ graphite substrates. W-SiC coatings exhibited a stepwise concentration gradient of 100% W at the surface to 100% SiC at the coating-bulk interface. These samples, along with W and ATJ graphite reference samples, were exposed to D RF plasmas in PISCES-E at a flux of $5 \times 10^{20}$ m$^{-2}$ s$^{-1}$, $T_e$ of ~3 eV, $n_e$ of $3.5 \times 10^{16}$ m$^{-3}$, and surface temperature of 500 K. In situ OES was used to track erosion products and was quantified via the SXB/DXB method. Overall erosion was measured using a microbalance with a resolution of 0.01 mg. AES was used to measure changes in surface composition due to plasma exposure. Post-mortem thermal desorption spectroscopy resolved the major traps present in the material and estimated overall retention. Qualifying new SiC-based materials in a dedicated plasma source may demonstrate a superior alternative for next-generation fusion reactor materials.

Work supported by General Atomics Internal Research & Development and the U.S. DOE under DE-FC02-04ER54698 and DE-FG02-07ER54912.

Structural components of nuclear reactors must fulfill a series of mechanical and stability properties according to the specific range of experimental conditions they will be submitted during the operation of the reactor. Since the beginning of the construction of generation-II Pressurized Water Reactors (PWR’s) in the 1960’s, austenitic stainless steels from the AISI 300 series have been widely used as structural components for the fuel cladding, due to their high-temperature corrosion-resistance and mechanical strength. The variation of neutron flux along the core of a nuclear reactor presents a challenge to the materials used to build the various components of the core, considering that for a non-steady flux the effects on structural properties also varies. Wiedersich, Okamoto and Lam (WOL) proposed a model to specify irradiation conditions of dose rate and temperature where significant RIS should occur, being limited by an increase in the thermal concentration of vacancies at high temperatures and recombination of vacancies with interstitials at higher dose rates. In this work, we report the formation of radiation-induced precipitation (RIP) on an AISI 316L steel under in-situ 325 keV Xe ion irradiation/implantation for three different fluxes (1, 2 and $4 \times 10^{12}$ ions.cm$^{-2}$.s$^{-1}$) up to the same total dose within a transmission electron microscope (TEM) at MIAMI facilities at the University of Huddersfield, UK. All experiments were performed at 550 °C. Statistical analysis from bright-field images under phase contrast and selected area electron diffraction (SAED) were used to characterise the precipitates formed in the samples analysed. The nucleation and growth of second phase precipitation are observed to vary significantly according to the flux the sample is submitted. An overlapping of consecutive cascades at higher fluxes is proposed to explain the different behaviours for the evolution of RIP’s, and a small deviation on the lower limit of the WOL’s model is suggested.

SESSION EN17.10: Nuclear Materials—Ceramics and Composites

Radiation Damage in Ceramics—The View From Microscopy Karl R. Whittle; University of Liverpool, United Kingdom

In the continued development of materials for use within a nuclear reactor, whether it be fission or fusion based, how a material behaves under the extremes of damage radiation is a key factor in its applicability. The impacts arising from radiation induced damage are generally damaging, ranging from local damage through to full amorphisation, or the formation of new phases both by equilibrium or non-equilibrium synthesis. Such changes often have macro-scale impacts, for example a reduction in thermal conductivity, or change in a ductility. However, they key length scale at which all changes can be considered is at the nano-scale, where damage can be visualised most easily.

Using electron microscopy as a key aid in determining the impacts from damage, a range of systems, primarily ceramic in nature, will be discussed. Such materials are key components in multiple next generation reactor technologies, whether it be fission or fusion, fuel or structural in application. Regardless of the application, there are common factors that influence a response to radiation induced damage, and the examples presented here will help link the common themes, whether they be compositional or structural in nature.

8:45 AM EN17.10.02
Modelling of Crack Nucleation and Propagation in SiC/SiC Accident-Tolerant Fuel During Routine Operational Transients Using Peridynamics Thomas Haynes and Mark R. Wenman; Imperial College London, United Kingdom

Zirconium-based alloys have been successfully used for light water reactor fuel claddings since the 1960s. Despite their excellent performance during routine operation, during severe accidents such as the one which occurred at Fukushima Daiichi in 2011, they can undergo rapid exothermic oxidation. This releases hydrogen and supplies a great deal of heat, accelerating the accident. Over the last decade, there has been a concerted effort by the nuclear fission community to develop and implement accident-tolerant fuel designs. One design showing promise is SiC/SiC composite claddings. These consist of a β-phase fibre weave surrounded by β-phase SiC matrix. Despite their
strength and improved oxidation performance, the proposed claddings have a number of drawbacks. Namely their
irradiation swelling and low thermal conductivity. Their irradiation swelling saturates after a number of months in
reactor and is greater on the colder outer surface than the warmer inner surface. The thermal conductivity lower
than for zirconium alloys and is worsened by irradiation swelling.

Peridynamics is a developing non-local modelling technique which has the ability to model crack initiation,
propagation and branching. Unlike finite element analysis, the technique uses an integral formulation to determine
the forces upon material points. This means that crack patterns can be predicted without any a priori knowledge of
the loading or crack pattern.

A peridynamic model for composite SiC/SiC cladding has been developed in the Abaqus finite element code. The
material model was isotropic and considers matrix cracking and fibre pull-out. The thermal expansion, swelling and
the degradation of the thermal conductivity are modelled under typical LWR irradiation conditions. The swelling on
the outer surface is greater than the inner surface due to the lower irradiation temperature, causing a tensile stress on
the inside of the cladding. This stress increases during the decrease in power at the start of a typical pressurised
water reactor refuelling outage and causes microcracking of the matrix on the cladding inner surface. In models
without fibres, cracks would propagate through the cladding. If fibres are modelled, matrix cracking will extend to a
depth of around 20% through the cladding from the inner surface. If an inner monolith of SiC is additionally
modelled, cracking propagates through the monolith and acts as a stress raiser for matrix cracking in the composite.
If an outer SiC monolith is modelled, fibre pull-out on the inner surface of the cladding was increased by just under
70%.

9:00 AM EN17.10.03
Irradiation of Carbide Composites for Next Generation Nuclear Reactors Daniel Rutland; University of
Liverpool, United Kingdom

Future generations of nuclear reactors are required to operate at higher temperatures and under more extreme
radiation conditions than the current generation, creating a need for novel materials for use in these environments.
Silicon carbide (SiC) has a number of desirable characteristics for use in reactors but some properties can deteriorate
under irradiation. A potential option to improve the radiation resistance is to combine SiC with other carbides such
as Titanium carbide (TiC) and Zirconium carbide (ZrC).
To determine the properties of these samples, they can be exposed to high radiation environments and electron
microscopy and diffraction techniques can be used for characterisation and analysis of the materials.

Initial samples of SiC/TiC composites have been produced and irradiated in several facilities, with bulk irradiation
using 93 MeV Pb ions and in-situ irradiation using 1 MeV Kr ions. The in-situ TEM imaging indicates different
responses rates to radiation damage in the TiC phases and the SiC phases. Diffraction of these areas indicates almost
immediate amorphisation of the SiC phases, with TiC phases retaining distinct grain boundaries, which is supported
by X-Ray Diffraction (XRD) of bulk irradiated samples. The results from these samples are used to guide the
fabrication and characterisation of the next set of samples. These samples produced are SiC/ZrC and SiC/TiC
composites, each with ratios of 30:70, 50:50, and 70:30. The raw powders are milled at low-speed in inert gas,
before being sintered using spark plasma sintering (SPS) at 1600-1900 °C. The results of these samples will be
discussed in this talk.

9:15 AM EN17.10.04
Radiation Tolerance of Stabilized Alumina Coatings—An In Situ Irradiation Study Matteo Vanazzi1, Davide
Loiacono1,2, Wei Chen3, Meimei Li3, Marco G. Beghi2 and Fabio Di Fonzo1; 1Istituto Italiano di Tecnologia, Italy;
2Politecnico di Milano, Italy; 3Argonne National Laboratory, United States

Future generation nuclear reactors – either fission or fusion systems – present intrinsic benefits in terms of
economics, safety and waste management. However, to allow the deployment of these technologies, innovative
material strategies must be designed and implemented. Recently, coatings have earned great attention in the nuclear
field as a reliable cost-efficient solution. Indeed, they could tackle major issues such as corrosion, erosion,
hydrogen/tritium confinement, etc. In this framework, amorphous/nano-crystalline alumina coatings developed by
the Istituto Italiano di Tecnologia (IIT) have been extensively characterized as corrosion-resistant anti-diffusion
Alumina films have been tested under ion irradiation, proving high stability up to 150 dpa. This radiation tolerance is related to the amorphousness of the pristine material, which evolves towards a crystalline structure under irradiation. To preserve these enabling mechanisms and improve the range of operation (in terms of life time and operation temperature), the amorphous matrix must be conserved as long as possible. In this work, the stabilization of alumina by doping is evaluated under different conditions. Firstly, pure and doped materials have been compared by thermal annealing, showing a significant increase in the crystallization temperature (from 650 °C to more than 800 °C) for the stabilized alumina. Then, irradiation tests have been performed with *in situ* TEM at the IVEM-Tandem facility at ANL. Samples have been irradiated with different ions (350 KeV Kr and 500 KeV Au) up to 20 dpa. Experiments have been conducted at 600 °C - for the sake of consistency with previous ion irradiation tests - and at 800 °C, to observe the accelerating effect of irradiation on the thermally activated crystallization process. Albeit both the materials withstand the ion irradiation without delamination or structural failure, doped alumina retards the crystallization threshold even under irradiation. Moreover, at significant levels of radiation damage, the presence of doping stabilizes the low-energy metastable phases of alumina, conserving partially the pristine characteristics. This behavior, especially at the highest temperature, improves further the radiation tolerance of the material: while pure alumina suffers from voids formation after crystallization (a traditional phenomenon for the bulk oxide), no swelling appears in the doped counterpart. To conclude, *in situ* ion irradiation tests have been performed on stabilized nano-ceramic coatings. The presence of doping slows down the material evolution under irradiation, preserving the well-established properties of the pristine coating. The outcomes of these experiments represent a major step forward in the qualification process of coatings for nuclear reactors.

*Metal/Carbon Nanotube Composites Enhance Strength and Ductility, Even During Radiation Damage* Kang Pyo Seo¹, Penghui Cao², Young Hee Lee³, Michael P. Short¹ and Ju Li¹; ¹Massachusetts Institute of Technology, United States; ²University of California, Irvine, United States; ³Sungkyunkwan University, Korea (the Republic of)

The accumulation of defects during irradiation leads to material property degradation modes such as embrittlement and swelling, eventually causing material failure. Effective and efficient removal of defects is of crucial importance to design radiation damage-tolerant materials. Here, by biasing defect migration pathways via carbon nanotube (CNT) infiltration, we present a greatly enhanced damage-tolerant Al-CNT composite with defect storage measured to be one order of magnitude lower than that in pure, irradiated Al. Furthermore, extreme-value statistics (largest size) of defect clusters are significantly changed in the presence of CNT. *In situ* ion irradiation transmission electron microscopy (TEM) experiments and atomistic simulations together reveal the dynamic evolution and convergent diffusion of radiation-induced defects to CNTs, facilitating defect recombination and enhancing radiation tolerance. The occurrence of CNT-biased defect convergent migration is tuned by the thermodynamic driving force of stress gradient in Al matrix due to the CNT phase transformation. This approach to controlling defect migration using 1D interface engineering creates a new opportunity to enhance the properties of nuclear materials.

*Investigation of Helium Precipitates in Ta(Ti)/Zr(Ti) Nanocomposites* Sisi Xiang, Kelvin Y. Xie, Ian McCue and Michael J. Demkowicz; Texas A&M University, United States

Metal degradation due to implanted helium (He) is a concern in nuclear energy applications. We investigate the size and distribution of He bubbles in Ta(Ti)/Zr(Ti) composites using transmission electron microscopy. He implanted composites are compared to both the unimplanted material as well as the individual constituents of the composite. Nano-scale He bubbles form in different quantities in the two components of this composite as well as at the curved Ta(Ti)/Zr(Ti) interfaces within the materials. We discuss the consequences of our findings for the development of radiation resistant materials with complex, hierarchical microstructures.

Reduced-Order Atomistic Method for Simulating High Dose Irradiation in Metal Elton Chen¹², Chaitanya Deo¹ and Remi Dingerville²; ¹Georgia Institute of Technology, United States; ²Sandia National Laboratories, United States

Atomistic modeling of irradiation damages through displacement cascades is deceptively nontrivial. Due to the high energy, high velocity nature of the atom collisions, individual cascade simulations can become very computational expensive and ill-suited for size and dose upscaling. In order to examine microstructural evolutions, and mechanical property changes due to defect accumulation, alternative methods of modeling radiation defect accumulation are needed. Originally developed for application in ceramic materials, the Frenkel Pair Accumulation (FPA) method generates point defect pairs by directly displacing atoms from its initial lattice site. The applicability of method is somewhat limited to metallic/dense materials, as it does not capture the important cascade process known as the thermal spike. The presence of the thermal spikes has shown to be influence both point defect clustering and sequential cascade overlaps. Instead, using FPA as the basis and incorporating a reduced-order approximation for thermal spike, a new method of modeling radiation damage is developed. By adopting the athermal recovery corrected (arc) formalisms, the new arc Damage Insertion (arc-DI) method is able to predict and replicate radiation events across a wide range of recoil energy. Using Cu and Nb as the case studies, arc-DI is verified against standard displacement cascades. Example applications for simulating high energy cascade fragmentation and large dose ion-bombardment are also provided for demonstration.

10:45 AM EN17.11.02
Exceptional Radiation Performance of Crystalline-Amorphous Nanocrystalline Metal Miaomiao Jin¹², Penghui Cao³ and Michael P. Short¹; ¹Massachusetts Institute of Technology, United States; ²Idaho National Laboratory, United States; ³University of California Irvine, United States

Nanostructured materials with amorphous intergranular films (AIFs) have demonstrated superior strength and ductility. The radiation performance is expected to be as high as grain boundaries, if not better, due to the large fraction of interfacial volumes, which can be efficient sinks for radiation-induced defects. Meanwhile, the concentrated solute atoms within the film can pin down interface migration. However, better understanding beyond qualitative speculation must be pursued towards the radiation behavior of such novel design for the potential deployment in nuclear applications. In this study, we examine the response of an AIF system (nanocrystalline Cu with Zr doped AIFs) under continuous irradiation with molecular dynamics (MD) simulations. The system behavior is evaluated from three perspectives: ion mixing, defect reduction, and interface evolution. We propose a diffusion model that well characterizes the cascade-driven mixing process, and the spread of Zr distribution scales linearly with the damage level. The exceptional radiation resistance of such design can be understood from three aspects: i) Zr mixing into the bulk enhances local defect annihilation, ii) Zr impedes radiation-enhanced grain growth by restraining AIFs from migration, and iii) Zr increases the interface stiffness to maintain AIF integrity. These findings suggest that the AIF-engineered system can be a promising candidate in applications where strong mechanical property, structure stability and self-healing capability of radiation damage are required.

11:00 AM EN17.11.03
Quantitative Phase Field Model for Void Nucleation and Growth under Ion Irradiation Rayaprolu Goutham Sreekar Annadanam and Anter El-Azab; Purdue University, United States

Voids develop in crystalline materials under energetic particle irradiation as in nuclear reactors. Understanding the underlying mechanisms of void nucleation and growth is of utmost importance as it leads to dimensional instability of the metallic materials. In the past decade, researchers have adopted phase field approach to study the phenomena of void evolution under irradiation. In the phase field approach, the boundary between the void and matrix is
modeled as a diffuse interface, while it is sharp in reality. This consideration of diffuse interface requires the phase field models to asymptotically match with their sharp interface counterparts in the limit of vanishing interface thickness. The asymptotic analysis of the phase field models has enabled in obtaining a quantitative vacancy-based phase field model, however, it failed to match with the sharp interface model when included interstitials concurrently with vacancies. In this communication, we introduce a thermodynamically consistent, quantitative diffuse interface formulation of type C for void evolution under irradiation, that includes vacancy, interstitial and phase field variable as order parameters. Test cases are presented to validate our new phase field model.

11:15 AM EN17.11.04
Investigation of Proton Radiation Damage Effects on the Tensile Strength of 3D Printed Acrylonitrile Butadiene Styrene Arielle J. Miller, Dharmaraj Raghavan and Grant Warner; Howard University, United States

Polymers are widely used in nuclear power plant (NPP) components and in the storage of radioactive materials. Radiation-induced polymer degradation is a known challenge to the lifetime of components. Additive manufacturing (AM) provides a cost-effective way to replace used parts to key NPP components, thereby extending the life of commercial NPP and reducing maintenance costs and reactor downtime. The radiation damage due to polymers by neutron irradiation is mainly due to secondary protons recoiled from the polymers themselves. Therefore the study of the effects of proton irradiation of polymers informs the damage study of neutron radiation and is a viable simulation of neutron damage. The radiation damage of 3D printed polymers with gamma beams has already been studied in terms of changes to mechanical properties such as tensile strength and flexural strength. The study aims to obtain an understanding of the proton radiation impact on the mechanical performance of fused filament fabrication (FF) acrylonitrile butadiene styrene (FF-ABS). The study addresses the effect of proton radiation damage at 40 MeV and high-level proton doses through experimental evaluation of both mechanical performance and material characteristic changes. Furthermore, it considers the comparison of mechanical damage caused by protons versus that caused by Co-60 gamma-ray radiation. The key components of this research are (1) material characterization to investigate irradiation damage to FF-ABS parts caused by exposure to protons with energies up to 40 MeV and a maximum dose of 1 MGy; and (2) tensile experiments to investigate the ionizing radiation effects on the mechanical properties of the FF-ABS. Preliminary results from irradiation performed at Texas A&M University Cyclotron Institute show a significant drop in tensile strength as the radiation dose increased. The molecular weight and decomposition temperatures decreased as the radiation dose increased.

11:30 AM EN17.11.05
In Situ Cantilever Testing of Radiation Damage in Tungsten for Fusion Applications James E. Darnbrough1, Markus Alfreider2, Daniel Kiener2 and David Armstrong1 ; 1University of Oxford, United Kingdom; 2Montanuniversität Leoben, Austria

Tungsten has a high melting point and low sputtering rate, this makes it ideal for use in fusion reactor walls and divertors [1]. In this environment the material is exposed to temperatures up to 1000°C and 14.1 MeV neutrons leading to 150dpa of damage in a lifetime [2]. For structural components (e.g. divertors) it is important to understand the effect that this extreme environment has on the mechanical properties throughout working lifetime. Previous work suggests that high irradiation doses can lead to embrittlement in tungsten [3]. To investigate this, Helium implantation of Tungsten with 2% Tantalum (WTa2%) (including the role of transmutants) was irradiated with He+ up to 3000appm at a temperature of 300°C [4]. The implantation was conducted using a range of energies (0.05-1.8MeV) and fluences (1-5x1015 ions/cm2) to produce a relatively flat implantation profile ~1.56μm deep.

This scale of damage therefore requires small scale characterisation to understand the mechanical properties that change during radiation damage. In this work we illustrate the use of nanoindentation and microscale cantilevers to find the changes in/to the elastic and plastic response of the material. We have developed a new geometry of cantilever in order to test material volumes that are removed from the edge of the sample. This methodology allows for observation of the elastic and plastic properties of irradiated material and opens up a wide range of possibilities for future work in terms of location specific characterisation.

[2]:- N. Baluc et al Nuclear Fusion 2007 47 pp S696-S717
[3]:- N. Yoshida Journal of Nuclear Materials 1999 266-269 pp 197-206
Additive manufacturing (AM) refers to the technique of producing complex three-dimensional objects directly from a digital model through layer-by-layer computer-controlled deposition and consolidation of feedstock powder materials. The AM technique is emerging into a mainstream manufacturing process and has the potential to find widespread application in nuclear technologies. Inconel 625 is a Ni-Cr-based alloy widely used in nuclear reactors. In this study we investigated the relations between the microstructure and associated high-temperature oxidation properties of additively manufactured IN625. Using Laser Engineered Net Shaping (LENS) technology, we fabricated 1x1x1 cm cubes from argon-atomized IN625 powders. The microstructure of these LENS-processed IN625 consisted of primary dendrites and fine cellular grains. Characterization revealed a significant microsegregation of Nb and Mo at the boundaries of the fine grains due to local rapid solidification processes. Thermogravimetric analysis was then conducted to determine the intrinsic oxidation resistance of the LENS-processed IN625 samples exposed to dry air at 800 C and 1000 C for up to 100 h. The kinetics results indicated that the LENS-processed IN625 exhibited less resistance to oxidation as compared to wrought IN625. The results will be discussed in the context of Nb and Mo microsegregation to the grain boundaries detrimentally affecting the oxidation resistance of the LENS-processed IN625.

SESSION EN17.12: Nuclear Waste Materials
Session Chairs: Kyle Brinkman and Ming Tang
Wednesday Afternoon, December 4, 2019
Sheraton, 3rd Floor, Hampton

1:30 PM *EN17.12.01
We Need More Realistic Corrosion Tests to Provide Confidence in Safety Cases for Radwaste Disposal
William E. Lee; Bangor University, United Kingdom

Understanding the behaviour of complex materials in complex environments over millennia is a challenge for both modellers and experimentalists but must happen to have confidence in the safety cases for permanent radioactive waste disposal. Current durability testing of ceramic materials (including glass, glass composite materials and cements) as hosts for radioactive wastes is based on overly simple materials and procedures including using powders or samples of defined size and shape, polished samples, distilled water, controlled flow rates, closely defined and constant temperatures, simple and inactive compositions (International Simple Glass, ISG) etc. While steps are being taken towards more realistic testing procedures to account for package corrosion products e.g. iron oxide from container, type of water in repository environments (salts), Engineered Barrier Systems (e.g. clay) and rock dissolution products etc. more is needed.

Recent work [1-2] has highlighted the need for improved standard testing procedures and modelling developments. In [1] the impact of partial water immersion on the International Simple Glass (ISG), a condition that is inevitable as a repository gradually becomes saturated with penetrating groundwater was examined. This revealed quite different degradation behaviour compared to standard tests in which the material is fully immersed. In particular, whilst in standard tests the system reaches a steady state with a very low alteration rate thanks to the formation of a protective gel layer, in partially-immersed tests this steady state could not be reached because of the continuous alteration from the condensate water film. The constant input of ions from the emerged part of the sample caused a supersaturation of the solution, which resulted in early precipitation of secondary crystalline phases. In [2] using highly radioactive 239Pu-doped and non-radioactive samples of borosilicate glass with chemical compositions and synthesis procedure similar to French standard SON68 glass showed dramatic differences in behaviour. Over 4 months the radioactive glass is fully covered by mechanically unstable alteration layer whereas the model glass remains virtually pristine. Such studies highlight the importance of understanding the evolution of (T, environment, activity) conditions with time and the inherent inhomogeneity of the wasteforms and how they change with time, and the need to work with active material.
This talk uses these, and other, data to highlight the need for improved durability testing of wasteforms.

2:00 PM EN17.12.02
Structure-Property Relationships of Copper Coating Materials for Canada’s Used Nuclear Fuel Containers
Jason Tam1, Bosco Yu1,2, Weiwei Li1, Jason Giallonardo3, Jane Howe1 and Uwe Erb1; 1University of Toronto, Canada; 2McMaster University, Canada; 3Nuclear Waste Management Organization, Canada

Nuclear energy offers many benefits including stable electricity generation and low carbon output; however, one of the major challenges of nuclear energy is the management of the used fuel. In Canada, the Nuclear Waste Management Organization (NWMO) has proposed a deep geological repository (DGR) solution where used Canada Deuterium Uranium (CANDU) fuel bundles are packaged into a used fuel container (UFC), which is then placed at a reference depth of 500 m underground in a geologically stable rock formation and surrounded by bentonite clay. The UFC consists of a structural steel containment vessel which is copper coated on the exterior surface for corrosion protection. Two methods are used to copper coat the UFC. The first method is electrodeposition (ED) process which is used to coat the shell and hemispherical factory components in a conventional manufacturing environment. After UFC is loaded with used fuel, the vessel is welded shut and the UFC corrosion barrier is completed by applying cold spray (CS) copper coating to the weld closure zone under radiological conditions. The as-deposited CS copper coating exhibits high hardness and low ductility. In order to restore ductility, local annealing (1 hour at 350°C) with a heating band is performed.

Since the Cu on the UFC are applied using two different methods, it is important to develop a better understanding of the structure-property-processing-performance relationships of these coatings. In this study, we apply various electron microscopy techniques including electron backscattered diffraction (EBSD), focused ion beam (FIB) and transmission electron microscopy (TEM) to establish the relationships between the coating processing conditions (ED, CS, annealing of CS-Cu) and microstructure of the coatings at different regions including the ED-Cu and CS-Cu interfaces, as well as the Cu particle-particle interfaces in the CS-Cu coatings. These structural characterization results will provide a basis for the ongoing mechanical and corrosion testing programs seeking to advance knowledge on strength and corrosion resistance of these Cu materials for long term storage in the repository.

2:15 PM EN17.12.03
Complexation/Speciation—New Insight Studies of the Secondary Phase Formation under Repository Conditions
Nieves Rodríguez-Villagra, L.J. Bonales and J. Cobos; CIEMAT, Spain

In a deep geological repository scenario, oxidized uranium in aqueous systems will be stabilized as UO_2^{2+} (hexavalent uranium), as a consequence of tetravalent uranium oxidation by radiolytic byproducts. Uranyl cationic species (UO_2^{2+}) in different complexation forms, such as uranyl oxyhydroxide hydrates are expected to be found at the whole pH range conditions. The importance of uranyl lies in its potential incorporation of trace radioelements onto secondary uranyl phases. In view of the difficulty of uranium chemistry in natural groundwater, it is worthy to improve speciation assessment techniques so as to characterize precipitated solid phases and understand chemical processes.

Recently Raman spectroscopy has been shown as powerful tool to analysis the speciation of various actinyl (UO_2^{2+}, NpO_2^{2+} and PuO_2^{2+}) and to determine distribution of those elements which are more likely to be stable in a near-field groundwater environment. Therefore, the aim of this work is to develop a quantitative procedure to follow uranyl speciation in aqueous solution under repository conditions, and understand the bonding, coordination and local surroundings of uranyl species, which will brings light to understand and predict the precipitated solid phases formed (solubility-limiting phases). Hydroxide and hydroxo-carbonate complexes of uranyl will be spectroscopically identified in aqueous solution in the absence and presence of carbonate. The proposed identification procedure of uranyl complexation will give a precise basis to assign better estimates of the predicted solid phase stoichiometry combining solubility analysis with speciation and precipitation of U(VI).
In this work, it is shown the use of Raman spectroscopy adapted to the empirical analysis of different nuclear applications for uranium concentrations higher than 0.05M at ambient atmosphere, i.e. monitoring tool for UO$_2^{2+}$ precipitation as a function of pH studying UO$_2$(NO$_3$)$_2$·6H$_2$O stability in aqueous solutions representative of groundwater, in particular at ionic strength I = 0.02 – 0.4 M and pH from 7 to 13.2 and to evaluate the effect of gamma radiation fields. Therefore, the obtained results will provided a complete picture of secondary phase formations, as a result of corrosion of spent nuclear fuel in a deep geological repository.

3:30 PM *EN17.12.04
Radiation Tolerant Ceramics for Nuclear Waste Immobilization—Structure and Stability of Zinc Substituted Hollandites with High Cesium Loading Kyle S. Brinkman; Clemson University, United States

The radiation tolerance of nuclear waste forms is dependent on the materials resistance to defect formation and its ability to accommodate the structural distortions that arise from defect formation. This study illustrates how the radiation tolerance of hollandite can be improved thorough compositional control of cesium stoichiometry. The barium (Ba) to cesium (Cs) ratio was varied in the tunnel sites referred to as the A site of the hollandite structure. Zinc (Zn) was substituted for titanium (Ti) on the B site to achieve the targeted stoichiometry with a general formula of Ba$_x$Cs$_y$Zn$_{x+y/2}$Ti$_{8-x-y/2}$O$_{16}$ (0<x<1.33; 0<y<1.33). The tunnel cross-section depended on the average A site cation radius while the tunnel length depended on the average B site cation radius. The enthalpies of formation from binary oxides of Zn doped hollandite measured using high temperature oxide melt solution calorimetry were strongly negative, indicating thermodynamic stability with respect to their parent oxides. The formation enthalpies became more negative, indicating hollandide formation is more energetically favorable, when Cs was substituted for Ba across the range of Zn doped compositions investigated in this study. This hollandite series was exposed to heavy ion (Kr$^{2+}$) irradiation at 27 °C, 100 °C, 200 °C and 300 °C followed by characterization with grazing incidence X-ray diffraction, transmission electron microscopy, and aqueous leaching tests. The radiation tolerance increased at elevated temperatures with a critical amorphization temperature between 200 °C and 300 °C. Elemental leaching decreased with increasing cesium content. Irradiated samples exhibited twice the fraction cesium release of pristine samples.

Ion Irradiation-Induced Volume Swelling and Microcracking in Multiphase Glass Ceramic and Crystalline Ceramic Nuclear Waste Forms Ming Tang$^{1,2}$; $^1$Los Alamos National Laboratory, United States; $^2$Clemson University, United States

Crystalline ceramics and glass ceramics are candidate host materials for immobilizing alkaline/alkaline earth + lanthanide + transition metal fission product waste streams from nuclear fuel reprocessing. The major phases in these multiphase borosilicate glass ceramics are powellite, oxyapatite, pollucite, celsian, and durable residual glass phases. Al$_2$O$_3$ and TiO$_2$ were combined with these waste components to produce multiphase crystalline ceramics containing hollandite-type phases, perovskites, zirconolite/pyrochlores and other minor metal titanate phases. These alternative waste form materials offer increased solubility of troublesome components in crystalline phases compared to glass. This, in turn, leads to increased waste loading. During the long term storage, radiation stability and chemical durability always are most important concerns for nuclear waste forms. The focus of this presentation is the radiation-induced volume swelling and microcracking. These radiation damage effects would affect chemical durability of nuclear waste forms. In this study, selected glass ceramic and crystalline ceramic samples are exposed to various ion beam irradiations, which are used to simulate self-irradiations in a waste form. Several individual crystalline phases and pure glass are fabricated and tested under the same ion irradiations. Specifically, light ion (Helium) irradiation is used to simulate alpha particles and ionization process; and heavy ion (Krypton) irradiation is used to simulate alpha recoil and produce displacement damage. Ion irradiation-induced microstructural modifications, volume swelling and microcracking are examined using X-ray diffraction, transmission electron microscopy, scanning electron microscopy, atomic force microscopy, and other characterization methods. Our preliminary results show that (1) similar radiation damage responses from single crystalline phases and corresponding crystalline phases in multiphase samples; (2) different crystalline phases in these multiphase waste forms exhibit different radiation-induced volume swelling and microcracks formation under the same ion irradiation damage environment, and different ion species radiations induce different volume swelling and microcracks in the same crystalline phase; (3)
helium irradiation induced volume swelling and microcracks in glass and some crystalline phases are similar to the previous results of corresponding glass and crystallines irradiated by neutron or doped by actinide.

4:30 PM EN17.12.07
Physics-Based Mesoscale Models of Ion Exchange in Hierarchical Materials Yulan Li1, Shenyang Hu1, Chuck Henager1, Theodore M. Besmann2, Agnes Grandjean3,4 and Hans-Conrad Zur Loye2; 1Pacific Northwest National Lab, United States; 2University of South Carolina, United States; 3Univ Montpellier, France; 4CEA, France

The performance of advanced nuclear wasteform materials containing radionuclide absorbing nanoparticles such as zeolite, hexacyanoferrate (HCF), and salt-inclusion materials (SIMs) depends on hierarchical microstructures as well as thermodynamic and kinetics properties of ion exchange processes. For example, the wasteform morphology including particle size and particle aspect ratio, anisotropic mobility, and electrochemical potential affect the uptake kinetics of radionuclides. A physics-based mesoscale model of ion exchange in hierarchical materials is presented that takes into account the effects on ion exchange processes of inhomogeneous microstructures, anisotropic and inhomogeneous diffusivity of charged particles, electrochemical potentials, and operational conditions. Wasteforms consisting of zeolite or SIMs particles are taken as model systems. The thermodynamic and kinetic properties of diffusive ions are assessed using atomistic simulations and thermodynamic calculations. Simulation results showed that anisotropic mobility and larger aspect ratios of particles dramatically decrease ion exchange kinetics if the migration mobility is faster along the largest dimension anisotropic particles, such as needle-shaped particles. Electric fields associated with inhomogeneous ion distributions is an additional driving force that typically increases ion exchange kinetics depending on particle aggregation and ion mobility. The capability of the model for investigating the physics and mechanisms behind ion exchange in complicated microstructures and for predicting the effects of microstructure on ion exchange kinetics will be presented.

4:45 PM EN17.12.08
Progress in Flash Sintering of UO2 Erofili Kardoulaki, Darrin Byler and Ken McClellan; Los Alamos National Laboratory, United States

Early studies on the onset of flash sintering (FS) for UO2 have identified that flash is induced by a critical field, at a critical onset time (incubation time) and they are both shown to be dependent on temperature and O/M. UO2+x has been shown to flash at lower critical fields, compared to UO2.00, and a bifurcation stability model has been used to model the Joule heating effects [1] taking place during flash onset with reasonable agreement with experimental data [2]. Densification of stoichiometric and hyper-stoichiometric UO2 has been achieved via FS and has resulted in 81% and 92% theoretical density (TD) pellets, respectively [3]. Still, the resulting microstructures were significantly cracked and featured porosity. The latest studies on FS of UO2 have concentrated on producing high density pellets with structural integrity and uniform microstructure. FS using the current control method has been implemented to minimize thermal shock and achieve control in the resultant microstructures. The current control method has been shown to produce more structurally sound pellets, although additional difficulties with FS of UO2 result from atmosphere and subsequently stoichiometry control of the pellet. More specifically, during FS of UO2+x using Direct Current (DC), an O/M gradient can develop due to the concentration of O2 close to the anode, resulting in hyper-stoichiometric material in the vicinity which can sinter at a faster rate. This produces pellets with differential densification along their length. To overcome this issue, a pseudo-Alternating Current (pseudo-AC) has been used and it has been shown to produce pellets with slightly higher densities and more homogeneous macroscopic characteristics. Finally, the pseudo-AC and current controlled methods have been applied to FS of doped UO2 and the results are compared to doped UO2 that has been sintered conventionally.

8:30 AM *EN17.13.01
Crystal Growth and Scintillation Properties of Ternary Halides for Gamma Spectroscopy Mariya Zhuravleva and Matthew Loyd; The University of Tennessee, Knoxville, United States

In this report, we will review the crystal growth and scintillation properties of simple and mixed cation and mixed anion ternary halides that belong to the ABX3, AB2X5, A4BX6 families (A – one or more alkaline metals, B – one or more alkaline earth metals, X – one or a mixture of chlorine, bromine or iodine). They are of interest for scintillation applications due to their relatively high density, congruent melting, large band gaps, and availability of a divalent lattice site to accommodate a Eu2+ luminescence activator. They have attractive spectroscopic performance that is competitive with the industry standard, NaI:Tl, or state-of-the-art SrI2:Eu and LaBr3:Ce2+ scintillators, and therefore are suitable for use in portable radiation detectors for radio-isotope identification. Details of compositional uniformity, growth defects, and gamma-ray spectroscopic performance as a function of Eu concentration, crystal volume and growth parameters are presented to provide understanding of the best achievable performance. Particular attention is paid to thermal and structural properties to design the crystal growth parameters via the vertical Bridgman method. Additionally, the potential for scale-up is evaluated by simultaneous growth of multiple large size crystals (1” – 1.5” in diameter) using the Multi-Ampoule Growth Station.

9:00 AM EN17.13.02
Robust Perovskite Single Crystal Devices for Efficient Gamma-Ray Detection Jeremy Tisdale, Michael Yoho, Shreetu Shrestha, Kasun Fernando, Sergei Tretiak, Duc Vo and Wanyi Nie; Los Alamos National Laboratory, United States

Gamma-ray detection and spectroscopy is the quantitative analysis of gamma energy spectra, and is of critical importance in many applications, such as nuclear safeguards, nuclear forensics, and many more. Recently, single-crystalline, hybrid (and inorganic) perovskites have been proposed as new semiconducting materials for gamma-ray spectroscopy. In just a few short years, early reports have shown promising results for perovskite-based semiconductor gamma detectors. Some of the most impactful results in this new application for perovskite materials include: CsPbBr3 showing gamma-ray spectra with a resolution of 3.8% at room temperature for a 662 keV 137Cs source at room temperature;1 MAPbI3 showing gamma-ray spectra with a resolution of 6.8% at a lower temperature of 2 °C for a 122 keV 57Co source;2 and MAPbBr2.94Cl0.06 showing gamma-ray spectra with a typical resolution of 12% for a 662 keV 137Cs at room temperature.3 Although first reports for this class of materials have shown significant results with high-resolution gamma detectors, many new issues have arisen for this new application of radiation sensing.

High electric field device stability and ion migration are deeply explored to understand the effects of high bias applications in hybrid perovskites and ways to suppress/eliminate the negative effects towards high-resolution, room temperature gamma-spectroscopy. In a Cr/MAPbBr2.85Cl0.15/Cr device, low electric fields (≤25 V/mm) pulses with extremely low rise times (average of 30 to 65 µs). In order to increase the rise time, the device needs to be operated at higher electric fields, (≥ 50 V/mm) which increases the rise time to an average of 15 µs. However, at high electric fields, the signals become noisy in roughly 10 seconds to 1 minute. We directly probed the cause of the noise using long-term high voltage biasing, while studying the hysteretic behavior via IV characteristics. A new Cr/MAPbBr2.85Cl0.15/Cr exhibits pure Ohmic behavior with negligible hysteresis between -200 to +200 V (E = 100 V/mm). However, after biasing the device for only 10 minutes at +200 V, a large hysteresis loop is observed. After letting the device rest in the dark for two days, the hysteresis loop becomes even larger, rather than restoring to its original properties, showing that the interfacial damage caused is non-reversible. Using the same electrodes in the device architecture allows us to use a technique termed voltage cycling to avoid permanent interfacial damage while operating the detectors. The signals from positive and negative polarity are roughly the same in the metal/semiconductor/metal device. Therefore, when noise appears, we are able to switch polarity to eliminate the noise and continue counting for gamma spectra. Cooling the detector to temperatures of -30 °C further increases the
speed of the detector pulses by about 30%. However, the standard deviation in the pulse heights and rise times are still quite large, resulting in low resolution for the detectors with about 30-35% resolution for 59.6 keV γ-rays and 20-25% resolution for 662 keV γ-rays. Further development in hybrid (or non-hybrid) perovskite materials, such as CsPbBr3 and MAPbI3, should prove beneficial, as they are more stable under high electric fields required to achieve high resolution γ-ray spectroscopy. Also, further development in areas such as interfacial engineering and pixelated detector designs will be the next required steps in investigating the improvement for single crystalline, perovskite radiation detectors.

Passive Radiofrequency Dosimeter Tag Based on Flexible Radiation-Sensitive Oxide Field-Effect Transistor
Tobias Cramer1, Ilaria Fratelli1, Pedro Barquinha2, Rodrigo Martins2, Elvira Fortunato2 and Beatrice Fraboni1; 1University of Bologna, Italy; 2Universidade Nova de Lisboa, Portugal

Distributed ionizing radiation dosimetry is crucial in diverse security areas with significant environmental and human impacts such as nuclear waste management, radiotherapy, or radioprotection devices. We present a fast, real-time dosimetry detection system based on flexible oxide thin-film transistors that show a quantitative shift in threshold voltage of up to 3.4 V/gray upon exposure to ionizing radiation. The transistors use indium-gallium-zinc-oxide as a semiconductor and multilayer dielectric based on silicon oxide and tantalum oxide. [1] Our measurements demonstrate that the threshold voltage shift is caused by the accumulation of positive ionization charge in the dielectric layer due to high-energy photon absorption in the high-Z dielectric. The high mobility combined with a steep subthreshold slope of the transistor allows for fast, reliable, and ultralow-power readout of the deposited radiation dose. The order-of-magnitude variation in transistor channel impedance upon exposure to radiation makes it possible to use a low-cost, passive radiofrequency identification sensor tag for its readout. In this way, we demonstrate a passive, programmable, wireless sensor that reports in real time the excess of critical radiation doses. [2]

9:30 AM EN17.13.04
Thermal Diffusivity Degradation and Defect Density Prediction in Self-Ion Implanted Tungsten Using Transient Grating Spectroscopy
Mohamed Abdallah Reza1, Hongbing Yu1, Kenichiro Mizohata2 and Felix Hofmann1; 1University of Oxford, United Kingdom; 2University of Helsinki, Finland

We study the degradation of thermal diffusivity in self-ion implanted tungsten, and utilise this degradation to predict point defect densities. The defect density predictions are consistent with previous transmission electron microscopy (TEM) and molecular dynamics (MD) studies of self-ion implanted tungsten. Tungsten, due to its high melting point, high thermal diffusivity and low sputtering yield, is the prime candidate for plasma facing components in future fusion reactors. Armour components in the so-called divertor, the exhaust of the fusion reactor, will receive the highest heat and radiation loads in the reactor. The damage created in the tungsten matrix as a result of intense neutron irradiation and plasma exposure decreases its thermal diffusivity, reducing its heat removal capability. Self-ion implantation is a convenient, low cost proxy to neutron irradiation to study the displacement damage created by neutrons. It efficiently singles out the displacement damage from other
effects such as transmutation. However self-ion implantation even at energies as high as 20 MeV create damage layers that are only a few microns thick. The transient grating spectroscopy method used in this study enables us to measure the thermal diffusivity of these thin layers with high accuracy. In this study, a simple kinetic theory model is used to predict the point defect densities from the measured changes in thermal diffusivity as a function of ion dose. These predictions are compared to dislocation loop and point defect densities observed in TEM and predicted by MD.

20 MeV self-ion implanted tungsten, over a dose range of 0.0001 – 10 dpa, shows a significant degradation in thermal diffusivity above doses of 0.001 dpa. This degradation progresses up to 0.01 dpa, beyond which the decrease in thermal diffusivity saturates. Full saturation is achieved by 0.1 dpa, and the thermal diffusivity ceases to deteriorate with additional implantation. The reduction in room temperature thermal diffusivity at this damage level is 55% of the value of pristine tungsten.

The extracted point defect densities from the TGS data are about 2 orders higher than anticipated when considering solely defects visible in TEM. By combining TEM observations with predictions from MD, the density of point defects associated with defect clusters too small to be seen by TEM can be estimated. Once these “invisible” defects are accounted for, the total point defect concentration agrees to within an order of magnitude with that inferred from the TGS measurements of thermal diffusivity.

The reduction in thermal diffusivity observed in this study provides a much more complete picture of the degradation of thermal diffusivity with increasing damage dose. It also suggests that the diffusivity degradation due to the displacement damage from neutron irradiation will saturate beyond 0.1 dpa, which is an important result for predicting the in-service performance of armour components in future fusion reactors. The defect prediction results demonstrate the novel capability of TGS in quantitatively determining defect densities in irradiation-damaged materials. It also shows that the finely distributed smaller defects affect material properties such as thermal diffusivity to a larger extent than the bigger dislocation loops that are visible to TEM.

Processing-Structure Related Performance of Irradiated Relaxor-Ferroelectric Thin Films Evelyn Chin¹, Cory D. Cress² and Nazanin Bassiri-Gharb³;¹ ¹Georgia Institute of Technology, United States; ²U.S. Naval Research Laboratory, United States

Ferroelectric (FE) materials show a spontaneous polarization, reversibly switchable with an electric field, in addition to large dielectric, pyroelectric and piezoelectric response. Such properties make them attractive for fulfilling multiple functionalities in MEMS devices as sensors, actuators, and energy harvesting units. Traditionally, lead zirconate titanate (Pb[Zr₁₋ₓTiₓ]O₃, PZT) has been the most used ferroelectric in piezoelectric MEMS. However, relaxor-FE bulk single crystals, such as (1-x)Pb(Mg₁/₃Nb₂/₃)O₃-xPbTiO₃, (1-x)PMN-xPT, exhibit even larger electromechanical response than ceramic PZT, when cut and poled along the (001) direction with compositions on the rhombohedral side of the morphotropic phase boundary (x~0.32).

Lead-based materials are often radiation-hard, and numerous studies have shown PZT’s exceptional capabilities of retaining functional response after radiation exposure. The radiation hardness enables applications in high radiation exposure environments (e.g., aerospace, medical physics, x-ray/high energy source measurement tools, continuous monitoring of nuclear power plant applications, radiation disaster relief, etc.). However, PZT films still suffer from response degradation, especially for radiation doses at, or superior to 5 Mrad(Si). The high B-site chemical heterogeneity and disorder of PMN-PT is expected to result in a more radiation-hard material than PZT. Such perceived advantages are offset by challenges in processing pore- and crack-free PMN-PT thin films. Here we report on the radiation hardness of 0.7PMN-0.3PT thin films with varying microstructures, as modified through processing parameters.

All films were deposited on platinized Si substrates through chemical solution deposition (CSD). A 0.3M precursor solution of PMN-PT was prepared through a 2-methoxyethanol route and deposited onto the substrate via spin coating. A PbTiO₃ seed layer was used to induce (100) crystallographic orientation in PMN-PT films. Heat treatment conditions were modified in order to control porosity and grain morphology. Specifically, the samples were pyrolyzed at 250 to 430 °C for 1 to 5 minutes, and annealed at temperatures of 700 to 800 °C for 1 or 2 minutes. The deposition and heat treatment process were repeated in order to obtain final film thicknesses up to 500 to 600 nm. All samples showed strong (100) perovskite orientation with Lotgering factors > 80%, as evidenced by X-ray diffraction patterns. The samples were irradiated using a ⁶⁰Co source with ionization doses ranging from 0.2 to 10 Mrad(Si). A zero-dose sample was used for aging reference and background radiation control. Dielectric, polarization, and piezoelectric responses were conducted using sputtered Pt top electrodes, before and after irradiation.
In general, higher crystallization temperatures led to larger grains and columnar grain growth. All PMN-PT samples showed degradation in dielectric and saturated polarization within 5%, and in piezoelectric coefficients within 15%, within the radiation dose range used. Some films showed improvement in response up to 5% at lower doses, possibly due to annihilation of defects through low radiation exposure. Greater radiation hardness and lower functional response was observed in films with smaller, stacked grains, compared to films with larger, columnar grains. The influence of grain microstructure and porosity on both functional response and radiation-hardness, and a phenomenological model to quantify defect-defect interactions in irradiated functional materials will be discussed.

Quantifying Morphological Features of Uranium Oxides for Nuclear Forensics Luther W. McDonald; The University of Utah, United States

In the past five years, it was only hypothesized that morphological features could be used as signatures for nuclear forensics. The physicochemical connection between the processing parameters such as precipitation conditions, calcination temperature, and the composition of the starting material was generally thought to affect the morphology of the resulting material. However, quantifying these features was the limitation that prevented this signature from being utilized. In the past two years, we have published multiple papers demonstrating quantitative morphological analysis of UO₂, U₃O₈, and UO₂. To move from qualitative morphological analysis to quantitative analysis, the SEM images were processed using the Morphological Analysis of MAterials (MAMA) particle segmentation software. Following particle segmentation, the MAMA software was used to calculate morphological particle attributes for each of the segments. We generally segment enough images to acquire several hundred particles for statistical analysis. Our initial studies focused on synthetic parameters from the uranyl peroxide route in which we showed quantitative differences in the particle morphology of Am-UO₃ and U₃O₈ based on the calcination temperature.

We have also shown that incorporation of impurities with the U-oxide will alter the final product morphology. For example, four impurities: calcium, magnesium, vanadium, and zirconium were separately introduced to pure uranyl nitrate hexahydrate from stock solutions. Following the addition of the impurities, the solutions were precipitated using hydrogen peroxide. Incorporation of the impurity was quantified using inductively coupled plasma mass spectrometry (ICP-MS). The uranyl peroxide precipitate was then calcined to U₃O₈ at 800°C. ICP-MS was used again, to evaluate the incorporation of the impurity in the calcined uranium oxide. SEM was used to investigate morphological changes, and SEM-Energy dispersive spectroscopy (EDS) was used to identify any concentrated regions of the impurity in the SEM images. Results will be discussed highlighting the potential of using particle morphology for nuclear forensics, but also highlighting the challenges that need to be overcome for this to be a viable signature of processing history.

Non-Destructively Uncovering Aging and Irradiation Relationships for Nuclear Material Health Assessment and Forensics Michael P. Short¹, Cody Dennett¹, Saleem Aldajani¹, Benjamin Dacus¹, Caitlin Huotilainen², Ulla Ehrnsten³, M. Grace Burke³, Kudzanai Mukihawa³, Ihor Radchenko⁴, Kai Chen⁵, Ziv Ungarish⁵, Michael Aizenshtein⁵, Eyal Yahel⁵, Pål Efsing⁷, Thak Sang Byun⁸ and Joe Wall⁹; ¹Massachusetts Institute of Technology, United States; ²VTT Technical Research Centre, Finland; ³University of Manchester, United Kingdom; ⁴Xi’an Jiaotong University, China; ⁵Nuclear Research Center Negev (NRCN), Israel; ⁶Ben-Gurion University of the Negev, Israel; ⁷Vattenfall AB, Sweden; ⁸Pacific Northwest National Laboratory, United States; ⁹Electric Power Research Institute (EPRI), United States

Nuclear materials age in service, with their properties changing as a combined result of how they were produced and to what they were exposed. This aging, which can be due to a combination of thermal and irradiation origins, sometimes results in degraded performance which can lead to failure. It also often leaves fingerprints, measurable either directly or indirectly. In this talk we will explore the use of transient grating spectroscopy (TGS) as a method to both assess the health of key light water reactor (LWR) components due to spinodal decomposition, short range ordering, and phase precipitation, and to reconstruct their irradiation history. Changes in thermal, elastic, and acoustic material properties are indirectly linked to the quantities of interest, such as Charpy impact energy via surface acoustic wave peak splitting for structural materials, and irradiation dose history to reconstruct reactor usage, particularly for additively manufactured materials. This wide variety of examples highlights the vast, unexplored
space where non-destructive, indirect techniques can far more rapidly uncover new science and assist industry in nuclear materials forensic and health assessment issues.

11:30 AM EN17.13.08
Thermodynamics and Electronic Structure of Actinide Based Metal-Organic Frameworks from Density Functional Theory Calculations
Shubham Pandey1, Zhilin Jia1, Brian Demaske1,2, Otega Ejegbavwo1, Natalia Shustova1, Wahyu Setyawan2, Chuck Henager2 and Simon R. Phillpot1; 1University of Florida, United States; 2Sandia National Laboratories, United States; 3University of South Carolina, United States; 4Pacific Northwest National Laboratory, United States

Metal-Organic Frameworks (MOFs) are emerging as a novel class of hybrid materials for the purpose of radionuclide sequestration. Significant research has been reported on MOFs for applications such as gas storage, sensing and heterogeneous catalysis; however, radionuclide incorporated MOFs are relatively unexplored. The unique and desirable properties of MOF structures like high porosity, modularity, and synthetic diversity make them attractive candidate materials to contain the radionuclides present in the nuclear wastes. Density Functional Theory (DFT) calculations were used to determine the favorability of ion-exchange (at the metal node) of relevant radionuclides in various parent MOF clusters. A range of DFT methods, including various flavors of exchange-correlation functionals, DFT+$U$, relativistic effects, and magnetic effects were employed to establish robustness in results. The electronic structures of MOFs are also determined and are correlated with experimental data.

11:45 AM EN17.13.09
Nanoscale Cross-Plane Thermal Transport and Structural Characterization of Swift Heavy Ion Irradiated LiF Crystals
Ainur Koshkinbayeva1, Azat Abdullaev1, Zhanatay Nurekeyev1, Vladimir Skuratov2,3,4 and Zhandos Utegulov1; 1Nazarbayev University, Kazakhstan; 2Flerov Laboratory of Nuclear Reactions, Joint Institute for Nuclear Research, Russian Federation; 3National Research Nuclear University MEPhI, Russian Federation; 4Dubna State University, Russian Federation

Thermal transport in insulators is of great interest in high temperature nuclear reactors application. External irradiation by swift heavy ions (SHIs) such as Bi at hundreds of MeV energy is used to simulate the fission product impact in nuclear and model materials like LiF with well-known structural response to dense excitation effects [1, 2]. We report the results of color centers formation analysis in bulk lithium fluoride crystals irradiated at room temperature by 98 MeV, 244 MeV, 465 MeV and 710 MeV Bi ions at fluence $10^{11}$ cm$^{-2}$ and 710 MeV ions at fluencies ranging from $10^{10}$ to $10^{13}$ cm$^{-2}$ using optical absorption (OA) and photoluminescence (PL) spectroscopy. The irradiation of LiF samples was carried out at the U-400 FLNR JINR cyclotron (Dubna, Russia). The proliferation of ion-induced F (245 nm) and F$_2$ (445 nm) color centers were studied by OA spectroscopy. As the fluence of irradiation ions grows, the integrated absorption intensity of F-peak gradually decays, whereas that of F$_2$-peak broadens and increases, which indicates that color centers tend to aggregate. The corresponding defects densities were estimated using Smakula-Dexter formula [2]. Since F$_2$ and F$_3$ color center related bands in absorption spectra overlap, the complementary technique, PL spectroscopy, was performed. Specifically, the F$_2$ and F$_3$ color centers in irradiated LiF samples were distinguished by their characteristic peaks observed at around 530 and 670 nm, respectively. For the fluencies $10^{10}$ - $10^{13}$ cm$^{-2}$, the integrated fluorescent intensity of F$_2$ appears to dominate in the spectrum for the lower ion doses and drops to the level comparable to that of F$_3$ as the ion dose increases. Cross-plane near-surface thermal conductivity of SHI irradiated LiF crystals was characterized by picosecond time-domain thermo-reflectance (TDTR) in the thermally probed region extending down to 290 nm, where the electronic stopping / ionization processes dominate over nuclear stopping. TDTR results show that thermal transport in this sub-surface domain irradiated by 710 MeV ions with the dose of $10^{12}$ cm$^{-2}$ has degraded by the factor of $\sim$ 2 compared to non-irradiated sample. Theoretical analysis was based on Klemens analytical thermal transport model [3] by fitting into TDTR measured thermal conductivity values. Given TDTR probed sub-surface region overlapped with ionization depth determined by SRIM calculation, we conclude that defects are formed primarily by electronic energy loss / ionization. Measurement and simulation of nano-scale thermal transport degradation in irradiated LiF will be discussed with results of structural defects proliferation as determined by OA and PL measurements. Funding by MES RK grant AP05130446, state-targeted program BR05236454 and NU FDCRG grant 110119FD4501 is acknowledged.

TUTORIAL
Advances in Large-Scale Synthesis of Beyond Graphene 2D Materials

Sunday Afternoon, December 1, 2019
Hynes, Level 2, Room 208

The research areas of beyond graphene 2D and layered materials remain highly active and is continuously expanding. This is particularly true with many growth techniques emerging as promising methods for controlled large scale synthesis of single monolayers and heterostructures. This tutorial will showcase the current status and future directions in the area of largescale synthesis, doping and alloying of 2D materials and van der Waals heterostructures. Specifically, this tutorial will cover the science and practice of molecular beam epitaxy (MBE), metalorganic chemical vapor deposition (MOCVD) and solution-phase processing approaches that will ultimately enable the practical development of wafer scale electronics from beyond graphene 2D and layered materials.

1:30 PM
Metalorganic Chemical Vapor Deposition of 2D Layered Materials Joan M. Redwing, The Pennsylvania State University

Metalorganic chemical vapor deposition (MOCVD) has emerged as a promising method for the synthesis of wafer-scale epitaxial films of monolayer transition metal dichalcogenides (TMDs) and related 2D materials. This tutorial will cover the science and practice of MOCVD as it pertains to the growth of van der Waals bonded chalcogenide films. Practical considerations including reactor design, precursor selection, growth conditions and substrates will be reviewed. The role of kinetics and thermodynamics in the nucleation, domain shape and lateral versus vertical growth will be discussed. Characterization techniques for wafer-scale monolayer films as well as prospects for future advances, including in situ characterization and layer-by-layer growth of heterostructures, will be detailed.

2:30 PM BREAK

3:00 PM
Molecular Beam Epitaxy of 2D Layered Materials Christopher Hinkle, University of Notre Dame
Molecular beam epitaxy (MBE) can enable high-quality 2D layered chalcogenides through the combination of high purity elemental sources and an ultra-high vacuum growth environment. This tutorial will cover the science and practice of MBE as it pertains to the growth of van der Waals-bonded chalcogenide films and their heterostructures. Fundamental nucleation and growth behavior of transition metal dichalcogenides by MBE will be discussed, focusing on important parameters to control domain orientation and grain size in MBE to achieve wafer scale grown films. This tutorial will also feature novel advances in MBE system designs and highly developed in situ materials characterization techniques to enable the fundamental understanding of the growth thermodynamics and kinetics, the structure of these van der Waal monolayers and abruptness of heterostructures.

**4:00 PM**

**Liquid Phase Exfoliation of 2D Layered Materials and Applications** Mark C. Hersam, Northwestern University

Beyond conventional crystal growth techniques, liquid phase exfoliation of 2D sheets from layered bulk crystals represents a viable solution for producing monolayer films on a wafer scale through standard processing technologies such as spin coating and roll-to-roll manufacturing. Here, we review different strategies for exfoliation of 2D and layered materials in the liquid phase and discuss important parameters that govern the thickness and lateral size of the exfoliated sheets. Practical considerations on the role of surfactants and dispersing solvent medium as well as control of concentration and viscosity of dispersed exfoliated 2D sheets will also be highlighted. This tutorial will provide practical guidelines for the process of liquid phase exfoliation that may be generalized to different types of layered materials, with a short discussion on the impact of this process on device applications.

Parametric Study on Solution Crystal Growth of Hexagonal Boron Nitride  
Eli Janzen, Jiahan Li and James H. Edgar; Kansas State University, United States

Hexagonal boron nitride (hBN) has many unique properties such as a strong interaction with thermal neutrons, a wide energy bandgap (>6.0 eV), and surface phonon polaritons. These properties make it a good candidate for compact, efficient, and low-cost neutron detectors, deep UV light emitters and detectors, and infrared nanophotonic devices. Thus, high quality hBN single crystals are needed for national defense (detection and monitoring of nuclear weapons by neutron detectors), health (sterilization of surfaces by radiation from deep UV LEDs), and microscopy (deep sub-wavelength optical imaging).

Molten metal solutions in nitrogen at atmospheric pressure have proven effective in growing large, monoisotopic, high purity, and high quality hBN single crystals. Single crystals have been grown that are up to 3mm across, hundreds of microns thick, and with etch pit densities of 10^7 to 10^8 cm^-2. Monoisotopic ^10^B and ^11^B enriched hBN crystals were also grown simply by using isotopically pure boron as the source material. While epitaxial growth techniques (CVD and MBE) have also proven effective at growing hBN, these methods require more complex apparatus and processes than solution growth and require a substrate which introduces lattice constant and thermal expansion coefficient mismatches. Furthermore, they cannot produce crystals as thick as solution growth, nor readily produce monoisotopic hBN, as they require specialized chemical sources, which are rarely available and quite expensive. However, to become commercially viable, solution growth must be further refined to produce much larger crystals with lower defect densities, and lower residual impurity concentrations.

One of the primary obstacles to optimizing this process is the lack of a cohesive understanding of how the melt composition impacts hBN crystal growth. For example, several different combinations of metals (Ni, Ni/Cr, Fe, Fe/Cr), two different boron sources (pure boron powder and hot-pressed boron nitride), and other additives such as silicon have been used in varying concentrations within the melt. In each case, the crystal nucleation density, grain size area, thickness, and other characteristics have been affected by the particular composition used. However, how the melt composition affects these characteristics and what specific properties are responsible for these effects has not been thoroughly analyzed. Thus, it is difficult to explain why certain compositions of boron, metals, and nitrogen yield excellent quality crystals while others do not.

In this work, processes employing various combinations of Ni, Cr, Fe, and other additives with a boron source were systematically analyzed according to the crystal size (obtained from micrographs), defect density (determined via defect-selective etching), and quality (determined via a variety of spectrographic tools including XRD and Raman spectroscopy). Specific features of the melt were analyzed with respect to these criteria to pinpoint exactly which properties were most important in the process. For example, pure Ni and Fe both have high boron solubilities, but nitrogen solubility is negligible in pure Ni. While alloying with Cr greatly increases the nitrogen solubility, it also increases the nucleation density. Thus, relatively large hBN single crystals can be produced in pure Fe, but not pure Ni. Thick hBN layers can be produced in Ni/Cr solutions, but with small crystal grain sizes. In addition, residual impurities present in the source materials, intentionally added impurities, and the interaction of the melt with the furnace and crucible materials significantly affects the process and the crystal properties. This project gives new insights into the interplay between melt composition and hBN crystal growth and reveal new, direct pathways toward optimizing the process.

Expanding the Palette of Layered Materials and Their 2D Counterparts by Materials Chemistry Approaches  
David J. Lewis and Niting Zeng; University of Manchester, United Kingdom

Layered bulk materials have attracted much attention for various technological applications including tribology and catalysis [1]. One of the most recent applications is in their study in the two-dimensional limit i.e. atomically thick materials such as graphene. Inorganic graphene analogues such as few layer molybdenum disulphide, black phosphorus and main group chalcogenides have also been the subjects of much intense research as two-dimensional semiconductors that would be complementary to graphene in a future electronics industry [2]. We have devised top-down routes to 2D black phosphorus [3] and tin(II) sulphide [4] both of which have layer dependent band gaps.
However, these top-down processes suffer from a major drawback: often commercially available layered bulk crystals are used as feedstock and this inherently limits the palette of two-dimensional materials available for study without resorting to expensive processing via CVD.

As a solution to this, we have devised new routes based on solventless thermolysis of metal-organic precursors that can produce layered materials in bulk at relatively low temperatures and in relatively high purity. Because the precursors used are on the molecular scale, we can control the extent of doping or alloying of materials and this then widens range of layered materials available for exfoliation. I will present the synthesis of layered transition metal oxides and chalcogenides [5] and main group chalcogenide alloys [6], the latter also studied as post-processed 2D materials as an example of a new route to 2D materials with wide applicability.

Liquid-Phase Exfoliated Semiconducting Transition Metal Dichalcogenide 2D Nanoflakes for Large-Area Optoelectronic Applications Kevin Sivula; Ecole Polytechnique Federale Lausanne, Switzerland

Given their established robustness and favorable optoelectronic properties, the semiconducting transition metal dichalcogenides (TMDs, e.g. MoS2 and WSe2) are attractive for optoelectronic applications including solar energy conversion (photovoltaic and photoelectrochemical solar fuel production).[1] Recent advances in the liquid-phase exfoliation (LPE) of semiconducting TMDs into mono- or few-layered 2D nanoflake dispersions suggests that inexpensive roll-to-roll processing can be used to prepare TMD-based devices inexpensively over large area.[2] However, the high concentration of defects in these materials act as recombination sites for photogenerated carriers and limit the performance. In this presentation the challenges with charge transport, separation, recombination, and interfacial transfer in LPE TMD nanoflake thin film devices will be discussed with respect to the 2D flake size and defect passivation/charge extraction treatments.[3] Our results give insight into the roles of both edge and internal defects and suggest routes for improvement. Overall it is shown that LPE semiconducting TMDs with suitable defect mitigation can achieve internal quantum efficiency for photon harvesting similar to bulk single crystal samples. Specifically, we show that WSe2 nanoflake thin films achieve absorbed-photon-to-current efficiency over 50% and photocurrent densities for solar water reduction at 4 mA cm–2 under standard testing conditions.[4]

8:45 AM FF01.01.04
Large-Area Chemically Synthesized Molybdenum Disulfide with Aqueous Thermolysis Method Akira Fujimoto, Shoji Maeda, Ryota Isu, Kei-ichi Sakamoto, Kentaro Matano, Masatoshi Koyama, Yoshiyuki Harada, Kazuto Koike, Shigehiko Sasa and Mitsuaki Yano; Osaka Institute of Technology, Japan

Graphene and 2-dimensional (2D) materials such as molybdenum disulfide (MoS2) have attracted much attention in a wide range of unique electrical and optical properties. But they are basically very small flakes and difficult to control thickness. In comparison with the exfoliation method, chemical vapor deposition has a better potential for fabricating large area 2D materials, but the synthesis is still a challenge. Furthermore, MoS2 films have been prepared by dip-coating ammonium tetrathiomolybdates ([NH4]2MoS4) followed by the annealing process in the atmosphere of Ar and S in order to make up for S deficiencies [1]. The purpose of our study is to synthesize large-area high-quality MoS2 on SiO2/Si substrate by thermolysis of (NH4)2MoS4. By means of employing thioacetamide
(CH₃CSNH₂), we are trying to compensate for deficiency of S in MoS₂ thin films and to improve the crystallinity. Moreover, we are performing Raman scattering measurements in order to explore the molar concentration dependence of the chemical precursors used for the growth of MoS₂.

Aiming for chemically synthesizing MoS₂, we employed the aqueous thermolysis method. (NH₄)₂MoS₄ and CH₃CSNH₂ with the same molar concentration were mixed in deionized water and the mixture was heated at 95 degree C for 5 hours. The solution containing the synthesized MoS₂ was spin-coated onto the 90-nm SiO₂/Si substrates. We confirmed that for the thin films synthesized with the molar concentration less than or equal to 10 mM, Raman double peaks E₁2g and A₁g appeared at about 383 cm⁻¹ and 407 cm⁻¹, respectively. The E₁2g and A₁g peak positions shift to a lower wavenumber with increasing the molar concentration. The Raman peak energy difference can be used to identify the number of MoS₂ layers. We found the thickness of our MoS₂ is as thick as that of MoS₂ natural crystal. On the other hand, for the films synthesized with the larger molar concentration E₁2g and A₁g peaks did not appear and another two Raman peaks strongly appeared at around 810 and 1000 cm⁻¹ originating in MoO₃ [2]. We found a synthesis of MoS₂ using aqueous thermolysis method should be performed under the condition of a lower molar concentration of the chemical precursors.

Furthermore, as for the sample synthesized with the lower molar concentration of (NH₄)₂MoS₄ and CH₃CSNH₂, we performed Raman scattering measurement again after a week. As the result, Raman peak strongly appeared at around 810 cm⁻¹ originating in MoO₃. It is conceivable that oxidation of Mo is caused by a reaction with the residue of water after the synthesis, therefore we consider the residue of water should be evaporated completely to prevent the oxidation of MoS₂. For this purpose, we coated the solution directly on a SiO₂/Si substrate and heated at 200 degree C for 3 hours. Even in a week after the synthesis by means of this improved process, we confirmed E₁2g and A₁g double peaks appeared and Raman peaks derived from MoO₃ did not. Now we are evaluating the electrical properties of these MoS₂ thin films. Moreover, we will stack the MoS₂ thin films and graphene for the application of gas sensors, which transduces gas-molecules adsorption on the surface of these 2D materials and at the MoS₂/graphene interface into a change of the resistance.

9:00 AM FF01.01.05
Synthesis of Molecular 2D Materials via Low-Energy Electron Irradiation Induced Chemical Reactions
Andrey Turchanin1,2; 1Friedrich Schiller University Jena, Germany; 2Center for Energy and Environmental Chemistry Jena (CEEC Jena), Germany

After the demonstration of a variety of inorganic two-dimensional (2D) materials (graphene, hBN, MoS₂, etc.), molecular 2D materials have attracted a significant research interest as well. However, the direct synthesis of these materials is an exceptionally challenging task for material scientists. In this contribution, a simple and robust physical method for the synthesis of molecular 2D materials is presented based on low-energy electron irradiation induced chemical reactions in aromatic molecular layers. In this way, ultrathin (~1 nm) molecular nanosheets with adjustable chemical and physical properties called Carbon Nanomembranes (CNM) can be prepared. Moreover, the method enables the synthesis of various other 2D organic-inorganic hybrids (e.g., MoS₂-CNM, graphene-CNM lateral heterostructures, etc.) [2] or ~20 nm thick nanosheets of organic semiconductors [3]. Functional properties of these molecular 2D materials including their chemical functionalization and engineering of hybrid hierarchical structures for application in electronic and energy conversion devices will be discussed [4-5].

Atomically Thin Three-Dimensional Membranes of van der Waals Semiconductors by Wafer-Scale Growth
Gangtae Jin1,2, Chang-Soo Lee3, Xing Liao4, Juho Kim1,2, Zhen Wang5, Odongo Francis Ngome Okello1, Bumsu Park2, Jaehyun Park1,2, Cheolhee Han1,2, Hoseok Heo3, Jonghwan Kim1, Sang Ho Oh4, Si-Young Choi1, Hongkun Park2 and Moon-Ho Jo1,2; 1Pohang University of Science and Technology, Korea (the Republic of); 2Institute for Basic Science (IBS), Korea (the Republic of); 3Harvard University, United States; 4Sungkyunkwan University, Korea (the Republic of)
We report wafer-scale growth of atomically thin, three-dimensional (3D) van der Waals (vdW) semiconductor membranes. By controlling the growth kinetics in the near-equilibrium limit during metalorganic chemical vapor depositions of MoS$_2$ and WS$_2$ monolayer (ML) crystals, we have achieved conformal ML coverage on diverse 3D texture substrates, such as periodic arrays of nanoscale needles and trenches on quartz and SiO$_2$/Si substrates. The ML semiconductor properties, such as channel resistivity and photoluminescence, are verified to be seamlessly uniform over the 3D textures, and are scalable to wafer-scale. Additionally, we demonstrated that these 3D films can be easily delaminated from the growth substrates to form suspended 3D semiconductor membranes. Our work suggests that vdw ML semiconductor films can be useful platforms for patchable membrane electronics with atomic precision, yet in large-areas, on arbitrary substrates.

Wafer-Scale Hybrid Organic-Inorganic Superlattices from Monolayer 2D Polymers and Atomic Crystals Yu Zhong$^1$, Baorui Cheng$^1$, Chibeom Park$^1$, Ariana Ray$^2$, Sarah Brown$^1$, Fauzia S. Mujid$^1$, Jae-Ung Lee$^1$, Hua Zhou$^3$, Joonki Suh$^1$, Kan-Heng Lee$^1$, Andrew J. Mannix$^1$, Kibum Kang$^4$, Steven J. Sibener$^1$, David A. Muller$^2$ and Jiwoong Park$^1$; 1University of Chicago, United States; 2Cornell University, United States; 3Argonne National Laboratory, United States; 4Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials own many interesting properties due to their atom-thick characteristics and versatile heterostructures built layer-by-layer. The capability of assembling both organic and inorganic 2D materials into heterostructures will lead to the formation of artificial van der Waals solids that takes advantage of molecular functionalities brought by the organic 2D materials. Towards this end, the biggest hurdle has been the lack of a general method to synthesize organic monolayers at macroscopic dimensions and integrate them with monolayer precision. Herein, we report the general synthesis of monolayer 2D polymers, the molecular analogs of 2D atomic crystals, with wafer-scale homogeneity and the fabrication of the hybrid superlattices. For this, we develop a new interfacial synthesis technique compatible with various molecular building blocks and polymerization chemistries. This approach incorporates key features necessary for scalable and facile processing, including large-area synthesis, ambient growth conditions, and compatibility with established patterning and integration methods. Enabled by those characteristics, hybrid organic-inorganic superlattices of monolayer 2D polymers and 2D atomic crystals were fabricated with molecular precision. The employment of versatile 2D polymers allows the incorporation of functional molecular moieties into two-dimensional electronic circuits. These materials show promising applications in multifunctional 2D electronic devices.

SESSION FF01.02: Chemical Vapor Deposition of 2D Materials
Session Chairs: Amber McCreary and Joan Redwing
Sunday Morning, December 1, 2019
Hynes, Level 2, Room 208

10:15 AM FF01.02.01
Controlled Growth, Transfer and Device Integration of Large Crystal Monolayer Hexagonal Boron Nitride Vitaly Babenko$^1$, Ruizhi Wang$^1$, Ye Fan$^1$, Vlad-Petru Veigang-Radulescu$^1$, Oliver Burton$^1$, Jack Alexander-Webber$^1$, Robert Weatherup$^2$ and Stephan Hofmann$^1$; 1Cambridge University, United Kingdom; 2The University of Manchester, United Kingdom

Utilisation of hexagonal boron nitride (h-BN) in applications requires further advancements in the production, processing, integration methods and also their cost reduction. We focus here on catalytic chemical vapour deposition (CVD) and discuss two very different catalysts for monolayer h-BN growth, iron and platinum, examples of a high and low precursor solubility transition metals. For Fe, we systematically explore the role of bulk dissolved species, and find that a simple pre-growth step enables us to tailor a scalable CVD process to give mm-sized h-BN domains,[1] among the largest reported to date. For Pt, we developed sequential step growth to enable independent control of h-BN nucleation and domain expansion to also give large (> 0.5 mm) h-BN domains and continuous
We show that targeted h-BN transfer methods are required for the different catalysts or even tweaked to the processing of the catalyst, whereby we develop a moisture oxidation and acid release method for the iron and a dry peeling approach for platinum. The utilisation of h-BN with graphene is demonstrated as an encapsulating layer for integration with common ALD dielectrics and in FET devices. Additionally, we demonstrate the use of monolayer CVD h-BN as an active material for room temperature single photon emission.

Epitaxial Growth of Layered β-In2Se3 Thin Films via Metalorganic Chemical Vapor Deposition Xiaotian Zhang, Sora Lee, Anushka Bansal, Fu Zhang, Mauricio Terrones, Thomas Jackson and Joan M. Redwing; The Pennsylvania State University, United States

2D materials have attracted wide interest because of their potential performance and diversity of function as electronic and optoelectronic materials. Growth of transition metal dichalcogenides (TMDs) such as MoS2 and WSe2 typically requires high temperatures (>700 °C) for large domain size and epitaxy. This restricts the applications of these materials, especially considering the growing interest in 2D materials integration with silicon in back-end-of-line (BEOL) applications that require processing temperature < 450 °C. In contrast, group III metal chalcogenides (indium selenide and gallium selenide) possess lower melting temperatures than TMDs and thus high crystal quality films are anticipated at lower growth temperature. In addition, depending on their stoichiometry and phase, they also have a layered structure that offers interesting physical, electronic, and piezoelectric properties down to the monolayer limit. In the case of indium selenide, there is interest in γ-InSe due to its high carrier mobility (>1000 cm2/Vs) and β-In2Se3 and α-In2Se3 which are ferroelectric phases. Despite the intriguing properties, there have been few studies thus far aimed at investigating the epitaxial growth and properties of indium selenide films.

In this study, we demonstrate the growth of β-In2Se3 thin films on various substrates in a vertical cold-wall metalorganic chemical vapor deposition (MOCVD) system at 400 °C using trimethylindium (TMIn) and hydrogen selenide (H2Se) in a H2 carrier gas. The In2Se3 films were grown epitaxially on c-plane sapphire and Si (111) surfaces. The films were identified as β-In2Se3 by both Raman and XRD. A low reactor pressure (100 Torr) and high total gas flow rate were required to suppress gas-phase reactions between TMIn and H2Se based on their Lewis acid and base properties. β-In2Se3 films were formed on both c-plane sapphire and Si (111) surfaces in this work, however, γ-In2Se3 films were synthesized on amorphous SiO2/Si substrates indicating the importance of substrate type determining the crystal structure of the films. Top-gated thin film transistors (TFTs) fabricated on β-In2Se3 thin films reasonable mobility and on/off ratio and therefore offer potential applications in electronic devices.
SrTiO$_3$ is greatest when maximum commensuration between the lattices is achieved. Therefore, a key finding of this work is that the vdW interaction between MoS$_2$ and SrTiO$_3$ substrates determines the supported crystal shapes and orientations by epitaxial relations. Controlled crystal orientations make the growth of large sheets of MoS$_2$ possible when there are multiple nucleation sites. This minimizes the number of grain boundaries and optimizes the electronic properties of the material, e.g., charge mobility, which is crucial for the application of monolayer MoS$_2$ in next-generation nanoelectronics devices.

11:00 AM FF01.02.04
Accessing High Optical and Structural Quality of CVD Grown MoS$_2$ Monolayers Shivangi Shree$^1$, Antony George$^2$, Tibor Lehner$^3$, Cedric Robert$^1$, Xavier Marie$^1$, Kenji Watanabe$^4$, Takashi Taniguchi$^4$, Ute A. Kaiser$^1$, Bernhard Urbaszek$^1$ and Andrey Turchanin$^2$; $^1$CNRS LPCNO INSA-CNRS-UPS, France; $^2$Friedrich Schiller University Jena, Institute for Physical Chemistry, Germany; $^3$University of Ulm, Germany; $^4$National Institute for Materials Science, Japan

Transition metal dichalcogenides (TMDs) are ideal for exploring fundamental physics and applied optics as they are semiconductors with a direct bandgap in the monolayer (ML) limit. Therefore, it is very important to have access to high quality and also large surface area films. Here we show that chemical vapour deposition (CVD) growth can yield high quality MoS$_2$ monolayers on SiO$_2$/Si substrates.

We show high structural quality of CVD grown MoS$_2$ MLs on SiO$_2$ [1] in 4k x 4k high-resolution transmission electron microscopy (HRTEM) images using the chromatic and spherical aberration-corrected low-voltage TEM instrument operated at 60 kV. We determine a defect concentration of $10^{13}$/cm$^2$ in as grown MoS$_2$ MLs. But we observe broad optical transitions in as-grown samples (50 meV FWHM at T = 4K) on SiO$_2$ that are not expected for high structural quality, therefore indicating detrimental ML-substrate interactions. Therefore, we lift off the CVD grown layers from the growth substrate and encapsulate them in hBN flakes, which give us access to the intrinsic optical quality of the MoS$_2$ MLs.

We compare the optical quality of MoS$_2$ MLs in three different structures: CVD grown MoS$_2$ films on SiO$_2$, exfoliated MoS$_2$ ML from bulk MoS$_2$ in exfoliated hBN and most importantly MoS$_2$ ML grown by CVD encapsulated in hBN crystals prepared by mechanical exfoliation. For the latter structure, we show (i) in photoluminescence the neutral A-exciton emission linewidth reduced to 5 meV at T = 4 K, as compare to 50 meV linewidth in the as grown CVD sample and (ii) in absorption well separated optical transitions A:2s stemming from excited states of the A-exciton Rydberg series, indicating comparable quality of our CVD MLs to exfoliated MoS$_2$ material. We optically generate valley coherence and valley polarization in our CVD grown MoS$_2$ layers, showing the possibility for studying spin and valley physics in CVD samples of large surface area.

11:15 AM FF01.02.05
High Temperature CVD of Hexagonal Boron Nitride on Sapphire Using Carbon Free Precursors Anushka Bansal, Tanushree H. Choudhury, Mikhail Chubarov and Joan M. Redwing; The Pennsylvania State University, United States

Hexagonal Boron Nitride (hBN) is a 2D, III-nitride wide bandgap semiconductor that has a structure very similar to graphene. Due to its extraordinary physical properties, such as high resistivity, high thermal conductivity, stability in air up to 1000°C, large bandgap (Eg $\sim$ 5.9 eV), hBN appears to be a promising material for emerging applications, including deep UV (DUV) optoelectronics, electron emitters and neutron detectors. There is also significant interest in monolayer and few-layer hBN as an encapsulating layer for 2D devices based on graphene and transition metal dichalcogenides.

While high quality hBN bulk crystals are available for exfoliation, the size of the crystals is limited, consequently there is continued interest in the epitaxial growth of large area hBN films using chemical vapor deposition (CVD). The low temperature (500-1000°C) CVD growth of hBN on metallic substrates such as Cu, Ni, Pt, Ru etc. has been widely studied using ammonia borane (H$_3$N-BH$_3$) and borazine (B$_3$N$_6$H$_6$) as single-source precursors. However, NH$_3$ has been used in some cases to control the N/B ratio. In addition, borazine is thermally unstable and readily reacts forming low volatility polymers. While growth on metal substrates is a viable approach, there is significant
interest in the growth of hBN on non-metallic surfaces for device applications. The growth of hBN on a sapphire substrate was initially reported by Nakamura et. al. in 1986 followed by Kobayashi et. al in 2008 and others at a growth temperature greater than 1200°C. The precursors used for these growths includes triethyl boron (B(C₂H₅)₃, TEB), trimethyl boron (B(CH₃)₃, TMB) and NH₃ as the source of N. It is well known, however, that organic sources such as TEB result in carbon incorporation which is the biggest concern for the growth of epitaxial high purity BN films.

In this work, we are studying the growth of crystalline sp² BN in a vertical cold wall MOCVD reactor using a mixture of diborane (5% B₂H₆ in H₂) and NH₃ as precursors for B and N, respectively using H₂ as a carrier gas. The growths are performed on nitrided c-plane sapphire substrates at temperatures ranging from 1100-1500°C. Diborane reacts with NH₃ at temperatures as low as room temperature to form H₃N-BH₃ and other volatile B-N species, consequently, gas phase chemistry plays an important role in this deposition process. The influence of temperature, N/B inlet gas ratio and precursor flow method (pulsed versus continuous) on the material quality, characteristics and deposition rate were studied. In the lower temperature range (<1200°C), stoichiometric sp² BN films were obtained on sapphire using a N/B ratio of ~600 under continuous precursor flow giving a growth rate of ~10 nm/hr. Sequential pulsing of the B₂H₆ and NH₃ precursors resulted in a significant increase in the growth rate (~18 nm/hr) due to a reduction in the extent of gas phase reaction. Additional studies are underway to investigate growth at higher temperatures and over a wider parameter space to ascertain the growth mechanism as a function of conditions to provide additional insights into the role of gas phase chemistry on the properties of highly crystalline sp² BN films on sapphire.

11:30 AM FF01.02.06
Catalytically Enhanced Metal Organic Chemical Vapour Deposition of WS₂ Monolayer Films Stephan Hofmann, Ye Fan, Kenichi Nakanishi, Vlad-Petru Veigang-Radulescu, Jack Alexander-Webber, Ryo Mizuta and James C. Stewart; University of Cambridge, United Kingdom

Despite an abundance of reported growth methods, a key challenge for both current research and future technologies is the efficient and scalable growth and device integration of “electronic-grade” 2D layers. Metal organic chemical vapour deposition (MOCVD) has emerged as highly suitable particularly for transition metal dichalcogenide (TMDC) layer growth [1]. However, the understanding of the MOCVD process and control over detailed TMDC micro-structure remains currently limited, and carbon contamination and long growth times are of concerns. Our motivation is to advance the understanding of the growth mechanism of TMDCs with the focus on developing improved, scalable process technology. We employ here a “deconstructed” MOCVD process for WS₂, based on a simple sequential exposure pattern using precursors with low toxicity, namely tungsten hexacarbonyl and dimethylsulfide [2]. Combined with the use of a cold-walled reactor set-up, this minimises precursor pre-reactions and warrants a substrate surface bound reaction path. We use this as model system to systematically explore each growth aspect, including different substrates and their pre-treatment. For Au support, we find a significant catalytic effect that not only allows a significant reduction of the carbon contamination but also a self-limiting behaviour to mono-layer WS₂ with reasonable crystallinity, and full coverage within 10min exposure times. We discuss in this context of overlap between MOCVD and ALD processes, and, in parallel to other 2D materials, of suitable device integration strategies [3].

Van der Waals Epitaxial Growth of Transition Metal Dichalcogenides on Sapphire—Surface Chemistry Effect and Lessons for Other 2D Materials Assael Cohen, Kamal Ranganathan, Avinash Patsha and Ariel Ismach; Tel Aviv University, Israel

The ability to synthesize large-area and high quality atomic films is a prerequisite for their successful integration into a wide variety of novel and existing technologies. Here we show the growth of transition metal dichalcogenides (MoS₂, WS₂ and WSe₂) via modified chemical vapor deposition (CVD) methods using volatile precursors [1,2]. The use of high vapor pressure precursors allows for the controlled delivery to the growth sample [3], and therefore,
suitable for homogeneous and large-scale synthesis, as required for many applications. However, one of the problems with these precursors is the small domain size usually obtained [3]. In this scheme, a modified approach in which the metal and chalcogen precursors are delivered in a pulsed fashion is demonstrated. This approach allows to achieve a ten-fold increase in the domain size, from ~500 nm (or below) to ~10s of microns. Moreover, we demonstrate that the growth kinetics is highly dependent on the surface chemistry and by controlling it, the growth of ad-layers is inhibited and thus, more than 95% monolayer films are obtained. Another advantage of using volatile precursors is the ability to control the lateral and vertical heterostructures formation, and will be described as well. Following this work and in order to expand our growth capabilities, the growth of monochalcogenides using lessons learned while growing TMDs will be briefly described. Systematic structural, chemical, spectroscopic and electrical characterization will be shown for both systems as well. This work presents a big step towards the controlled growth of 2D materials.

SESSION FF01.03: Novel Stabilized 2D Materials and Heterostructures
Session Chairs: Zakaria Al Balushi and Deep Jariwala
Monday Morning, December 2, 2019
Hynes, Level 3, Room 312

8:00 AM FF01.03.01
In Situ Growth of Group V 2D Materials Matthieu Fortin-Deschênes¹, Robert Jacobberger², Charles-Antoine Deslauriers¹, Michael S. Arnold² and Oussama Moutanabbir¹; ¹Polytechnique Montreal, Canada; ²University of Wisconsin–Madison, United States

Although the existence of thousands of new 2D materials are being theoretically predicted [1], only a handful can be experimentally synthesized with the level of control required for their large-scale integration in future innovative devices and technologies. This is mainly due to the insufficient control over the nucleation at vdW interfaces, to the difficulty of implementing self-limiting monolayer growth in many systems and to the lack of experimental data regarding the van der Waals growth dynamics. In this talk, we will present in situ Low-Energy Electron Microscopy (LEEM) studies of the van der Waals growth dynamics of novel group V 2D materials. By combining LEEM and LEED measurements of the growth dynamics of antimonene on germanium and graphene substrates [2, 3] with semi-empirical modelling of the growth kinetics, we are able to determine the mechanisms governing the lateral and vertical growth modes of this new 2D material and to achieve a better control over the growth morphology. Moreover, we will present experimental evidence of the synthesis of a new 2D AsₓSb₁₋ₓ alloy with tunable As content. These results lay the groundwork for the implementation of novel group V 2D materials and heterostructures in electronic, optoelectronic and quantum devices.

8:15 AM FF01.03.02
Electron Beam Evaporated 2D Bismuth for Innovative Nanoelectronics Xinghao Sun¹, Wen Zhong¹, Zhaoying Dang¹, Seth Bank², Deji Akinwande², Beibei Zhu¹ and Li Tao¹; ¹Southeast University, China; ²The University of Texas at Austin, United States

Two-dimensional elemental materials (X-enes) have attracted increasing research attention due to tunable bandgap in between graphene and TMDs. As an emerging 2D X-ene, bismuthene, is expected to yield descent carrier
2D bismuth thin film is grown on Si (111) or SiO2/Si substrates in an e-beam evaporator. Before the deposition, Si (111) and SiO2/Si substrates were cleaned by ultrasonic in acetone for 5 min and rinsed by isopropyl alcohol and deionized water. Deposition of bismuth was initiated from a 99.999% pure Bi source at a rate of 0.1 Å/s under 5.0×10^-4 Pa pressure. The thickness of our Bi thin films can vary from 1-50 nm. Annealing effect is also studied via a tube furnace at 50-260°C in Ar atmosphere. Raman spectroscopy confirmed the successful growth of 2D bismuth with signatures at 70.4 cm⁻¹ (Eg) and 96.1 cm⁻¹ (A1g) which have a blue shift as thickness increases. X-ray diffraction on evaporated 20-nm thick Bi films observed expected hexagonal (001) orientation - a good crystallinity. A typical surface roughness is ~1nm indicated by atomic force microscope imaging over a 10×10μm² area, indicating a smooth surface for following device fabrication. The evaporated 2D bismuth, as the channel material, on SiO2/Si or Si (111) substrates, was then subjected to a field effect transistor fabrication process via lithography and Ti/Au electrodes evaporation. Electrical characterization, such as I-V curve for different thickness 2D bismuthene has been characterized on a Cascade® EPS150 probe station. A linear I-V curve reveals a good ohmic contact with conductivity ~3.65×10⁴ S/m for 20-nm 2D Bi and ~6.27×10⁴ S/m for 30-nm. Experimental research on photoelectric and thermoelectric behavior of e-beam evaporated 2D bismuthene has been carried out, which exhibited similar properties comparable to MBE bismuthene samples we prepared under the same material and device configuration in this study. Photoelectricity is observed under a wide range (visible to IR) laser exposure with photo responsibility ~10 A/W at unit power exposing to 800-nm laser. The Seebeck coefficient of our 2D bismuth was measured as -17.8μV/k (N type) at room temperature, which is greater than graphene. This study explored e-beam evaporation of 2D bismuth film and its material/device characterization comparable to MBE counterpart. This cost-effective method to prepare good quality bismuthene and its device holds great promise for innovative photoelectric and thermoelectric applications.

8:30 AM FF01.03.03
Chemically Tunable 2D Layered Materials via Intercalation and Deintercalation Mengjing Wang¹ and Kristie J. Koski²; ¹University of Central Florida, United States; ²UC Davis, United States

2D layered materials reside in a class of crystals consisting of weakly bonded atomic layers by van der Waals attraction. In particular, this distinct structure feature renders 2D layered materials exceptional physical and chemical properties inaccessible in bulk crystals, e.g., quantum confinement and surface effects, which offer 2D materials a wide range of applications in electronics, optoelectronics, energy storage, catalyst, and chemical sensing fields. One of the remaining challenges in the 2D material arena is to explore novel layered materials with breaking new properties. Rather than searching for new materials, we pursued developing reliable chemical routes, intercalation/deintercalation of metals, to tailor the original 2D materials with tunable chemical and physical properties. This talk will cover a series of innovative chemical intercalation/deintercalation of metals in layered crystals (chalcogenides and oxides), followed by examples of unusual phenomena introduced by intercalation, including polytypic phase transitions in metal intercalated Bi₂Se₃, and the chemo-chromism/thermochromism of MoO₃ intercalated with metal.

Creating Atomically-Thin Metals for Next Generation Quantum Architectures Joshua A. Robinson; The Pennsylvania State University, United States

Quantum materials are prime candidates for next-generation energy-efficient technologies, such as topological quantum computing, quantum sensing, and neuromorphic computing. While van der Waals 2D materials exhibit a compellingly wide range of exotic and potentially useful properties such as charge density waves, topological insulator edges, and superconductivity, one can also realize these properties by stabilizing new 2D allotropes of traditionally 3D superconductors and magnets. In this talk I will discuss our pioneering work in confinement heteroepitaxy (CHet) that enables the creation of 2D forms of 3D materials (e.g. 2D-Ga, In, Sn, Ag, Au, etc.) and decouples the growth of the metals from other 2D layers, thereby enabling a new platform for creating artificial quantum lattices with atomically sharp interfaces and designed properties. As a specific example, we synthesize
plasmonic layers that exhibit >2000x improvement in nonlinear optical properties, and 2D-superconductors combined with topological insulators as the building block of next generation “2D” topological superconductors. Confinement heteroepitaxy opens up avenues for enabling a virtual “legoland” of hybrid quantum materials.

**Stable Silicene in Graphene/Silicene van der Waals Heterostructures**

Yuyang Zhang¹, Geng Li¹, Lihong Bao¹, Shixuan Du¹, Sokrates Pantelides² and Hong-Jun Gao¹; ¹Chinese Academy of Sciences, China; ²Vanderbilt University, United States

As a two-dimensional analog of graphene, silicene has recently been the subject of extensive research interest. The easy oxidation of silicene in air limits its applications in device design and fabrication. In this talk we report the experimental fabrication of silicene protected by a graphene overlayer. The graphene layer is grown first on a Ru(0001) substrate and silicene is grown under it by Si intercalation. By controlling the amount of silicon, ordered arrays of pseudomorphic silicene nano flakes as well as single layers and multilayers of silicene can be successfully fabricated under graphene that is epitaxially grown on Ru(0001). Density-functional-theory calculations show weak interactions between graphene and silicene layers, indicating that the fabricated structures are silicene/graphene van der Waals heterostructures. The as-prepared silicene-based structures show no observable damage after air exposure for two weeks. The vertical graphene/silicene/Ru heterostructure shows rectification behavior with an ideality factor of ~1.5 [1].

**CVD Synthesis and Properties of Bilayer Graphene and TMDs**

A T Charlie Johnson; University of Pennsylvania, United States

Two-dimensional (2D) van der Waals (vdW) materials fabricated by stacking of homogeneous or heterogeneous monolayer “building blocks” are attracting increased attention, since their unique physical and chemical properties offer great promise for use in atomically thin electronic and optoelectronic devices. For stacks of homogeneous 2D vdW materials, the number of layers plays a crucial role in the ultimate optoelectronic properties. Since the change in properties from monolayer to bilayer to trilateral is typically more significant than that resulting from additional layers, there is great interest in achieving precise control over bilayer/trilayer formation, including the stacking geometry. In this talk I will discuss how we have made progress in this area through new methods of controlling the catalytic growth substrate, in the case of graphene, and growth promoting compounds in the case of TMD materials.

10:30 AM FF01.03.07
**Tuning the Dimensionality and Optical Properties of TMDs with Substrate Directed Synthesis**

Thomas J. Kempa, Tomojit Chowdhury and Jungkil Kim; Johns Hopkins University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) exhibit an intriguing array of layer-, topology-, and morphology-dependent properties, which have demonstrated enormous potential in optoelectronics, energy conversion, and quantum information science. Although “top-down” approaches can be used to define crystal morphologies and dimensions, explicit synthetic control of the physical properties of TMD crystals is desirable, but also a major challenge. We demonstrate a gas-phase synthesis method that significantly transforms the structure and dimensionality of MoS₂ and other TMD crystals without lithography. Synthesis of MoS₂ on Si (001) surfaces pre-treated with phosphine (PH₃) furnishes high aspect ratio nanoribbons of crystalline 2H phase MoS₂. The widths of these nominally 1D crystals are exceptionally uniform and their edges are sharper than those of TMD crystals prepared by most other means. Notably, the widths of the MoS₂ nanoribbons can be systematically controlled between 70 nm and 500 nm by varying the concentration of PH₃ gas introduced during the Si surface treatment step. Detailed kinetic studies supported by cluster expansion and DFT calculations indicate that the structure and concentration of the underlying Si–phosphide moieties is instrumental in transforming growth of MoS₂ from a conventional 2D triangular to nominally 1D morphology. Notably, far-field and near-field photoluminescence (PL)
studies of 1D MoS$_2$ crystals show that they exhibit an emission peak which is blue-shifted by 50 meV relative to that of 2D MoS$_2$ nanocrystals. Our efforts highlight future opportunities for development of designer substrates that could mediate the synthesis of new low-dimensional crystals with prescribed structures and properties.

Large Scale Synthesis of MoS$_2$: One-Dimensional Nanostructures and the Precision Manipulation
Yun Huang$^{1}$, Kang Yu$^{1,2}$, Zexi Liang$^{1}$, Paulo Ferreira$^{2,1}$, and Donglei Fan$^{1,1}$; $^{1}$The University of Texas at Austin, United States; $^{2}$International Iberian Nanotechnology Laboratory, Portugal

In the family of two dimensional (2D) materials, molybdenum disulfide (MoS$_2$) has received immense attention owing to its unique electrical, catalytic, biological and mechanical properties. Herein, we report a robust and scalable approach to synthesize MoS$_2$ nanoribbons with controlled dimensions. Advanced characterizations confirm the chemistry, morphology, and crystalline structures of materials obtained at different reaction stages when synthesizing MoS$_2$, including MoO$_3$, MoS$_2$/MoO$_2$ hybrid, and MoS$_2$ nanoribbons. With the electric tweezers based on combined AC and DC electric fields, the MoS$_2$ nanoribbons can be readily manipulated with desired orientations along arbitrary trajectories, e.g. a cat drawing. Moreover, it is found that the electromechanical behaviors of the particles obtained at different stages strongly correlate with their electric properties, the demonstration of which could be utilized to monitor and understand the synthesis of targeted nanomaterials. This work could lead to a new paradigm in the large-scale fabrication of 2D materials with designed dimensions and inspire their innovative applications in nanorobotics, micro/nanoelectromechanical system devices (MEMS/NEMS), as well as molecule delivery and release.

11:00 AM FF01.03.09
Helical van der Waals Crystals with Discretized Eshelby Twist
Yin Liu$^{1}$, Jie Wang$^{2}$, Sujung Kim$^{1}$, Haoye Sun$^{1}$, Fuyi Yang$^{1}$, Zixuan Fang$^{1}$, Nobumichi Tamura$^{1}$, Ruopeng Zhang$^{1,3}$, Xiaohui Song$^{1}$, Jianguo Wen$^{2}$, Qin Yu$^{1}$, Michael Wang$^{1}$, Emory Chan$^{1}$, Dafet Jin$^{2}$, Robert O. Ritchie$^{1}$, Andrew M. Minor$^{1,3}$, Daryl Chrzan$^{1}$, Mary Scott$^{1,3}$ and Jie Yao$^{1}$; $^{1}$University of California, Berkeley, United States; $^{2}$Argonne national laboratory, United States; $^{3}$Lawrence Berkeley National Laboratory, United States

The ability to manipulate the twisting topology of van der Waals (vdW) structures enables a new degree of freedom to tailor their electrical and optical properties. In particular, the twist angle has been shown to strongly affect the electronic states, excitons and phonons of the twisted structures via interlayer coupling, giving rise to exotic optical, electric and spintronic behaviors. In twisted bilayer graphene, at certain twist angles, long-range periodicity associated with Moiré pattern introduces flat bands and highly localized electronic states, resulting in Mott insulating behavior and superconductivity. Beyond bilayer graphene, recent theoretical studies suggest these twist-induced localization and the formation of flat bands are phenomena common to various layered materials such as transition metal dichalcogenides and black phosphorus. Twisted vdW structures are usually created using transfer-stacking method, where atomic layers are mechanically exfoliated and transferred to stack with controlled twist angles in a layer-by-layer configuration. This approach, however, is not suitable to create twisted structures of a variety of layered materials with relatively strong interlayer binding. In contrast, facile bottom-up growth methods could provide an alternative means to create twisted vdW structures. Herein, we demonstrate that the Eshelby twist, associated with a screw dislocation, a chiral topological defect can drive the formation of twisted vdW structures on multiple scales ranging from nanoscale to mesoscale. In our synthesis method, axial screw dislocation was first introduced into vdW nanowires with growth direction along the vdW stacking direction (cross-plane direction), yielding vdW nanostructures with continuous twisting. Further growth on the dislocated nanowires adhered to the substrate results in the discretization of the Eshelby twist in the mesoscale structures, yielding unique twisting structures consisting of a helical assembly of nanoplates. In these mesoscale helical crystals, atomically sharp interfaces with various twist angles are created, providing an intriguing tunable platform to explore various interlayer coupling effects. Our theoretical modeling suggests that the formation of the discretized twisting results from the interplay between the interfacial energies associated with the twist interfaces and the elastic strain energy defined by the Eshelby twist. We further show that the twisting topology can be tailored by controlling the radial size of the structure.

Stabilization of Tellurene—A New Group VI 2D Material
Moon J. Kim$^{1}$, Wenzhuo Wu$^{2}$, Peide P. Ye$^{2}$, Robert Klie$^{3}$ and Maria K. Chan$^{4}$; $^{1}$The University of Texas at Dallas, United States; $^{2}$Purdue University, United States;
Since the discovery of graphene [1], other 2D materials such as silicene, germanene, borophene, phospherene, and various transition metal dichalcogenides (TMDs) have been explored in a great deal due to their novel structure and tunable properties. In contrast, group VI elements such as tellurium or selenium have yet to be stabilized in purely 2D forms, which may be due to its stable covalently bonded Te atomic chains that spiral along its c-axes. In this case, a typical exfoliation technique to produce 2D monolayers would not work. However, the density functional theory calculations by Zhu et al. predict that 2D atomic layers of tellurium might exist in stable 1T-like structure (a-Te), and the metastable tetragonal (b-Te) and 2H-like (g-Te) structures [2].

Here, we report the first experimental realization of a 2D group VI tellurium chalcogen, namely tellurene. Ultra-thin flakes of tellurium with controlled thickness were produced by substrate-free solution process. Each 2D tellurene flakes have thicknesses ranging from 15 to 100 nm. Tellurene flakes with a thickness smaller than 10 nm were also produced through a solvent-assisted post-growth thinning process [3]. A single atomic layer 2D tellurium was also synthesized by a wafer-bonding assisted self-assembly process, a new approach to synthesize and stabilize the low-dimensional structure. Each monolayer Te atom has four nearest neighbors within the plane with inter-atomic distances of 0.31 – 0.32 nm. Atomic-resolution chemical mapping and structural characterization via scanning transmission electron microscopy (STEM) leading to the definitive identification of single atomic layer tellurene.

First-principles calculations found tellurene to be metallic, with electronic band structures containing Dirac-cone-like features and exhibiting significant asymmetric spin-orbit band splitting. These findings enable further research into the suitability of tellurene for device applications, such as spintronics and quantum computing.

Organic-Inorganic 2D Halide Perovskites Mercouri G. Kanatzidis: Northwestern University, United States

Two-dimensional (2D) layered halide perovskites are highly promising semiconductors for optoelectronic applications ranging from solar cells, light emitting diodes and detectors. This class of 2D materials gaining significance as they offer high synthetic versatility and allow for more specialized device implementation due to the directional nature of the crystal structure. A remarkable advantage of the 2D perovskites is the readily tunable functionality by incorporating a wide array of organic cations into the 2D framework and by controlling the slab thickness, in contrast to the 3D analogues which have limited scope for structural engineering. We present the new homologous series, (C(NH2)3)(CH3NH3)nPbnI3n+1 (n = 1, 2, 3), of layered 2D perovskites which is different from Ruddlesden-Popper type. These compounds adopt an unprecedented structure type which is stabilized by the alternating ordering of the guanidinium and methylammonium cations in the interlayer space (ACI). The these 2D perovskites combine structural characteristics from both Dion-Jacobson (DJ) and Ruddlesden-Popper (RP) structure archetypes. We also report the first examples of hybrid DJ hybrid 2D lead iodide perovskites which consist of thick perovskite slabs (n>1) with layer number (n) ranging from 1 to 5. We describe two new DJ perovskite series based on bivalent (+2) spacer cations deriving from a piperidinium (C5NH12) organic backbone. The new DJ perovskites are built from 3AMP (3AMP = 3-(aminomethyl)piperidinium) and 4AMP (4AMP = 4-(aminomethyl)piperidinium) spacers and methylammonium (MA) perovskitizers cations to form A'(MA)n-1PbnI3n+1 (A' = 3AMP or 4AMP, n = 1-4) homologous series acting as spacers. Surprisingly, a slight difference in the position of the-CH2NH3+ group on the piperidine chair (3- and 4- position with respect to the piperidine nitrogen) exerts a strong influence on the crystal structure, which is reflected on the distortion of the inorganic layers.
Emerging Neuromorphic Devices Based on Two-Dimensional Materials
Mark C. Hersam; Northwestern University, United States

The exponentially improving performance of conventional digital computers has slowed in recent years due to the speed and power consumption issues that are largely attributable to the von Neumann bottleneck (i.e., the need to transfer data between spatially separate processor and memory blocks). In contrast, neuromorphic (i.e., brain-like) computing aims to circumvent the limitations of von Neumann architectures by spatially co-locating processor and memory blocks or even combining logic and data storage functions within the same device. In addition to reducing power consumption in conventional computing, neuromorphic devices also provide efficient architectures for emerging applications such as image recognition, machine learning, and artificial intelligence. With this motivation in mind, this talk will explore the opportunities for two-dimensional materials in neuromorphic devices. For example, by combining p-type black phosphorus with n-type transition metal dichalcogenides, gate-tunable diodes have been realized, which show anti-ambipolar transfer characteristics that are suitable for artificial neurons, competitive learning, and spiking circuits [1]. In addition, by exploiting field-driven defect motion mediated by grain boundaries in monolayer MoS2, gate-tunable memristive phenomena have been achieved, which enable hybrid memristor/transistor devices (i.e., “memtransistors”) that concurrently provide logic and data storage functions [2]. The planar geometry of memtransistors further allows multiple contacts to the channel region that mimic the behavior of biological neurons such as heterosynaptic responses [3]. Overall, this work introduces new foundational circuit elements for neuromorphic computing in addition to providing alternative pathways for studying and utilizing the unique charge transport characteristics of two-dimensional materials [4].

2D Heterostructure-Based Neuromorphic Computing
Sanghoon Bae, Beomseok Kang, Chansoo Kim and Jeehwan Kim; Massachusetts Institute of Technology, United States

A current artificial intelligence (AI) system consumes massive computing resources from supercomputers to handle computing traffic inside deep neural networks (DNN). Although interesting application-specific integrated circuits (ASIC) solutions in CMOS have been introduced, we are still suffering limitations on memory footprint, in-memory computing, and on-/off-chip communication. In this regard, a novel computing architecture based on non-volatile resistive switching devices called RRAM has shown a great potential as the RRAM device can continuously tune its analog conductance under moderate voltage stimulation, and thus each device can efficiently execute the “synaptic weight” in the neural network. In addition, the RRAM based computing can accomplish considerably higher integration density compared with the current CMOS technologies and highly efficient parallel computing. Therefore, people have put intensive effort in development of the RRAM array-based system beyond the current supercomputing system [1].

Here, we propose a novel approach to demonstrate stable RRAM array based on 2D heterostructure, which enables real neuromorphic computing for the first time. 2D materials have been known to have atomically thin feature for high integration density and anisotropic ionic transport characteristic in the in-plane and the out-of-plane direction for stable switching filament formation. It makes them promising as a switching medium for neuromorphic computing. Despite of this great potential, there was no study for real neuromorphic computing demonstration using 2D materials based memristors because limited approaches exist for large scale, uniform 2D materials demonstration. Last year, we reported an interesting method for large-scale, uniform 2D materials which ensures pristine interface at interface of heterostructures [2]. With the method, we, for the first time, have realized a 2D
heterostructure memristor array having large memory window over $10^4$ and stable filament formation even after 100 times set-reset cycling test, which successfully functions to implement image recognition simulation. We strongly believe that this innovative approach can open a new opportunity for the neuromorphic computing.

**All-Solid-State Non-Volatile Memory Gated by a Monolayer Electrolyte**

Jierui Liang¹, Ke Xu¹, Maokun Wu², Benjamin Hunt³, Wei-Hua Wang⁴, Kyeongjae Cho⁴ and Susan Fullerton¹; ¹University of Pittsburgh, United States; ²Nankai University, China; ³Carnegie Mellon University, United States; ⁴The University of Texas at Dallas, United States

A non-volatile, solid-state, one-transistor (1T) memory is demonstrated based on electric double layer (EDL) gating of a WSe₂ field-effect transistor (FET) using an electrolyte that is a single molecular layer thick. The “monolayer electrolyte” consists of cobalt crown ether phthalocyanine and lithium ions, which are positioned by field-effect at either the surface of the WSe₂ channel or a h-BN capping layer to achieve ‘1’ or ‘0’, respectively. Bistability in the monolayer electrolyte memory is significantly improved by the h-BN cap, with density functional theory (DFT) calculations showing an enhanced trapping of Li⁺ near h-BN due to a $\sim 1.34$ eV increase in the absolute value of the adsorption energy compared to vacuum. The threshold voltage shift between the two states corresponds to a change in charge density of $\sim 2.5 \times 10^{12}$ cm$^{-2}$, and an on-off ratio exceeding $10^4$ at a back gate voltage of 0 V. The on-off ratio remains stable after 1000 cycles and the retention time for each state exceeds 6 hours (max measured). When the write time approaches 1 ms, the on-off ratio remains $> 10^2$, showing that monolayer electrolyte-gated, 2D non-volatile FET can respond on timescales similar to existing flash memory. The data suggest that faster switching times and lower switching voltages could be feasible by top gating.

The research is supported by the National Science Foundation (NSF, U.S.) under Grant No. ECCS-GOALI-1408425 and DMR-CAREER-1847808. M. Wu and W. Wang acknowledge support from the National Key Research and Development Program of China with No. 2016YFB0901600 and National Natural Science Foundation of China with No. 11874223 and 51871121.

**Nonvolatile Resistive Memory Realized by the Morphological Control of Two-Dimensional Layered Double Hydroxide**

Haein Cho¹, Chan Woo Jeon², Jingon Jang¹, Il Kyu Park² and Gunuk Wang¹; ¹Korea University, Korea (the Republic of); ²Seoul National University of Science & Technology, Korea (the Republic of)

Diverse forms of two-dimensional (2D) materials have been attracting a lot of attention as emerging materials for low-power and high-performance electronic or optoelectronic devices. Layered double hydroxide(LDH) is a kind of 2D layers consisting of a positively charged metal hydroxide layer and intercalated charge-balancing anions, expressed by $[\text{M}^{2+}_{1-x}, \text{M}^{3+}_x \text{(OH)}_2]^x$ $(\text{A}^{6+})^{x/2} \cdot \text{mH}_2\text{O}^2$. In this study, we synthesized three LDH layers using three divalent cations such as Zn$^{2+}$, Ni$^{2+}$, and Co$^{2+}$ and controlled each packing density, which all were confirmed by XRD and SEM analysis. Then, we analyzed and performed the electrical properties for each LDH in a form of two-terminal vertical junction structures using Pt and FTO electrode. Interestingly, only densely-packed ZnAl-LDH based device exhibited unipolar switching behavior with $10^4$ ON-OFF ratio and acceptable stability, while all others did not show any switching feature. The potential reason for the switching success or failure might be attributed to the morphology difference in LDH layers induced by different ion components and concentrations during LDH synthesis. A potential switching mechanism can be suggested by space-charge-limited conduction (SCLC) transport and directional motion of ionic vacancy by the electric field. Our result indicates the importance of 2D LDH stacking morphology for the implementation of the nonvolatile resistive switching device.

Memristive Behavior and Switching Mechanism in Transfer-Free 2D WS2/MoS2 Heterojunction Wenguang Zhang, Chunsan Deng, Sanlue Hu, Hao Wu, Jingwei Liu and Wei Xiong; Huazhong University of Science and Technology, Wuhan National Laboratory for Optoelectronics, China

The recent progress in memristor technology has made it an appealing competitor for future computing architectures and neuromorphic computing systems. However, the scale-down ability and uncertain switching mechanism are still the stumbling blocks to the development of memristor. The emerging transition metal dichalcogenides (TMDCs) has been recognized as a promising candidate for the nanoscale memristive devices owing to their flexibility, transparency and especially scale-down ability. In this work, we demonstrate a type of metal-semiconductor-metal (MSM) memristor architecture based on transfer-free WS2/MoS2 heterojunction, completely different from the conventional metal-insulator-metal (MIM) architectures using insulating metal oxides as the function layer. This MSM device is forming-free and shows a reproducible bipolar memristive behavior with $R_{ON}/R_{OFF}$ ratio up to $10^4$. Moreover, the programming voltages of this device is around 1.4 V with currents lower than 10 µA and the thickness of the function layer down to 10 nm. Finally, we discuss the switching mechanism in the WS2/MoS2 heterojunction. Different from the filament-based mechanism, the resistance switching of the WS2/MoS2 2D heterojunction memristor is mainly ascribed to the electric-field modulation of the band structure of the WS2/MoS2 heterojunction, which is promising for the development of high-speed and low-power memristors.

3:45 PM *FF01.05.02
Potential Electronic Applications of Graphene and 2D Layered Materials Hyeon Jin Shin; Samsung Electronics, Korea (the Republic of)

Two dimensional (2D) layered materials are crystalline materials with layered structures, including Graphene, h-BN, and Transition Metal Di-chalcogenides (TMD’s). We have studied 2D layered materials in two directions. For the near future application, we have been investigated 2D layered materials for Si technology to enhance their performance. To overcome performance limit for the long term downscaling of Si technology, we have focused 2D layered materials as interface materials due to the chemical inertness and their atomically thin nature. We investigated Graphene/metal hybrid interconnect. Although high quality graphene can be produced on catalyst metals, Si technologies are limited by the high temperature growth and the post transfer process. W/nanocrystalline graphene (ncG)/TiN is realized by direct growth on noncatalytic TiN, up to 12" wafer, at a low temperature of 560 °C which is below the semiconductor integration temperature. ncG acts in the interconnect not only a diffusion barrier to metal silicide formation but also a promoter of the preferential grain growth of the W layer. Overall, a significant reduction (27%) in the resistance of the interconnect is achieved by the insertion of ncG between W and TiN. This work points to the possibility of practical graphene applications via direct ncG growth that is compatible with current Si technology.[1] Also, We demonstrated that 2D layered materials are good candidates for interface materials between metal and Si to reduce the Schottky barrier heights and contact resistance in source and drain, which is one of the most critical issues for scaling down.[2,3,4] We found that 2D materials may change the pinning point of Schottky barrier and end up reducing contact resistance. We realized the lowest specific contact resistivity of 3.30 nΩcm² (n-type Si, 10^{15}/cm³) and 1.47 nΩcm² (n-type Si, 10^{21}/cm³) via Graphene and h-BN insertion in 6" wafer are approaching the theoretical limit of 1.3 nΩcm².[3] As one of the long term applications, we are developing transistors beyond the 5 nm node for high integration / high performance / low power, and beyond Si devices for optoelectronic applications in the IR domain. In pursuit of these research directions, we are studying a large area growth and doped structure growth. Recently, we grew MoS2 monolayer on 6 inch wafer within 10min by sequential growth method. [5] To explore 2D application, we examined triboelectric nanogenerator, which has been explored as one of the possible candidates for the auxiliary power.
source of portable and wearable devices. [6] We investigated the triboelectric charging behaviors of various 2D layered materials, including MoS$_2$, MoSe$_2$, WS$_2$, WSe$_2$, graphene, and graphene oxide and confirms the position of 2D layered materials in the triboelectric series. It is also demonstrated that the results are related to the effective work functions. This study provides new insights to utilize 2D layered materials in triboelectric devices, allowing thin and flexible device fabrication. [7]

4:15 PM FF01.05.03
Gate-Tunable Diodes and Switches Based on van der Waals Heterostructures of 2D and 3D Semiconductors
Jinshui Miao$^1$, Ravindra Saxena$^1$, Kiyoung Jo$^1$, Huiqin Zhang$^1$, Myung-Geun Han$^2$ and Deep M. Jariwala$^1$;
$^1$University of Pennsylvania, United States; $^2$Brookhaven National Laboratory, United States

Semiconductor p-n junction diodes and field-effect transistors are essential building blocks of electronic and optoelectronic devices. Over the past several decades, in the quest for higher performance, the dimensions of functional devices comprising 3D bulk semiconductors continue to decrease. However, the inherent scaling limitations of 3D devices such as short-channel effects, have fueled the exploration of alternative semiconductors. 2D layered materials have been a central focus of materials research for More Moore and More-than-Moore device applications because each layer of 2D materials consists of a covalently bonded and dangling-bond-free lattice and is weakly bound to neighboring layers by van der Waals interactions.$^{1,2}$ Consequently, 2D layered materials can be integrated with an array of materials of different dimensionalities to form mixed-dimensional van der Waals heterostructures without the constraints of lattice matching and processing compatibility. $^3$ Very recently, the integration of 2D materials with 3D bulk semiconductors offers promising platforms for heterojunction device applications, which allows the combination of novel properties of 2D materials with the proven merits of well-developed 3D semiconductors.$^4$

Here we have demonstrated highly gate-tunable heterojunction diodes using van der Waals assembly of 2D layered semiconductors (MoS$_2$, WSe$_2$ and InSe) and 3D bulk semiconductors (silicon and gallium nitride). The vertical stacking of these semiconductors forms a heterojunction with charge transport behavior that can be fully modulated by an applied gate electrostatic field. We observe gate-tunable current rectification with forward-to-reverse bias current ratios of up to 10$^7$. More importantly, when operated as three-terminal devices, the 2D/3D heterojunction diodes exhibit a unipolar n-type transistor behavior with current on/off ratios exceeding 10$^7$ sufficient for digital logic circuitry applications. These devices also deliver a large current density exceeding $\sim$130A/cm$^2$ which is attributed to ohmic metal contacts as well as a conductive 2D/3D junction. Our devices present new avenues for future nanoscale electronic and optoelectronic devices for both digital logic and radio frequency applications.

Electric Double Layer Gating of Two-Dimensional Field-Effect Transistors Using a Single-Ion Conductor Ke Xu, Jierui Liang, Eli Bostian, Aaron Woeppe, Hangjun Ding, Eric Beckman and Susan Fullerton; University of Pittsburgh, United States
Two dimensional (2D) van der Waals (vdW) semiconductors have recently emerged as next-generation channel materials for field effect transistors (FETs) owing to their atomically flat surface, improved electrostatic gate control and enhanced scalability [1]. Theoretical calculations have shown that elemental vdW crystals such as 2D black phosphorous (BP) and 2D arsenic can show high mobilities, layer dependent tunable bandgap along with extremely light anisotropic carrier effective masses [2]. This makes them better candidates for FETs than transition metal dichalcogenides, which are marked with stochiometric defects and much lowered mobilities [3]. BP has already been effectively utilized to fabricate high performance MOSFETs and tunneling FETs with steep subthreshold swings, high on/off ratios and low off current [4,5]. However, for practical use, deterioration under the ambient environmental conditions is still a major bottleneck that needs to be overcome before BP based electronic devices can be realized. 2D arsenic - isostructural to BP, is much more stable in ambient conditions [6]. Moreover, recent experiments have shown that 2D arsenic has superior or comparable electronic and thermal properties than other 2D materials due to the presence of highly anisotropic effective masses along the two crystal directions [6,7]. Due to its low bandgap, 2D arsenic should show ambipolar electrical conduction, however, in the literature only p-type conduction has been reported [6]. In this work, we present the first ever demonstration of ambipolar 2D arsenic FETs and analyze the device performance and transport for both electrons and holes in this material.

Flakes (exfoliated from crystals obtained from a commercial vendor) with varying thicknesses were used to fabricate a series of devices on a 300-nm-thick SiO2 dielectric grown on an n+ Si wafer. Electron dispersive spectroscopy (EDS) mapping was used to verify the composition of the material and the results showed that the obtained material was >99% pure arsenic. Angle resolved polarized Raman spectroscopy revealed a two-fold symmetry for $A_{1g}^1$ (220.1 cm$^{-1}$) and $A_{2g}^1$ (253.62 cm$^{-1}$) modes (with maximum and minimum intensities along armchair and zigzag direction respectively) further establishing the presence of the anisotropic puckered crystal structure [8]. In FET
devices, it was found that the subthreshold slope and off-state leakage current improved with decrease in thickness or decrease in source/drain voltage bias which is indicative of the layer dependent bandgap of 2D arsenic. At room temperature, on/off ratios as high as 2.5 x 10^5 and 3 x 10^2 were obtained for hole and electron conduction, respectively, with respective mobility values (for thickest to thinnest samples) ranging from 150 to 40 cm^2/Vs for holes and 175 to 10 cm^2/Vs for electrons. For thick flakes, hole and electron drive currents obtained were 30 μA/μm and 10 μA/μm respectively at |VDS| = 1 V. Low temperature transfer and output characteristics were taken, and a thermionic transport model was used to extract the Schottky barrier height at the metal/semiconductor contact. The tunability of the barrier height for both electron and hole transport was further explored by changing the applied backgate bias.

This work was supported by the NSF (Award # ECCS-1708769). Portions of this work also used shared facilities at the University of Minnesota, supported through the NSF NNCI (Award # ECCS-1542202) and MRSEC (Award # DMR-1420013) programs.

SESSION FF01.06: Poster Session I: Beyond Graphene 2D Materials—Synthesis, Properties and Device Applications I

Session Chairs: Zakaria Al Balushi, Deep Jariwala, Olga Kazakova and Amber McCreary

Monday Afternoon, December 2, 2019
8:00 PM - 10:00 PM
Hynes, Level 1, Hall B

Substitutional Doping and Heterostructuring of Monolayer Transition Metal Dichalcogenides Inspired by Sol-Gel Technique
Tianyi Zhang, Kazunori Fujisawa, Fu Zhang, Mingzu Liu, Yu Lei, Kevin Crust, Rafael N. Gontijo, He Liu, Ana Laura Elias and Mauricio Terrones; The Pennsylvania State University, United States

Doping and heterostructuring lie at the heart of modern semiconductor technologies, which allow for the control over the functionalitites of semiconductors, and the formation of junctions that make semiconductor devices operational. Recent studies have indicated that, by substitutional doping of semiconducting 2D TMDs materials with judicious selection of dopants, a series of their physicochemical properties can be effectively modified. Furthermore, laterally stitching TMDs with dissimilar compositions enables the formation of atomically thin in-plane heterojunctions, endowing them with great potential for electronic and optoelectronic applications. In light of this, it is desired to develop a reliable doping method for TMDs that can be potentially suitable for a wide range of dopant selections, as well as an efficient route for creating in-plane heterostructures between two dissimilar TMDs. Herein, to solve this challenge, a reliable in situ substitution doping method for monolayer TMDs is reported. Specifically, a solution precursor-based chemical vapor deposition (CVD) technique is developed. By varying the composition of precursor solutions, it is demonstrated that iron (Fe)-doped WS2 and rhenium (Re)-doped MoS2 can be achieved by the developed technique. In addition, monolayer in-plane W6Mo1sS2-MoSxW1-xS2 heterostructures with molybdenum (Mo)-rich inner regions and tungsten (W)-rich outer regions is also successfully synthesized. This doping and heterostructuring method may also be extended for the incorporation of a variety of other elements into 2D TMDs. This work shed light on the design and control of the functionalities of 2D TMDs, enabling novel applications based on these 2D materials and heterojunctions.

FF01.06.05
Materials Solubility Engineered Wafer Scale Growth of High Quality Black Ti2O3 Layers
Il-Suk Kang, Kwonjae Yoo, Gyungtae Kim and Yun Chang Park; National Nanofab Center, Korea Advanced Institute of Science and Technology, Korea (the Republic of)
Black Ti$_2$O$_3$ is one of titanium oxide compounds with very stable properties in air, bio, and space environments. It also shows superconductivity in the high quality thin films which can be used for the quantum technology. High quality black Ti$_2$O$_3$ layers were successfully grown using Cu-Ti very low solubility phase and fast cooling approach from near the Cu melting temperature. Here we present the properties of ultrathin black Ti$_2$O$_3$ layers on SiO$_2$ substrate in large scale for solid state device applications.

Strikingly black Ti$_2$O$_3$ nanoparticles are known to exhibit narrow-band gap property compared to wide-band gap TiO$_2$ materials, which is suitable for photothermal applications as reported by T. Wu’s group. It was one of long seeking materials for a complement and alternative material of TiO$_2$, which can absorb sun light beyond UV range. Mao’s group also found that disordered black TiO$_2$ covered around TiO$_2$ nanoparticles, which later turned out to be as black Ti$_2$O$_3$, effectively increase solar absorption ability. However it is a difficult task to apply Ti$_2$O$_3$ nanoparticles to solid state device applications. Wafer level Ti$_2$O$_3$ thin films are required in the standard fab processing for cost effective and mass production of sensor and bio detection devices as well as photothermal conversion applications.

Wafer size Ti$_2$O$_3$ layers of about 10 nm thickness were grown using conventional thermal furnace by employing the concept of very low soluble property of Ti-Cu layers. Raman spectra with very narrow width at 274 cm$^{-1}$ in the samples grown above the growth temperatures of 1000-1090 Celsius degree indicate that the Ti$_2$O$_3$ layers are highly ordered and PL spectra show broad weak peaks near 500 nm in addition to the strong signals at near 574 nm at room temperature which is commonly observed in different forms of TiO$_2$.

We started from the Ti(20nm)/Cu(600nm) template deposited on SiO$_2$/Si wafer using sputtering evaporation method at room temperature. It is known that the Ti-Cu system has very low solubility which is difficult to make of alloy. The maximum Ti solubility in Cu is about 8% at 885 Celsius degree that can be found in the phase diagram literature. It is well known that Cu layers with less than about 1000 nm thickness dominantly form (111) crystal phase due to low surface free energy. The deposited ultrathin Ti layers are randomly arranged in a few Ti atomic layers on Cu(111). Then a few Ti atomic layers were exposed with very small amount of O$_2$ at high temperature and subsequently quenching under H$_2$ environments. This lead to the formation of Ti$_2$O$_3$ layers because of more oxidation affinity between oxygen and Ti. The Ti-Cu system under fast cooling with a little O$_2$ make the most stable Ti$_2$O$_3$ surface layers removing any other TiO$_2$ phase structures. Actually more O$_2$ with slow cooling lead to anatase TiO$_2$ layers.

The grown Ti$_2$O$_3$ layers showed the diffraction patterns of (012), (104), (110), and (113) planes from grazing incidence of X-ray diffraction measurements, which are well agreed with Ref. [1] and [2]. Detailed atomic crystal structure was also confirmed in TEM measurements. Raman spectra with very narrow width at 274 cm$^{-1}$ in the samples indicate high quality of the crystals. Raman peaks of any other TiO$_2$ structure phases are completely suppressed. XPS and AFM results will be presented.

produce high yield nanocomposites associated with high quality nanosheets. There are several methodologies to obtain 2D-MoS$_2$, such as: CVD, mechanical exfoliation and ionic intercalation. One interesting approach is use liquid exfoliation and ultrasonication to obtain, in a single-step, 2D-MoS$_2$ nanosheets functionalized with a polymer (e.g. polybutadiene)[1]. The C-S bond on the edges of the sheets of the composite provides chemical stabilization of the 2D structure during exfoliation increasing the yield of the reaction.

In this study, we propose a novel and scalable single step synthetic method to exfoliate functionalize and polymerize MoS$_2$-polystyrene (MoS$_2$-PS) nanocomposites starting from bulk MoS$_2$ and the monomer (styrene). In this case, the vial containing styrene, bulk MoS$_2$, NMP and AIBN was introduced in the ultrasonic bath and kept for 6 days at 70°C. For a comparative experiment, the same reaction was carried out, but toluene was added in the mixture above. After this time, the colloidal dispersion was centrifuged at 5000rpm for 1hr and the greenish supernatant was collected for further analysis. Moreover, pure PS was synthesized with AIBN in the ultrasonic bath at 70°C. Thin film of the MoS$_2$-PS was made by casting in a wafer of monocrystalline silicon. Raman spectroscopy showed the characteristics peaks of polystyrene-, C-H bands at 3000cm$^{-1}$, C-C bands at 800cm$^{-1}$, C=C bands of the aromatic ring at 1600cm$^{-1}$, indicating polymerization. The A$_{1g}$ and E$^{1'2g}$ bands of MoS$_2$ can be located at 383.9cm$^{-1}$ and 409.1, respectively, with a frequency distance of 25.2cm$^{-1}$, whilst 26.5cm$^{-1}$ value is expected for a bulk MoS$_2$, indicating high degree of exfoliation and the peak in 630cm$^{-1}$ represents the C-S bond confirming the functionalization of the nanocomposite. XRD of the MoS$_2$-PS composites showed a broad basal plane (002) peak confirming the reduction of the initial size of bulk MoS$_2$. Also, it is possible to notice the absence of other peaks that indicates exfoliated material except for the (103) and (105) planes due to restacking. TGA allowed quantifying the amount of 2D-MoS$_2$ in the film of the nanocomposite as well as to verify the thermal stability compared to the pure PS film. In this case, TGA showed a 2.33% concentration of bounded 2D-MoS$_2$ in the PS film and the initial degradation temperature was 185°C for the MoS$_2$-PS whilst 162°C was reported for pure PS. DSC showed a shift in the glass transition temperature (Tg) from 148°C of the pure PS film to 162°C in MoS$_2$-PS. The MoS$_2$ exfoliated with toluene/NMP/styrene/AIBN was not able to form thin films indicating a low degree of polymerization which can be confirmed by a 0.52% weight loss of organic matrix in TGA and showed all characteristics of crystallographic peaks of bulk MoS$_2$ as well as the Raman modes, confirming the low degree of exfoliation of the MoS$_2$. The yield of the MoS$_2$-PS reaction was 50% for polymerization reaction and 11% for exfoliation. Therefore, this approach opens opportunities of new scalable single step synthetic routes with high degree of exfoliation. We thank FAPESP (CDMF proc. 2013/07296-2) for the financial support (2016/20493-0) CNPq and CAPES.

Weak van der Waals (vdW) interactions between the stacking layers of transition metal dichalcogenides (TMDCs) accommodate intercalation of various species from monovalent alkali, divalent alkaline earth and multivalent metal ions to organic molecules. The research over the past decades have revealed that intercalation of foreign species in the gap can drastically alter the physical properties of layered materials. Especially, controlled electrochemical intercalation can be used as a means to tune the electronic and optoelectronic properties. Among various TMDCs, MoS$_2$ is an important semiconductor with promising field-effect transistor (FET) applications. 2H to 1T' phase transition via chemical and electrochemical intercalations has previously been reported. However, many aspects of intercalation effects are still unclear and require further research. Here, the effects of alkali metal electrochemical intercalation on the transport properties of few-layered MoS$_2$ are presented. The intercalation was performed in top-contact and h-BN encapsulated edge-contact devices, which exhibit distinct behaviors. Additionally, careful magneto-transport studies were carried out on those intercalated MoS$_2$ flakes at various Li ion concentrations to investigate the effects of intercalants on the scattering mechanism and electron doping of MoS$_2$ flakes.

**Quasi-2D Group-IV Monochalcogenides—A Density Functional Theory (DFT) Search**

NFN Sri Ranga Jai Likith and Cristian V. Ciobanu; Colorado School of Mines, United States

Quasi-2D materials have recently gathered significant interest since the discovery and application of transition metal dichalcogenides (TMDCs). Subsequently, the hunt for new families of quasi-2D materials has led us to group-IV
monochalcogenides. In addition to having structures very similar to black phosphorus, they have the added advantage of showing much higher carrier mobilities. In this study, we use density functional theory (DFT) to perform structural relaxation on group-IV monochalcogenides of the form AX (where A: C, Si, Ge, Sn, Pb; X: S, Se, Te) each in 6 different prototype van der Waals-layered quasi-2D structures in an attempt to find new quasi-2D group-IV monochalcogenides. We then scan the structures that remain quasi-2D after relaxation for dynamic stability. For the dynamically stable structures, we compute the piezoelectric tensor values ($e_{ij}$). We find a total of 20 quasi-2D, dynamically stable, and piezoelectrically active structures amongst the 90 structures that are studied here. In addition to helping similar future computational searches, our study also provides guidance to experimental efforts to synthesize new quasi-2D piezoelectric materials.

Scanning Tunneling Microscopy and Spectroscopy of Wet Chemically Synthesized Porous and Nitrogen-Sulfur-Nitrogen Functionalized Graphene Nanoribbons

Kaitlyn Parsons$^1$, Abigail Berg$^1$, Steven Kolaczkowski$^1$, Adrian Radocea$^1$, Mohammad Pour$^2$, Amir Taqieddin$^1$, Tao Sun$^1$, Narayana R. Aluru$^1$, Alexander Sinitskii$^3$ and Joseph W. Lyding$^1$; $^1$University of Illinois at Urbana-Champaign, United States; $^2$University of Nebraska–Lincoln, United States

Graphene nanoribbons (GNRs) are promising candidates for semiconductor logic device applications. Lithographic edge roughness limits the utility of top-down fabricated GNRs due to carrier scattering effects. Bottom-up fabricated atomically precise GNRs can circumvent this issue. We are studying atomically precise GNRs that can be fabricated on the gram scale through wet-chemical synthesis methodology [1]. A fascinating aspect of the bottom-up GNR synthesis is the ability to tailor the atomic structure of the GNR through the choice of the starting molecules. GNR edge structure and width can be controlled with atomic precision. An unexplored class of GNRs contain atomically precise built-in pores. These GNRs contain multiple pores in a single ribbon and the electronic details of the ribbon have not been reported. In this work, we use dry contact transfer (DCT) to deposit porous GNRs onto hydrogen passivated Si(100) surfaces in UHV. These GNRs have been characterized by UHV scanning tunneling microscopy (STM) and spectroscopy (STS). STM imaging confirms the porous structure and indicates a unique electronic feature at the graphene nanopores. Intuition would suggest nanopores appearing as valleys due to the missing carbon atoms. However, STM indicates an electronically tall peak at the pore sites. STS measurements indicate a $1.62 \pm 0.11$ eV bandgap in the bulk GNR and a $2.50 \pm 0.02$ eV bandgap at the pores. These results are compared to first-principles density functional theory (DFT) simulations in which an increased local density of states at the pores is predicted. GW correction shows a $2.89$ eV bandgap. Results will also be reported for GNRs with nitrogen-sulfur-nitrogen (NSN) functionalizations. These GNRs are new chemically synthesized variations for which the fabrication procedure and electronic details have not yet been reported.

Origins of Zero Phonon Line Emission Broadening for Hexagonal Boron Nitride Quantum Emitters in Films Grown by Chemical Vapor Deposition

Hamidreza Akbari, Wei-Hsiang Lin, Benjamin Vest, Pankaj K. Jha and Harry A. Atwater; California Institute of Technology, United States

Single photon emitters in hexagonal boron nitride (hBN) have shown promising electrical and optical properties for utilization in quantum light source applications, owing to the ability of emitters to show Fourier transform-limited zero phonon line emission, which is crucial in applications in which sources of indistinguishable photons are required. Here we investigate the zero phonon line broadening mechanisms of emitters located in 5-10nm thick CVD-grown hBN, films of which can be grown scalable over large areas as needed for monolithic integration of quantum emitters in future chip-based quantum photonic systems. By comparing the lifetime-limited homogeneously broadened linewidth obtained from luminescence decay lifetime measured by time-resolved photoluminescence and low temperature spectroscopy of photoluminescence we observe that even at 4K, the linewidth of the zero phonon line is broader than the Fourier limited value by 2 orders of magnitude. Furthermore, we investigate sources of ZPL broadening, such as spectral diffusion (inhomogeneous) and thermal broadening (homogeneous) by performing spectroscopy and analyzing the Voigt profile at various temperatures (4K-300K). Our studies show at 4K the main broadening source is inhomogeneous but at higher temperatures homogenous.
broadening mechanisms (such as thermal broadening) are more dominant. By comparing the emitter luminescence linewidth for hBN films on several different substrates and excited at varying pump intensities, we can conclude that the main broadening mechanism is spectral diffusion at low temperature. Origins of this phenomenon and possible mitigation strategies will be discussed.

FF01.06.11
Spontaneous Relaxation through Graphene Suggests an Alternative Strain Relaxation Mechanism in Heteroepitaxy

Sanghoon Bae, Kuangye Lu, Sungkyu Kim and Jeehwan Kim; Massachusetts Institute of Technology, United States

While conventional epitaxy produces high-quality epitaxial layers, the limited set of commercially available wafers restricts the number of material choice that can be grown through epitaxy. To extend the set of epi-materials, heteroepitaxy has been widely used although the epi-materials have severe lattice mismatch from wafers. The problem of heteroepitaxy of the lattice mismatched systems is that introducing dislocations is unavoidable because of the strain energy built up in epitaxial layers exceeds the threshold energy value to create dislocation. As the dislocations significantly reduce the materials’ properties, people have put intensive effort into finding a new way to resolve this issue.

Here, we introduce a new strain relaxation approach which can efficiently engineer the lattice with minimizing dislocation formation. Remote epitaxy allows single-crystalline growths on graphene-coated substrates as atomic potential field guides atomic registry through graphene while weakening binding energy of epilayer to the substrate. We discovered that this weakened interface offers a new pathway for strain relaxation during epitaxy in the lattice mismatched systems. While conventional heteroepitaxy relaxes accumulated strain energy through involving misfit dislocations, heteroepitaxy on graphene-coated substrates spontaneously relaxes its strain minimizing dislocation density. Thus, at the same thickness and misfit strain, the epilayer grown on graphene-coated substrates shows full relaxation with substantially reduced dislocations while that by conventional heteroepitaxy exhibits slight relaxation with full of dislocations. It means that full of strain relaxation at much lower thickness is available through this approach. We strongly believe that our strategy allows broadening range of available semiconductors through epitaxy, which could lead high performance electronic and photonics.

FF01.06.12
Spectral Responsivity in Black Phosphorus Photodetectors

Junjia Wang, Adrien Rousseau, Elad Eizner, Anne-Laurence Phaneuf-L’Heureux, Léonard Schue, Sebastien Francoeur and Stéphane Kéna-Cohen; Polytechnique Montreal, Canada

Black phosphorus (BP) has shown significant promise for use in infrared photodetectors due to its high carrier mobility, tunable bandgap and anisotropic properties. To date, characterization of BP detectors has been limited to the visible and NIR, or single IR wavelengths. We will present results on the optical characterization of black phosphorus photodetectors across the entire spectral range where photoresponse occurs. These devices show broadband photodetection from <400 nm to the nearly 4 um bandgap. This full spectral characterization allows us to establish a sharp contrast between the visible and infrared behavior. In the visible, a responsivity of >6 A/W can be obtained due to a large photoconductive gain, while the infrared responsivity is nearly independent of gate voltage and incident light intensity under most conditions. We attribute this to a photogating contribution from the surface oxide. Furthermore, we observe that the polarization anisotropy in responsivity along armchair and zigzag directions can be as large as 10⁵ and extends from the band edge to 500 nm. This anisotropy is much larger than that in previous reports and the result of measuring in an intensity regime where photoconductive gain is absent. This opens up significant opportunity for a number of applications including IR polarimetry. The devices were fabricated in an inert atmosphere and encapsulated by Al₂O₃ providing stable operation for more than 6 months.

FF01.06.13
Optical Devices from Covalent Functionalized, Redox-Exfoliated, Layered Transition Metal Dichalcogenides (Group IV – VII)

Ali Jawaid¹, Anderson Gomes², Isabel Carvalho³, Christiano de Matos⁴, Ruth Pachter¹ and Richard A. Vaia¹; ¹Air Force Research Laboratory, United States; ²Universidade Federal of Pernambuco, Brazil; ³Pontifical Catholic University, Brazil; ⁴Mackenzie Presbyterian University, Brazil

Exfoliated Transition Metal Dichalcogenides (TMDs, MX₂) have attracted considerable attention for infrared optical elements due to their high refractive index and extreme nonlinearities (e.g. MoS₂, TiS₂). Multiphoton absorption,
nonlinear scattering, and nonlinear refraction are useful in technologies from reverse saturable absorption to optical limiting and gradient index coatings. Optimizing performance necessitates fabrication of dispersions, composites, and nanolaminates with high monolayer content, robust chemical stability, and high optical transmission. Energy intensive sonication methods to exfoliated TMDs limit scalable strategies to high quality films and coatings, due to poor oxidative stability, low concentration of TMDs, and a small choice of stabilizing solvents. The recently developed sonication-free, redox exfoliation approach address these challenges by drastically reducing reaction times for gram scale exfoliation of the entire TMD material space (Group IV – VII). This process provides TMDs dispersions in polar organic solvents (acetonitrile, acetone, alcohols) at high concentration (10% w/w) and with high monolayer content. The expansion of solvents and lack of additional stabilizers enables direct hybridization of Group VI 2H-MX₂ TMDs (e.g. MoX₂) via alkyl organometallic chemistry, as well as reduction of Group V 2H-MX₂ (e.g. VS₂, TaS₂, NbX₂) via amines and phosphines. This hybridization increases oxidative stability and tunes optoelectronic properties, including absorption and nonlinear response. The resulting access to surfactant free, monolayer populations enable design and fabrication of optical filters, GRIN optics, and non-linear absorbers.

FF01.06.14
The Halogen Etch for Scalable Production of Layered MXene’s Ali Jawaid¹, Asra Hassan², Dhriti Nepal¹, William Kennedy¹, Subramanian Ramakrishnan², Ruth Pachter¹ and Richard A. Vaia¹; ¹Air Force Research Laboratory, United States; ²Florida State University, United States

Layered metal carbides and nitrides (MXenes) have generated substantial research interest since their discovery in 2011. Their production requires selective etching of the A layer (A = Si, Al) from bulk MAX phases, yielding a new class of layered ceramics with excellent conductivity. HF is commonly used to selectively remove the A layer; however, its acute toxicity prevents safe, scalable MXene production. The complex, environmentally-sensitive reaction mechanism, as well as degradation processes in water and oxygen, challenges MXene yield optimization and compositional control of surface termination. On top of batch-to-batch heterogeneity, this leads to mixed surface termination (-F and -OH) that limits modification of the surface and layer properties. Here, we present an alternative method to fabricate MXenes that utilizes halogens in oxygen-free non-polar solvents for selective removal of the A layer. The etch products are stabilized and dispersed in non-polar solvents (THF, CHCl₃, DCM), leaving oxidatively robust, homogeneously halogenated surfaces (Cl, Br, I). Combined, this enables access to new chemistries for surface derivatization (organometallics), which result in uniform and tunable optical, electrical and chemical properties. The process is safe, scalable, and easily transferred across the MAX material space, giving access to previously un-explored MXene’s. The development of such alternative routes for etching and delamination are crucial for large-scale manufacturing for paints, coatings, and EMI shielding applications.

FF01.06.15
A Dielectric-Defined Lateral Heterojunction in a Monolayer Semiconductor M. Iqbal B. Utama¹,², Hans Kleemann¹,³ and Feng Wang¹,²; ¹University of California, Berkeley, United States; ²Lawrence Berkeley National Laboratory, United States; ³Technische Universität Dresden, Germany

Owing to their low dimensionality, two-dimensional semiconductors, such as monolayer molybdenum disulfide, have a range of properties that make them valuable in the development of nanoelectronics. For example, the electronic bandgap of these semiconductors is not an intrinsic physical parameter and can be engineered by manipulating the dielectric environment around the monolayer. Here we show that this dielectric-dependent electronic bandgap can be used to engineer a lateral heterojunction within a homogeneous MoS₂ monolayer. We visualize the heterostructure with Kelvin probe force microscopy and examine its influence on electrical transport experimentally and theoretically. We observe a lateral heterojunction with an approximately 90 meV band offset due to the differing degrees of bandgap renormalization of monolayer MoS₂ when it is placed on a substrate in which one segment is made from an amorphous fluoropolymer (Cytop) and another segment is made of hexagonal boron nitride. This heterostructure leads to a diode-like electrical transport with a strong asymmetric behaviour.

FF01.06.18
Joule Heating and Its Impact on Thermal Management in Few-Layer WSe₂ Arnab K. Majee, Cameron J. Foss and Zlatan Aksamija; University of Massachusetts Amherst, United States

The persistent down-scaling of nanostructures, such as electronic devices, sensors, NEMS, and nanocomposites, increases the surface-to-volume ratio and introduces atomic-scale disorder at boundaries and interfaces. To avoid
these issues, the nanoelectronics community has turned to intrinsically 2D materials platforms such as transition metal dichalcogenides (TMDs), where atomic flatness and the absence of dangling bonds prevent scattering due to surface roughness (SR), which severely limits mobility in ultra-thin body 3D silicon-on-insulator field-effect transistors (FETs). Despite immunity to SR scattering, the mobility of single layer TMDs are largely deteriorated by charge impurity scattering from the substrate [1]. Researchers have demonstrated that encapsulation of TMDs with hexagonal boron nitride significantly improves mobility [2]; however, encapsulation is expensive and time-intensive. Another route to improving mobility and boosting drive current is to replace the monolayer with few-layered (FL) TMDs. Despite recent advances on demonstrating improved electrical performance of FL TMD FETs [3], there has been less attention towards their thermal management, which is crucial for modern nanoelectronic devices.

In this work, we develop a coupled electro-thermal model for FL-WSe$_2$ stacks where we simultaneously solve for the current and Joule heating by treating the stack a resistor network. The resulting rise in temperature is obtained from a FL-TBC model [4] to shed light on self-heating and heat dissipation in such devices. We found that the distribution of current and Joule heating across layers in a FL-stack is highly non-uniform and strongly dependent on the back-gate voltage ($V_g$), in agreement with previous studies on FL graphene [5] and MoS$_2$ [6]. Interestingly, we found a similar behavior with respect to the drain-source voltage ($V_{DS}$) as well. For a given $V_g$, the current mostly flows through the top layers for small $V_{DS}$. But when $V_{DS}$ is increased, the current penetrates deeper into the stack and flows mostly through the bottom layers. We attribute the change to self-heating of these devices at large $V_{DS}$. We find that the temperature rise in the top layers is significantly larger than the bottom layers because the bottom layers have higher TBC and conduct heat more efficiently to the substrate [4,7]. The higher temperature of top layers, in turn, significantly reduces their mobility, which is strongly temperature-dependent as they are shielded by the bottom layers from substrate impurity scattering. Consequently, both the current and the dissipation hotspot move towards the bottom layers with increasing $V_{DS}$. We also uncover that, unlike monolayer FETs, a significant amount of heat is dissipated laterally through the contacts in FL devices at high $V_{DS}$ due to relatively large thermal healing lengths of the top layers.

In conclusion, we have developed a robust and detailed coupled electro-thermal model to solve for the non-uniform and layer-dependent temperature rise in response to Joule heating. Our findings help develop a deeper understanding of dissipation and thermal management in FL 2D materials and vertical heterostructures.

FF01.06.19
Transcending Graphene—The Unique Properties Atomically-Thin Graphene-Templated Metal Films Faisal Alamgir, Ali Abdelhafiz, Matthew Drexler, Dong Chan Lee and Crystal Bell; Georgia Institute of Technology, United States

We will present our results large-area, atomically-thin metal films (Pt, Pd and Cu) can be grown epitaxially on graphene (GR) using electrodeposition. We will focus particularly on Pt films that are one to several multilayers thick (Pt$_{ML}$) epitaxially grown on graphene (Pt$_{ML}$/GR). These Pt$_{ML}$/GR 2D systems have covalent bonds at the Pt$_{ML}$/GR interface and this intimacy between the layers serves to make the GR a ‘chemically transparent’ barrier that allows catalytic chemistry to take place above it, while protecting the Pt below it from loss. We will specifically show that graphene does not restrict access of the reactants for the canonical oxygen reduction reaction (ORR) but does block Pt from dissolution or agglomeration. These architectures simultaneously achieve enhanced catalytic activity and unprecedented stability, retaining full activity for ORR beyond 1000 cycles. Using x-ray photoemission/absorption spectroscopy (XPS/XAS), high resolution TEM, AFM, Raman, and electrochemical methods, we show that Pt/GR hybrid architectures induce a compressive strain on the Pt films, thereby increasing their ORR activity. Our room-temperature, fully-wetted synthesis approach, should allow for efficient charge, strain, phonon and photon transfer, between the films and their support, impacting not just the performance of catalysts, but also those of electronic, thermoelectric and optical materials.

FF01.06.20
Substitutional Re Doping of Monolayer Epitaxial WSe$_2$: Azimkhan Kozhakhmetov$^1$, Alex Vera$^1$, Michael LaBella III$^{2,3}$, Vince Bojan$^2$, Chengye Dong$^1$ and Joshua A. Robinson$^{1,4,5}$; $^1$The Pennsylvania State University, United States; $^2$Materials Research Institute, The Pennsylvania State University, United States; $^3$The Penn State Nanofabrication
Doping is one of the main cornerstones of modern semiconductor technology. Recent re-discovery of 2D transition metal dichalcogenides (TMDs) attracted great interest in semiconductor doping in such low dimensional systems. Numerous efforts have been devoted to extrinsic doping of TMDs to tune optical, electronic and magnetic properties with various synthesis methods such as chemical vapor transport, powder vaporization, and plasma treatment. Establishing controlled and reliable doping techniques are indispensable for the realization of TMD based CMOS-type devices for next-generation electronic devices. However, all previously reported studies still lack a fundamental understanding of doping mechanisms and have not been extensively examined.

In this work, we present finely controlled, scalable Re doping of monolayer epitaxial WSe₂ films on c-plane sapphire and epitaxial graphene (EG) substrates via gas source metal organic chemical vapor deposition method. The MOCVD synthesis is carried out in a vertical cold-wall CVD reactor at 800 °C using hydrogen selenide (H₂Se), tungsten hexacarbonyl (W(CO)₆) and dirhenium decacarbonyl (Re₂(CO)₁₀) in a hydrogen gas atmosphere. By controlling the partial pressure of the (Re₂(CO)₁₀) in the growth chamber we demonstrate that Re dopant concentration in the epitaxial WSe₂ lattice can be tuned from 5% down to <1%. High-resolution X-ray photoelectron spectroscopy (XPS) is used to quantify Re concentration at high doping levels. Time of flight secondary ion mass spectroscopy (ToF-SIMS) is further performed to confirm a presence of Re atoms in WSe₂ at low doping concentrations. The high concentration (5%) of Re dopant atoms leads to a formation of ReSe₂ and phase segregation from WSe₂; however, the undesired phase segregation is eliminated by reducing the Re flux during the growth which is further confirmed by Raman and photoelectron spectroscopies. Back-gated field effect transistors are constructed and demonstrate a clear trend as a function of Re concentration in WSe₂ from ambipolar conduction to degenerately n-type doping. Currently, high-resolution transmission electron spectroscopy, selective area electron diffraction, electron energy loss spectroscopy, and scanning tunneling microscopy studies are under investigation to further elucidate the effect of in-situ Re doping on atomic scale structural and electronic properties of epitaxial WSe₂.

Highly Stretchable MXene/RGO Composite Supercapacitors

MXene (Ti₃C₂TX) is a newly discovered family of 2D carbide material with superior electrical and electrochemical properties. Benefitting from its metal-like conductivity (6500 S/m), high volumetric capacitance (900 F/cm³) and stable dispersion in various solutions, MXene has been successfully adopted in various electronic and energy applications such as supercapacitors, batteries and electromagnetic shielding. However, the incorporation of MXene materials into emerging stretchable electronics and energy storage devices remained unexplored possibly due to their large mechanical modulus, low ultimate strain, and weak sheet interactions. The current study investigates the design, fabrication, and characterization of robust and highly stretchable MXene/RGO composite supercapacitors through wavy-shape design. The effect of RGO concentration is systematically studied.

In the fabrication of stretchable MXene electrodes, it was found that cracks formed during the prestrain-relax process leading to significant degradation of electrochemical performance of stretchable MXene electrode in the fully stretched state. To overcome this issue, Reduced Graphene Oxide (RGO) was added into the system to tune the mechanical properties of the MXene/RGO composite paper because of its lower mechanical modulus and stronger sheet interaction. It was found that MXene/RGO composite paper could maintain its mechanical integrity when the weight ratio of RGO increased to 50%. Mechanical strain tests revealed that elongation of MXene/RGO increased with RGO concentration and remained at a similar level when the RGO concentration was larger than 50%. The as-fabricated stretchable MXene/RGO composite paper (50% weight ratio) can maintain consistent resistance for more than 1000 stretch-relax cycles with uniaxial strains up to 250% which to our knowledge is the highest stretchability reported for a MXene composite. When tested as supercapacitor electrodes, the stretchable MXene/RGO (50% weight ratio) composite paper demonstrated high and identical specific capacitance in different strain states (e.g., 0%, 100%, 200% and 300%) for various charge/discharge rates. Symmetric supercapacitors made of MXene electrodes and PVA-H₂SO₄ gel electrolyte exhibit robust electrochemical performance in agreement with the electrode measurements.

The present study demonstrates a facile strategy to fabricate highly stretchable MXene/RGO composite.
supercapacitors. These results demonstrate the prospects of a robust, high performance and highly stretchable MXene composite in emerging applications such as wearable electronics, bioimplants, and stretchable electronics.

**Evidence of Spontaneous Time Reversal Symmetry Breaking in Graphene Grain Boundaries** Kimberly Hsieh, Vidya Kochat, Tathagata Biswas, Abhishek Mishra, Gopalakrishnan Ramalingam, Chandra Sekhar Tiwary, Kamanio Chattopadhyay, Srinivasan Raghavan, Manish Jain and Arindam Ghosh; Indian Institute of Science, India

Magnetism in graphene and other 2D materials has long been a holy grail for modern spintronics. The conventional routes towards inducing magnetism in graphene involve either functionalization of graphene with ferromagnetic adatoms or irradiation to generate vacancies and correlated defects. In this work, we provide direct experimental evidence for the existence of localized magnetic moments at the grain boundaries (GBs) of graphene, formed as a natural consequence of the chemical vapour deposition growth. The spontaneous breaking of time reversal symmetry at the graphene GBs is observed using low frequency 1/f noise arising from universal conductance fluctuations (UCF) via the ergodic hypothesis. The gate-tunable magnetism is attributed to the formation of localized magnetic moments at the octagon-pentagon defects of the disordered GB region, further enhanced by the inbuilt lattice strain leading to the dephasing of spins.

**Scanning Tunneling Microscopy Induced Polymerization of Bromoaromatic Graphene Nanoribbon Precursors** Steven Kolaczkowski1,2,3, Adrian Radocea2,1, Abigail Berg1,2,3, Kaitlyn Parsons1,2 and Joseph W. Lyding1,2,3; 1University of Illinois at Urbana-Champaign, United States; 2Beckman Institute for Advanced Science and Technology, United States; 3Nick Holonyak Jr. Micro and Nanotechnology Laboratory, United States

Both thermal and wet bottom-up chemical synthesis of graphene nanoribbons (GNRs) have been shown to create ribbons with atomic precision in widths and edges. This precision is essential in maintaining band-structure uniformity across the structure. However, both these recipes for GNR synthesis result in a stochastic distribution of ribbon length, location, and orientation, when studied on a substrate. This random distribution on the surface makes it impractical for devices to be made from these GNRs as there is no feasible scheme to attach metal contacts to the ribbons. To address this challenge, we utilize dry-contact-transfer of bromoaromatic precursors to a Au(111) surface and, through the use of electron tunneling currents induced by ultra-high vacuum scanning tunneling microscopy (UHV-STM), spatially control the precursor polymerization. Here we demonstrate that at sufficiently high scanning biases, 10,10′-dibromo-9,9′-bianthracene (DBBA) polymerizes into polyanthrylene only along the path that the STM tip traverses. These results introduce the feasibility of electron-tunneling controlled bromoaromatic monomer polymerization and, in the future, high degrees of spatial control over atomically precise GNR synthesis.

**Langmuir-Blodgett of Black Phosphorus Nanosheets and Devices** Jian Mao, Junjia Wang, Orlando Ortiz and Stéphane Kéna-Cohen; Polytechnique Montréal, Canada

Black phosphorus (BP), the most stable allotrope of phosphorus, has attracted considerable attention in recent years due to its extraordinary electrical and optical properties, which makes it an excellent candidate for applications in transistors, photodetectors, and lithium-ion batteries. 1 BP, like graphite, has a layered structure and can be fabricated into monolayers and nanosheets from its bulk form through micromechanical and liquid exfoliation. 2 Mechanical exfoliation (the scotch-tape method) has been predominantly used for proof-of-concept devices, 3 but it is inherently unscaleable and typically limited to sheets with lateral dimensions below ten micrometers. For practical applications, scalable approaches for fabricating BP large-area films are essential. We will present our results on the development of a Langmuir-Blodgett (LB) protocol which is developed for assembling BP nanosheets into thin films. Through functionalization, we increase the electrostatic force between BP nanosheets to avoid the overlapping of BP nanosheets during compression, which allows us to achieve large-area (centimeters), smooth, and compact BP thin films. In addition, this protocol is well-adapted to assembly thin and thick BP nanosheets as well as arsenic-BP alloy nanosheets.

The optoelectronic properties of transistors and photodiodes fabricated from the BP LB film are investigated. With suitable carrier transporting materials, The BP photodiodes exhibit a good optical response from visible to infrared region. Our work highlights the great potential of BP in applications of near- and middle- infrared detection and
imaging.

Polyaniline against Black Phosphorus Degradation—Thin Films with High Chemical and Electrochemical Stability
Jessica E. Fonsaca¹, Sergio H. Domingues², Elisa Orth¹ and Aldo J. Zarbin¹; ¹Federal University of Parana, Brazil; ²Mackenzie Presbyterian University, Brazil

Black phosphorus (BP) has begun to gain attention in 2014, when its stripping has led to 2D layers of phosphorene. The promising properties of this material have, however, been severely limited by its high instability under environmental conditions which rapidly leads to its degradation. Thus, the interest in exploring BP has been growing as well as the concern in protecting it. In this sense, we have synthesized a BP-polymeric nanocomposite, aiming to overcome BP deterioration in a novel material with synergic and enhanced properties. For this purpose, different samples have been prepared through the following steps: 1. a liquid exfoliation of BP resulting in a stable dispersion (0.025 mg mL⁻¹ in deaerated acetonitrile); 2. aniline polymerization in the dispersion of BP, resulting in BP/polyaniline (BP/PANI) nanocomposites; 3. thin film deposition of the BP/PANI nanocomposites through the liquid/liquid interfacial route developed in our research group. Raman spectroscopy showed the coexistence of the two components modes in the BP-PANI spectra, confirming the successful synthesis of the nanocomposite, with the polymer in its conducting form (emeraldine salt). Infrared spectra attested the unstable nature of BP, exhibiting bands related to modes resulting from the phosphorus oxidation, and suggested the protective role of PANI with the absence of these bands for BP-PANI. Thus, the stability of both bare and capped material was evaluated through their exposure to the same ambient conditions and evaluated through different techniques. Scanning electron microscopy (SEM) images evidenced the beginning of degradation of the uncapped material with only 3 days of exposure, showing the characteristic bubbles on BP surface. The same was observed through Raman, indicated by the gradual decrease in the intensity of BP bands that completely disappear with its total degradation (at about 15 days). BP-PANI nanocomposites, however, have taken up to 60 days for the same process to begin, indicating a material 2000% more stable than the bare one.

After establishing BP chemical stability, we evaluate the electrochemical properties of the nanocomposites targeting energy storage devices. Electrochemical response and stability of BP/PANI nanocomposites were evaluated through cyclic voltammetry (CV) and charge-discharge (CD) studies (NaCl 0.5 mol L⁻¹ pH 3), in order to evaluate energy storage properties. Films of BP-PANI were evaluated and compared to pure PANI and BP, under air and inert atm (N₂(g)). Bare BP is degraded right after the first cycle, evidencing the expected low stability. For the nanocomposites, BP has shown a high stability even after 200 CVs in the presence of O₂(g). BP integrity was confirmed through post-characterizations (Raman spectroscopy and SEM images). Finally, aiming to evaluate the performance of the materials as electrodes for sodium ion batteries, CD studies were performed. Current densities of 0.2 A g⁻¹ to 3 A g⁻¹ were applied and the capacities reached up to 120 mAh g⁻¹ at 0.5 A g⁻¹ rate. Overall, this work not only provides the synthesis of a novel nanocomposite, but also prints to an innovative route towards the development of transferable and stable thin films, suitable to build new BP-based devices operating in water and under ambient atmosphere. Authors acknowledge UFPR, CNPq, CAPES, INCT-Nanocarbon, PhosAgro/UNESCO/IUPAC, L’Oréal-UNESCO-ABC and FAPESP (SPEC project 2012/50259-8).

Low-Temperature Growth of Monolayer MoS₂ by Metal-Organic Chemical Vapor Deposition
Ji-Hoon Park, Pin-Chun Shen, Ang-Yu Lu and Jing Kong; Massachusetts Institute of Technology, United States

Molybdenum disulfide (MoS₂) is a representative material among transition-metal dichalcogenides (TMDCs). it has a direct bandgap of ~1.8 eV and advantages of high stability, fast electrical mobility, and high current on/off ratio compared to other TMDCs. The growth of MoS₂ is relatively simple and easy by using chemical vapor deposition (CVD) which is a conventional method to ensure large-area and high-quality. Metal-organic chemical vapor deposition (MOCVD) is one of the branches among various CVD methods. One of the advantages of MOCVD use
the metal-organic precursors which can be easily decomposed at low temperature. Another advantage is precise control of flow rate between two or three precursors by using the mass flow controller (MFC) system. Here, we report that monolayer MoS₂ flake and film were grown on a various substrate (SiO₂, sapphire, soda-lime-glass, and gold film/SiO₂) by using MOCVD with the modified solid bubbler system to ensure a stable supply of Mo source without the heating process of solid Mo(CO)₆. The minimum growth temperature of MoS₂ is below 400 °C which allowed its growth on the gold film. Also, the shapes of MoS₂ flake can be modified through the control of the ratio of flow rate between Mo and S source. Finally, the maximum electron mobility of MoS₂ field-effect transistor showed about 45.4 cm²V⁻¹s⁻¹ due to reducing strain or interaction between MoS₂ and the substrate.

FF01.06.28
Lithium Intercalation in Twisted Bilayer Graphene Daniel T. Larson and Efthimios Kaxiras; Harvard University, United States

Lithium atoms intercalating between layers of graphene show an energetic preference for regions of AA stacking. Thus the triangular array of AA regions in the moiré pattern of twisted bilayer graphene allows for control over the location of intercalants in layered materials and devices. We use density functional theory to directly calculate the energetics of lithium atoms between layers of graphene in commensurate supercells with twist angles of 7.3° and 2.5°. The two cells show universal behavior in the energy profile for single Li intercalants when the location of the intercalant is measured as a fraction of the distance between AA and AB regions. This behavior can be expected to persist down to angles of about 2.0°. For the 2.5° cell we demonstrate clustering of the Li atoms in the AA regions when the average Li concentration is relatively low. The Li intercalants cause a local increase in the interlayer separation as well as charge transfer to the nearest carbon atoms. These regions of localized charge hold the potential for interesting catalytic properties. The charge donated by the Li atoms also raises the Fermi level above the Dirac point and causes qualitative changes to the band structure, especially near the I-point. The combination of twisting with intercalation gives the added power of spatial control over the material properties that can be tuned by intercalation.

FF01.06.29
3D Graphene Foams—Synthesis and Properties Carolina Rojas Michea, Neida Santacruz, Frank Mendoza, Loida Rosado, Stephanie Colón, Laura Méndez, Gerardo Morell, Brad Weiner and Ana Guadalupe; University of Puerto Rico, United States

Graphene is a 2D material with diverse applications. However, there are important applications in gas and liquid media that can benefit from the unique properties of graphene but require a 3D structure able to interact thoroughly with the medium. Thereby, the systematic and reproducible fabrication 3D Graphene would enable further applications useful both for research and industrial processes, such as catalysis, energy storage, and environmental remediation. Thereby, we developed a method to fabricate 3D Graphene Foams using the Chemical Vapor Deposition technique, acetone as carbon source, and Ni foams as scaffolds. We studied how the structural properties of the 3D Graphene Foams depend on the growth parameters, such as temperature, precursor concentration, and Ni foam thickness. Through this study, we optimized the pore size and mechanical stability of the foams produced. We are also reporting on the interaction of these 3D Graphene Foams with representative gases and liquids to understand the effective surface area and surface terminations of these foams.

FF01.06.30
Synthesis, Characterization and Fabrication of Graphene/Boron Nitride Nanosheets Heterostructure Tunneling Devices Muhammad Sajjad¹, Muhammad Shehzad Sultan², Vladimir I. Makarov², Brad Weiner² and Gerardo Morell²; ¹Austin Peay State University, United States; ²University of Puerto Rico - Rio Piedras, United States

The various types of 2D heterostructure prototype devices based on graphene (G) and boron nitride nanosheets (BNNS) were fabricated to study the charge tunneling phenomenon. Specifically, G/BNNS/Metal, G/SiO₂, and G/BNNS/SiO₂ heterostructures were investigated under DC-bias conditions at room temperature. Bilayer graphene and BNNS samples were grown separately on copper foil and transferred subsequently between the substrates to fabricate 2D devices architecture. The high resolution transmission electron microscopy confirmed bilayer graphene structure and few layer BNNS sheets having an interpretable hexagonal B₃N₃ lattice. The I(V) characterizations for G/BNNS/Metal device have shown typical Schottky barrier behavior with very low forward voltage drop due to out-
of-plane tunneling and low sheet resistance of G layer. A theoretical model based on current tunneling is proposed to qualitatively describe hetero-2D G/BNNS/Metal devices behavior.

FF01.06.31
Refraction Index of Janus MoSSe Monolayer  Jing Zhang, Tianshu Zhai and Jun Lou; Rice University, United States

Janus type of two-dimensional chalcogenide monolayers are predicted to permanently polarize in the out-of-plane direction, due to the structural asymmetry therein. The aligned dipoles, which cause the spontaneous polarization, are experimentally difficult to identify as they are confined in a Van der Waals layer, unless through the detection of electromagnetic wave-dipole interaction. We measured the refraction index of Janus monolayer MoSSe in the range of visible light. Comparison of the pattern of Janus MoSSe with MoS2 and MoSe2 reveals the existence of the built-in dipoles in the Janus monolayer. The discovery indicates the great potential of Janus type of 2D chalcogenide monolayers in optical applications.

FF01.06.32
Effect of Boundaries on the Microscopic Conductivity and Photoexcited Carrier Dynamics in Vertical SnS2 Nanoflakes  Kateryna Kushnir, Binod Giri, Maryam Masroor Shalmani, Tao Yan, Alexander D. Carl, Curtis W. Doiron, Ronald L. Grimm, Pratap M. Rao and Lyubov V. Titova; Worcester Polytechnic Institute, United States

Tin disulfide (SnS2) is a two dimensional (2D) van der Waals material with a moderate band gap of ~ 2.1 eV, strong optical absorption and high carrier mobility that make it attractive for solar energy conversion applications. We have recently demonstrated that nanostructuring SnS2 in the form of vertically-aligned nanoflakes is beneficial to SnS2 photoanode performance [1]. It balances ~ 1 micron film thickness necessary for absorbing incident light with the highly exposed steps and edges suitable for photoelectrochemical applications. However, nanostructuring comes at a cost of increased carrier trapping at surface and edge states. Here we use time-resolved THz spectroscopy (TRTS) to elucidate the effect of nanostructuring on photoexcited carrier lifetime and mobility in vertically-aligned SnS2 nanoflake array synthesized using close space sublimation method.

SnS2 vertical nanoflakes were excited with 400 nm, 100 fs laser pulses, and transient photoconductivity was measured using a terahertz probe in the 0.25 – 1.70 THz frequency (or, equivalently, 1-7 meV) range. To delineate the effect of edges and surfaces, we have compared transient THz conductivity of nanoflakes to that of SnS2 single crystals grown using chemical vapor transport method. Photoconductivity in both single crystal SnS2 and vertical SnS2 nanoflakes exhibits a multi-exponential decay. The fastest components, ~2-3 ps and 10-15 ps, are much more pronounced in the nanoflakes, and are ascribed to the carrier-carrier scattering (former) and the carrier trapping at defect and edge states (latter). Finally, a much slower component, ~ 0.25-1.30 ns, corresponds to free carrier recombination, as confirmed by the time-resolved photoluminescence measurements. We find that the photoexcited carrier mobility in single crystal SnS2 as high as ~ 800 cm²V⁻¹s⁻¹. In vertical nanoflakes, intrinsic (intra-flake) mobility is comparable to the single crystal value at 330 cm²V⁻¹s⁻¹, while the long-range (inter-flake) mobility is reduced to 90 cm²V⁻¹s⁻¹ by the confining effect of nanoflake surfaces and edges. Based on experimental free carrier mobility and lifetime, we estimate the inter-flake photoexcited carrier diffusion length to be ~1 μm, in agreement with the nanoflake length that results in the best photoelectrochemical device performance.

Nylon-6/Ti3C2Tz MXene Nanocomposites Synthesized by In Situ Ring Opening Polymerization of ε-Caprolactam and Their Water Transport Properties  Michael Carey, Zachary Hinton, Maxim Sokol, Nicolas Alvarez and Michel Barsoum; Drexel University, United States

Typically, MXene polymer composites have been limited to small scales and polymers that are soluble in aqueous solutions. This is largely due to the use of MXene in its colloidal form – where concentrations are relatively low (~10-20 mg mL⁻¹) and stability is restricted to neutral aqueous solutions or polar solvents. Additionally, synthesis generally revolves around dissolving the polymer, mixing in colloidal MXene and then solvent casting samples. In
order to make samples on an industrial scale, use of multilayer MXene and in-situ polymerization techniques is a must. Clay-reinforced nylon-6 nanocomposites (NCs), characterized by the full exfoliation of the nanofiller were introduced in the marketplace in the 1990s. Herein, we demonstrate, for the first time, a scalable technique to disperse multilayer Ti$_3$C$_2$T$_z$ MXene into nylon-6 to synthesize melt-processable nanocomposites with excellent water barrier properties (94% reduction in water vapor permeation). To intercalate the ε-caprolactam monomer, the MXene multilayers were first treated with 12-aminolauric acid, a low-cost, nontoxic, biodegradable, and long shelf life compound. Upon heating to 250 °C, in the presence of 6-aminocaproic acid, in-situ polymerization occurred, yielding melt-processable nylon-6/MXene NCs that were in turn, studied by thermogravimetric analysis, differential scanning calorimetry, X-ray diffraction, scanning and transmission electron microscopy, infrared spectroscopy, and dynamic vapor sorption analysis. Using the latter, moisture-sorption isotherms of a neat and a 1.9 vol % NC at 60 °C, were fit to the Guggenheim, Anderson, and de Boer equation. Solubility, permeation, and diffusion coefficients of water through the NCs were measured as a function of temperature and found to be the lowest ever reported for nylon-6, despite the fact that, at ~1.9 and 5.0 vol %, the MXene loads were relatively low. This record low diffusivity is ascribed to the very large aspect ratios ~ 500 to 1000 of Ti$_3$C$_2$T$_z$ flakes and their dispersion. The water permeation rate is a factor of 5 lower than the best reported in the much more mature nylon/clay field, suggesting lower values can be achieved with further optimization. Lastly infrared spectroscopy spectra of neat and NC samples suggest the surface terminations of the 12-Ti$_3$C$_2$T$_z$ flakes bind with nylon-6, limiting water adsorption sites, resulting in reduced solubility in the NC films. This facile, low cost and scalable technique allows for the complete dispersion of MXene into the polymer matrix. By building upon this knowledge and tailoring the chemistry of the surfactant, we are continuing to utilize this method in order to disperse MXene into a variety of thermoplastic and thermosetting polymeric host matrices.

**High-Resolution, Active-Matrix Arrays of Pressure Sensors**

Jiuk Jang$^{1,2}$, Hyobom Kim$^1$ and Jang-Ung Park$^{1,2}$;  
$^1$Yonsei University, Korea (the Republic of); $^2$Center for Nanomedicine, Institute for Basic Science (IBS), Yonsei-IBS Institute, Korea (the Republic of)

The active-matrix pressure sensors as an electronic device have become of great interests as a critical component for recently emerging electronic skin and biomedical applications for artificial intelligence and human-machine interfaces. The conventional pressure sensors still has limitations such as the narrow sensing range and low pixel density, and they confines the applicability of the device to specific area. Here, we fabricate the active-matrix arrays of pressure-sensitive monolayer MoS$_2$ field-effect transistor (FET) with air-dielectric layer, which is supported by elastomer spacer. The air-dielectric monolayer MoS$_2$ FET was acting as pressure sensor solely by incorporating air as the gate dielectric layer with elastomeric supporting spacer, and hysteresis of this pressure-sensitive transistor was very small because of the clean surface states between a MoS$_2$ channel and air. The double-layered elastomer in which the two elastomeric materials had different elastic moduli allowed a wide detectable range of pressures. By utilizing the light emission of the ML composites induced under the external stress, ZnS:Cu phosphors were implemented to the elastomer layer to induce a photocurrent effect in the MoS$_2$ FETs, resulting in the enhancement of the sensitivity at high pressure (> 0.5 MPa). Furthermore, the pressure on the 20 X 20 MoS$_2$ FETs active-matrix pressure sensor array was mapped spatially even at 10 µm of pixel resolution. Since this resolution is fine enough to measure 2D pressure distribution of the cell, we demonstrated a 2D mapping of pressure distribution during the pulsing of single cardiomyocyte in the first time. We believe this unique FET structure and its active-matrix array will contribute to future applications of prostheses, robotics and biomedical electronics.

**FF01.06.36**

**A Plausible Method of Preparing an Ideal Interface of a p-n Junction by Surface Treatment**

Imgeong Ho-Soon Yang; Pusan National University, Korea (the Republic of)

The study of p-n junctions has been of interest in condensed matter physics and materials sciences. Especially, the fabrication of a p-n junction out of atomically thin two-dimensional crystals has drawn attraction in the field of semiconductors as it allows a high-quality interface with very high electron conductivity in the absence of strong chemical bonds at the interface. Here we report an atomically thin p-n junction prepared using a Van der Waals material, SnSe whose bulk property is a p-type semiconductor. The electron band structure of SnSe has been investigated using angle-resolved photoemission spectroscopy (ARPES). By depositing metallic atom on the surface, the valence band maximum shifts towards higher binding energy as much as 0.28 eV, leading to an n-type
charge carriers in the surface. A comparison to a theoretical work suggests that this charge transfer appears only at the top-most layer, leaving the rest of the bulk to remain a p-type semiconductor. This result suggests that an atomically well-defined vertical p-n junction is fabricated in between n-type surface and p-type bulk of SnSe.

**Charge Transport Behavior and Ultrasensitive Photoresponse Performance of Exfoliated F16CuPc Nanoflakes** Hang Yan¹,², Yang Li²,², Jing-Kai Qin²,², PingAn Hu²,², Liang Zhen¹,²,² and Cheng-Yan Xu¹,²,²; ¹State Key Laboratory of Advanced Welding and Joining, Harbin Institute of Technology, China; ²Harbin Institute of Technology, China

Air-stable, photosensitive copper hexadecafluorophthalocyanine (F16CuPc) is a promising n-type semiconductor for organic electronics and optoelectronics. However, the performance of F16CuPc-based devices is significantly limited by the poor crystallinity of thin films. In this work, the charge transport and electrical contact behavior of F16CuPc nanoflakes, mechanically exfoliated from high-quality needle-like bulk single crystals, are probed by analyzing the temperature-dependent carrier mobility and conductance, where the multi-trap/release and band-like transport mechanism govern the charge transport at different temperature ranges and carrier densities. F16CuPc nanoflakes based field effect transistors (FETs) exhibit high on-state current and ON/OFF ratio, one-order magnitude than those of reported F16CuPc nanowires, thin films and nanoribbons. Besides, F16CuPc nanoflake-based phototransistors exhibit attractive photoresponse performance in the spectral range of 300−750 nm even at quite low operating source-drain voltage (~ 1V), with maximum photoresponsivity of 19 A W⁻¹, detectivity of 8×10¹² Jones, and fast response speed of 36 ms, which is attributed to the single-crystalline characteristic of nanoflakes, and the resultant efficiently exciton diffusion and charge transport. Our results demonstrate that two-dimensional organic nanoflakes with single-crystalline feature will be promising candidates for flexible electronic and optoelectronic devices.

**FF01.06.38**
**Efficient Mechanochemical Exfoliation Process of Highly Soluble Two-Dimensional MoS2 Nanoflakes** Seulgi Kim¹, Dohoon Kim¹, Jiyeon Kang¹, Dongju Lee¹ and Sungho Song²; ¹Chungbuk National University, Korea (the Republic of); ²Chungbuk National University, Korea (the Republic of)

Transition-metal dichalcogenides(TMDs), such as molybdenum disulfide (MoS₂), have attracted huge interest as two-dimensional materials because of their novel electronic and optical properties. Several methods of fabricating few-layered TMDs have been developed, however, methods for mass production of intrinsic nanoflakes of TMDs are still challenge. Mass production of two-dimensional nanoflakes is highly desirable to their practical applications. In the present work, we present facile method for fabricating MoS₂ nanoflakes by using hydrazine-assisted ball-milling via synergetic effect of chemical intercalation and mechanical peeling. The MoS₂ nanoflakes obtained through the hydrazine-assisted ball milling process have lateral size of 600 to 800 nm and thickness of 4 nm or less with high quality. The resultant MoS₂ nanoflakes form stable dispersion in various solutions that can be used for many applications. For a potential application, flexible photodetectors are prepared by solution-based process using the MoS₂ nanoflakes and the optical properties evaluated.

**FF01.06.39**
**Synthesis of Bi₂Te₃ Single Crystals by Vapor Transport and Its Potential for Thermoelectric Applications** Jihoon Ahn; Korea Maritime & Ocean University, Korea (the Republic of)

Bismuth telluride (Bi₂Te₃) has recently attracted significant attention owing to its unique physical properties as a three-dimensional topological insulator and excellent properties as a thermoelectric material. Meanwhile, it is important to develop a synthesis process yielding high-quality single crystals over a large area to study the inherent physical properties and device applications of two-dimensional materials. However, the maturity of Bi₂Te₃ vapor-phase synthesis is not good, compared to those of other semiconductor twodimensional crystals. In this study, therefore, we report the synthesis of relatively large-area Bi₂Te₃ crystals by vapor transport method, and we investigated the key process parameters for a synthesis of relatively thin and large-area Bi₂Te₃ crystals. The most important factor determining the crystal synthesis was the temperature of the substrate. A Bi₂Te₃ device exhibited a
considerable photocurrent when the laser was irradiated inside the electrode area. This indicated that the photothermoelectric effect was the main mechanism of generation of photocurrent. The estimated Seebeck coefficient of the device was $\sim 196 \mu V/K$, which is comparable to the previously reported high Seebeck coefficient of Bi$_2$Te$_3$. This synthesis method can guide the development and applications of various types of layered crystals with the space group of R-3m.

FF01.06.40
Large-Area and Plasma Doped p-Type Multilayer MoS$_2$: Photodetectors with Gate Tunable Effect Xiao-Mei Zhang; Tokyo Institute of Technology, Japan

Two-dimensional (2D) transition metal dichalcogenides (TMDCs), such as MoS$_2$, have attracted considerable attention owing to the unique optical and electronic properties related to its 2D ultrathin atomic layer structure [1]. MoS$_2$ is becoming prevalent in post-silicon digital electronics and in highly efficient optoelectronics due to its extremely low thickness and its tunable band gap ($E_g = 1–2$ eV) [2]. For low-power, high-performance complementary logic applications, both p- and n-type MoS$_2$ FETs (NFETs and PFETs) must be developed. NFETs with an electron accumulation channel can be obtained using unintentionally doped n-type MoS$_2$. However, the fabrication of MoS$_2$ FETs with complementary p-type characteristics is challenging due to the significant difficulty of injecting holes into its inversion channel [3]. Plasma treatments with different species (including CF$_4$, SF$_6$, O$_2$, and CHF$_3$) have also been found to achieve the desired property modifications of MoS$_2$ [4-5].

In this work, we demonstrated a p-type multilayer MoS$_2$ enabled by selective-area doping using CHF$_3$ plasma treatment. Compared with single layer MoS$_2$, multilayer MoS$_2$ can carry a higher drive current due to its lower bandgap and multiple conduction channels. Moreover, it has three times the density of states at its minimum conduction band. Large-area growth of MoS$_2$ films on 300 nm thick SiO$_2$/Si substrate are carried out by thermal decomposition of ammonium tetrathiomolybdate, (NH$_4$)$_2$MoS$_4$, in a tube furnace. A two-step annealing process is conducted to synthesize MoS$_2$ films. For the first step, the temperature is set to 280 °C for 30 min in an N$_2$ rich environment at 1.8 Torr. This is done to transform (NH$_4$)$_2$MoS$_4$ into MoS$_3$. To further reduce MoS$_3$ into MoS$_2$, the second step of annealing is performed. For the second step, the temperature is set to 750 °C for 30 min in a reducing atmosphere consisting of 90% Ar and 10% H$_2$ at 1.8 Torr. The grown MoS$_2$ films are subjected to out-of-plane doping by CHF$_3$ plasma treatment using a Dry-etching system (ULVAC original NLD-570). The radiofrequency power of this dry-etching system is set to 100 W and the pressure is set to 7.5 mTorr. The final thickness of the treated samples is obtained by etching for 30 s.

Back-gated MoS$_2$ PFETs were presented with an on/off current ratio in the order of $10^3$ and a field-effect mobility of 65.2 cm$^2$V$^{-1}$s$^{-1}$. The MoS$_2$ PFETs photodetector exhibited ultraviolet (UV) photodetection capability with a rapid response time of 37 ms and exhibited modulation of the generated photocurrent by back-gate voltage. This work suggests the potential application of the mild plasma-doped p-type multilayer MoS$_2$ in UV photodetectors for environmental monitoring, human health monitoring, and biological analysis.

Two-dimensional (2D) transition-metal dichalcogenides (2D TMDs) in the form of MX2 (M: transition metal, X: chalcogen) exhibit intrinsically anisotropic layered crystallinity wherein their material properties are determined by constituting M and X elements. 2D platinum diselenide (2D PtSe2) is a relatively unexplored class of 2D TMDs with noble-metal Pt as M, offering distinct advantages over conventional 2D TMDs such as higher carrier mobility and lower growth temperatures. Despite the projected promise, much of its fundamental structural and electrical properties and their interrelation have not been clarified, and so its full technological potential remains mostly unexplored. In this work, we investigate the structural evolution of large-area chemical vapor deposition (CVD)-grown 2D PtSe2 layers of tailored morphology and clarify its influence on resulting electrical properties. Specifically, we unveil the coupled transition of structural–electrical properties in 2D PtSe2 layers grown at a low temperature (i.e., 400 °C). The layer orientation of 2D PtSe2 grown by the CVD selenization of seed Pt films exhibits horizontal-to-vertical transition with increasing Pt thickness. While vertically aligned 2D PtSe2 layers present metallic transports, field-effect-transistor gate responses were observed with thin horizontally aligned 2D PtSe2 layers prepared with Pt of small thickness. Density functional theory calculation identifies the electronic structures of 2D PtSe2 layers undergoing the transition of horizontal-to-vertical layer orientation, further confirming the presence of this uniquely coupled structural-electrical transition. The advantage of low-temperature growth was further demonstrated by directly growing 2D PtSe2 layers of controlled orientation on polyimide polymeric substrates and fabricating their Kirigami structures, further strengthening the application potential of this material. Discussions on the growth mechanism behind the horizontal-to-vertical 2D layer transition are also presented.

**2D-GaN Modified by Hydrogen and Vacancies—DFT Studio**

Roberto Gonzalez-Araiza1, Oscar Martinez-Castro1, Maria G. Moreno-Armenta2, Alvaro Gonzalez-Garcia1, William Lopez-Perez2 and Rafael J. Gonzalez-Hernandez2; 1Universidad del Norte, Colombia; 2Universidad Nacional Autonoma de Mexico, United States

Similar to graphene, III-V semiconductors offer extraordinary properties on a diversity of morphologies. In the last two decades, gallium nitride (GaN) and related group III-nitrides have become key materials in light emitting diodes (LEDs) and laser diodes [1,2]. Therefore, GaN-based device technologies have improved substantially, and are still under intense investigation for improved performance. GaN crystallizes in the wurtzite structure (nonlayered). Therefore, the probability to be exfoliated with traditional methods is almost null. However, this phase of gallium nitride has been experimentally produced via encapsulation between two graphene sheets and theoretical results have predicted a stable 2D graphene–like phase for GaN, known as g-GaN in which gallium and nitrogen atoms are in the honeycomb-like hexagonal disposition. We have studied the graphene phase of gallium nitride (g-GaN) structural and electronic properties by using first-principle calculations within the framework of the Density Functional Theory (DFT). We tried two different approaches: in the first one we considered the hydrogen adsorption at different levels of coverage over each kind of atom and in the second we introduced vacancy charged defects [3].

We considered hydrogen adsorption in a range from the diluted limit, as a 1/64 of the monolayer, up to the full coverage of the monolayer. It was found that N–N distances around the gallium atom with adsorbed hydrogen were similar to the clean distances. Contrarily, Ga-Ga distances around the N atom with adsorbed hydrogen increased as the hydrogen percentage decreased. The 2D g-GaN-H configurations are the most stable, having lower formation energy. Nonetheless, the ferromagnetic system with a hydrogen atom in the gallium position presents a nonzero magnetic moment. As it could be observed in the band structure, a defect level induced by the H adatom is the source of this magnetic moment, a phenomenon which can be exploited for spintronic applications. This ferromagnetism is mainly localized in the first and second closest N atoms around the gallium atoms where adsorption occurred [4].

It was found from the second approach that the Ga-Ga (or N-N) bond lengths around the vacancy increased for the gallium vacancies and decreased for the nitrogen vacancies with respect to the bond distance without vacancy. Vacancy-induced defect levels are responsible for the total magnetic moment in g-GaN, generating a magnetic moment located at the nitrogen atoms for gallium vacancies or delocalized in the lattice for nitrogen vacancies. Thermodynamic transition levels close to the conduction band minimum are identified for both the Ga and N vacancy. In addition, N vacancy has formation energy lower than the Ga vacancy. N vacancy is the dominant defect in g-GaN and could be responsible of the n-type behavior of GaN observed experimentally. Similarly, the w-GaN, gallium vacancies have a higher formation energy than those of nitrogen. However, gallium vacancies could be
successfully grown in order to design a two dimensional $p$-type semiconductor. It is expected that the results of these studies will contribute to the analysis of hydrogen adsorption on 2D g-GaN, as well as to the design of 2D H-g-GaN and 2D g-GaN-H based devices in electronic and spintronic fields.

Tunable Luminescence in Stacked Bulk-Like Hexagonal Boron Nitride Controlled by a Twist Angle Haeyeon Lee1, Mohammed AlEzzi2, Nimisha Raghuvasahi3, Kenji Watanabe4, Takashi Taniguchi3, Slaven Garaj2, Shaffique Adam2 and Silvija Gradecak1; 1Massachusetts Institute of Technology, United States; 2National University of Singapore, Singapore; 3National Institute for Materials Science, Japan

Van der Waals (vdW) heterostructures formed by layering twisted monolayers of two-dimensional materials result in formation of Moiré superlattices, which leads to new physical phenomena, including emergence of flat energy bands or tunable conductivity. So far, Moiré superlattice physics has been explored in graphene-related system and various combinations of monolayer transition metal dichalcogenides. Hexagonal boron nitride (hBN) forms a similar honeycomb lattice as graphene, but in contrast to graphene, has a large band gap with luminescence in ultraviolet region. Because of its properties, hBN has been recently extensively used as a substrate or dielectric spacer in vdW heterostructures.

Here, we show that the optical properties of stacked bulk-like (hundreds of nanometers in thickness rather than monolayers) hBN layers are dominated by the innermost interface layers and their relative twist angles as a consequence of the Moiré superlattice formation. Both the luminescence intensity and energy can be tuned using the relative twist angle between stacked layers. hBN multilayers were exfoliated from an hBN single crystal and these were used to form twisted hBN multilayers by a dry transfer method. The relative twist angles between the stacked hBN layers were measured using electron diffraction in a transmission electron microscope (TEM) and the optical properties of the resulting structure were measured simultaneously using TEM-based cathodoluminescence (CL). We show the strong functional dependence of the luminescence properties as a function of the twist angle. Our results demonstrate a new way of controlling optical properties of thin-film materials, beyond conventionally used heterostructures.

8:30 AM FF01.07.03
Near Ultraviolet Light Electroluminescence in Hexagonal Boron Nitride Based van der Waals Heterostructures Sanghoon Chae1, Dongjea Seo2, Qingrui Cao1, Xiang Hua1, En-Min Shih1, Sunho Park3, Seungjun Lee1, Takashi Taniguchi4, Kenji Watanabe5, Junyoung Kwon5, Gwan-Hyong Lee2, Cory Dean1, David Schiminoovich1, Irving P. Herman1, Heon-Jin Choi2, Young-Kyun Kwon3, Ioannis Kymissis1, Young Duck Kim3 and James Hone1; 1Columbia University, United States; 2Yonsei University, Korea (the Republic of); 3Kyung Hee University, Korea (the Republic of); 4National Institute for Materials Science, Japan

The ability to assemble van der Waals heterostructures from two-dimensional (2D) crystals provides a wealth of new opportunities for novel optoelectronic devices. To date, most such devices have shown functionality in the infrared to visible range, whereas ultraviolet (UV) applications are less well explored. Here we describe electrically driven light emission from vertical heterostructure devices consisting of thin hexagonal boron nitride (hBN) between graphene electrodes, with additional hBN encapsulation. Upon illumination at low electric fields, optically excited
carriers tunnel and generate interlayer photocurrent through Gr/hBN/Gr heterostructures. At high electric fields, hBN shows bright light emission with a strong peak in the near ultraviolet (NUV) regime at 394 nm (3.14 eV), and stable response over a wide voltage range. Light emission is accompanied by a rapidly increasing current and appearance of new photoluminescence peaks, indicating that it is facilitated by creation of color centers, whose potential structures are explored by density functional theory calculations. Finally, we report the generation of red-green-blue (RGB) color-mixed white light by a standard down-conversion approach using phosphors. These results demonstrate the promise of hBN-based van der Waals heterostructures for light emission in the NUV to visible regime.

Atomically Thin Canvas for Quantum Optoelectronics Hongkun Park; Harvard University, United States

All-optical integrated circuits have long been a major pursuit for scientists and engineers because they may allow ultra-fast computing with ultra-low power consumption. The actual realization of this dream has been very difficult, however, because photons rarely interact with each other and, even with the aid of nonlinear optical materials, interact very weakly. My research group tries to leverage the advances in photonics, plasmonics, optoelectronics, and quantum optics and develop new material and technology platforms for solid-state all-optical information processing that work all the way down to single quantum level. In this presentation, I will describe our recent efforts to realize solid-state quantum optoelectronic devices by combining atomically thin semiconductors and nanoscale photonic/plasmonic structures. In particular, I will discuss how we improve the optoelectronic properties of these atomically thin materials and how we leverage them to gain detailed insight into their optoelectronic properties. I will then discuss our efforts to realize atomically thin, electrically tunable mirrors and excitonic “drums” as well as solid-state optoelectronic devices that are built upon quantum mechanical principles.

9:15 AM FF01.07.05
Strong Light-Material Interactions in Atomically Thin Metasurfaces Huiqin Zhang1, Bhaskar Abhiraman1, Qing Zhang2, Jinshui Miao1, Kiyong Jo1, Stefano Roccasecca1, Mark W. Knight3, Artur Davoyan4 and Deep M. Jariwala1; 1University of Pennsylvania, United States; 2National University of Singapore, Singapore; 3Northrop Grumman Corporation, United States; 4University of California Los Angeles, United States

Visible spectrum band-gaps with strong excitonic absorption make transition metal dichalcogenides (TMDCs) of molybdenum and tungsten attractive candidates for investigating light-material interactions and applications as absorbing media in opto-electronics.1, 2 Further, the excitonic features become more prominent as the layers are thinned down and dominant in the monolayer limit where the TMDCs transition into direct band-gap semiconductors with strong photoluminescence. Their excitonic character and luminescence in monolayer regime has been heavily investigated in fundamental science as well as exploited for device applications.2 However, the excitonic character in TMDCs persists even for few-layer thick samples and bulk crystals which has led to recent demonstrations of some interesting photonic and light trapping phenomena. Further, TMDCs are known to have very large values of optical constants which allows strong light trapping even in ultrathin samples.3 Here, we explore the fundamental material properties of light trapping in multi-layer TMDCs (namely WS2) when coupled to plasmonic substrates. Our calculations and demonstrations are primarily in WS2 which can be easily extended to other excitonic TMDCs. We systematically demonstrate via calculations and matching experiments that the presence of strong excitonic resonances in multilayers (< 20 nm thickness) combined with surface plasmon excitations of the nearby metals can achieve strongly coupled modes with apparent voided crossings in reflectance spectra. Further, we explore additional light confinement by patterning 1D arrays of rectangular resonators of varying widths and periods (100 nm to 500 nm). We find that there is a critical thickness of TMDC (~15 nm) beyond which we observe photonic modes emerging in the TMDC/metal hybrids that are strongly dispersive as a function of resonator width. Newer and higher order modes appear with increasing TMDC thicknesses and widths. Simulated field profiles suggest that these modes are mainly plasmonic and hybrid in nature. For longer wavelengths and thicker TMDCs, guided modes emerge as well. Further, the plasmonic modes exhibit strong dependence on 1D array grating period.

Finally, we will show the detailed multi-dimensional phase diagram of geometric parameters that lead to voided crossings between various resonant photonic modes and excitons and demonstrate sensing applications in the strong coupling regime. Our work may pave the way to novel hybrid photon-polariton states that are of interest for all-optical information processing, quantum and classical computing.

References:
Two-dimensional materials are inherently anisotropic – with strong bonding in-plane and weak bonding out-of-plane. Consequently, their optical properties are birefringent, particularly at frequencies close to the energies of their optically active infrared phonons. At these frequencies, certain 2D materials support hyperbolic behaviour, where along one (two) crystal axes they behave as metals (negative dielectric function), and along the other two (one) behave as dielectrics (positive dielectric function). Typically, two of these axes are in the plane of the 2D layers, and the third is out of the plane, the most well studied example being hexagonal boron nitride (hBN). Materials which exhibit hyperbolicity can support polaritonic modes, which have a wavelength much shorter than that of light in free space. Such spatially compressed modes have important implications for infrared technology, as they may be utilized to create infrared optics that are much more compact than the current state of the art. In particular, 2D materials can be used to realize metasurfaces, capable of shaping both nearfield- and far field light waves for a broad range of applications.

Conventional metasurface designs use geometrically fixed structures, or materials with excessive propagation losses, thereby limiting their potential applications. Here we show how to overcome these limitations by demonstrating a reconfigurable hyperbolic metasurface comprising a heterostructure of isotopically enriched hexagonal boron nitride (hBN) in direct contact with the phase-change material (PCM), single-crystal vanadium dioxide (VO2). Metallic and dielectric domains in VO2 provide spatially localized changes in the local dielectric environment to tune the wavelength of hyperbolic phonon polaritons (HPhPs) supported in hBN by a factor of 1.6. In contrast, propagation was only seen above a low loss dielectric phase with non-anisotropic materials supporting surface polaritons. Using this platform, we demonstrate the first reduction to practice of in-plane HPhP refraction, and the means for launching, reflecting and transmitting of HPhPs at the PCM domain boundaries. Ultimately, this phenomenon can be used to create devices based on refractive effects, such as lensing, but on length scales far below the diffraction limit. This relies on the unique properties of the 2D materials themselves, aided by the changing dielectric function of the PCM substrate.

9:45 AM BREAK
annealing of nanocrystalline metallic films with 2DC overlayers results in a ‘surface templated epitaxial’ process where the metal films become highly textured, with micron-sized, well-faceted grains in close crystallographic registry to the 2D crystal orientation. Dewetting of the encapsulated metal film occurs through the formation of pores that can span up to 60% of the planar surface area, creating an orientated pore enabled network (OPEN) film. This process has been demonstrated for a number of mechanically-exfoliated and chemical-vapor deposited 2DCs (e.g., graphene, h-BN, and transition-metal dichalcogenides (TMDs)). In the OPEN film structure, the 2DC overlayer can remain suspended above or coat the inside of the metal pores. OPEN-TMD films exhibit appreciably distinct properties, including enhancement in photoluminescence, spatially varying surface potential, and routes for coupling surface plasmon-polaritons (SPPs) to photon emission. SPPs were found to propagate throughout the OPEN film structure following generation by either free-space laser excitation or TMD-emitted photons at the metal pore sites, enabling non-local emission at room and low temperatures. We also find a high density of single photon emitters (SPEs) across an OPEN-WSe2 film and demonstrate non-local SPE excitation at distances of at least 17 mm with minimal loss of photon purity. Our results suggest the OPEN film geometry is a versatile platform that could facilitate the use of layered materials in quantum optics systems.

Work performed at NRL was supported through Base Programs funded by the Office of Naval Research. J.JF acknowledges the NRC Research Associateship Programs for their support.

11:00 AM FF01.08.03
Near-Infrared Optical Properties and Ultra-Fast, Diffusion-Less Phase-Change Functionality of Tin Selenide (SnSe) Seong Soon Jo1, Jian Zhou1,2, Akshay Singh1, Yifei Li1, Zhongzhen Luo1, Mercouri G. Kanatzidis3, Ju Li1 and Rafael Jaramillo1; 1Massachusetts Institute of Technology, United States; 2Xi’an Jiaotong University, China; 3Northwestern University, United States

Future integrated photonic circuits need materials to perform ultra-fast and low-power optical switching. Chalcogenide phase-change materials (PCMs) and two-dimensional (2D) materials contain many promising candidates to meet this need. Among layered 2D chalcogenides, IV-VI materials are particularly interesting for their trirefringent optical properties and low-processing temperature.

Here we propose a new mechanism for optical switching in anisotropic materials, and we report results obtained for SnSe. a-SnSe has an orthorhombic crystal structure that can be visualized as a highly-distorted rock salt lattice. We present theoretical predictions that, owing to strong dielectric anisotropy, short pulses of linearly polarized light can switch between ferroelastic variants of the a-SnSe structure.[1] Switching occurs because the light field changes the potential energy landscape and eliminates the barrier for switching. We predict a critical power density of 7.7 x W/cm² for near-IR photons for a barrier-less transition. We report experimental results obtained on crystals and mechanically-exfoliated sheets. We use spectroscopic ellipsometry to measure the full optical property tensor of trirefringent a-SnSe, to test theoretical calculations and to optimize the design of optical switching, and we report preliminary results using short laser pulses to perform ferroelastic switching.

The study presented on trirefringent a-SnSe can be generalized to a class of optical martensitic transitions that we predict to be ultra-fast, barrier-less, and diffusion-less. These transitions happen at the speed of lattice vibrations and are inherently non-thermal, and therefore low-power. 2D materials are ideal for realizing the predicted phenomena and for application because the transformation strains are lower than in 3D crystal structures. Optical martensitic transitions may therefore offer an improvement on existing PCMs for photonics in terms of switching energy, speed, and device lifecycle.

11:15 AM FF01.08.04
Near-Infrared Optical Properties and Phase-Change Behavior of Transition Metal Dichalcogenides Akshay Singh1, Yifei Li1, Balint Fodor2, Laszlo Makai2, Jian Zhou1, Haowei Xu1, Austin Akey4, Sergiy Krylyuk4, Ju Li1, Albert Davydov5 and Rafael Jaramillo1; 1Massachusetts Institute of Technology, United States; 2Semilab Semiconductor Physics Laboratory Co. Ltd, Hungary; 3Xi’an Jiaotong University, China; 4Harvard University, United States; 5National Institute of Standards and Technology, United States

Transition metal dichalcogenides (TMD) exist in several polymorphs including 2H (usually semiconducting), and 1T (or 1T', semi-metallic). These polymorphs are expected to have significantly different opto-electronic properties, and phase change between these polymorphs offers a new way for controlling light. This phase change is particularly interesting for near-infrared (NIR) integrated photonics, where materials with strong light-matter
interaction are required.
We present an experimental and theoretical study of sulfides (MoS₂, TiS₂ and ZrS₂) and tellurides (MoTe₂ and Mo₁₋ₓWₓTe₂) in the NIR. Our density functional theory (DFT) calculations predict a large refractive index contrast in the 1-1.5 um spectral range (relevant for telecommunications and photonics) between 2H and 1T (or 1T') phases. We measure the complex optical constants of bulk crystals via spectroscopic ellipsometry and Fourier transform IR (FTIR) spectroscopy, and find significant differences between 2H and 1T materials. By explicitly measuring native oxide thickness using transmission electron microscopy and subsequent optical modelling, we extract true optical constants of TMDs. Further, for structural polymorphs of the same material (MoTe₂ and Mo₁₋ₓWₓTe₂ in both 2H and 1T phases), we measure a large difference in refractive index and optical loss, in agreement with our DFT calculations. Our work lays the foundation for TMDs for use as active IR materials that can be switched optically and electrically.

11:30 AM *FF01.08.05
Electronic and Optical Properties of 2D Materials and Their Heterostructures Su Ying Quek; National University of Singapore, Singapore

Two-dimensional materials are known to exhibit an amazing range of novel electronic and optical properties, as demonstrated in many state-of-the-art experiments. First principles calculations play an important role in identifying the atomic-scale origins of these properties, as well as in predicting properties of new materials. In this talk, I will draw upon examples from recent work in my group on first principles calculations in 2D materials and their heterostructures. Comparison with experiment will be made throughout the talk. Firstly, I will show convincing evidence that oxygen-related point defects are dominant in mechanically-exfoliated and chemical-vapor-deposition (CVD)-grown WSe₂ samples, in contrast to mechanically-exfoliated MoS₂ samples, where sulfur vacancies are dominant. Furthermore, based on state-of-the-art, numerically converged, GW-BSE calculations, we show that oxygen interstitials in the WSe₂ lattice (in conjunction with strain gradients) are most likely responsible for experimentally observed single photon emission in these materials.1 Secondly, I will present the electronic properties of covalently functionalized organic-MoS₂ heterostructures that have been experimentally synthesized. Interestingly, we find that local magnetic moments are present. Furthermore, while the organic molecules can either withdraw or donate electrons from the MoS₂ layer, depending on the electron affinity of the molecules, electrons are always the predominant carrier type in the MoS₂ layer. Thirdly, I will show how our recent theoretical developments have enabled the prediction of quasiparticle level alignment at organic-2D material interfaces, in good agreement with experiment.2,3 Fourthly, I will show that experimentally observed Dirac cones in black phosphorus can be explained by quantum confinement and anisotropic interlayer interactions.4 If time permits, other results, including predictions on novel materials from high throughput calculations, will be presented.

SESSION FF01.09: Atomic Scale Characterization of 2D Materials
Session Chairs: Olga Kazakova and Humberto Terrones
Tuesday Afternoon, December 3, 2019
Hynes, Level 3, Room 312

1:30 PM FF01.09.01
Chemical Identification of Interlayer Contaminants within van der Waals Heterostructures with IR Nano-Spectroscopy Jeffrey J. Schwartz1,2, Hsun Jen Chuang3, Matthew R. Rosenberger3, Saujan V. Sivaram3, Kathleen McCready3, Berend T. Jonker4 and Andrea Centrone5; 1National Institute of Standards and Technology, United States; 2University of Maryland, United States; 3U.S. Naval Research Laboratory, United States

Van der Waals heterostructures (vdWHs) consist of layers of dissimilar 2D materials that provide novel and unique and properties. vdWHs are commonly assembled in a myriad of combinations by stacking 2D materials using
polymeric stamps. However, the properties of such heterostructures frequently are degraded by contaminants, typically of unknown composition, that are trapped between the constituent layers and impede studies of the heterostructures’ intrinsic properties, thus hindering their applications.

In this work, I will introduce the photothermal induced resonance (PTIR) technique, an atomic force microscopy (AFM)-based infrared technique that enables IR spectroscopy and imaging with nanoscale resolution. I will show that PTIR enables detection and identification of contaminants down to a few amomoles.

Heterostructures comprised of WSe2, WS2, and hBN layers were found to contain significant amounts of polydimethylsiloxane (PDMS) and polycarbonate, corresponding to the stamp materials used in their construction. Notably, polymer contamination between layers occurs even when ‘dry’ fabrication methods are used. Having identified the source of the contaminants, we develop a stamp cleaning procedure that eliminates or reduces PDMS contamination within the structures below the limit of detection. Our measurements suggest that the assessment of contaminants in vdWHs should not be conducted based on AFM topographic images alone but, rather, aided by nanoscale composition-sensitive methods, such as PTIR. We believe that knowledge of the contaminant composition obtained with the methods presented here will aid better understanding of vdWH properties and guide improvements to fabrication method for producing intrinsic, contaminant-free heterostructures with precisely tuned properties.

1:45 PM FF01.09.02
Abnormal Interlayer Coupling in Janus MoSSe/MoS2 Heterostructures Kunyan Zhang¹, Yunfan Guo², Hua Wang³, Alexander Puretzky⁴, Xiaofeng Qian⁵, Jing Kong⁶ and Shengxi Huang⁷; ¹The Pennsylvania State University, United States; ²Massachusetts Institute of Technology, United States; ³Texas A&M University, United States; ⁴Oak Ridge National Laboratory, United States

Janus transition metal dichalcogenide (TMD) is a newborn of the two-dimensional (2D) materials family. Its structure is similar to TMDs such as MoS2, but one layer of the chalcogen is different from the other layer, one example being MoSSe. As the first successfully synthesized Janus TMD, MoSSe has motivated a series of theoretical investigations on the Janus TMDs. Due to the unique crystal structure of Janus TMDs, unconventional phenomena have been theoretically predicted, including out-of-plane piezoelectricity and exciton disassociation by the intrinsic out-of-plane dipole moment. However, experimental investigations are extremely insufficient in terms of the principle properties of monolayer Janus TMDs and their heterostructures with other van der Waals materials. Such properties, for example interlayer coupling and phonon properties, are essential to electronic transport and optoelectronic applications.

In this work, we study the fundamental phonon properties and interlayer coupling of Janus monolayer MoSSe and MoSSe/MoS2 heterostructures. Interlayer breathing and shear modes of high-symmetry 2H and 3R heterostackings are probed by low frequency Raman spectroscopy. The uniform selenization from MoS2 to MoSSe is confirmed by the disappearance and the emergence of signature Raman modes of MoS2 and MoSSe, respectively. Low frequency Raman modes for different stacking patterns of MoSSe/MoS2 show noticeable variations in frequencies. This observation indicates that stacking configuration leads to different layer-to-layer interactions. Unintuitively, interlayer coupling in the heterostructures is stronger than their pure MoS2 counterparts possibly due to the compressive (tensile) strain in MoSSe (MoS2) introduced during synthesis. Difference in high frequency modes between MoSSe/MoS2 and pure MoS2 is consistent with variations in the low frequency modes. Both the low frequency and high frequency Raman responses are strong evidence for the abnormally enhanced interlayer coupling. These spectroscopic features can serve as a fingerprint of stacking configurations, interlayer coupling in heterostructures, and degree of conversion in the fabrication process from TMDs to Janus TMDs.

2:00 PM *FF01.09.03
Nanoscopy of 2D Materials Aleksandra Radenovic; Ecole Polytechnique Federale Lausanne, Switzerland

The simplicity and versatility of optical microscopy make it from the start the workhorse technique in the characterization of 2D materials (1). Optical microscopy is used to locate and determine the thickness of the 2D material by measuring its optical contrast with respect to the Si/SiO2 substrate (2). Although in terms of technology, the large-area growth of 2D materials is about to be mastered soon, as-grown 2D materials still host abundant and different types of defects such as vacancies, adatoms, grain boundaries (GBs), edges, and impurities, which strongly influence their properties (3). In most cases, the presence of defects is disadvantageous. However, not all defects in 2D materials are detrimental. Some 2D materials have been shown to host defects that can serve as single-photon emitters (SPEs) at cryogenic temperatures for TMDs (4-7) and room temperature for h-BN (8). This discovery has motivated the search for single-photon sources in other 2D materials and efforts that aim to engineer the defects in
well-controlled locations either using strain-induced potential traps (9) or via quantum dot confinement (7). The advent of single quantum emitters in 2D materials offers new opportunities to construct a scalable quantum architecture. Transmission electron microscopy TEM, SPM or confocal microscopy techniques are not ideal for fast, high-throughput, in-situ imaging of defects in 2D materials with nanometer resolution. There is a clear demand for the development of advanced optical technology that images individual defects at better temporal, spectral and spatial resolutions. We have explored the single molecule localization microscopy to characterize defects in hexagonal boron nitride (10). In addition to precise location of the optically active defects we record as well their spectral properties using spectral SMLM (11).

2:30 PM *FF01.09.04
Characterization of 2D Material Heterostructures Using Nanoscale Angle Resolved Photoemission Spectroscopy (nanoARPES) Eli Rotenberg; Lawrence Berkeley National Laboratory, United States

Angle-resolved photoemission spectroscopy (ARPES) is a premier technique for determining the electronic structure, state symmetry, and many body interactions (MBIs) in correlated and topological materials. These MBIs involve exchange of momentum among electrons or with excitations such as phonons, and can therefore couple to nanoscale structures. By controlling the structure at the nanoscale, we can therefore hope to control or enhance the ground state properties of materials through nanoscale engineering. This dream has motivated the development of ARPES with nanoscale spatial resolution (nanoARPES), in order to probe these effects. MAESTRO, the Microscopic and Electronic Structure Observatory, is a new synchrotron based user facility for the study of in situ prepared materials, including oxides, 2D van der Waals material, semiconductors, metals, and surfaces. With a combination of three ARPES microscopes with complementary spatial/energy/momentum resolutions, and in situ sample preparation (molecular beam epitaxy, pulsed laser deposition, and micro-mechanical sample transfer) we are able to examine the relationship between electronic structure and topology with unprecedented spatial resolution, currently around 100nm, with 50 nm performance on the horizon.

As an example, I will show the spatially resolved electronic structure of two-dimensional metal dichalcogenide heterostructures of WS2, graphene, BN and TiO2 [1, 2]. Among the findings is a striking renormalization of the spin-orbit splitting of the WS2 valence band, which can be controlled by chemical doping or by choice of substrate. This is attributed to the impact of trion (charged exciton) formation on the self-energy of carriers in WS2. We have also observed modifications in the electronic structure of “twisted” layers of WS2 on graphene. Such twisted heterostructures are garnering a lot of attention due to the possibility of engineering novel electronic structures.

https://aip.scitation.org/doi/10.1063/1.5088968
Black phosphorus is one of the most promising 2D semiconductors because of its layer-dependent bandgap and high mobility carriers. Its corrugated crystal structure also creates a unique electronic anisotropy which may create opportunities for novel angle-dependent electronic and optoelectronic devices. Native defects and their impact on the electronic structure of 2D semiconductors are understudied, especially when compared to defects in 3D semiconductors. Additionally, the degradation of black phosphorus in air, which is likely exacerbated by defects, creates a major limitation to applications. This talk will present scanning tunneling microscopy and spectroscopy studies of surface structures in black phosphorus, including defects, nanoscale stripes, and islands. We will use a temperature-dependent study of the native defects in black phosphorus to compare defect hopping rates at different temperatures to theoretical expectations. Additionally, we will present data on nanometer-scale black phosphorus islands, created by partially sublimating the top layers of the crystal. These islands appear to lose their crystallinity as they shrink to 10s of nanometers in diameter. Finally, we will present newly observed periodic, 5 nm stripes, whose appearance depends strongly on temperature. The voltage dependence of these stripes suggests an electronic superstructure. We will present the data and possible interpretations of this new superstructure.
electronic properties of interfaces that were specifically characterized in situ. We believe that achieving control of 2D/3D interfacial structure and dynamics will facilitate systematic design of contacts, heterostructures, and coupled materials for future devices with distinct properties and applications.

4:15 PM FF01.09.07
Determining the 3D Atomic Coordinates and Crystal Defects in 2D Materials with Picometer Precision
Dennis S. Kim1, Xuezeng Tian1, Shize Yang2, Christopher J. Ciccarino3, Yongji Gong4, Yongsoo Yang1, Yao Yang1, Yakun Yuan1, Pulickel Ajayan4, Juan-Carlos Idrobo5, Prineha Narang3 and Jianwei Miao1; 1University of California, Los Angeles, United States; 2Brookhaven National Laboratory, United States; 3Harvard University, United States; 4Rice University, United States; 5Oak Ridge National Laboratory, United States

To understand the structure-property relationship of 2D materials and heterostructures at the fundamental level, defects and crystalline imperfections need to be accounted for with high precision. AET allows the determination of 3D atomic structure of crystal defects and disorder systems and has recently been advanced to capture nucleation at 4D atomic resolution. However, AET has thus far been limited to metallic nanoparticles and needle-shaped samples. We have developed scanning atomic electron tomography (sAET) to localize the 3D atomic coordinates in 2D materials and heterostructures with picometer precision. Using a Re-doped MoS2 monolayer, we demonstrated the sAET method and determined the 3D atomic coordinates with picometer precision and identified 3D crystal defects such as dopants, vacancies and atomic-scale ripples. We measured the 3D atomic displacement and the full strain tensor of the Re-doped MoS2 and observed strong correlations between local atomic strains and Re, and S vacancy concentrations. Furthermore, the experimental 3D atomic coordinates were used as direct input to DFT calculations to correlate crystal defects with the electronic band structure at the single-atom level. We observed stark differences between the band structures obtained from the experimental and relaxed atomic models. The local atomic strains from Re-dopants were found to drastically alter the overall electronic properties and was corroborated by photoluminescence spectra measurements. We also demonstrate the capabilities of the sAET method through accurate reconstructions and 3D atomic coordinate determination of a multislice simulated MoSe2-WSe2 moire patterned van der Waals heterostructure. We anticipate that sAET is not only generally applicable to the determination of the 3D atomic coordinates of 2D materials, heterostructures and thin films, but also could transform ab initio calculations by using experimental atomic coordinates as direct input to reveal more realistic physical, material, chemical and electronic properties.

Nanoscale Electrical Mapping of Vertically Stacked Heterostructures  Manoj Tripathi1, Xiang Zhang2, Matthew Large1, Sean P. Ogilvie1, Yuanyang Rong1, Peter Lynch1, Frank Lee1, Antonios Michail3, Konstantinos Papagelis3, John Parthenios4, Konstantinos Papagelis3, Aline Amorim Graf1, Alice King1, Jonathan Salvage5, Nicola M. Pugno6,7,8, Pulickel Ajayan2 and Alan B. Dalton1; 1University of Sussex, United Kingdom; 2Rice University, United States; 3Foundation for Research and Technology Hellas, Aristotle University of Thessaloniki, Greece; 4Institute of Chemical Engineering Sciences, Greece; 5University of Brighton, United Kingdom; 6University of Trento, Italy; 7Queen Mary University of London, United Kingdom; 8Ket Lab, Edoardo Amaldi Foundation, Italy

The stacking of heterogeneous 2D materials using transition metal dichalcogenides (TMDC) allows the development of the hybrid artificial structures for unique application of tuned physical, electrical and optical properties1. The artificial integration of heterogeneous sheets has produced abundant functionalities in the hybrid structure through interface engineering2. Hence, hetero-junction hybrids are incredibly favourable to fabricate p-n junction, tunneling FET, memory devices and other optoelectronics devices3. Some of the crucial contributions of hetero-layer devices is controlled doping, bandgap tailoring and modulation of Schottky barrier height without the implementation of conventional dopant diffusion, ion implantation and laser treatment4 that leads to crystal damage and surface defect5. Nevertheless, stacked heterogeneous structures are susceptible to mechanical strain, interfacial charge transfer and unpinning of Fermi energy level through inter-layer van der Waals interaction. Thus, it has become pivotal to decouple the contribution between the electrical and mechanical properties of the overlapped heterogenous structure to fabricate flexible electronics.

The present work demonstrates nanoscale electrical properties and interfacial characteristics of two versatile heterogeneous stacked structures beyond graphene; WS2/MoS2 and the graphene/MoS2. The interactions of the monolayer MoS2 with WS2 and graphene is collated comprehensively for the mobility of charges, doping and work function. The topping of conductive graphene over the pyramidal arrangement of MoS2 sheets up to three layers revealed the unpinning of Fermi energy level at different step-edges of the hybrid structure. Consequently, the work
function and the amount of charge transfer was found different at each layer of the hybrid structure. The nanoscale conductivity map showed the higher values of currents/area (nA/µm²) in graphene/MoS2 configuration at thicker MoS2 layers. Therefore, a transition from indirect to direct band gap in the CVD MoS2 increases the charge mobility at the interface. Finally, we deconvoluted the strain in the hybrid structure from doping by Raman correlation plots for E2g Vs A1g and G Vs 2D peaks for TMDC (MoS2 and WS2) and graphene Raman modes, respectively. This investigation will address to establish a functional method to tailor the nanoscale electrical and mechanical properties of the scalable engineered 2D heterostructure for high-performance flexible electronics.

Direct Measurement of Gap States Energy Distribution and Fermi Level Pinning in MoS2 Monolayers and Multilayers Yossi Rosenwaks, Ronen Dagan and Yhonatan Vaknin; Tel Aviv University, Israel

Transition Metal Dichalcogenides (TMDs) are promising materials for beyond silicon electronics due to their unique electrical, including tunable band gap in the visible regime, mechanical and thermal properties. The electronic quality of such materials is highly effected by lattice impurities, such as Sulfur vacancies and other atomic defects which generates atomic gap states in TMDs, as well as the semiconductor/oxide interface imperfection. To-date, even though some recent progress has been reported, the study and understanding of gap states in TMDs materials and devices is very limited. First, reliable, sensitive and quantitative methods to measure the concentration and energy distribution of such states are not fully developed. Second, fundamental issues surrounding the origin of gap states in TMDs materials are not known, and relatively very little is reported about the effect of these states on electronic device properties.

In this work, we use Kelvin Probe Force Microscopy (KPFM) under inert atmosphere to measure the gap states concentration, their energy distribution and Fermi level pinning in MoS2 monolayers and multilayer transistors. The method is based on applying back gate voltage to a working MoS2 Field Effect Transistors in-operando. The voltage applied to the back gate induce injection of electrons/holes into the transistor channel; these charge carriers populate the gap states and consequently change the Fermi level position. The Fermi level energy is measured directly by the KPFM, and the gap states energy distribution is then extracted using the injected charge concentration obtained from the transistor capacitance as described in our previous works. We have measured the gap states of both MoS2 monolayers and multilayers exfoliated on SiO2 and found that in monolayers the Fermi level is unpinned throughout most of the energy gap, and the states distribution is fairly constant at a concentration of around 10¹⁸ cm⁻³ eV⁻¹. In samples which are several multilayers thick, the states distribution decays exponentially from the conduction band edge similar to our measured bulk samples. Gap states measurements at the interfaces of MoS2 with other dielectrics will be presented and discussed.

SESSION FF01.10: Poster Session II: Beyond Graphene 2D Materials—Synthesis, Properties and Device Applications II

Piezo-Phototronic Effect Enhanced High-Performance Flexible In₇₋ₓSnₓSe Photodetector Christy Roshini Paul Inbaraj1,2,3, Roshan Jesus Mathew1,2, Raman Sankar3, Yit-Tsong Chen4, Chih-Hao Lee1 and Yang-Fang Chen3;
Piezoelectricity is widely considered to be one of the emerging research fields owing to its promising applications in diverse areas including sensors, nanogenerators, energy harvesting, and biomedical devices. Recent studies on the piezoelectricity in two-dimensional materials show remarkable features for manipulating band structure and many important physical characteristics. Here, we demonstrate the piezo-phototronic property observed in the In$_{1-x}$Sn$_x$Se flexible photodetector, where the performance of the device can be tuned by applying systematic mechanical strain. The piezoelectric property and changes in the band gap of the material were carefully studied with several spectroscopic analysis under strained conditions. Quite interestingly, we discover that in the fabricated In$_{1-x}$Sn$_x$Se device, the dark and photo drain-source current can be increased by 5-fold under a bending strain of 2.7 %, which shows a great promise for the design of high performance, multifunctional device as strain sensor and photodetector. The maximum photoresponsivity and strain sensitivity are obtained as 1037 AW$^{-1}$ and 206, respectively, which outperform the flexible devices in the same class of two-dimensional materials. In addition, we show that the few-layer In$_{1-x}$Sn$_x$Se devices can be attached on a freeform surface with high performance. Thus, our designed multifunctional device is very useful for the development of advanced applications to circumvent the requisite demand for emerging technologies.

Contact Resistance Engineering in MoS$_2$ Using Hexagonal Boron Nitride Taesoo Kim$^{1,2}$, Hyun Kim$^1$ and Young Hee Lee$^{1,3}$; 1Center for Integrated Nanostructure Physics (CINAP), Institute for Basic Science (IBS), 16419, Korea (the Republic of); 2Sungkyunkwan University, Korea (the Republic of); 3Sungkyunkwan University (SKKU), Korea (the Republic of)

Molybdenum disulphide (MoS$_2$), one of the most widely applicable transition metal dichalcogenide (TMD) is known to have high electron mobility at room temperature as well as optical property for monolayer. The band gap of single layer MoS$_2$ shows direct transition which values ~1.8 eV [1] is believed to be the source of its rectifying behavior. MoS$_2$ shows Schottky behavior when it is electrically contacted to metal by forming Schottky barrier (SB) at metal/MoS$_2$ interface. The potential barrier at the interface is directly related to contact resistance which should be minimized to achieve lower power consumption for high device performance. Many efforts to engineer contact resistance at the metal/TMD interface such as adopting low work function metal for contact [2], doping the channel material with molecular dopant [3], transferring conductive layer at the contact/channel interface [4] and introducing thin insulating material on top of the channel [5] have been reported. In this study, we used centimetre-scale synthesized hexagonal boron nitride (hBN) on top of the MoS$_2$ channel layer in order to take advantage of absence of fermi level pinning which is considered to be a main reason of forming high Schottky barrier at the interface.

Light-Induced Local Reconfigurable Doping of 2D van der Waals Semiconductor Seung-Young Seo$^{1,2}$, Gunho Moon$^{1,2}$, Jaehyun Park$^{1,2}$ and Moon-Ho Jo$^{1,2}$; 1Pohang University of Science and Technology, Korea (the Republic of); 2Institute for Basic Science, Korea (the Republic of)

The development of fast and reliable doping techniques of two-dimensional (2D) van der Waals (vdW) semiconductors are required for next generation 2D circuit fabrication. Many attempts are being reported, but such techniques are still hard to find. Here we demonstrated that light illumination can induce chemical doping on channel of 2D semiconductor molybdenum ditelluride (2H-MoTe$_2$). Moreover, the doping carrier types are selective by controlling the light illumination conditions such as wavelength and optical intensity. We found that the channel was doped to $p$-type under visible light illumination, whereas to $n$-type under ultraviolet light illumination. This light induced doping process is fast and reliable, so it can be used to assemble various functional devices or circuit elements. As a representative example, we demonstrated that we could directly write 2D CMOS inverter consisting of $n$- and $p$-type FET channels. Moreover, this CMOS inverter can also be easily converted to a CMOS switch using
Hexagonal Boron Nitride (BN) exhibits its own unique sets of properties, such as high chemical and thermal stability, transparency to visible light, electrical insulativity, and high thermal conductivity. The latter two properties are unique because of their contradictory nature, which attracts great attention for thermal dissipation applications. Furthermore, combined with the fact that BN is transparent to visible light, it has great potential to be used as a thermal conductive layer in light entrance part of optoelectronic devices.

In order for BN to exhibit high thermal conductivity and transparency to visible light, it needs to be densely stacked and aligned along the horizontal direction to suppress backward scattering of phonons and photons. However, fabrication of this aligned structure faces several processing challenges. Although liquid-phase deposition methods such as ink-jet printing and spray coating offer good scalability, they usually lack uniformity and poor adhesion due to the coffee ring effect and BN nanosheets crumpling.

Herein, we propose a new fabrication method of high-performance BN films by combining the vacuum-filtration and transfer-printing. The process is facile, rapid, and applicable to various substrates having thickness scalability with higher functionality compared to conventional deposition techniques. Controlled vacuum-filtration enables BN nanosheets, which is immediately followed by transfer-printing based on solvent-evaporation-induced adhesion-switching between BN-membrane and BN-substrate interfaces. The fabricated BN films with a few micron thickness has compact, anisotropically aligned nanostructure, achieving an unusually high thermal conductivity over 23 W/m.K and optical transparency over 90%. Additionally, thermal dissipation effect of the BN layer characterized with simple joule heating apparatus. Finally, we report that the transfer-printed BN has an outstanding light diffusion property that optically enhances the performance of various optoelectronic applications including LEDs, thin film solar cells and organic dyes by facilitating both light out-coupling and absorption.

Role of Native Defects in Post-Synthesis Alloying of Transition Metal Dichalcogenides Hossein Taghinejad1, Daniel Rehn2, Ali Eftekhar1, Xiang Zhang3, Sufei Shi4, Pulickel Ajayan5, Evan J. Reed2 and Ali Adibi1; 1Georgia Institute of Technology, United States; 2Stanford University, United States; 3Rice University, United States; 4Rensselaer Polytechnic Institute, United States

Post-synthesis alloying is an important method for tailoring properties of two-dimensional (2D) transition-metal dichalcogenides (TMDs). In such a method, a binary crystal (i.e., MX2) serves as a host lattice in which the partial substitution of a native element (e.g., X) with a dissimilar counterpart (e.g., X’) yields a 2D alloy (i.e., MX’2xX2(1-x)) [1]. However, the detailed mechanism of the post-synthesis alloying in 2D TMDs is largely unknown. Here, we show that native vacancy-type defects play a major role in such an alloying scheme. In a case study, we use MoSe2 films as host crystals in which exchanging “Se” atoms with “S” atoms yields MoS2xSe2(1-x) alloys. Our study reveals that Se vacancies in host MoSe2 films (1) mediate the Se-S exchange process, and (2) further take part in the lateral diffusion of S atoms within the MoSe2 lattice. Accordingly, we show that alloying of CVD-grown MoSe2 with abundant Se vacancies is more efficient than that of exfoliated MoSe2 with fewer vacancies [2]. Practical consequences of this important conclusion will also be discussed.

Ultrafast Coherent Lattice Vibrations in 1T’-MoTe2 Bulk Crystal Takumi Fukuda1, Kotaro Makino2, Yuta Saito2, Paul Fons2, Alexander V. Kolobov23, Keiji Ueno4, Richard Mondal1 and Muneaki Hase5; 1University of Tsukuba, Japan; 2National Institute of Advanced Industrial Science and Technology (AIST), Japan; 3Faculty of Physics, Herzen State Pedagogical University, Russian Federation; 4Saitama University, Japan; 5Faculty of Pure and Applied Sciences, University of Tsukuba, Japan

Following the extensive investigation of the physical properties of two dimensional (2D) graphene, attention has turned to transition metal dichalcogenides (TMDs) as 2D-materials for fundamental physics and device engineering, owing to the wide variety of possible crystal structures due to the large number of accessible chemical combinations as well as unusually long lifetime carrier transport properties. Because of the possibility low energy phase switching, TMDs can also be considered as promising candidates for high-performance phase-change materials in the next generation of nonvolatile memory. In particular, phase transitions between the monoclinic phase of 1T’-MoTe2 (being stable at room temperature, RT) and the orthorhombic phase Td-MoTe2 (being stable below 250K) structures may be useful as ultrafast symmetric switching [1], since their crystal structures are similar, except for distortions along the a- or b-axes. Very recently Zhang et al. examined photoinduced structural transitions in Td-MoTe2, showing subpicosecond lattice symmetry switching by means of second harmonic generation, although the related coherent lattice vibrations were not well observed at RT [2]. Here we investigate the dynamics of coherent lattice vibrations in the monoclinic 1T’ phase using femtosecond optical pump-probe spectroscopy at RT. Preliminary results show a total of seven coherent phonon modes, which are approximately consistent with the corresponding Raman active modes. Among these modes, however, the lowest frequency mode at 0.38 THz, unexpectedly observed at RT, is primarily thought to exist only in the Td phase along the shear layer direction. Moreover, unlike the other six optical phonon modes, the amplitude of the shear phonon mode decreases with increasing pump fluence. The shear phonon mode is key in breaking the lattice symmetry, which results in the formation of a topological Weyl semimetal phase. We argue that our data demonstrate a possible ultrafast structural modulation between 1T’ and Td phases upon excitation of a shear phonon mode at RT.

Highly Conductive, Flexible and Solution-Processed Two-Dimensional Titanium Carbide (MXene) Electrode for Organic Light-Emitting Diode under Alternating-Current Operation

Seokyeong Lee, Euihyuk Kim, Soyeon Baek and Cheolmin Park; Yonsei University, Korea (the Republic of)

MXenes (Ti₃C₂), a new class of the two-dimensional (2D) transition-metal carbides and nitride, are currently at the forefront of 2D materials research. MXenes are promising new materials for next generation electrodes of the other electronics, in which various properties are required, including conductivity, transparency, mechanical reliability and conformability. Among the classes of various MXene family, Ti₃C₂Tx MXene, that firstly introduced from Drexel University, exhibits metal-like conductivity and hydrophilic surface including majority terminal group (-OH). Although MXene has been widely used as an electrode in many electronic devices such as supercapacitors, sensors, and batteries, it has not been applied to light-emitting diode (LED) devices yet. Herein, we prepared MXene (Ti₃C₂) thin film electrode with transparency, high conductivity and flexible for operating Organic Light-Emitting diode. This OLED with MXene electrode are very unstable in DC (Direct Current) operation but shows stable property in AC (Alternating-Current) operation. Our AC-driven OLED based on MXene electrode shows a high performance than device made from other 2D materials capable of solution processing. Moreover, the MXene electrode prepared on the non-rigid substrate (PET) with solution-processing exhibited both physical stability and durability under mechanical deformation. Therefore, we expect that this new MXene (Ti₃C₂) electrode with solution processable 2D materials will provide tremendous potential to fabricate OLEDs toward high-performance, flexible, and transparent as well as a variety of other functionality.

Wafer-Scale MXene Electrode Array for Large-Area Flexible Electronics

Benzheng Lyu¹, Seongchan Kim¹, Hong Gi Min², Hyungseok Kang¹ and Jeong Ho Cho²; Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); Yonsei University, Korea (the Republic of)

MXene, an emerging category of two-dimensional (2D) transition metal carbides and nitrides, have the potential to be high-performance and low-cost electrodes in organic field-effect transistor (OFET), due to the water dispersibility, the high conductivity, and the work function tunability. In this manuscript, we demonstrated a large-scale and uniform MXene electrode array formation on a plastic substrate for high-performance OFETs. The work function of MXene electrode was also effectively modulated through the chemical doping with NH₃. The resulting OFETs with MXene electrodes exhibited the excellent device performances such as maximum carrier mobility of ~1 cm²/V·s and on-off current ratio of ~10⁷ for both p-type and n-type OFETs, even though all electrode and dielectric layers were fabricated using solution process onto the plastic substrate. Furthermore, the MXene electrode-based complementary logic circuits such as NOT, NAND, and NOR have been integrated using p-type and n-type OFETs. The proposed method is expected to expand the application of MXene in other OFETs-involved electronic devices such as organic light emitting display and electronic skin.

Large Scale and Low-Temperature Synthesis of WS₂ Using PECVD

Vinit K. Kanade¹, Hyeong-U Kim², Seokjun Hong¹, Chaitanya K. Kanade¹, Jae-Hyun Lee¹ and Tae Sung Kim¹; Sungkyunkwan University, Korea (the Republic of); Northwestern University, United States; Ajou University, Korea (the Republic of)

The discovery of 2D graphene has attracted many researchers to synthesize a 2D transition metal dichalcogenides (TMDCs) materials. The TMDCs represented as MX₂ (M stands for Mo or W, Nb, Ta, etc. and X= S, Se, etc.) has the covalent bonds between metal and chalcogens that form the three layers which are held together by a weak van der Waals force. The stable layered structure formations in TMDCs is achieved by the absence of out-of-plane dangling bonds. Tungsten Disulfide (WS₂) is reported as one of the promising TMDC materials due to its various application in electronics, catalysis, optical, and other fields. The synthesis of WS₂ was previously reported by multiple techniques such as mechanical exfoliation, chemical exfoliation, chemical vapor deposition, etc. The limited research in large scale and high-quality synthesis of WS₂ materials restricts the use in the widescale application.

In this work, we are reporting the synthesis of a few layers WS₂ using plasma enhanced chemical vapor deposition (PECVD) technique at relatively low temperature (300°C). The PECVD technology is utilized to grow WS₂ thin film directly on the 4-inch Si-SiO₂ wafer. The quality of a synthesized WS₂ was confirmed using Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), high-resolution transmission electron microscopy (HR-
TEM), and energy dispersive spectrometry (EDS) mapping techniques. The thickness of the synthesized WS₂ film was found to be around a few nanometers and showed multilayered structure (~5-6 layers). Our unique approach shows the distinct advantage of the synthesis of WS₂ thin film with high uniformity and purity with reproducibility for mass production. Further, the WS₂ thin film was used to check the hydrogen evolution reaction (HER) catalytic performance with direct growth on the glassy carbon electrode. The PECVD synthesized WS₂ shows promising HER performance comparable with previously reported materials.

**A New Class of Layered Nanocrystals from Aromatic Molecular Units**

Veronica Barone and Isaiah A. Moses; Central Michigan University, United States

Novel two-dimensional(2D) materials in which simple molecular units are used as building blocks are currently being synthesized through bottom-up approaches. In this work, aromatic six-membered ring units, namely benzene, pyridine, phosphinine, arsinine, 1,3-diazine, 1,3,5-triazine and borazine are each utilized to build 2D graphene-like monolayers. Our density functional theory calculations revealed the stability of different 2D layers made out of heterocyclic molecular units, for the first time. The electronic properties of the holey materials as well as band gap tuning resulting from the different stacking of consecutive layers are also examined. This set of 2D materials presents a whole new class of layered nanostructures with great potentials for applications in areas such as catalysis, gas separation, optoelectronics, and nanoelectronics.

**FF01.10.13**

**Realization of 2D Crystalline Metal Nitrides via Selective Atomic Substitution**

Jun Cao, Tianshu Li, Hongze Gao and Xi Ling; Boston University, United States

Two-dimensional (2D) transition metal nitrides (TMNs) are emerging members in 2D family with promising potential for a range of applications. Their applications can be further extended to electronic and optoelectronic devices through the acquisition of high crystalline and large-area thin films. However, materials that meet such requirements have not been achieved using previous methods. Here, we report the synthesis of few-nanometer thin Mo₅N₆ crystals with satisfactory area and quality via chemical conversion of layered MoS₂ crystals. The structure and quality of the ultrathin Mo₅N₆ crystal are confirmed using transmission electron microscope, Raman spectroscopy and X-ray photoelectron spectroscopy. The lateral dimensions of Mo₅N₆ crystals are inherited from the MoS₂ crystals that are used for the conversion. Atomic force microscopy characterization indicates that the thicknesses of Mo₅N₆ crystal reduce to about 1/3 of the MoS₂ crystal, matching well with the crystal structure model. Electrical measurement shows the high conductivity of Mo₅N₆ (resistivity is 108.4 Ω/sq). In addition, this chemical conversion strategy is found versatile for the synthesis of various metal nitrides including W₅N₁₀, and TiN using their corresponding metal sulfides. Our strategy offers a new direction for preparing 2D TMNs with desired characteristics, opening a door for future exploration of fundamental physics and devices applications.

**FF01.10.14**

**Application of 2D Interlayer to β-Ga₂O₃ Optoelectronic Devices**

Suhyun Kim and Jihyun Kim; Korea University, Korea (the Republic of)

Recent application of mechanical exfoliation method to beta-gallium oxide (β-Ga₂O₃) has allowed various device structures through integration with different two-dimensional (2D) materials. Combining the unique properties of β-Ga₂O₃ and 2D materials can yield higher performance in (opto)electronic devices. The direct ultrawide bandgap of 4.6-4.9 eV and the superior electrical breakdown field make β-Ga₂O₃ especially advantageous for solar-blind ultraviolet (UV) photodetectors and power devices. The mechanically exfoliated β-Ga₂O₃ nanobelts can also be easily stacked on to the 2D flakes to form van der Waals heterostructures without any strain issues through dry transfer techniques just like other 2D materials; an exceptionally large lattice constant along one direction in β-Ga₂O₃ crystal structure allows easy mechanical cleavage along (100) direction. Therefore, the excellent electronic properties, high transparency or the atomic thickness of 2D layered materials such as graphene, transition metal dichalcogenides (TMDC) and hexagonal boron nitride (hBN) can be used to develop β-Ga₂O₃ device structures. In this work, a 2D material was applied as an interlayer between the electrodes and channel of β-Ga₂O₃ devices, and the UV photoresponse properties of the fabricated devices based on van der Waals heterostructure were analyzed. First, hBN can be applied to β-Ga₂O₃ metal-semiconductor-metal (MSM) type UV photodetector. hBN, which is a
2D insulating material, can be used as a thin barrier in addition to the Schottky barrier between the source electrode and the channel to lower the dark current of the photodetector. Graphene with very high electrical conductivity can also be applied as UV-transparent electrodes to enhance the photocurrent of the MSM photodetector. Graphene with very high electrical conductivity can also be applied as UV-transparent electrodes to enhance the photocurrent of the MSM photodetector. Secondly, a 2D TMDC such as molybdenum disulfide (MoS2) can be used to modify the contact properties and observe the effects on the photoresponse properties of β-Ga2O3 devices. Inserting a 2D interlayer between the metal and β-Ga2O3 would reduce the Schottky barrier and thus improve the ohmic properties of the metal contacts on β-Ga2O3. Further results and discussion will be presented in detail.

**FF01.10.15**

**Multiple Heterojunction Negative Differential Transconductance Device for Realization of Multi-Valued Logic Circuits**

Hyeonje Son1, Young Jae Kim1, Haeju Choi1, Sung Kyu Jang1, Jin-Hong Park1 and Sungjoo Lee1,2; 1Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); 2Sungkyunkwan University, Korea (the Republic of)

Recently, 2D material based multi-valued logic circuits, which can reduce power consumption and complexity of integrated circuits compared to binary logic circuits, have received significant attention in an effort to overcome fundamental limits of conventional silicon technology. Based on the development of 2D material preparation processes, heterogeneous integration of 2D materials can be simply achieved for logic gate design. However, reported three-valued NOT gates (ternary inverters) based on 2D materials require limited condition and/or complex fabrication process for obtaining distinctive three logic states. Here, we demonstrate CMOS ternary inverter circuit consisting of a series connection of three-heterogeneous 2D transistors (WSe2-MoTe2-MoS2). Due to the ambipolar nature of MoTe2 channel, which can drive both n-type transistor and p-type transistor depending on the applied gate voltage range, distinctive three logic states can be obtained by complementary operation between WSe2/MoTe2 heterojunction transistor and MoTe2/MoS2 heterojunction transistor. Furthermore, a quaternary inverter based on 2D multiple heterojunction is demonstrated by controlling trans-conductance of a part of MoTe2 channel via spatially controllable surface charge transfer doping method.

**FF01.10.16**

**MOVPE of Large-Scale WS2-Graphene and MoS2-Graphene 2D-2D Heterostructures for Optoelectronic Applications**

Annika Grundmann1, Clifford McAleese2, Ben R. Conran2, Andrew Pakes2, Kenneth B. Teo2, Michael Heuken1,3, Holger Kalisch1 and Andrei Vescan1; 1RWTH Aachen University, Germany; 2AIXTRON Ltd, United Kingdom; 3AIXTRON SE, Germany

Two-dimensional (2D-2D) heterostructures combine the unique intrinsic chemical, physical and (opto)electronic properties of different types of 2D materials. Not hampered by restrictions of lattice matching, this allows for tailored heterostructure designs for (opto)electronic devices and circuits. The semiconducting transition metal dichalcogenide (TMDC) WS2 is interesting due to its direct bandgap in the visible range in combination with a high radiative quantum efficiency. Unlike graphene, WS2 has a large optical absorption coefficient (105-106 cm⁻¹), thus its implementation is an ideal method to increase the external quantum efficiency of e.g. graphene-based optoelectronic detectors. Similarly, the TMDC MoS2 could complement graphene-based electronics by a transistor channel material that can be pinched off efficiently.

The main preparation strategy of such 2D-2D heterostructures has been sequential stacking of the layered materials using wet or dry transfer methods. However, those mostly complicated transfer processes generate defects and leave residues at the interfaces of the stacked materials. In recent years, the well-established technique of metalorganic vapor phase epitaxy (MOVPE) has been used to deposit several types of 2D materials. MOVPE enables the development of a reproducible and scalable deposition process for high-quality 2D-2D heterostructures. Here, we investigated key process parameters, including growth temperatures, pressures and growth times for the single-step deposition of WS2 and -MoS2 on CVD (chemical vapor deposition)-graphene using MOVPE.

Monolayer and bilayer/multilayer graphene films were directly grown on sapphire (0001) using an AIXTRON CCS 2D system in 19 x 2" configuration. The metal-free CVD process was carried out at 1400 °C for 6 minutes using CH4 with N2 as carrier gas. The deposition of MoS2 and WS2 on these graphene samples was performed in an AIXTRON planetary hot-wall reactor in 10 x 2" configuration. Tungsten hexacarbonyl (WCO), molybdenum hexacarbonyl (MCO) and di-tert-butyl sulfide (DTBS) were used as metalorganic precursors (avoiding toxic hydride sources) and N2 as carrier gas. All samples were characterized using Raman spectroscopy, photoluminescence spectroscopy (PL), scanning electron microscopy (SEM) and atomic force microscopy (AFM).

WS2 was deposited for 20 h at 845 °C and 30 hPa on the different graphene samples. Deposition on monolayer
graphene results in triangular domains up to 800 nm and a surface coverage of about 64 % whereas deposition on bilayer/multilayer graphene leads to crystallites up to 1.5 µm in size and 60 % surface coverage. Extending growth to 30 h yields nearly no increase of the monolayer WS\textsubscript{2} domain size on neither monolayer nor bilayer/multilayer graphene, but an enhanced bilayer WS\textsubscript{2} nucleation. Thus, the surface coverage increases only slightly up to about 71 % for monolayer and 67 % for bilayer/multilayer graphene. A rise of the total pressure at lower growth temperature (550 °C) in 10 h processes increases the domain size from about 140 nm (30 hPa) to 660 nm (200 hPa).

Using the same initial process parameters (845 °C, 30 hPa) for MoS\textsubscript{2} growth for 24 h, we find an enhanced lateral growth rate compared to WS\textsubscript{2}. This is the same trend as previously observed for growth directly on sapphire. The MoS\textsubscript{2} monolayers are nearly fully coalesced on all graphene samples (> 98 % surface coverage). Unlike the growth of WS\textsubscript{2} on graphene or both TMDC directly on H\textsubscript{2}-desorbed sapphire, MoS\textsubscript{2} crystallites exhibit a distinct hexagonal structure when deposited onto graphene. Only MoS\textsubscript{2} crystallites from secondary nucleation, which grow on top of monolayer MoS\textsubscript{2} domains, are also of hexagonal shape. The hexagonal shape generally hints on a close-to-ideal stochiometry at the crystallite edges and the absence of a significant substrate influence. Unlike the deposition of MoS\textsubscript{2} and WS\textsubscript{2} on sapphire, MoS\textsubscript{2} and WS\textsubscript{2} domains on graphene do not show any preferred orientation.

**High Current Gains in Heterojunction Bipolar Transistors Based on 2D Materials**

Geonyeop Lee, Janghyuk Kim, Suhyun Kim and Jihyun Kim; Korea University, Korea (the Republic of)

Two-dimensional materials (2DM) have received great attention because of their unique electrical, mechanical and optical properties. Especially, the weak van der Waals interaction and atomically sharp interface without dangling bonds make 2DMs suitable for heterojunction devices. Therefore, 2DMs-based heterojunction devices can avoid the problems of lattice constant mismatch and show high-performance compared to those fabricated by conventional epitaxy. Studies on heterojunction-based devices based on 2DMs have mostly focused on fundamental structures such as a single p-n junction diode, but not on active devices like heterojunction bipolar transistors (HBT).

In our study, we successfully fabricated double HBTs (pnp or npn) by vertically stacking n-type or p-type 2DM flakes. P-type (Black phosphorus or WSe\textsubscript{2}) or n-type (MoS\textsubscript{2}) flakes were vertically stacked in order of npn or pnp on to SiO\textsubscript{2}/Si using a micro-manipulator. Then, electrodes (Ti/Au or Pt/Au) for the emitter, base, and collector were defined using standard e-beam lithography. The interface between each flake was clean without strain and bubbles as observed in the cross-sectional TEM images of the vertically stacked heterojunction structure. The formation of the two p-n junctions in base-emitter and base-collector was experimentally confirmed by the rectifying behavior in I-V characteristics. An npn double HBT showed excellent electrical characteristics with high current gain ($\beta = \sim 100$) which is comparable to those of conventional bipolar junction transistors. The detail of our experiment and results will be presented at the meeting.

**Dimensional Confinement of Magnetic Soliton Phase in Exfoliated 2D Cr\textsubscript{1/3}NbS\textsubscript{2} Thin Flakes**

Siwei Tang\textsuperscript{1}, Randy Fishman\textsuperscript{2}, Satoshi Okamoto\textsuperscript{2}, Qiang Zou\textsuperscript{2}, Anping Li\textsuperscript{2}, David Mandrus\textsuperscript{3} and Zheng Gai\textsuperscript{2}; 1Central South University, China; 2Oak Ridge National Laboratory, United States; 3The University of Tennessee, Knoxville, United States

Thin flakes of Cr\textsubscript{1/3}NbS\textsubscript{2} are fabricated successfully via microexfoliation techniques. Temperature-dependent and field-dependent magnetizations of thin flakes with various thicknesses are investigated. When the thickness of the flake is around several hundred nanometers, the softening and eventual disappearance of the bulk soliton peak is accompanied by the appearance of other magnetic peaks at lower magnetic fields. The emergence and annihilation of the soliton peaks are explained and simulated theoretically by the change in spin spiral number inside the soliton lattice due to dimensional confinement. Compared to the conventional magnetic states in nanoscale materials, the stability and thickness tunability of quantified spin spirals make Cr\textsubscript{1/3}NbS\textsubscript{2} a potential candidate for spintronics nanodevices beyond Moore’s law.

**Wafer Scale Large Area ReS\textsubscript{2} Photodiode by Sputtering**

Dae Young Park and Mun Seok Jeong; Sungkyunkwan University, Korea (the Republic of)

Among transition metal dichalcogenides (TMDCs), rhenium disulfide (ReS\textsubscript{2}) has unique insensitive direct bandgap from monolayer to bulk [1]. Combining with this unique property and large area film fabrication techics can
overcome the limitation of TMDCs. Herein, we synthesized polycrystalline ReS$_2$ via solid state reaction route and then sputtering target was prepared using spark plasma sintering. Uniform ReS$_2$ films were deposited on 2 inch wafer by sputtering with deposition temperature and time variations. Large area ReS$_2$ films were characterized and its morphology and thickness can be controlled systematically by changing deposition temperature and time. Basic p-n diodes with p-Si and ReS$_2$ film were fabricated and it demonstrated fast response time (7 us) and typical diode behaviors. These large area ReS$_2$ films have potential to expand the applications of TMDCs.

**FF01.10.20**

**Density Functional Exploration of Two-Dimensional Transition Metal Dichalcogenides from Fe-, Co-, Ni- and Cu-Groups** Rafael Besse$^1$, Matheus P. Lima$^2$ and Juarez L. F. Da Silva$^3$; $^1$São Carlos Institute of Physics, University of São Paulo, Brazil; $^2$Federal University of São Carlos, Brazil; $^3$São Carlos Institute of Chemistry, University of São Paulo, Brazil

Two-dimensional (2D) transition metal dichalcogenides (TMDs) exhibit unique properties which create a platform to investigate novel phenomena and point to their application in several fields, such as electronics, catalysis and energy storage [1,2]. TMDs from Ti-, V-, and Cr-groups are most easily obtained in layered crystal structures and have been extensively explored as 2D materials [3], however a large diversity of crystal structures is known for compounds with the remaining transition metals, and the exploration of the physical and chemical properties of 2D dichalcogenides based on transition metals from Fe-, Co-, Ni-, and Cu-groups has been very limited. Therefore, in order to design novel two-dimensional materials based on TMDs and explore their structural, energetic, and electronic properties, we performed an investigation of 36 $MQ_2$ compositions ($M$ = Fe, Co, Ni, Cu, Ru, Rh, Pd, Ag, Os, Ir, Pt, Au; $Q$ = S, Se, Te), by means of density functional theory calculations with semi-local and hybrid exchange-correlation functionals, and van der Waals (vdW) corrections. For each composition, a set of 11 crystal structures experimentally reported for TMDs, both with layered and non-layered frameworks, has been employed. We found that layered phases are energetically favored for Ni-group compositions, and the octahedral intralayer coordination is the most favored among the layered phases. The layered crystals of Fe- and Ni-group materials have weak interlayer binding, dominated by vdW interactions, whereas in the remaining materials a strong interlayer binding with non-vdW chemical bonds is observed. The electronic band gaps of the lowest energy phases were screened, and selecting the lowest energy layered structure for each compound, 17 semiconductors were identified among their monolayers, all based on the Fe- and Ni-groups transition metals. The conduction and valence band offsets of the semiconductor monolayers were obtained, and the trends originate primarily from the changes on the $M$-d and $Q$-p energy levels. Based on the band alignments, we applied the Anderson rule to classify the semiconductors heterojunctions formed with the combinations of these monolayers, which mainly fall in the type-II classification, although Ni-group layers are more prone to the formation of type-I junctions. To explore the potential of these materials for application in solar energy harvesting, the power conversion efficiencies of solar cells based on type-II heterostructures were estimated, and values comparable to and higher than those estimated for the widely studied Mo- and W-based TMDs were found. Our findings provide important information to guide the design and search for novel 2D TMDs and van der Waals heterostructures. We acknowledge financial support from grant 2017/11631-2, São Paulo Research Foundation (FAPESP). R. Besse is recipient of PhD fellowship, Grant 2017/09077-7, FAPESP.

**New Study of 2D Layered Structure Based 1D van der Waals Materials and Their Electrical Properties** Bum Jun Kim, Hyung Kyu Lim and Jae-Young Choi; Sungkyunkwan University (SKKU), Korea (the Republic of)

Two-dimensional (2D) materials, such as graphene and transition metal dichalcogenide (TMDs), have activated enormous interests in exploration of van der Waals (vdW) materials. One of key features of 2D materials, which enables their high performance, is dangling bond-free surfaces, since interlayer bonds in these materials are vdW rather than covalent. However, dangling bonds on edges in 2D materials still act as scattering centers and recombination centers when scaled down to less than a few tens of nanometers. In recent years, interest in 2D vdW materials has expanded to include one-dimensional (1D) vdW structures that consist of vdW bonded molecular chains. There are two types of 1D vdW structures; a true 1D structure with a pure vdW inter-chain bond and a quasi
1D structure with additional non vdW bonds among molecular chains. Unlike the 2D vdW materials that yield 2D atomic sheets upon exfoliation, 1D vdW materials produce various 1D nanomaterials such as ribbons, wires, and molecular chains. These 1D materials could contribute to many interesting physics, such as topological insulator, charge-density waves, superconductor-insulator transitions, ultralong ballistic phonon transports, low-frequency electronic noise and molecular-scale connectivity.

In this study, we synthesized a vdW 1D nanomaterials on a bulk scale stacked with chain-like 1D materials. The as-grown single crystal materials contains numerous single chains linked by vdW interactions. It was confirmed that the bundle of chains can be easily separated by mechanical exfoliation. Interestingly, the isolated 1D materials exhibit a quasi-two-dimensional layered structure. The variation of the work function depends on the thickness of the layered structure, as determined by scanning Kelvin probe microscopy (SKPM) measurements. Moreover, we implemented a field effect transistor (FET) based on nanoscale vdW 2D materials stacked with chain-like single crystal 1D materials to determine proper metal electrode.

FF01.10.23
Two-Dimensional Transition Metal Dichalcogenide(TMD)/Germanium Hybrid Photodiode Youngseo Park¹, Aujin Hwang¹, Geonwook Yoo² and Junseok Heo¹; ¹Ajou University, Korea (the Republic of); ²Soongsil University, Korea (the Republic of)

Two-dimensional (2D) transitional metal dichalcogenide (TMD) such as MoS₂ and WSe₂ has been actively researched due to superior electrical and optical properties. Heterojunction of 2D based TMD and bulk semiconductor such as Silicon (Si), Germanium (Ge), and compound semiconductors, in particular, has attracted considerable attention in recent years due to new possibilities for the next-generation nanoelectronics and optoelectronics. Ge has large absorption coefficient at near IR, widely used in optoelectronics device. Combination of TMD and Ge will have a potential to absorb a broadband light. The broadband photodiodes with photosensitivity from UV to near IR can use various applications such as color imaging, night vision and environmental monitoring. In this work, we have investigated the electrical and optical characteristics of MoS₂/p-Ge photodetector for broadband photodetection.

The fabrication starts with a deposition of 100 nm thick SiO₂ on a cleaned p-Ge substrate by PECVD method. Some portions on the substrate were exposed using a wet chemical etching process to make the junction between MoS₂ and Ge. Surface passivation of Ge was carried out in (NH₄)₂S solution (40-48 wt.% in H₂O, Sigma-Aldrich) for 30 min at 90 °C. By conventional scotch tape method, few layers of MoS₂ were mechanically exfoliated from bulk MoS₂ (Graphene Supermarket, USA), and then they were transferred onto the substrate. 5/80 nm Ti/Au was deposited on the top surface of the SiO₂ as the electrode for MoS₂ by e-beam evaporation by conventional lift-off technique. Finally, 100 nm Al was deposited on the back of Ge.

The exposed area of the MoS₂ flake is approximately 1.67 × 10⁻⁵ cm². Electrical property of the device was characterized using a semiconductor analyzer (B1500A, Keysight, USA) in a dark box. I-V curve of the MoS₂/Ge photodiode is measured from -10 V to 10 V. The device shows the excellent rectification characteristic with a rectification ratio up to approximately 10⁴ within ±10 V. Threshold voltage is 4.07 V, higher than expected, due to barrier of junction by band pinning. I-V curves are measured for voltage ranging from -10 V to 10 V under incident power densities of 5, 15, and 50 mW/cm² with 466 nm DPSS (Diode Pumped Solid State) laser in N₂ ambience. We calculated photocurrent (Iₚ) from Iₚ = Iₚ - Iₚ, where Iₚ is the current with the incident laser and Iₚ is the current in the dark box, which is 0.52, 1.31, and 2.63 nA under the incident power densities of 5, 15, and 50 mW/cm², respectively, at V = -10 V.

We calculated the responsivity (R) as a function of the wavelength, obtained from 400 nm to 700 nm with the voltage of -10 V using a monochromator. The responsivity is calculated as R = Iₚe/P, where P is the incident optical power. The responsivity shows a peak at 670 nm (174.4 mA/W). External quantum efficiency (EQE) is defined by R×hc/λ×q, where h is Planck’s constant, c is the velocity of light in vacuum, λ is the wavelength of the incident light, and q is the electronic charge. The obtained EQE peak is approximately 32.3% at 670 nm.

To confirm the response behavior about the incident light, the time-dependent current was measured under pulsed DPSS laser illumination (λ = 466 nm) with 5 mW/cm². To characterize the speed of the photodiode by rise time tₕ, we plotted the rise of photocurrent for turning on the laser light. The tₕ is 11 ms, which defines the time required for the current to increase from 10% to 90% of the average current for turning on the laser. At the falling edge, we confirm the fall time tₕ of 15 ms, which defines as opposed to tₕ.

In conclusion, we have fabricated the p-Ge/MoS₂ hybrid photodiode and characterized their electrical and optical properties. We observed the excellent rectification characteristic and the responsivity of wavelength from 400 nm to 700 nm. We will measure the responsivity of the wavelength above 1000 nm and present the corresponding

**Transition Metal Dichalcogenide—Sensing Layer Heterojunctions Based Ion Sensitive Electrodes for Heavy Metal Sensing**  
Priya Vinayak, Mohammed Samim Hassan, Ajeet Singh, Sameer Sapra, Bhaskar Mitra and Madhusudan Singh; Indian Institute of Technology Delhi, India

The World Health Organization recognizes heavy metal toxicity arising from contaminated water supplies as a major challenge affecting millions of people worldwide, especially in rapidly developing economies of Asia. The maximum permissible limit for heavy metals has been identified as 3 ppm for Cd^{2+}, 10 ppm for Pb^{2+}, and 20 ppm for Ni^{2+}. Low-cost methods relying on ion exchange of Cd detection include the use of chalcogenide glasses, nanomaterials, and polymers that exhibit limits of detection (LoD) ~ 0.1-3 ppm. It is thus possible to detect Cd ions at human health-relevant ppm levels reliably, but cross-sensitivities of sensing films to other ions such as Pb, Ni, etc. complicate the analysis. Further, while combinatorial sensing of different ions by using arrayed detectors is possible, followed by principal component analysis, each detector has to be independently fabricated before system-level integration and packaging that interfaces each detector to the analyte, and readout electronics. This complication can be addressed by using a common transducing layer composed of a high mobility two-dimensional transition metal dichalcogenide (TMD). The ion exchange process at the surface of the sensing layer is expected to produce changes in local charge densities due to analyte-driven changes in the local potential. These charges can be conducted laterally to contacts by the underlying TMD layer, incorporated in the nanoscale form in a spin-coated sensing film to form ion sensitive electrodes (ISEs). In this work, we have grown proof of concept nanoscale heterojunctions composed of two dimensional n-MoSe_{2} with a vertically grown p-Cu_{2}S sensing layer using a colloidal synthesis route via defect passivation of MoSe_{2}. Cu_{2}S is chosen intentionally because the cation exchange between Cu⁺ and Cd^{2+} is known to be favored in an aqueous solution. Powder X-ray diffraction (PXRD) data reveals the growth of hexagonal 2H MoSe_{2} nanosheets and a hexagonal close-packed array of Cu_{2}S. Transmission electron microscopy (TEM) measurements were carried out on the dried sample to obtain a film thickness of approximately 1 nm. A micro glass slide was cleaned and bottom contacts (Cr (10 nm)/Au (50 nm)) were thermally evaporated through a shadow mask at a base pressure of 3.4 x 10^{-6} Torr. An ink composed of the nanoscale heterojunctions was spin-coated to form a uniform film to complete the ISE. The properties of the material have been tested by electrochemical impedance spectroscopy (EIS) measurements (with Pt as counter and Ag/AgCl as reference electrode on a PAR PMC 2000 electrochemical workstation) and open circuit potential measurements (Keithley 6514 system electrometer). A series of test solutions were prepared by spiking the electrolyte with [Cd^{2+}] in the range ~[1mM, 1nM]. Charge transfer resistance values derived by fitting Randle's equivalent circuit to the Nyquist plots were found to be approximately 5.5 kΩ near the LoD. These resistance values decrease with the increasing [Cd^{2+}] due to increasing cation exchange at the Cu_{2}S/analyte interface. Open circuit potential measurements revealed that a ~20mV/decade [Cd^{2+}] increase in potential was generated with respect to the Ag/AgCl reference electrode with increasing [Cd^{2+}]. A linear response to a logarithmic rise in [Cd^{2+}] is found for the sensing device with an estimated LoD ~0.1 ppm for this initial device. Through careful tailoring of the interface between the sensing layer and the underlying 2D TMD, the strength of the molecular interactions can be enhanced, resulting in greater sensitivity to the analyte.

**A Reconfigurable Remotely Epitaxial VO_{2} Electrical Heterostructure**  
Yuwei Guo¹, Xin Sun¹, Toh-Ming Lu¹ and Jian Shi¹;²; ¹Rensselaer Polytechnic Institute, United States; ²Rensselaer Polytechnic Insitit, United States

The reconfigurability of the electrical heterostructure featured with external variables, such as temperature, voltage and strain, enabled electronic/optical phase transition in functional layers has great potential for future photonics, computing and adaptive circuits. VO_{2} has been regarded as an archetypal phase transition building block with superior metal-insulator transition characteristics. However, reconfigurable VO_{2}-based heterostructure and the associated devices are rare due to the fundamental challenge in integrating high quality VO_{2} in technologically important substrates. In this report, for the first time, we show the remote epitaxy of VO_{2} and the demonstration of a vertical diode device in graphene/epitaxial VO_{2}/single crystalline BN/graphite structure with VO_{2} as a reconfigurable phase change material and hexagonal boron nitride (h-BN) as an insulating layer. By diffraction and electrical transport studies, we show that the remote epitaxial VO_{2} film exhibits higher structural and electrical quality than direct epitaxial one. In the reconfigurable diode, we find that the Fermi level change and spectral weight shift along with metal-insulator transition of VO_{2} could modify the transport characteristics. The work suggests the
feasibility of developing single crystalline VO₂-based reconfigurable heterostructure with arbitrary substrates and sheds light on designing novel adaptive photonics and electrical devices and circuits.

**FF01.10.26**
Confinement Heteroepitaxy and Electrochemical Properties of 2D Metals
Ana de la Fuente Duran, Natalie Briggs, Derrick J. Butler, Joshua A. Robinson and Aida Ebrahimi; The Pennsylvania State University, United States

Air-stable, crystalline, atomically-thin metals can be realized at the epitaxial graphene (EG)/silicon carbide (SiC) interface through a method termed confinement heteroepitaxy (CHet). This EG/SiC interface plays a crucial role in the creation of crystalline, 2-dimensional (2D) metals, and it provides a unique environment in which material structures with mixed interfacial van der Waals and covalent bonding can be formed. Through this thermal evaporation-based technique, intercalation of group-III elements (Ga, In) through epitaxial graphene can be achieved to create atomically-thin layers at the EG/SiC interface.

CHet is a unique EG intercalation method as it utilizes graphene defects and high-pressure (1-700 Torr) thermal evaporation. In this intercalation method, graphene defects created through exposure to O₂ plasma serve as entry points for a metal that is vaporized at high temperatures (>700°C). The defective graphene layers that result from plasma treatment correlate with the increase of the Raman D:G peak intensity ratios seen between as-grown and plasma-treated EG. During intercalation, the engineered graphene defects are shown to heal. This can be observed in the significantly decreased Raman D peak intensity measured post-intercalation. Regardless of the metal intercalated, CHet also produces a 3-4× increase in the Raman G peak intensity. This effect is attributed to plasmonic resonance. Due to their potential for high optical sensitivity and tailorability, 2D metals are promising materials for plasmonic applications.

Developing efficient photosynthetic systems that can economically convert solar energy into chemical energy on a large scale is crucial for the realization of a sustainable economy. The production of hydrogen gas by reducing water is a promising solar energy conversion technique, and it has been extensively researched in semiconductor-based photoelectrochemical devices. Semiconductors are often the foundation for solar energy-harvesting technologies because they have the ability to effectively capture photons. Due to the reflective properties of bulk metals, they are not generally used for such applications. Metals on the nanoscale, however, have proven to be effective at trapping photons due to local surface plasmon resonance. Research involving plasmon-induced charge separation for photocatalysis without the use of semiconducting materials is limited. Here, we explore how 2D allotropes of 3D metals perform as photocatalysts and how their tunable plasmonic properties can play a role in developing reaction selectivity.

In order to test the photocatalytic performance of the 2D metals realized through CHet, a white-light source is utilized in conjunction with a three-electrode system in an electrochemical cell. Because plasmons can decay via uphill electron transfer to a chemical species in direct contact, plasmon-induced charge separation (PICS) can be utilized to convert light energy into electrochemical energy. If the induced charge separation is large enough, it can generate an electronic potential that is suitable to drive the electrochemical production of fuels such as hydrogen gas. Standard measurements including electrochemical impedance spectroscopy, cyclic voltammetry, and linear sweep voltammetry completed with and without the use of light serve to elucidate the plasmonic properties of 2D metals and the role that PICS can play in catalyzing reactions that yield carbon-neutral fuels.

Enhancement in Photo-Detecting Performance of Multilayer MoS₂ Phototransistors by Reduction Treatment with Tannic Acid
Sujin Jung¹, I Sak Lee¹, Byung Ha Kang¹, Seong In Hong¹, Jusung Chung¹, Hyukjoon Yoo¹, Sunkook Kim² and Hyun Jae Kim¹; ¹Yonsei University, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Recently, two-dimensional nano-materials such as graphene and transition metal dichalcogenide (TMDC) have been explored with substantial interest due to their potential in various applications including nanoelectronics, optoelectronics, and bioelectronics. One type of TMDCs, molybdenum disulphide (MoS₂) is regarded as a promising material for optoelectronic application because MoS₂ has tuneable bandgap whose range is from 1.2 eV for monolayer to 1.8 eV for multi-layer. Despite the proper band gap energy for absorbing wide-range of light covering from visible light to ultraviolet, the phototransistors based on MoS₂ channel layer have some issues regarding relatively low photoresponsivity and photosensitivity due to their low efficiency of light absorption resulting from ultrathin channel layer. In this sense, intensive efforts have been widely devoted on improving the photo-related characteristics of MoS₂ phototransistors.
In this work, we propose a simple method to enhance the photo-detecting performance of MoS2 phototransistors where the reduction treatment is introduced. The reducing agent used in this research is tannic acid (C76H52O46) which is a nature-friendly material extracted from various vascular plants. The reducing reaction by tannic acid is originated from its monomer with dozens of hydroxyl groups (-OH) which forms hydrogen bonds with oxygen. The reduction treatment is simply processed by dipping the device in tannic acid solution. During the dipping process, hydroxyl groups in tannic acid make hydrogen bonds with oxygen atoms that intrinsically exist in the lattice of MoS2 by substituting the sulfur atoms. Then, the oxygen atoms bonded with tannic acid monomers are detached from lattice of MoS2. Those broken Mo-O bonds result in increased number of sulfur vacancies which are relevant for the formation of sub-gap states in MoS2 band gap. Thus, sub-gap states formed by sulfur vacancies in MoS2 induce narrower effective optical band gap energy and light absorption capability could be improved.

The multilayer MoS2 flakes were transferred onto the thermally oxidized heavily boron-doped silicon wafers by mechanically exfoliating from a bulk MoS2 crystal. Then, titanium and gold electrode sequentially deposited by electron-beam evaporation. After completing fabrication of MoS2 transistor, the device is dipped in 0.3 M tannic acid solution for 10 min.

We have measured the electrical and photo-detecting performance of tannic acid treated MoS2 phototransistor. The improvement or degradation in electrical performance was not observed in MoS2 phototransistor after reducing treatment by tannic acid. But, the difference between dark current and photoinduced current under red, green, and blue laser illumination becomes more distinguishable because of more efficient light absorption in tannic acid treated MoS2 layer. As a result, both photoresponsivity and photosensitivity of the tannic acid treated MoS2 phototransistor were improved as compared to the device without treatment. With an intensity of 10 mW/mm², photoresponsivity increased from 126.85 A/W to 807.36 A/W under red light, from 109.00 A/W to 819.29 A/W under green light, and from 166.44 A/W to 928.25 A/W under blue light. Also, with same intensity of light, photosensitivity increased from 9.51 to 243.93 under red light, from 16.23 to 527.05 under green light, and from 26.51 to 1700.98 under blue light. Therefore, we proposed a novel method for improving the performance of MoS2-based phototransistor with simple reduction method which makes it possible to be applied in various optoelectronic applications.

**FF01.10.28**

**Nanostructuring 2D Layered Nanomaterials by Low Power Focused Laser Irradiation** Kiran S. Hazra; Institute of Nano Science and Technology, India

Optical and electronic properties of 2D nanomaterials such as Graphene, Transition metal di-chalcogenides (TMDCs), Phosphorene etc. are already emerging field of research for their wide range of applications in nano-electronics, opto-electronic, solar cell, electrochemical activity etc. We have developed a novel and easy way to create various nanostructures on wide range of 2D materials in a single step process by using simple focused laser beam of a Raman spectrometer at low power irradiation. The feature size can go down up to diffraction limit of the laser used and the shape of the etched point can be used to find the orientation of the lattice structure of the material. In this presentation we focus on various applications of such nanostructures, fabricated on 2D by simple laser irradiation technique. We will demonstrate that nanostructuring on MoS2 flake can create periodic modulation in capacitive response. Optimized geometry of these nanostructures alongwith selective deposition of Au nanoparticles demonstrate ultrasensitive SERS. These nanostructures were capable of enhancing interestingly we have found that the edges of such nanostructures are more catalytically active for electrochemical deposition of Au nanoparticles. Using this route we were also able to create nanostructures on Phosphorene flakes and rGO flakes. Controlled formation of nano-voids array on few layer BP flake induces enhanced local electric field (hot spots) at the vicinity of the nano-voids, resulting in ~30% Raman intensity enhancement. Such nano-voids induced hotspots on BP flake open up a new species of metal free SERS substrate, demonstrating pronounced enhancement in Raman signal of Rhodamine B as high as of the order of ~10⁴. Nano-patterning on rGO flakes leads to the observation of radiation pressure on solid-air interface.

The discovery of 2D layered materials has opened new frontiers in science and technology. The implication of these 2D nanomaterials in gas sensing, has gained tremendous attention owing to their outstanding virtues such as high surface to volume ratio, unique electronic and structural properties. Further, the high surface reactivity of 2D materials, offers potential for room temperature gas sensing leading to low power consumption, which is highly desirable for practical applications. Among these 2D nanomaterials, the Transition Metal Dichalcogenides (TMDC’s) such as MoS2 and WS2, have been explored for the detection of various gases including NH3, NO, NO2, etc. However, these TMDC’s are prone to degradation on exposure to ambient environment due to the significant oxygen adsorption on its surface. This limits the practicability of a sensor in real environment. The engineering of these 2D materials by incorporating another nanomaterial can provide solution to this aforesaid problem. This strategy of forming nanohybrids can not only provide the air-stability, but also improve the overall performance of the sensor.

In this work, we demonstrate the fabrication of a novel nanohybrid of Iron oxide nanoparticles (NP)- decorated WSe2 nanosheets (NS) for air-stable room temperature detection of ammonia with very high response magnitude and lowest limit of detection. The aforesaid nanohybrid was fabricated using modified co-precipitation method. At room temperature, the sensor demonstrated significant response of 510% to 3 ppm ammonia while achieving the lowest limit of detection (llod) of 50 ppb, with a response of 2.4%. The iron oxide – WSe2 nanohybrid sensor response was dramatically higher when compared to pristine WSe2, as the sensing material which exhibited only 53.5% response towards 3 ppm of ammonia, and 300ppb as llod. In addition, we observed improved recovery of the nanohybrid sensor (148s recovery time in contrast to 436s recovery time for pristine WSe2) by incorporating iron oxide nanoparticles. These findings suggest that the decoration of nanoparticles can aid in tuning the properties of 2D layered materials and hence can open up new avenues for several applications.
strategy to overcome the limits of conventional top-down technologies in the semiconductor industry. Silicene allows to reach the ultimate target for thickness scaling while combining an ultra-high carrier mobility with the unique opportunity to tune the bandgap.

However, silicene oxidizes rapidly when exposed to ambient conditions, therefore requiring a reliable passivation process. Graphene represents an ideal passivation material, due to its inertness, high flexibility and outstanding impermeability, as well as being non-Raman active in the fingerprint region of silicene, allowing a precise analysis of the structural properties of the encapsulated layer.

We report the successful passivation, for up to 48 h, of silicene by few-layers graphene (FLG) flakes. The monolayer silicene was epitaxially grown on a well-ordered Ag(111) film on mica by exposing the substrate, kept at a temperature of 530 K, to a constant flux of Si (≈ 0.02 ML/min). After the growth, silicene formation was verified via LEED analysis.

For the passivation, natural graphite was mechanically exfoliated on top of a vacuum-compatible polyimide adhesive tape and inserted into a specially designed UHV chamber. Then, FLG flakes were mechanically transferred atop of the silicene monolayer by direct exfoliation in UHV.

The encapsulating flakes allowed us to perform a subsequent ex-situ Raman characterization of the 2D silicon layer. The analysis was performed at room temperature in a back-scattering geometry using a confocal μ-Raman setup. The collected spectrum is characterized by two clear peaks located at 216 cm⁻¹ and 515 cm⁻¹, consistent, respectively, with the predicted out-of-plane and in-plane vibrational modes for silicene. Polarization-dependent measurements show that the 216 cm⁻¹ peak is related to a fully symmetrical phonon mode, a clear indication of the 2-dimensionality of the passivated silicene layer.

In Situ Monitoring of Chemical Vapor Deposition Graphene on Cu by Reflectance Contrast Using Confocal Laser Scanning Microscopy Yun Sung Woo1,2, Dong Jin Kim3,2, Chang-Won Lee4, Heejeong Jeong5 and Byung Hee Hong1; 1Korea Polytechnic, Korea (the Republic of); 2Graphene Square, Korea (the Republic of); 3Seoul National University, Korea (the Republic of); 4Hanbat National University, Korea (the Republic of); 5University of Malaya, Malaysia

In order to realize the industrialization of chemical vapor deposition (CVD) graphene, it is essential to develop a method capable of characterization in real time as well as mass synthesis. In this study, we report that the reflection mode of confocal laser scanning microscopy (CLSM) enables highly visible and distinct image of CVD-grown graphene on Cu compared to dark field optical microscopy (DM). Reflectance contrast, RC, defined as the intensity ratio of light reflected from graphene grown on Cu to bare Cu, depends on the incident laser wavelength, of which maximum was obtained at 405 nm in this experiment. Remarkably, it was observed that RC of CVD-grown graphene on Cu varies with doping and crystallinity of graphene and decreases as the intensity of D peak increases in Raman spectrum. The RC over 1 calculated using the Fresnel’s interference formula with the optical conductivity of graphene estimated by tight-binding model is in good agreement with the measured RC. Consequently, it is demonstrated that RC of CVD-grown graphene on Cu is affected by the quality of graphene related with its optical conductivity. Based on these results, we suggest that the reflection mode CLSM can be applied as a powerful tool for in-situ monitoring of CVD graphene growing on Cu by analyzing RC of graphene.

Tailoring Conduction Band Edges in Molybdenum Sulfide/Selenide Alloys Enhances CO Faradaic Efficiency in Aqueous CO2 Reduction Yi-Rung Lin1,1, Wen-Hui Cheng1,1, Matthias H. Richter1,1, Joseph S. DuChene1,1, Elizabeth A. Peterson3,3, Cora Went1, Zakaria Al Balushi1,1, Deep M. Jariwala1, Jeffrey B. Neaton3,4, Li-Chyong Chen2,2 and Harry A. Atwater1,1; 1California Institute of Technology, United States; 2National Taiwan University, Taiwan; 3University of California, Berkeley, United States; 4Lawrence Berkeley National Laboratory, United States

Selective conversion of CO2 into a single chemical product remains one of the greatest challenges in CO2 reduction. Transition-metal dichalcogenides have shown potential for electrocatalytic conversion of CO2 to CO with high selectivity in ionic liquid-based electrolytes, but in fully aqueous environments the evolution of hydrogen is commonly observed to be the dominant catalytic reaction. Despite much promise, further progress in the design of layered two-dimensional materials for the CO2 reduction reaction (CO2RR) is needed to enable the sustainable synthesis of chemical fuels from CO2 feedstocks. In this work, we demonstrate that the valence band maximum and the conduction band minimum of transition-metal dichalcogenides can be tuned via chemical alloying to form MoS2(1-x)Se2x alloys (where x ranges from 0 to 1).
The band structure of few-layered transition metal dichalcogenides was tuned by changing the chemical composition of the chalcogens (sulfur, S and selenium, Se) in the resulting alloy. Systematic studies of electrochemical CO2 reduction with various MoS2(1-x)Se2x compounds demonstrate that the distribution of chemical products generated by the electrocatalyst can be controlled by the chemical composition of the alloy. Specifically, we find that the MoS1.48Se0.52 compound exhibited the best selectivity of all studied alloys, with a Faradaic efficiency for CO production of ~27% at an applied potential of ~0.2V vs. RHE in fully aqueous 50mM K2CO3 electrolytes. In general, the alloy compounds show superior CO2RR performance relative to pure MoS2 or MoSe2-based electrocatalysts. Such a trend in synthesized MoS2(1-x)Se2x alloys is consistent with that observed from bulk crystals, indicating that chemical alloying of layered two-dimensional materials is a promising approach to tuning the selectivity of transition-metal dichalcogenides for CO2RR in aqueous electrolytes.

**Synthesis of Few-Layered ZrS2 and ZrS2xSe2-2x Nanosheets**

Giulia Z. Zemignani1,2, Mauro Och1, Pawel Palczynski1 and Cecilia Mattevi1; 1Imperial College London, United Kingdom; 2Politecnico di Milano, Italy

Group IV transition metal dichalcogenides (TMDs) have recently drawn attention due to their predicted ultra-high charge carrier mobilities (1-3000 cm2/Vs) and bandgap in the VIS-NIR region. These materials are considered to be highly promising for high-performant FETs and ultra-responsive photodetectors, in addition to their possible use as energy materials and in catalysis. However, very little work has been reported on the synthesis of two-dimensional few-layered Group IV-TMDs. Here, we report the growth of ZrS2 and ZrS2xSe2-2x thin films over cm2 areas on SiO2/Si and Au foil starting from ZrCl4 and sulphur powder as precursors. The interest in ZrS2xSe2-2x results form the possibility to tune a low energy band gap. The synthesis has been performed via chemical vapour deposition (CVD) using a tubular furnace where thickness control has been achieved tuning the growth time. Our ZrS2 thin film has been characterized via Raman spectroscopy, which revealed two fingerprint peaks at 250 cm-1 and at 335 cm-1 corresponding to the Eg and the A1g peak respectively. HRTEM and SAED characterizations have confirmed the hexagonal crystal structure and the atomically thin thickness of 2-3 layers of individual platelets. XPS and EDX has provided evidence of the expected stoichiometry and composition. Furthermore, the material exhibits photoluminescence (PL) signal at 1.4 eV, which matches with theoretical predictions ranging from 1.2 to 2 eV for the Γ-M indirect bandgap. Annealing the ZrS2 film with Se we can achieve the synthesis of ZrS2xSe2-2x, which shows morphological characteristics similar to the starting material and Raman peaks at 250 cm-1 and 300 cm-1.

**Mechanistic Understanding of Lithium Intercalation and Phase Transformation Behavior in MoS2 at Atomic Scales**

Shayani Parida1, Jie Chen1, Hetal Patel1, Avanish Mishra1, Arthur Doble2, Barry Carter1,3 and Avinash M. Dongare1; 1University of Connecticut, United States; 2EaglePicher Technologies LLC, United States; 3Sandia National Laboratories, United States

Design and discovery of layered materials for next-generation Lithium-ion batteries require a thorough understanding of the role of structure (bonding environment) on the energetics of Lithium (Li) intercalation and the accompanying structural accommodations. In this study, density functional theory (DFT) calculations have been used to investigate the energetics and mechanisms of lithiation/delithiation in thin films of MoS2. The work aims at presenting a comprehensive study on thermodynamics of lithiation in order to sequentially investigate the process of Li-ion intercalation between layers of MoS2 films and the resultant structural transformations.

Simulations have been performed to investigate the energetics of Li-ion binding and diffusion in the 2H and 1T phases of MoS2. Li binding is observed to be stronger in 1T phase and hence, the activation energy for diffusion is higher. Sequential insertion of Li suggests that intercalation of one Li atom in the spacing between two MoS2 layers results in easier diffusion of successive Li atoms in the same gap until all of the tetrahedral binding sites are occupied. Further lithiation results in Li intercalation into successive gaps between 2H-MoS2 layers and promotes phase transformation of adjacent 2H layers to 1T phase. Thus, partial lithiation across layers creates hybrid 2H-1T phase with a stable phase boundary perpendicular to c-direction. This 2H to 1T phase transformation of MoS2 layers between the Li layers is attributed to a change in charge density around the transition metal following ionization of Li to Li+ cation.

Such phase transformations accompanying lithiation are found to be irreversible and hence, quite detrimental to the cycling stability of batteries. With the understanding gained on the binding of Li, various combinations of transition
metals and chalcogenides are tested to identify layered materials which render or resist phase transformation during lithiation. The energetics of lithiation in the various phases of layered materials will be presented. These results parallel insights gained from in-situ TEM studies and can shed light on Li-ion intercalation/de-intercalation mechanisms in thin films of layered materials. This work is being supported by NSF grant No. 1820565. CINT is an Office of Science NSRC User Facility operated for the U.S. DOE.

**Evaluation of Film Quality for Various Deposition Conditions of MOCVD MoS2 Films Fabricated with a Novel Mo Precursor i-Pr2DADMo(CO)3**

Kota Yamazaki1, Yusuke Hibino1, Yuya Oyanagi1, Yuya Oyanagi1, Yusuke Hashimoto1, Naomi Sawamoto1, Hideaki Machida2, Masato Ishikawa2, Hiroshi Sudo2, Hitoshi Wakabayashi3 and Atsushi Ogura1; 1Meiji University, Japan; 2Gas-Phase Growth Ltd., Japan; 3Tokyo Institute of Technology, Japan

Molybdenum disulfide (MoS2) is a layered material that is expected to be used in various devices such as TFT due to the presence of band gap (bulk to monolayer: 1.2 to 1.8 eV[1]), high mobility (mono to multilayer: 380 to 700 cm²/Vs[1,2]), high flexibility, transparency and stability. However, establishing a film fabrication method with high quality and high productivity is a major issue for its practical applications. Therefore, we focused on cold-wall MOCVD method as a deposition technique. In this film fabrication method, utilization efficiency of the precursor is high since the reaction only occurs at the substrate. In addition, fine controllability of the film quality can be achieved by facilitating control of various deposition conditions such as supply amount of Mo and S by using the organic precursors having high vapor pressure at low temperature.

We have previously proposed i-Pr2DADMo(CO)3 as a novel Mo precursor. We have reported so far that i-Pr2DADMo(CO)3 decomposes below 300°C, and 1L MoS2 without C and N contamination can be fabricated on SiO2/Si substrate at low temperature of 250°C with the Mo precursor and sulfur source (t-C4H9)2S2[3]. In this research, with the aim of further improving the quality of the MoS2 film using i-Pr2DADMo(CO)3, various film fabrication conditions were controlled and the influence on the film quality was investigated. XPS, AFM and Raman spectroscopy were used as evaluation techniques of the samples. It was suggested that the increase of substrate temperature contributes to the expansion of the grain size through the increase of Mo migration. High substrate temperature also increases the deposition rate by accelerating the thermochemical reaction of i-Pr2DADMo(CO)3 and (t-C4H9)2S2. It was also suggested that higher deposition pressure contributes to the increase in deposition rate caused by larger degree of supersaturation. Higher deposition pressure also decreases the deposition rate caused by lower concentration of the precursor in the chamber. Thus an optimum value is considered to exist for high-quality film synthesis.

**The Physical and Chemical Properties of MoS2(1-x)Te2x Alloy Synthesized by Co-Sputtering and Chalcogenization and Their Dependence on Fabrication Conditions**

Yusuke Hibino1,2, Kota Yamazaki1, Yusuke Hashimoto1, Yuya Oyanagi1, Naomi Sawamoto1, Hideaki Machida3, Masato Ishikawa2, Hiroshi Sudo2, Hitoshi Wakabayashi4 and Atsushi Ogura1; 1Meiji University, Japan; 2Japan Society for the Promotion of Science Research Fellow, Japan; 3Gas-Phase Growth Ltd., Japan; 4Tokyo Institute of Technology, Japan

The alloying of transition metal dichalcogenides (TMD) and their various properties are expected to be a significant factor for the TMDs to expand in its applications. Although TMD alloys show appealing electrical, optical, and chemical properties, the synthesis method is still at its early stage. The alloy materials under research are mostly MoS2(1-x)Se2x, Mo1-xWxS2, WS2(1-x)Se2x, and so on. There have not been many reports on the alloy that incorporate Te in the system. In the past reports, we have demonstrated that Mo-S and Mo-Te bonds can be formed in the product film, but physical structure evaluation was not sufficient. Thus in this study, the alloy films were evaluated with XRD in addition to XPS. The physical structure evaluation revealed that the as-sputtered samples, i.e. samples prior to thermal treatment, shows alloy formation depending on the sputter power of MoTe2 targets. Use of compound MoS2 target promotes layer structure formation at the sputtering stage, however, use of merely-sintered (not compound) MoTe2 target may disrupt this behavior. It was also revealed that different chalcogen composition in MoS2(1-x)Te2x requires different optimal temperature in the post-deposition thermal treatment. For the sulfurization samples, the alloy showed phase segregation, MoS2 and MoS2(1-x)Te2x, when the temperature is well over or under
400°C. In other words, when the sulfurization temperature is at 400°C, the alloy showed uniform distribution of Te and S throughout the film. On the other hand, for the tellurization samples, the alloy with no phase segregation was observed at 450°C. This shows that higher Te composition for MoS$_2$($1-x$)Te$_x$ may require thermal treatment with higher temperature.

Wednesday Morning, December 4, 2019
Hynes, Level 3, Room 312

8:00 AM FF01.11.01
Exciton Dynamics in Atomically Thin Transition Metal Dichalcogenides Samuel Brem, Simon Ovesen and Ermin Malic; Chalmers University of Technology, Sweden

Monolayers of Transition Metal Dichalcogenides (TMDs) present a giant leap forward towards the realization of semiconductor devices with atomic scale thickness. As a natural consequence of their two-dimensional character, TMDs exhibit a reduced dielectric screening, leading to the formation of unusually stable excitons. Excitons dominate the optical response as well as the ultrafast dynamics in these atomically thin materials. As a result, a microscopic understanding of excitons, their formation, relaxation and decay dynamics becomes crucial for technological applications of TMDs. A detailed theoretical picture of the internal structure of excitons and their scattering channels allows for a controlled manipulation of TMD properties enabling an entire new class of light emitters, absorbers and detectors.

We provide a fully quantum mechanical description of momentum- and energy-resolved exciton dynamics in TMD mono- and hetero-bilayers [1-3] unraveling the many-particle processes governing the ultrafast dynamics of excitons in these materials. Our approach provides novel insights into exciton-phonon and exciton-photon interaction mechanisms and the impact of dark exciton states. This includes the formation of bound excitons out of a free electron-hole gas up to their eventual radiative recombination. Furthermore, we study the formation of interlayer excitons in Van-der-Waals heterostructures, i.e. spatially separated excitons composed of electrons and holes located in different layers of two stacked TMDs.

Our theoretical model allows us to predict fundamental formation and relaxation time scales as well as spectral features accessible in ultrafast pump-probe experiments. In particular, we show that the relaxation of hot excitons throughout the Rydberg series of excited exciton states gives rise to population inversions between s- and p-type excitons resulting in transient optical gain in the THz spectrum [1]. Moreover, in a joint experiment-theory study on Van-der-Waals heterostructures [3], we demonstrate how the binding energy as well as the time resolved formation of interlayer excitons can be measured using mid infrared pulses.

Spin-Layer Locking of Interlayer Valley Excitons Trapped in Moiré Potentials Mauro Brotons i Gisbert, Hyeonjun Baek, Dale Scerri, Alejandro Molina-Sánchez, Kenji Watanabe, Takashi Taniguchi, Cristian Bonato and Brian D. Gerardot; 1Heriot-Watt University, United Kingdom; 2Universidad de Valencia, Spain; 3National Institute for Materials Science, Japan

Semiconductor heterostructures formed by vertically stacked two-dimensional transition-metal dichalcogenides (TMDs) sustain interlayer excitons - electron-hole Coulomb bound states between electrons and holes spatially
separated in different monolayers [1, 2]. In addition, heterostructures formed by vertically stacking two different monolayer TMDs (heterobilayers) can feature a spatially periodic moiré superlattice in which a periodic potential landscape for excitons is controlled by the lattice mismatch and/or the relative angle twist between the constituent monolayers. For moiré periods larger than the exciton Bohr radius, the moiré potential minima can act as smooth quantum-dot-like confining potentials [3, 4]. Bilayer TMDs offer an additional degree of freedom to engineer the properties of moiré-trapped interlayer excitons in vertical semiconductor heterostructures. In addition to the spin-valley coupling characteristic of monolayer TMDs, bilayer TMDs also present a layer pseudospin [5]. Because the bottom layer in an AB-stacked bilayer is a 180° in-plane rotation of the top layer, AB-stacked bilayer TMDs show spin-layer locking, i.e., a spin-valley configuration that is locked to the layer pseudospin.

In this work, we exploit the spin-layer locking of bilayer 2H-MoSe2 to probe the spin-valley properties of interlayer moiré-trapped excitons in a WSe2/MoSe2 heterostructure. Low-temperature (4 K) magneto-optical spectroscopy reveals the coexistence of two species of moiré-trapped excitons with different spin-layer pairings for electrons in MoSe2. Both trapped exciton species yield narrow (< 100 meV) linewidths and saturate with increasing excitation power, hallmarks of quantum dots. Although for both species of interlayer trapped excitons the hole is localized in the WSe2 layer, the electron in bilayer MoSe2 can be localized either in the bottom or top layer. The natural AB stacking of bilayer 2H-MoSe2 gives rise to AA (AB) relative stacking between the WSe2 and the bottom (top) layer of MoSe2, respectively. Due to the spin-layer locking in bilayer MoSe2, electrons in the bottom (top) MoSe2 layer present parallel (antiparallel) spin and valley contributions, which results in an effective layer-locking of the Landé g-factors of the trapped excitons. Our results reveal that the trapped excitons present g-factors that are homogeneous across the sample and take only two values: -7.0 ± 0.6 and -15.76 ± 0.13 for Moiré-trapped excitons originating from the AA- and AB-stacked WSe2/MoSe2. Finally, helicity-resolved photoluminescence measurements confirm that the trapped excitons exhibit both strong circular and valley polarization, which indicates that the confinement potential preserves the rotational C3 symmetry and the trapped interlayer excitons inherit the spin-valley properties of the constituent monolayers.

Probing and Controlling Excitons in 2D Semiconductors and Heterostructures
Tony F. Heinz1,2; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States

In this paper we review recent developments in our understanding of the optically excited states of monolayer semiconductors and heterostructures in the family of the transition metal dichalcogenides. In particular, we will focus on the exciton character of the excited states, discussing our current understanding of the 2-, 3-, 4-, and 5-body exciton, charged exciton, biexciton, and charged bie exciton species. We will also describe the presence of spin-forbidden dark excitons and how they may be observed optically. In addition to the range of different excitonic states, the 2D semiconductors feature strong electrostatic coupling to the external environment. We will describe the corresponding influence of external dielectric screening on the band- and exciton structure of the materials and how we can use this effect to tune locally the properties of 2D semiconductors. Finally, we will consider the new states that arise in 2D heterostructures and how they can be modified by electric fields and the relative crystallographic orientation of the component layers.

9:00 AM FF01.11.04
Local Strain Control for Active and Reversible Exciton Funneling in a Monolayer Semiconductor
Hyowon Moon1, Gabriele Grosso2, Chitalema Chakraborty1, Cheng Peng1, Takashi Taniguchi3, Kenji Watanabe3 and Dirk Englund1; 1Massachusetts Institute of Technology, United States; 2The City University of New York, United States; 3National Institute for Materials Science, Japan

The ability to control the flow of excitons underlies high-speed excitonic devices and energy transport [1,2]. Two-dimensional (2D) semiconductors are well suited for these applications in that their large exciton binding energy enables room temperature operation and their enormous stretchability provides engineerable exciton potential
surfaces [3]. Since excitons are hardly respond to in-plane electric field due to their charge neutrality, the control was limited to interlayer exciton with quantum confined Stark Effect in vertical heterostructure [4,5]. Strain-engineered bandgap modulation offers a new tool for monolayer excitons. Recent studies have observed excitonic flux in predetermined non-uniform geometries, an important remaining challenge concerns active and reversible controllability [6]. Here, we tune the bandgap of suspended 2D semiconductors dynamically by applying local strain gradient with a nanoscale tip. This method enables active and reversible control of the exciton drift over several hundreds of nanometer at room temperature through the energy gradient, which has been demonstrated by wide field imaging and time resolved photoluminescence measurement. Our results pave the way for broad applications including broadband photovoltaic devices and efficient excitonic devices.

with different dipole orientations at room temperature. Besides, these excitons persist from the bulk down to the monolayer. Here, we study the anisotropic diffusion of excitons and free carriers in ReS$_2$ with transient absorption microscopy (TAM) for thicknesses from the monolayer to the bulk.

In TAM, a 10 fs pump pulse focused to the diffraction limit generates excitons and charge carriers, a 10 fs probe pulse in the wide field then monitors their temporal and spatial dynamics. A comparison of the spatial profile of the transient absorption signal following photoexcitation allows studying the movement of excited species with a sub-diffraction-limit resolution of 10 nm.

Varying the pump and probe linear polarisations we analyse the strongly anisotropic diffusion of the two lowest exciton populations. We observe an increase in the exciton lifetime and diffusion coefficients with the number of layers, which we attribute to a decrease in surface traps as the sample thickness increases.

Directional Exciton Transport in a Monolayer WS$_2$–WSe$_2$ Lateral Heterostructure with a Wide Alloy Region

Masafumi Shimasaki$^1$, Naoki Wada$^1$, Zheng Liu$^3$, Kana Kojima$^2$, Yasumitsu Miyata$^2$, Keisuke Shinokita$^1$, Taishi Nishihara$^1$, Kazunari Matsuda$^1$ and Yuhei Miyauchi$^1$; $^1$Institute of Advanced Energy, Kyoto University, Japan; $^2$Tokyo Metropolitan University, Japan; $^3$National Institute of Advanced Industrial Science and Technology, Japan

Monolayer transition metal dichalcogenides have various intriguing optical properties mainly arising from room-temperature-stable excitons [1]. Recently, the exciton dynamics in monolayer vertical/lateral heterostructures or alloy monolayers have attracted much attention, because novel excitonic phenomena including the interlayer exciton [2], exciton dissociation [3], and exciton energy change [4] emerge owing to modulating electronic energy structures. These observations indicate that a combination of such structures potentially provides a platform for exploiting further novel exciton physics and applications.

Here, we report the exciton transport dynamics in a monolayer WS$_2$–WSe$_2$ lateral heterostructure with wide alloy region between the pure WS$_2$ and WSe$_2$ regions using photoluminescence (PL) spectroscopy. The lateral heterostructure was synthesized using a chemical vapor deposition method. It has the alloy region with the width of about 20 µm, where the composition ratio of WS$_2$ and WSe$_2$ gradually changes as a function of spatial coordinate. For the PL spectroscopy, we used the 2.33 eV or 2.22 eV continuous-wave (cw) lasers to excite the sample.

First, we conducted spectrally-resolved PL mapping on the lateral heterostructures across the wide alloy region in a confocal microscope at room temperature. The PL peak from the pure WS$_2$ region was observed at 1.94 eV and assigned to the A exciton. By scanning excitation laser spot across the alloy region of WS$_2$($1-x$)Se$_2x$ from the WS$_2$ side, the PL peak showed a gradual redshift, and finally reached to 1.70 eV that corresponds to the A exciton resonance energy in a pure monolayer WSe$_2$. The continuous shift of the exciton energies indicates formation of a built-in excitonic potential gradient across the wide alloy region, in contrast to the sharp potential change caused by lattice mismatch [5] and/or piezo effect [6] previously observed in various lateral heterostructures with sharp one dimensional interfaces.

Next, we examined the exciton transport properties in the wide alloy region at room temperature. We performed spatially- and spectrally-resolved PL measurements; note that these measurements are different from the confocal PL mapping described above. In this measurement, the excitation cw laser was tightly focused on the sample (spot size of c.a. 1.3 µm at FWHM), and the PL spectra at many points along the potential gradient direction (not only the directly excited spot) were simultaneously acquired. We found that the position showing the highest PL intensity deviated from the center of the laser excitation spot by c.a. 0.6 µm at maximum in the wide alloy region, and the direction of the deviation (exciton drift) was always along the excitonic potential gradient. This was contrast to the observations at the pure WS$_2$ and WSe$_2$ regions, where the highest PL intensity was always observed at the same position as the center of the laser excitation spot. We analyzed the spatial profile of the PL intensities using a drift-diffusion model taking the excitonic potential gradient into account, and confirmed that the potential gradient mainly causes the observed exciton drift. In the presentation, we will discuss the details of the exciton transport properties in the wide alloy region.

Critical Behavior and Thickness-Dependent Magnetic Order in CrI3 Cedomir Petrovic, Yu Liu, Lijun Wu, Xiao Tong, Lijun Wu and Yimei Zhu; Brookhaven National Laboratory, United States

Two-dimensional (2D) materials with intrinsic ferromagnetism provide unique opportunity to engineer new functionalities in nano-spintronics. One such material is CrI3, a 2D Ising ferromagnet in monolayer with the Curie temperature \( T_c \) of 45 K [1]. Based on critical properties and scaling analysis, CrI3 shows three-dimensional (3D) long-range magnetic coupling [2]. In systematic reduction of crystal thickness down to 50 nm bulk \( T_c \) of 61 K is gradually suppressed to 57 K, however, the satellite transition at \( T^* = 45 \) K is observed. The \( T^* \) is layer-independent and corresponds to \( T_c \) observed in the monolayer. The critical analysis around \( T_c \) reveals a crossover from 3D to 2D Ising ferromagnetism with mean field type interactions for microscale-thick crystals. This work shows that magnetic transition and critical properties can be continuously tuned on a mesoscale between monolayer and bulk crystals.

freedom is correlated with the antiferromagnetic ordering. The electronic band structure is dominated by the \([P_2X_6]^{4-}\) units, contributing s- and p-atomic orbitals, while the metal d-orbitals hybridize with X(p) orbitals. Most common MPX₃ compounds have monoclinic or orthorhombic crystallographic structures with a space group C₂ or P₂₁/c symmetry, respectively.

The talk at the MRS meeting 2019 will include description of the optical and magneto-optical properties of a vast number of MPX₃ single slabs, Moiré patterns and multiple layers. The description will focus on the influence of the internal magnetism on the optical properties of the materials, e.g., degree of circular polarization in the magneto-reflectance or magneto-photoluminescence spectra. Generally, the MPX₃ family exhibit merits beyond graphene and beyond the well-known (Mo,W)X₂ compounds, owed to the tune-ability of the electronic and magnetic properties.

Room-Temperature Dilute Magnetic Semiconductor in V-Doped Monolayer WSe₂
Dinh Loc Duong¹,², Seok Joon Yun¹, Manh Ha Doan², Kirandeep Singh¹, Thanh Luan Phan¹, Wooseon Choi², Young Kuk Kim¹, Young-Min Kim¹,² and Young Hee Lee¹,²,³; ¹Center for Integrated Nanostructure Physics (CINAP), Institute for Basic Science (IBS), Korea (the Republic of); ²Department of Energy Science, Sungkyunkwan University, Korea (the Republic of); ³Department of Physics, Sungkyunkwan University, Korea (the Republic of)

Diluted magnetic semiconductors such as Mn-doped GaAs are attractive materials for gate-controlled spintronic devices but the low Curie temperature of the ferromagnetic state is far from room temperature, limiting for practical applications. Here, we report the long-range ferromagnetic order occurs above room temperature in diluted V-doped monolayer WSe₂. Our unambiguous observations are based on micro magnetic domains and the well-defined structure of V-substituted W atoms, which are characterized by magnetic force microscopy and high-resolution transmission electron microscopy, respectively. Furthermore, the modulation of the magnetic domains by an electronic gate is demonstrated, indicating the capability of gate-controlled magnetic properties of the samples. Our findings open new opportunities for using two-dimensional transition metal dichalcogenides for spintronic devices.

Anomalous CDW Response in High Mobility Magnetic 2D Material GdTe₃
Yiping Wang¹, Shiming Lei², Leslie Schoop² and Kenneth Burch¹; ¹Boston College, United States; ²Princeton University, United States

Most known magnetic van der Waals (vdW) materials are insulating or semiconducting. It is crucial to find materials with magnetic order and high-mobility for high-speed spintronic device making. Anti-ferromagnet GdTe₃ satisfies both down to 2D limits. The mobility reaches ~28000cm²/Vs, which is among the highest in all the known vdWs. It also exhibits an incommensurate charge density wave (CDW) and becomes superconductor under pressure. Here, we report the recent Raman study of GdTe₃, we will talk about the temperature and polarization dependence of CDW.

11:45 AM FF01.12.05
Fermi Polarons and Magnetic Proximity Effects in Monolayer Semiconductor-Ferromagnet Nanostructures
Thomas Lyons¹, Jorge Puebla², Daniel Gillard¹, Prasanta Muduli³, Charalambos Louca¹, Yoshichika Otani²,³ and Alexander Tartakovskii¹; ¹The University of Sheffield, United Kingdom; ²RIKEN, Japan; ³The University of Tokyo, Japan

Conventional epitaxial ferromagnet-semiconductor multilayers have proven ripe systems for both advanced spintronics research and real-world applications in information technology. The highly ordered states inherent to ferromagnets, alongside their strong collective responses to external electromagnetic fields, makes them ideal candidates to enable control of charge and spin in closely proximitized semiconductors. Monolayers of MoSe₂ are atomically thin direct band-gap semiconductors which combine a regime of coupled spin and valley physics with an optically bright exciton ground state. As such, they are highly promising in the development of valleytronics, an analogue of spintronics which utilizes the carrier valley degree of freedom as an information carrying pseudospin. Crucially, MoSe₂ is also associated with robust chiral optical selection rules, efficiently bridging the gap between spin-valley polarization and optical addressability. By bringing MoSe₂ monolayers into contact with ferromagnetic materials, it becomes possible to bestow an additional, valley, degree of freedom onto the magnetic proximity coupled system.

Here, a monolayer of MoSe₂ is transferred directly on top of a 10nm thick film of europium sulfide (EuS), a
ferromagnetic insulator with a rock-salt crystal structure [1]. Reflectivity spectra from the sample display two clear absorption resonances ascribed to attractive and repulsive Fermi-polarons, associated with spin-based interactions between photogenerated excitons and the electron Fermi sea [2, 3]. The interfacial exchange field between the EuS and MoSe$_2$ strongly amplifies an external magnetic field, leading to robust enhancement of the repulsive polaron valley Zeeman splitting, which reaches an effective $g$-factor of 15. By tuning the external magnetic field, oscillator strength may be transferred between the two polaron resonances, culminating in a complete 100% degree of circular polarization of the attractive polaron when $B = 5T$. This indicates total spin polarization of the 2-dimensional electron gas, owing to robust paramagnetic susceptibility of the MoSe$_2$ [3, 4].

Going further, we incorporate the MoSe$_2$/EuS nanostructure into a zero-dimensional optical microcavity and observe valley selective strong light-matter coupling when $B$ exceeds 5T, corresponding to the formation of Fermi polaron-polaritons in one valley only, selectable by reversing the external magnetic field orientation. In effect, swapping sample illumination between left or right circularly polarized light switches on or off the strong light-matter coupling regime. Our findings unveil the complex interplay between nanoscale magnetism, Coulomb effects, many-body physics and the spin and valley degrees of freedom in atomically thin semiconductor-ferromagnet interfaces. In particular, we expose the enormous potential of 2D material platforms for future opto-valleytronic memories and information processing technology.

Another example is using Raman spectroscopy to probe magnetic phenomena in the antiferromagnetic metal phosphorus trichalcogenide family, including FePS$_3$, MnPS$_3$, and NiPS$_3$. Results on zone-folded phonons in FePS$_3$, the emergence of magnons in FePS$_3$ and MnPSe$_3$ with anomalous symmetry behaviors, and a two-magnon mode in NiPS$_3$ will all be discussed.

Finally, the magnetic field- and temperature-dependence of an exciting ferromagnetic 2D material, CrI$_3$, will be presented.

Electrical Control of Magnetism in 2D Kin Fai Mak; Cornell University, United States

Controlling magnetism by electrical means is a key challenge to better information technology. Electrical control of magnetism has been explored in a variety of materials including dilute magnetic semiconductors, ferromagnetic metal thin films and multiferroics. The recently emerged atomically thin magnetic materials provide unprecedented opportunities to study magnetism in the 2D limit and engineer devices through van der Waals heterostructures. In particular, CrI$_3$ is a model Ising ferromagnet with intriguing layer-dependent magnetic order: whereas monolayer CrI$_3$ is a ferromagnet, bilayer CrI$_3$ is an antiferromagnet with two ferromagnetic monolayers coupled antiferromagnetically. In this talk, I will present our recent results on switching the interlayer magnetic order in CrI$_3$ bilayers by either a pure electric field or electrostatic doping and discuss possible mechanisms for the observed effects in experiment.

van der Waals Layered Materials towards Room-Temperature Magnetic Semiconductors Young Hee Lee$^{1,2}$, Seok Joon Yun$^1$ and Dinh Loc Duong$^1$; $^1$Sungkyunkwan University, Korea (the Republic of); $^2$Institute for Basic Science, Korea (the Republic of)

The ferromagnetic state in van der Waals two-dimensional (2D) materials has been reported recently in the monolayer limit. Intrinsic CrI$_3$ and CrGeTe$_3$ semiconductors reveal ferromagnetism but the Tc is still low below 60K. In contrast, monolayer VSe$_2$ is ferromagnetic metal with Tc above room temperature but incapable of controlling its carrier density. Moreover, the long-range ferromagnetic order in doped diluted chalcogenide semiconductors has not been demonstrated at room temperature. The key research target is to realize the long-range order ferromagnetism, Tc over room temperature, and semiconductor with gate tunability. Here, we unambiguously observe a ferromagnetic hysteresis loop together with magnetic domains above room temperature in diluted V-doped WSe$_2$, while maintaining the semiconducting characteristic of WSe$_2$ with a high on/off current ratio of five orders of magnitude.

Magic Angle Graphene—Correlations, Superconductivity and Beyond Pablo Jarillo-Herrero; Massachusetts Institute of Technology, United States

The understanding of strongly-correlated quantum matter has challenged physicists for decades. Such difficulties have stimulated new research paradigms, such as ultra-cold atom lattices for simulating quantum materials. In this talk I will present a new platform to investigate strongly correlated physics, based on graphene moiré superlattices. In particular, I will show that when two graphene sheets are twisted by an angle close to the theoretically predicted
‘magic angle’, the resulting flat band structure near the Dirac point gives rise to a strongly-correlated electronic system. These flat bands exhibit half-filling insulating phases at zero magnetic field, which we show to be a correlated insulator arising from electrons localized in the moiré superlattice. Moreover, upon doping, we find electrically tunable superconductivity in this system, with many characteristics similar to high-temperature cuprates superconductivity. These unique properties of magic-angle twisted bilayer graphene open up a new playground for exotic many-body quantum phases in a 2D platform made of pure carbon and without magnetic field. The easy accessibility of the flat bands, the electrical tunability, and the bandwidth tunability though twist angle may pave the way towards more exotic correlated systems, such as quantum spin liquids or correlated topological insulators.

In Situ Monitoring of Graphene Growth on Cu by Reflectance Contrast Using Confocal Laser Scanning Microscopy Dong J. Kim1,2, Yeon Joon Suh1, Juhee Kim1, Mina Park1, Yun Sung Woo2 and Byung Hee Hong1; 1Department of Chemistry, Korea (the Republic of); 2Graphene Square Inc., Korea (the Republic of)

Large-area, high-quality, and continuous growth technologies for CVD graphene have been developed to meet the requirements for industrial applications. However, there has been a lack of proper methods to check the quality of graphene in a fast and non-destructive way for mass-production scale. Optical microscopy (OM) has been widely explored for imaging and characterizing CVD graphene directly on Cu. Dark field (DF) OM was employed to investigate CVD graphene grown on Cu foil using the Rayleigh light scattering from Cu steps beneath graphene, which can be adopted only for metals that generate steps with considerable height beneath graphene after growing. Moreover, the DF imaging by the weak scattered light is time-consuming and requires a sample of graphene on Cu foil to be placed over a period of time under illumination. On the other hand, confocal laser scanning microscopy (CLSM) is capable of scanning a large area in a few seconds in high-resolution, which is expected to enable the faster characterization of graphene on Cu regardless of its production scale. Thus, we demonstrate that the reflection mode CLSM can be utilized for the in-situ monitoring of the CVD-grown graphene on Cu foil as a possible quality assessment tool of mass-produced CVD graphene films. The CLSM generates the high-contrast optical images of CVD-grown graphene on Cu over a large area, in which the contrast between the graphene layer and Cu is greater for shorter incident laser wavelengths. The reflectance contrast calculated by Maxwell equation is in good agreement with the experiment as the interference of reflected light at the interface between air, graphene, and Cu.
provides a high image contrast between the areas with and without graphene. Furthermore, we found out that the quality of CVD graphene can be characterized by CLSM because the reflectance and the optical conductivity are proportional to the defect density.

**One-Step Synthesis and Properties of Cationic Nitrogen-Doped Graphene by Solution Plasma**  
Sangwoo Chae¹,², Gasidit Panomsuwan³ and Nagahiro Saito¹,⁴, ¹Nagoya University, Japan; ²Japan Science and Technology Corporation (JST), Open Innovation Platform with Enterprises, Research Institute and Academia (OPERA), Japan; ³Kasetsart University, Thailand; ⁴Conjoint Research Laboratory in Nagoya University, Shinshu University, Japan

Control of nitrogen bonding configuration in hexagonal graphene lattice is considered as the promising strategy in realizing desired electrical, chemical, and optical properties of graphene. Three bonding configurations are typically detectable, including quaternary nitrogen (or graphitic nitrogen), pyridinic nitrogen, and pyrrolic nitrogen. However, cationic nitrogen is another possible bonding, which has been rarely investigated and not well understood in graphene chemistry. Therefore, study of graphene with cationic nitrogen doping is very challenging for further development towards this area. In this work, cationic N-doped graphene (CNG) has been synthesized via a novel method called solution plasma (SP) at room temperature and atmospheric pressure. The mixture of 1-ethyl-3-methylimidazolium dicyanamide (EMIM DCA) and dimethylformamide (DMF) was employed as carbon and nitrogen sources in synthesis. The originality of this work consists of two points as follows: 1. Combination of solution plasma and ionic liquid (EMIM DCA) allows us to achieve one-step, rapid, substrate-free synthesis of p-type graphene with cationic nitrogen doping at room temperature and atmospheric pressure. 2. Cationic nitrogen-doped graphene exhibited p-type semiconducting behavior with a low sheet resistance of 16 Ω sq⁻¹ and a high carrier concentration of 10¹⁹ cm⁻³. These fascinating electrical properties can be attributed to two important effects: (i) presence of cationic nitrogen in graphene lattice and (ii) preservation of planar structure. The combination of SP and ionic liquid shows a promising strategy in design and synthesis of NG with cationic nitrogen-doping, which cannot be achieved in other existing methods. The CNG will be enable potential use in many applications in various fields, such as sensor, electronic, and energy devices.

**FF01.16.03**

**Edge Terminations Control of Tungsten Diselenide Domains Using Chemical Vapor Deposition**  
Yoobeen Lee and Jin Seok Lee; Sookmyung Women's University, Korea (the Republic of)

Variously shaped transitional metal dichalcogenides (TMDC) domains are of significant interest since the electronic properties of pristine TMDC are strongly dependent on its size, shape, and edge structures. As the reactivity of TMDC is governable by the electronic structure at its edge, a number of attempts have been made to grow differently shaped TMDC domains and to define their edge structures. Of the various TMDC synthesis techniques, it is well-known that the chemical vapor deposition (CVD) is the most reasonable and appropriate method to produce large-scale and low-defect TMDC domains. And, many CVD parameters such as growth temperature, annealing time, and the amount of precursors affect TMDC growth.

In this study, we investigated CVD method in order to grow tungsten diselenide (WSe₂) domains of various shapes. By regulating the amount of Se powder as precursor and growth temperature during the CVD process, we synthesized hexagonal, square, circular, and triangular WSe₂ domains, and characterized their morphologies and physical properties using scanning electron microscopy (SEM), Raman spectroscopy, photoluminescence (PL) analyses, atomic force microscopy (AFM) and scanning tunneling microscope (STM). Based on the atomic configurations of WSe₂ domain edges and size distributions of the WSe₂ domains, we proposed the edge termination mechanism of anisotropic WSe₂ domains, which is strongly dependent on the amount of Se precursor and growth temperature during the CVD process.

**FF01.16.04**

**MOCVD Growth of Tungsten Ditelluride Thin Films**  
Thomas McKnight, Xiaotian Zhang, Tanushree H. Choudhury and Joan M. Redwing; The Pennsylvania State University, United States

Tungsten ditelluride (WTe₂) is a layered, type-II Weyl semimetal transition metal dichalcogenide (TMD) typically observed in a distorted 1T (1T’ phase with an orthorhombic crystal structure comprised planes of distorted triangular lattices of tungsten atoms sandwiched by tellurium atoms. The distortion pushes tungsten atoms closer together in the x-axis than the y or z-axis, generating quasi-one-dimensional chains of these atoms, leading to
strongly anisotropic electronic properties throughout the material. It has been shown to have extraordinary physical properties, such as a high magnetoresistance, anisotropic ultra-low thermal conductivity and metal-insulator transition and it also exhibits interesting quantum phenomena such as the quantum spin-Hall effect and pressure-driven superconductivity. These unique properties make WTe₂ an exciting candidate for emerging applications, including phase change memory electrodes, magnetic field sensors, biosensors, microelectromechanical systems, hard disk drives and quantum computing. While bulk crystals of the material have been available for many years, to date, thin films of WTe₂ have only recently been synthesized using techniques such as molecular beam epitaxy and powder source chemical vapor deposition (CVD) that utilize Te powder and W-feedstock. Metalorganic CVD (MOCVD) growth is also of interest as it enables precise delivery of precursors to the substrate at moderate growth pressures (100-700 Torr) but has not yet been studied in detail.

In this study, we investigate the use of MOCVD for the growth of WTe₂ on c-plane sapphire substrates. The studies were carried out in a vertical cold wall MOCVD reactor using tungsten hexacarbonyl (W(CO)₆) and diethyltelluride (DETe) as precursors for W and Te, respectively, in a H₂ carrier gas. Initial studies, carried out at 100 Torr reactor pressure using a W(CO)₆ flow rate of 1.3 x10⁻⁴ sccm and Te/W ratio of ~8000 : 1, demonstrate the growth of WTe₂ as confirmed by Raman spectroscopy and X-ray photoelectron spectroscopy (XPS). The growth rate was found to decrease with increasing temperature over the temperature range from 350-600°C likely due to increased desorption of Te species from the substrate surface. Peaks at ~1340 cm⁻¹ and ~1600 cm⁻¹ were present in the Raman spectra of the films indicating the presence of carbon in the layers most likely due to the DETe source. Additional studies are underway to elucidate the growth mechanism and properties of MOCVD grown WTe₂. The synthesis of W(Se,Te)₂ alloy films via introduction of H₂Se during deposition will also be explored to explicate the consequences on phase control, oxidation stability, and the reduction of carbon contamination during growth.

**Integration of 2D Tungsten Disulfide on Carbon Nanotube-Coated Paper for Highly Sensitive and Flexible Gas Sensors** Lee Woo Sung and Jungwook Choi; Yeungnam University, Korea (the Republic of)

Sensitive and flexible chemical sensors fabricated by a low-cost process are promising since they can be attached on curved, complex structures, and even the human body while providing an environmental signal to the user. For this reason, many nanomaterial-based flexible sensors have been investigated. However, they required a complicated manufacturing process leading to expensive cost and labor intensity. Furthermore, their limited chemical sensitivity and mechanical flexibility pose challenges.

Here, a highly deformable chemical sensor is reported with improved sensitivity that uses the hybrid structure of multiwalled carbon nanotubes (CNTs) and 2D transition metal dichalcogenides (TMDCs) on cellulose paper. Liquid dispersions of CNTs and TMDCs (e.g., WS₂ and MoS₂) are absorbed and dried on porous cellulose paper for sensor fabrication, which is simple, scalable, rapid, and cost-effective. Owing to the flexibility of cellulose paper, the sensor enables reversible three-dimensional folding and unfolding, bending, and twisting without any degradation. At the same time, the CNTs form a percolation network and simultaneously provide gas reactivity. Functionalization of CNTs with WS₂ greatly improves the sensing response to exposure to NO₂ molecules by more than 1.5 times. The measured sensitivity toward NO₂ is 4.57% ppm⁻¹, which is much higher than that of previous paper-based NO₂ sensors. In addition, our sensor maintains high sensitivity even under severe deformation such as heavy folding and crumpling. This approach can be a suitable way for simple fabrication of highly flexible and sensitive chemical sensor which can be potentially applicable for low-cost portable device and disposable sensor.

**FF01.16.06**

**Convergent Ion Beam Alteration of 2D Materials and Metal-2D Interfaces** Zhihui Cheng¹, Hattan Abuzaid¹, Yifei Yu², Fan Zhang³, Yanlong Li², Steven G. Noyce¹, Yuh-Chen Lin¹, James Doherty¹, Chenggang Tao³, Linyou Cao² and Aaron D. Franklin¹,¹; ¹Duke University, United States; ²North Carolina State University, United States; ³Virginia Tech, United States

Tailoring the properties of two-dimensional (2D) crystals is important for both understanding the material behavior and exploring new functionality. Here we demonstrate the alteration of MoS₂ and metal-MoS₂ interfaces using a convergent Ar ion beam. Different beam energies, from 60 eV to 600 eV, are shown to have distinct effects on the optical and electrical properties of MoS₂. Defects and deformations created across different layers were investigated, revealing an unanticipated improvement in the Raman peak intensity of multilayer MoS₂ when exposed to a 60 eV Ar⁺ ion beam, and attenuation of the MoS₂ Raman peaks with a 200 eV ion beam. Scanning tunneling microscopy
(STM) was used to probe the altered 4-layer MoS$_2$ surface, showing that the MoS$_2$ crystallinity still remains. This largely intact crystallinity of the 4-layer MoS$_2$ surface is in contrast to the significantly diminished PL peak of monolayer MoS$_2$, suggesting that the defects spread throughout multiple layers rather than concentrating at the surface. Using cross-sectional scanning transmission electron microscopy (STEM), alteration of the crystal structure after a 600 eV ion beam bombardment was observed for the first time, including generated defects across layers and voids in the crystal. We show that the 60 eV ion beam yields improvement in the metal-MoS$_2$ interface by decreasing the contact resistance from 17.5 kΩ*μm to 6 kΩ*μm at a carrier concentration of $n_{2D} = 5.4 \times 10^{12}$ cm$^{-2}$.

These results advance the use of low-energy ion beams to modify 2D materials and interfaces for tuning and improving performance for application as sensors, transistors, optoelectronics, and so forth.

**FF01.16.07**

**Low-Temperature Synthesis of Transition Metal Dichalcogenides Nanowires with Increased Electron Scattering**

John M. Woods, David J. Hynek, Pengzi Liu, Min-Hui Li and Judy Cha; Yale University, United States

Transition metal dichalcogenides (TMDCs) have been widely studied for a variety of applications including catalysis for hydrogen evolution reaction, flexible optoelectronics, thermoelectrics, and battery and supercapacitor applications. Recently, tellurium-based TMDCs, such as WTe$_2$ and MoTe$_2$, are heavily studied for their desirable electrical properties, which include superconductivity down to the monolayer limit,$^{1,2}$ quantum spin Hall state in monolayer,$^3$ type II Weyl semimetallic nature,$^4$ and large magnetoresistance.$^5$ In recently published work$^6$ we report on the synthesis of single-crystalline nanowires of TMDCs (WTe$_2$, WS$_2$, WSe$_2$, and MoTe$_2$) through conversion of oxide nanowires. The synthesized WTe$_2$ nanowires may be well suited to study topological superconductivity and Majorana zero modes due to the approximation as a one dimensional system.

We perform current-dependent resistance vs. temperature measurements to characterize the transport properties of our WTe$_2$ nanowires. We find that the nanowires exhibit a resistivity that is an order-of-magnitude higher than flakes of similar thicknesses, even after removing the contributions from a tunnel barrier at the contacts. We hypothesize that this increased resistivity results from increased surface scattering of the nanowires owing to surface oxidation and increased contribution from side surfaces rather than basal planes. We investigate *in situ* passivation layer to protect the nanowires from surface oxidation. Future works to develop mitigation strategies to handle scattering at the nanowire surface will allow for investigations into the topological features of WTe$_2$.

**FF01.16.08**

**Nano-Encapsulation with 2D Materials for Ambient Operation of Field Emission Electron Devices**

Girish Rughoobur, Jiayuan Zhao, Ahmad Zubair, Lay Jain, Tomas Palacios, Jing Kong and Akintunde I. Akinwande; Massachusetts Institute of Technology, United States

The quest for transistors that operate in the THz regime is driven by the requirement for higher bandwidth to increase information bandwidth of networks. The replacement of the semiconductor transport channel with free-space is a potential path for achieving this objective. The so-called “Nano Vacuum Channel Transistors” (NVCTs) could potentially have superior performance compared to solid state devices of equivalent channel length owing to ballistic transport of electrons, shorter transit time and higher intrinsic breakdown voltage.$^1$ This is achievable as electrons are not scattered in free space (higher velocity) and there is no Avalanche carrier multiplication (no breakdown). Hence NVCTs have promise for very high Johnson Figure of Merit ($\sim 10^{14}$).$^2$

NVCTs operate by injecting electrons into the channel when electrons tunnel through the barrier as the barrier is “thinned” by the application of a gate voltage with respect to the emitter tip. This barrier height is of the order of the
electron affinity of Si ($\chi = 4.05$ eV). By scaling down all the critical device dimensions by a factor of 10, very high density (10^8 tips/cm^2), self-aligned gate field emitter arrays with low turn-on voltage (8.5 V), low operating voltage (20 V), high current density (150 A/cm^2) and long lifetime (>300 hours) have been demonstrated. However, these devices need ultra-high vacuum (UHV) for reliable operation as the field emission process is sensitive to barrier height variations induced by adsorption/desorption of gas molecules. Small changes in the barrier height lead to exponential variations in current. Poor vacuum also leads to generation of energetic ions that bombard the emitter tips, rendering the tips blunt and degrading electrical performance.

To overcome the need for UHV, we use atomically thin layers such as 2D materials to nano-encapsulate only the field emitter either in UHV or in a gas (e.g. helium) with high ionization energy. We exploit the higher transmission of smaller particles such as electrons through 2D materials compared to larger atoms/molecules such as gases. By separating the electron emission region from the acceleration region (where the electrons acquire energy), electrons can be transported in a non-ideal vacuum, if not atmospheric conditions. Furthermore, the nano-encapsulation layer can either function as an ion repeller if biased positively or can be used for secondary electron emission interface. For mechanical strength, multiple layers that are transparent to electrons while impervious to gas molecules/ions are used. In this work, we investigate the structural and electrical properties of 2D materials as nano-encapsulation layers for Si based field emission sources. The goal is to realize empty state electronics capable of functioning at higher power and harsher conditions (high radiation and high temperature) compared to solid state electronics.

Large, Low-Aspect Ratio Vanadium Dioxide Single Crystals as Actively Reconfigurable Substrates for 2D Materials Samuel T. White1, Ellis Thompson2, Peyton Brown1, Joseph Matson1, Thomas G. Folland1, Josh Caldwell1 and Richard F. Haglund1,1; 1Vanderbilt University, United States; 2Vassar College, United States

One of the main advantages of 2D materials is that their properties are dependent on their local environment, making them inherently controllable by effects such as electrostatic gating. Furthermore, 2D materials can be transferred onto arbitrary substrates, an excellent opportunity for device engineering. In particular, stacking 2D materials on tuneable or phase-change materials (PCMs), such as those exhibiting a metal-insulator transition (MIT), provides an avenue to further control the properties of 2D materials. Among PCMs, vanadium dioxide (VO2) has received a great deal of attention for its easily-accessible critical temperature (Tc) near 70°C, rich phase diagram, ultrafast optically-induced phase transition, and large change in optical properties (both n and k) especially pronounced in the near- and mid-IR; properties with promise for a variety of applications, including sensors, photonic modulators and switches, passive thermal control films—and the modulation of hyperbolic phonon polaritons (HPH) in hexagonal boron nitride (hBN). Single crystals of VO2—while less durable and scalable than thin films—have well-defined crystal lattices, sharp phase transitions, and, when strained, striped phases of coexisting insulating and metallic domains. These are ideal for situations where sharp, lateral boundaries are required within devices. Recently, these domain walls were used to demonstrate index-based launching, reflection, and refraction of HPHPs in hBN.

Developing such applications requires robust, reproducible techniques to create VO2 in a variety of forms and to locally adjust its phase transition. High-quality VO2 crystals can be grown via a physical vapor transport method, where V2O5 precursor is vaporized, transported to a growth substrate, and reduced to VO2. The size, shape, and structure of the resulting crystals depends heavily on growth parameters and the substrate used. Moreover, the Tc, existence of intermediate phases, and pattern of coexisting domains are sensitive to the crystal morphology and substrate interaction. While much work has focused on growing nanocrystals of various sizes and shapes, we seek to grow large, low-aspect ratio crystals to support large slabs of two-dimensional materials and to facilitate optical experiments on those heterostructures.

Specifically, we grow such VO2 microcrystals on a variety of crystalline oxide substrates with good lattice match to
VO₂. We discuss the optimization of growth parameters, and use optical microscopy, Raman spectroscopy, and XRD to analyze the effect of lattice match on the orientation and morphology of the crystals. Additionally, we use FTIR to measure the optical constants of single crystal VO₂ in the M1, M2, and R phases, and investigate the possibility of patterning metallic domains in VO₂ crystals with local laser heating. On c-cut sapphire—previously used to grow epitaxial nanowires—we observe large microcrystals stabilized in the insulating M2 phase at room temperature, which we attribute to strain arising from lattice mismatch and thermal expansion. On yttrium-stabilized zirconia (YSZ) (100)—previously used as a buffer layer to grow epitaxial VO₂ thin films—we observe preferred orientation of large microcrystals, as well as formation of yttrium vanadate and zirconia due to the instability of YSZ at high temperatures. These crystals exhibit unique surface morphologies, such as terrace-like steps. We also report on the growth of single crystals on other cuts of sapphire and YSZ, and on spinel (111) (MgAl₂O₄, known to support epitaxial VO₂ thin films). Finally, we describe the creation of 2D heterostructures using these crystals, and demonstrate their applicability for infrared spectroscopy experiments.

**FF01.16.10**

**Tailoring the Electronic Structure of Transition Metal Dichalcogenides Using Rationally Designed Small Molecules**

Milad Yarali¹², Yiren Zhong²¹, David Charboneau¹, Serrae Reed¹², Nilay Hazari¹, Hailiang Wang²¹ and Judy Cha¹²; ¹Yale University, United States; ²Yale University West Campus, United States

The exotic physical and chemical properties of layered transition metal dichalcogenides (TMDCs) make them prime candidates for use in a variety of applications including electronics, optoelectronics, valleytronics, and catalysis.[¹] The ability to rationally manipulate the electronic structure of atomically thin films of TMDCs is essential to enable their practical implementation. To achieve this goal, there are several examples of surface functionalization of TMDCs using small molecules to control the charge-carrier polarity and doping of TMDCs.[²] However, our understanding about the nature of the interaction between small molecules and the TMDCs or how the structure of small molecules impacts the properties of the TMDCs, remains limited. Here, we describe studies which rationally tune the electronic structure of MoS₂ monolayers using a library of systematically designed small molecules with different structures and redox properties. Electrical and magneto-transport measurements show a factor of ten improvement in electron mobility and carrier density of functionalized MoS₂ devices with well-defined organic reductants. To obtain a holistic description of the doping effects, a range of characterization techniques including X-ray photoelectron, photoluminescence, and Raman spectroscopies, and scanning tunneling and transmission electron microscopy, as well as secondary ion mass spectrometry are utilized.

**FF01.16.11**

**Structural Identification and Related Physical Properties of Red Phosphorus Polymorphs**

Jun-Yeong Yoon, Jeongheon Choe, Yangjin Lee, Sanghyuck Yu, Dong Gun Oh, Young Jai Choi, Seongil Im and Kwangyo Kim; Yonsei University, Korea (the Republic of)

Red phosphorus, an allotrope of phosphorus which is usually known to be amorphous, has several types of crystalline phases. The atomic structures and electrical properties of crystalline red phosphorus, however, have not been studied in detail due to the existence of various crystalline phases of complex structure. The red phosphorus polymorphs are categorized into five types, which include the amorphous phase (type-I). The crystal structures of type-IV (fibrous red phosphorus) and type-V (Hittorf’s phosphorus) have been previously revealed but those of type-II and type-III phases are yet to be identified. Here we investigate the crystal structures and electrical properties of crystalline red phosphorus polymorphs. Using chemical vapor transport method, we synthesize crystalline red phosphorus. Using Raman spectroscopy, electron diffraction, and X-ray diffraction measurements, we confirmed that synthesized red phosphorus is mainly type-II with some mixture of type-IV crystalline phases. The electron crystallography can be utilized to identify the crystal structure of type-II red phosphorus. With its semiconducting nature, the crystalline red phosphorus can be a promising material for electronic and optoelectronic applications.

**FF01.16.12**

**Spectroscopy Studies on Multi-Layer InSe with Visible Range Band Gap**

Srinivasa R. Tamalampudi¹, Raman Sankar², Ibraheem Almansouri³, Jin-You Lu¹ and Matteo Chiesa¹; ¹Khalifa University of Science and Technology,
United Arab Emirates; 2 Academia Sinica, Taiwan; 3 Laboratory for Energy and NanoScience (LENS), United Arab Emirates

Atomically thin, two-dimensional (2D) indium selenide (InSe) has attracted considerable attention owing to the dependence of its bandgap on sample thickness, making it suitable for small-scale optoelectronic device applications. In this work, by the use of Raman spectroscopy with three different laser wavelengths, including 488 nm, 532 nm, and 633 nm, representing resonant, near-resonant and conventional non-resonant conditions, a conclusive understanding of the thickness dependence of lattice vibrations and electronic band structure of InSe and InSe/graphene heterostructures are presented. Combining our experimental measurements with first-principles quantum mechanical modeling of the InSe systems, we identified the crystal structure as ε-phase InSe and demonstrated that its measured intensity ratio of Raman peaks in the resonant Raman spectrum evolves with the number of layers. Moreover, graphene coating enhances Raman scattering of few-layered InSe and also makes its photoluminescence stable under higher-intensity laser illumination. The optically induced charge transfer between van der Waals graphene/InSe heterostructures is observed under excitation of the E’ transition in InSe, where the observed mechanism may potentially be a route for future integrated electronic and optoelectronic devices.

FF01.16.13
High Electromagnetic Interference Shielding Effectiveness of Graphene Foam/Polymer Composites with Fe3O4 Nanoparticles-Intercalated 2D Ti3C2Tx
Van-Tam Nguyen1,2, Bok Ki Min1, Yoonsik Yi1, Seong Jun Kim1 and Choon-Gi Choi1,2; 1 Electronics and Telecommunications Research Institute, Korea (the Republic of); 2 University of Science and Technology, Korea (the Republic of)

Electronic devices such as personal computers, smartphones, and wearable devices with many highly sensitive precision electronic components can be malfunctioned due to electromagnetic interference (EMI). An EMI shielding is a solution to prevent electromagnetic (EM) radiation pollution but conventional metal-based EMI shielding materials cannot apply for stretchable and flexible devices. The 3D graphene foam/polymer composites have acquired noteworthy interests in flexible EMI shielding materials owing to the excellent electrical conductivity and large specific surface area. However, their shielding performance still needs further improvement to serve in real world applications.

Herein, the Fe3O4 nanoparticles intercalated 2D Ti3C2Tx (MXene) through ultrasonic method is decorated on the graphene foam that is grown on nickel skeleton by chemical vapor deposition (CVD) process, before embedding in the poly dimethyl siloxane (PDMS) matrix. After etching nickel away, the composite shows flexibility, elasticity, high conductivity, and a brilliant EM wave absorption. We propose the presence of the Fe3O4 nanoparticle intercalated MXene induces the internal multi-reflection, magnetic loss, and interfacial polarization in the graphene foam/polymer matrix resulting in the excellent EMI shielding effectiveness as high as 83.6 dB in the X-band frequency range (8.2-12.4 GHz). Consequently, the lightweight, flexible, and highly conductive graphene foam-based composite opens up the possibility to use as the high-performance EMI shielding materials applicable in the wearable electronics, flexible and stretchable electronics, etc.

AAO Assisted MoS2-Honeycomb Structures for Highly Sensitive and Ultrafast Moisture Detection
Shuvra Mondal1,2, Seong Jun Kim1 and Choon-Gi Choi1,2; 1 Electronics and Telecommunication Research Institute, Korea (the Republic of); 2 University of Science and Technology, Korea (the Republic of)

The climate change and necessity of monitoring dynamic changes of humidity in various fields starting from food processing industry, semiconductor fabrication facility, automobile and agriculture, to more sophisticated human respiration, non-contact epidermal sensing has increased the demand for highly sensitive humidity sensor material research. Two-dimensional (2D) material like molybdenum disulfides (MoS2) is an excellent material for humidity sensing due to the presence of inherent defects, and high moisture absorption even at room temperature. However, the humidity absorption of mono or multilayer MoS2 are limited by its atomically thin layers and their relatively low
defect sites for water molecules. Humidity sensor made from pure MoS2 films suffer from low sensitivity at room temperature has been reported. Recently, research on atmospheric humidity effect on the electrical characteristics of 3D nanostructure, MoS2 nanoflakes have been studied with the aim to increase moisture absorption and broaden detection range. However, previous studies are mostly focused on top or bottom gated complex devices that have limitations like hysteresis, stability at high humidity levels, durability.

In this study, we demonstrate a simple resistive type anodic aluminum oxide (AAO) assisted MoS2 honeycomb structure for superior humidity sensing with fast response. The honeycomb structured MoS2 tubes were fabricated by filtering the (NH4)2MoS4 solution through anodic aluminum oxide (AAO) membrane by vacuum filtration method. To achieve perfectly open surfaced MoS2 honeycomb for maximum water vapor absorption site, (NH4)2MoS4 solution vacuum filtration was repeated in cycles to eliminate larger particles from the solution. Next, T-CVD annealing process was used to synthesis MoS2 tube honeycomb. In our finding, this 3D honeycomb structure based on MoS2 tubes can respond fast to humidity from atmosphere, human skin, and human breath at the range of RH 20% ~ RH 85%. The sensitivity and response speed are heavily influenced by the MoS2 tubes, due to their wider surface area and open pores for higher moisture absorption sites. From experimental result, our MoS2 honeycomb structured humidity sensor showed excellent sensitivity of ~700 (ΔI/I0) at RH 83%, with a fast response and recovery time of 0.47s and 0.81s, respectively. This study paves the way to fast humidity sensing and non-contact sensation for next generation electronic devices.

Nanotube Templated Growth of Ultra-Narrow Transition Metal Dichalcogenide Nanoribbons Jeffrey D. Cain1,2, Amin Azizi1, Sehoon Oh1, Scott Meyer1,2, Peter Ercius2, Marvin Cohen1 and Alex Zettl1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Recently, the concept of dimensionality has emerged as an essential parameter for tuning material properties. Coinciding with the recent rise of two-dimensional (2D) materials, there have been extensive efforts to engineering additional levels of confinement, and thus lower dimensionality, in few- and monolayer materials. The greatest successes have been achieved in the fabrication and synthesis of graphene nanoribbons (GNRs), where rational bottom-up synthesis has been accomplished using the self-assembly of molecular precursors. This has enabled the growth of GNRs with specific edge structures and atomically precise widths, as well as single GNR heterojunctions with engineered band alignment and topology. Similarly, exciting physics are expected when the 2D transition metal dichalcogenides (TMDs) are further constrained to one-dimension (1D). However, the synthesis and/or fabrication of TMD nanoribbons (NRs) has lagged far behind that of GNRs both in terms of quality and width control. In the past, most studies have relied upon top-down fabrication methods that require lithography and etching processes. This results in NRs with widths greater than 50 nm (too large to observe quantum confinement effects) and a high degree of disorder. Here, we report the growth of ultra-narrow TMD nanoribbons as templated by multiwalled carbon nanotubes. The nanoribbons are grown within the hollow cavity of the carbon nanotubes, limiting their lateral dimensions and layer number, while simultaneously stabilizing them against the environment. The result is pristine nanoribbons that reach the monolayer limit and exhibit widths that can reach below 2 nm, while maintaining a defined edge structure. High-resolution transmission electron microscopy and scanning transmission electron microscopy reveal the detailed atomic structure of the material, and density functional theory is used to explore the effects of additional levels of confinement on electronic properties. The NR-in-nanotube structure represents a unique route toward nanoribbon growth and the exploration of materials under extreme dimensional constraint.

First-Principles Investigation of Dopants and Defects in 2D Materials Anne Marie Z. Tan1, Christoph Freysoldt2 and Richard G. Hennig1; 1University of Florida, United States; 2Max-Planck-Institut für Eisenforschung GmbH, Germany

Two-dimensional (2D) semiconductor materials, such as transition metal dichalcogenides, monochalcogenides, and phosphorene have attracted extensive research interests for potential applications in optoelectronics, spintronics,
photovoltaics, and catalysis. Understanding the effect of impurities, defects, and dopants on the electronic properties is crucial for the selection of materials. Choosing suitable synthesis and processing conditions allows for some control over their concentrations, and hence to tailor the carrier concentration, character, and mobility in 2D materials. Accurate determination of defect formation energies and charge transition levels enables us to predict their effect on the electronic properties and how they respond to changes in synthesis and processing.

Density functional theory (DFT) calculations of point defects in solids is a mature field with a proven record of experimentally validated predictions. However, modeling charged defects in single-layer materials with common plane-wave DFT approaches poses additional challenges which lead to the divergence of the energy with vacuum spacing. Recently, Freysoldt and Neugebauer developed a correction scheme which employs a surrogate model to restore the appropriate electrostatic boundary conditions for charged 2D materials. We apply this correction scheme to compute the formation energies and charge transition levels associated with point defects and defect complexes in technologically relevant materials such as MoS₂, WSe₂, and phosphorene. We find that dopants can bind with intrinsic defects such as vacancies to form defect complexes under certain experimental conditions, acting as compensating defects and modifying the electronic properties of the individual defects. An example of this is the Re dopant – S vacancy complex in MoS₂ which we found to be thermodynamically favorable and which if formed in fact passivate the n-type Re dopant. By further analyzing the defect electronic structures, we also predict interesting phenomena such as Jahn-Teller distortions which occur when the defects are in specific charge states. Finally, we are developing a Python-based workflow to facilitate efficient high-throughput calculations of charged point defects in 2D materials and interfacing it with existing materials databases to create a new database of defects in 2D and layered bulk materials.

FF01.16.17
Characterization of Functionalized Chevron-Type GNR Using STM and STS Abigail Berg¹,¹, Gang Li², Kaitlyn Parsons¹,¹, Amir Taqieddin¹, Steven Kolaczkowski¹,¹, Yulin He¹,¹, Pin-Chiao Huang¹,¹, Narayana R. Aluru¹,¹, Alexander Sinitskii² and Joseph W. Lyding¹,¹,¹; ¹University of Illinois at Urbana-Champaign, United States; ²University of Nebraska–Lincoln, United States

We report results on a new class of bottom-up synthesized functionalized atomically precise graphene nanoribbons (GNRs). These new ribbons are structurally related to the established chevron GNRs but are expected to have a smaller bandgap and thus higher electrical conductivity, and the edge functionalization is expected to improve their processability for device fabrication. The GNRs were synthesized in solution via Suzuki coupling of structurally different molecular precursors and characterized by a variety of spectroscopic techniques. Dry contact transfer (DCT) was used to deposit these GNRs in UHV onto hydrogen passivated Si(100) surfaces for STM imaging and spectroscopy (STS) to elucidate the structural and electronic features of these GNRs. STS results indicate a strong variation in electronic structure along the length of the GNR. Specifically, the bandgap of the functionalized ends of the reduced chevron GNR exceeds 3.3 eV while the center of the GNR exhibits a bandgap of 2.5 eV. First principle simulations using DFT and GW of the electronic structure will also be presented.

Magnetic Iron Defect Centers in Molybdenum Disulfide Monolayers Shichen Fu¹, Kamran Shayan¹, Kyungnam Kang¹, Xiaotian Wang¹, Lihua Zhang², Xiangzhi Li¹, Xiao Tong², Siwei Chen¹, Stefan Strauf¹ and Eui-Hyook Yang¹; ¹Stevens Institute of Technology, United States; ²Brookhaven National Laboratory, United States

Transition metal dichalcogenides (TMDs) have received considerable attention over the past decade, owing to its unique thickness-dependent electrical and optical properties. Chemical vapor deposition (CVD) is required to realize the scalable fabrication of TMD devices. However, the optical emission and carrier mobility of CVD-grown TMDs remain low due to the broad emission from defect bound excitons. A wide variety of approaches has been made to alter optical and electrical properties of TMD, including the incorporation of transition metals atoms (Mn, Nb, and Re) in monolayer TMDs using substitutional doping or intercalation. Among those transition metal atoms, iron (Fe) has attracted most attention due to its predicated magnetic properties and non-degenerate ground state with non-zero spin.

Here, we systematically investigated the temperature-dependent photoluminescence (PL) and magneto-PL properties of in situ Fe doping of polycrystalline MoS₂ monolayers via CVD. First, scanning transmission electron microscopy was employed to probe the atomic structure of the Fe-doped MoS₂ monolayers. Fe atoms with lower
relative intensity were visible in the MoS\(_2\) lattice at Mo sites, suggesting a substitutional Fe-doping of MoS\(_2\) monolayers. The temperature-dependent PL studies of both bare and Fe-doped MoS\(_2\) monolayers revealed significant suppression of the broad defect-bound emission related to chalcogen vacancies. In addition, we observed the emergence of new emission peaks after Fe atoms are introduced. Since the new emission peaks were absent in bare MoS\(_2\) monolayer, we attribute the new emission peaks to the optically active Fe ion sites. The light emissions from these optically active Fe ion sites had very strong thermal stability from 4K to 300K. Magneto-PL studies provided insights into the magnetic behavior of the Fe related emissions. We found \(\sim 30\%\) circular dichroism in the Fe-related emissions even at room temperature without applying a magnetic field. Furthermore, a ferromagnetic behavior of the Fe related emissions was observed by measuring the PL circular dichroism at different magnetic fields (-6.5 T to 6.5 T) with increasing and decreasing sweeping directions. These findings are pathfinders toward enabling potential applications on minimizing bit storage for future electronics based on TMDs.

**Monolayer Porous Molybdenum Disulfide**

Shuai Jia, Jing Zhang, Jiangtan Yuan, Hua Guo, Weibing Chen, Zehua Jin, Pulickel Ajayan and Jun Lou; Rice University, United States

Two-dimensional porous membrane is considered as promising candidate for photocatalyst or electrocatalyst, desalination and rapid DNA sequencing. Delicate preparation, low-efficiency and absence of scalability of the current high energy electron irradiation method for nanopores creation, has pushed the community to develop easy, low-cost and scalable methods to create nanopores onto two-dimensional materials. Here, we developed an oxidation and etching method to create easily multiple nanopores onto monolayer molybdenum disulfide (MoS\(_2\)). These nanopores are triangles with straight edges and their size is tunable by changing the oxidation temperature. With much more exposed fresh edge sites which are active sites for hydrogen evolution reaction, basal plane activity of monolayer porous MoS\(_2\) is significantly enhanced compared with pristine MoS\(_2\). Our findings imply great applications potential exist in two-dimensional porous membrane and this simple, effective and scalable method to create multiple nanopores on monolayer MoS\(_2\) paves the way to the applications of two-dimensional porous membrane.

**EELS Study of Vertically Grown Graphene Sheets on Ge**

Nitul S. Rajput, Abdulrahman S. Al Hagri, Ru Li, Jin-You Lu and Matteo Chiesa; Khalifa University of Science and Technology, United Arab Emirates

Vertically aligned graphene nanosheet arrays (VAGNAs) are grown on Ge substrate using a PECVD process. VAGNAs have unique tip morphology and large surface area, which make them as promising candidates for different applications, such as field emitting based devices, supercapacitors and batteries. Raman study implies that our PECVD-grown VAGNAs has the features of single-layer graphene termination at the top, which is further identified by our High-Resolution Transmission Electron Microscopy (HRTEM) characterization. In addition, to extract the quality of the grown layers, we also carry out the TEM based electron energy loss spectroscopy (EELS) investigation. EELS provides intricate information such as, the hybridization states and defect types present in the grown graphene sheets. Following the experimental EELS study, we also perform first-principles calculations to evaluate the effect of different types of defects on the electronic structures of VAGNAs. Moreover, the quality of the PECVD-grown graphene sheets on Germanium substrate is further compared with the graphene grown on metal substrate fabricated using the standard CVD process.

**Shelf-Stable 2D MXene Nanosheets Enabled by Antioxidants**

Xiaofei Zhao, Touseef Habib, Aniruddh Vashisth,
Evan Prehn, Smit Alkesh Shah, Wanmei Sun, Yexiao Chen, Zeyi Tan, Jodie Lutkenhaus, Miladin Radovic and Micah J. Green; Texas A&M University, United States

MXenes, such as Ti$_3$C$_2$T$_x$ and V$_2$CT$_x$, are fascinating 2D nanomaterials with an attractive combination of functional properties suitable for applications such as batteries, supercapacitors, and sensors. However, fabrication of devices and functional coatings based on MXenes remains challenging as they are prone to oxidize and degrade quickly in a matter of days from reacting with water and dissolved oxygen. We examine the oxidation of Ti$_3$C$_2$T$_x$, MXene nanosheets in various media (air, water, organic solvents, and polymer composite) via multiple types of measurements to assess their shelf stability. The degree of MXene oxidation is found directly indicated by the property and structure changes such as electrical conductivity and the TiO$_2$ content which is detected by X-ray Photoelectron Spectroscopy. The oxidation rate of MXene nanosheets is observed fastest in liquid media and slowest in solid media and can be accelerated by exposure to UV light. More importantly, we demonstrate an effective method to arrest the oxidation of colloidal Ti$_3$C$_2$T$_x$ MXene nanosheets by introducing the antioxidants. The success of the method is evident as the MXene nanosheets maintain their composition, morphology, electrical conductivity, and colloidal stability. Even in the presence of water and oxygen, the electrical conductivity of Ti$_3$C$_2$T$_x$ nanosheets treated with antioxidants is orders of magnitude higher as compared to untreated ones after 21 days. The conductivity changes also reveal that the resistance to oxidation persists in the dehydrated MXenes as well. In addition, our study includes a ReaxFF molecular simulation performed to elucidate the mechanism for MXene-antioxidant interactions. Our findings have the potential to be generalized to protect more types of MXenes as well and solve the most pressing challenge in the field of MXene engineering.

**FF01.16.22**

**Catalyst-Free and Morphology-Controlled Growth of 2D Perovskite Nanowires for Polarized Light Detection**

Debjit Ghoshal$^1$, Tianmeng Wang$^1$, Hsin-Zon Tsai$^2$, Michael Crommie$^2$, Nikhil Koratkar$^1$ and Sufei Shi$^1$;  
$^1$Rensselaer Polytechnic Institute, United States; $^2$University of California, Berkeley, United States

Two-dimensional (2D) perovskites or Ruddleson Popper (RP) perovskites have emerged as a class of material inheriting the superior optoelectronic properties of two different materials: perovskites and 2D materials. The large exciton binding energy and natural quantum well structure of 2D perovskite not only make these materials ideal platforms to study light-matter interactions, but also render them suitable for fabrication of various functional optoelectronic devices. Nanoscale structuring and morphology control have led to semiconductors with enhanced functionalities. For example, nanowires of semiconducting materials have been extensively used for important applications like lasing and sensing. Catalyst-assisted Vapor Liquid Solid (VLS) techniques, and template assisted growth, have conventionally been used for nanowire growth. However, catalyst and template-free scalable growth with morphology control of 2D perovskites have remained elusive. In this manuscript, we demonstrate a facile approach for morphology-controlled growth of high-quality nanowires of 2D perovskite, (BA)$_2$PbI$_4$. We demonstrate that the photoluminescence (PL) from the nanowires are highly polarized with a polarization ratio as large as ~0.73, which is one of the largest reported for perovskites. We further show that the photocurrent from the device based on the nanowire/graphene heterostructure is also sensitive to the polarization of the incident light with the photocurrent anisotropy ratio of ~3.62 (much larger than the previously reported best value of 2.68 for perovskite nanowires), thus demonstrating the potential of these nanowires as highly efficient photodetectors of polarized light.

**FF01.16.23**

**The Fabrication of CNT@MoS$_2$ Co-Axial Nanotube and Its Applications in Electrochemistry Field**

Yunsong Wang and Anyuan Cao; Peking University, China

Heterostructures among two-dimensional (2D) layered materials have attracted great interest due to their unique properties, and potential applications. And wrapping the 2D layered materials into one-dimensional nanotubes brings out opportunities in creating chiral tubular structures and radial heterojunctions, with more interesting functionalities and phenomena. Early efforts have focused on using a tubular template to confine the formation of another nanotube inside by capillary wetting method, such as PbI$_2$@WS$_2$ and PbI$_2$@CNT$^{[1,2]}$. But in those cases, the nanotube template ends must be open and a long-term thermal annealing process (up to 1 month) is usually carried out$^{[1]}$. For practical applications, it is more desired to have the target nanotube sitting outside the template and accessible to foreign environment.

As most of inorganic crystalline materials have rigid atomic planes, wrapping a conformal inorganic layer around
the outer surface of template (where spatial confinement is absent) turns to be rather difficult. Here, we report controlled fabrication of heterogeneous inorganic nanotubes consisting of a CNT core and crystalline MoS2 multishells with long-range continuity. Starting from a three-dimensional porous CNT sponge as template, we adopt a thiourea-assisted solvothermal method to deposit precursors and form the CNT@amorphous MoS2 structure at first. Then by high-temperature annealing process, the amorphous sheath is converted into highly crystalline multi-walled MoS2 nanotubes wrapping around individual CNTs throughout the sponge. The resulting core-shell CNT@MoS2 nanotube have a controllable layer number of outer MoS2 nanotube from 2 to 40 layers, by adjusting the precursor concentration during thiourea-thermal method. And such MoS2 nanotube shows increasing surface strain as the nanotube diameter decreasing. In this way, when used as oxygen reduction reaction (ORR) electrocatalyst, the heterogeneous inorganic nanotubes with thinner-walled (2~6 layers) MoS2 nanotube exhibits superior kinetics and lower overpotential. Besides, the stable hetero-nanotube structure endows CNT@MoS2 sponge with a specific capacity of 740 mAhg⁻¹ at 100 mAg⁻¹ and high cycling stability when used as a freestanding electrode for Li-ion batteries.

**FF01.16.24**

*Multiexciton and Excited States of Excitons in Monolayer MoS2 Observed Using Photoluminescence Spectroscopy*  
Juhi Pandey and Ajay Soni; Indian Institute of Technology Mandi, India

Two-dimensional semiconducting transition metal dichalcogenides (TMDCs) provides rich platform to study several interesting many body complexes such as excitons, trions, biexcitons and excitonic states for fundamental understanding and optoelectronic applications.¹,² Remarkably, strong Coulombic interaction with reduced dielectric screening effect in TMDCs makes experimental realization of such complexes even at room temperature which are otherwise observed at low temperatures. Further, similar to Hydrogen atoms, excitons exhibit excited states known as Rydberg states which are under scientific exploration and opens up new avenues for future quantum information processing, optoelectronic and photonics.³ Owing to weak signal from biexciton and excitonic Rydberg states in TMDCs, such complexes are less understood than excitons and trion. Further, the extent of spin orbit splitting of valence band due to d-orbital of transition metal plays an important role in observation of excitonic states. Large spin orbit splitting (> 400 meV) resulted in observation of series of Rydberg states of A exciton in ML of WS2 and WSe2 using several linear and non-linear spectroscopic techniques.⁴ On the contrary, the small spin orbit splitting ~ 150 meV in ML MoS2 provides an additional challenge in distinct realization of 2s state of A exciton (A₂s) because of the overlap with large spectral width of B exciton. Recently, A₂s state in ML MoS2 has been theoretically predicted and experimentally observed in ML MoS2 encapsulated by hBN ~ 2.1 eV using advance non-linear spectroscopic measurements.⁵ In our study, we performed temperature dependent photoluminescence (PL) studies up to 4 K to minimize spectral width of A and B excitons and accessed excitonic complexes as well Rydberg states. We discuss about the systematic observation of biexciton (~ 1.90 eV), sulfur vacancy mediated bound exciton (~ 1.90 eV), and A₂s state (~ 2.13 eV) distinct from A- trion (~ 1.92 eV), A exciton (~ 1.96 eV) and B exciton (~ 2.07 eV) in ML MoS2 using laser power dependent and temperature dependent PL spectroscopy from 4 K to 300 K. At low temperatures, the observed weak signal of excited state A₂s ultimately merges with spectral broadening of B exciton with raising temperatures.⁶ From the estimated binding energy of biexciton (~ 60 meV), we suggest that biexcitons can be stable even at room temperature.

Lateral Transition-Metal Dichalcogenide Heterostructures with Arbitrary Shapes and Band Alignments
Hossein Taghinejad1, Ali Eftekhar1, Xiang Zhang2, Sufei Shi3, Pulickel Ajayan2 and Ali Adibi1; 1Georgia Institute of Technology, United States; 2Rice University, United States; 3Rensselaer Polytechnic Institute, United States

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) with MX2 formula (M: transition metal, X: chalcogen) offer a plethora of opportunities for device engineering as well as fundamental studies. TMDs can exist in various crystalline phases including semiconducting and metallic. More importantly, the electronic bandgap of the semiconducting phase can be controlled via changing M or X elements, offering a digital portfolio of 2D materials for optoelectronic applications over a wide spectral range from visible to near infrared. In addition, this digital portfolio can be turned into an analog one through the alloying of 2D TMDs, [1, 2] a unique feature that enables the design of 2D materials with customized properties. Such a diversity of material properties renders 2D TMDs a family of unmatched qualities for the formation of heterostructures (HSs) via vertical stacking or lateral stitching of dissimilar TMDs. Unlike the diverse range of developed methods for the synthesis of vertical TMD HSs, the formation of lateral TMD HSs has been mostly limited to the edge-epitaxial growth in which a dissimilar TMD crystal (e.g., MX2) is grown on the unsaturated edge of a pre-grown TMD crystal (e.g., MX’2) to form a lateral HS (i.e., MX2-MX’2). [3] Despite the high-quality junctions, the edge-epitaxial method fails to provide a systematic control over the shape, lateral dimensions, and even the location of HSs, a set of features that are mandatory for the real-world applications.

Here we introduce an alternative method for the synthesis of lateral TMD HSs with highly controllable dimensions and shapes in predefined locations. Our method relies on combining the standard lithography with the post-growth alloying of TMDs [1] for converting a uniform MX2 monolayer into a MX2-MX’2 lateral heterostructure. We will show that the involvement of the lithography facilitates the control over the geometrical aspects of the HSs, and the post-growth alloying enables a full control over the electronic band alignment at the interface of the MX2-MX’2 HSs. Furthermore, using various spectroscopic characterizations and electrical measurements, we will demonstrate potentials of lateral TMD HSs for opto-electronic applications.

Electron Transport in Multi-Dimensional Fuzzy Graphene Nanostructures
Raghav Garg, Devashish Gopalan, Sergio de la Barrera, Thomas Nuhfer, Benjamin Hunt and Tzahi Cohen-Karni; Carnegie Mellon University, United States

Graphene, a two-dimensional (2D) allotrope of carbon, has exceptional surface-area-to-volume ratio (up to 2630 m² g⁻¹) and highly catalytic edges. To leverage these properties, efforts have been made to arrange graphene flakes in three-dimensional (3D) geometries with an eye towards integration into functional electronic devices. Electron transport mechanisms in 2D single-crystal graphene films have been extensively studied with relation to the material’s structure (e.g. edge termination, defect type and density, crystallinity, layer stacking and orientation). However, these mechanisms cannot be directly extrapolated to 3D polycrystalline nanostructures due to the added dimensionality and intricate morphology. Thus, integrating 3D arrangement of graphene flakes into functional electronic devices and developing fundamental understanding of electron transport in such structures remains an open challenge.

Here we report synthesis of a multi-dimensional graphene nanostructure: nanowire templated-3D fuzzy graphene (NT-3DFG), where each nanowire is composed of controlled 3D arrangement of graphene flakes free-standing on the surface of a one-dimensional (1D) silicon nanowire (SiNW). Such an arrangement exposes both surfaces of each graphene flake maximizing the surface-area-to-volume ratio and exposed edges. Free-standing graphene flakes form
a graphitic structure surrounding the SiNW core. Electron transport in NT-3DFG occurs through parallel channels formed by the graphitic shell (metallic transport) and the free-standing graphene (variable range hopping (VRH)). The material exhibits negative magnetoresistance from cryogenic conditions up to room temperature, which we attribute to a VRH-based interference mechanism distinct from weak localization. Our study opens new avenues for synthesizing and characterizing 3D arrangement of 2D materials to understand electron transport in multidimensional nanostructures.

**FF01.16.27**  
**Inkjet-Printed MXene/TMD Hybrid Films for Tunable Chemical Sensing at Room Temperature**  
Winston Y. Chen and Lia Stanciu; Purdue University, United States

Two-dimensional (2D) transition-metal carbides/nitrides (MXenes) have attracted great attention in energy storage and electrochemical applications because of their excellent electrical conductivity and flexible layered structures. 2D transition metal dichalcogenides (TMDs) are widely utilized in gas-sensing devices for the detection of NH₃, NO₂, H₂, and volatile organic compounds (VOCs) owing to their high specific surface area and tunable electronic structures. Therefore, hybridization of MXenes nanomaterials with TMDs, currently the main type of advanced sensing materials, is a promising approach to the manufacturing of low-cost, high-performance gas sensing devices. A wireless flexible gas sensor prepared by a simple fabrication process is appealing because it suits the needs of the internet of things (IoTs). We have been working on gas-sensing 2D materials by hybridization (and surface functionalization) of a given MXene, Ti₃C₂Tx, with a variety of TMDs (e.g., MoS₂, WSe₂). Herein, we report the results of using liquid phase exfoliation (LPE) and inkjet printing, both being the most promising cost-effective, mass-production methods, to synthesize a typical TMD/MXene nanohybrids, 2D MoS₂/Ti₃C₂Tx. The hybridization of MoS₂ and Ti₃C₂Tx films through surface modification and electrostatic interaction will be reported. The research results indicated that, even at room temperature, a MoS₂-decorated Ti₃C₂Tx gas sensor exhibited superior ability to detect extremely low concentrations (1 ppm) of VOCs, as compared to a pristine Ti₃C₂Tx (reference) sensor. Furthermore, the sensitivity of the MoS₂/Ti₃C₂Tx sensor is more than 10-fold higher than that of the pristine Ti₃C₂Tx sensor resulting from the synergetic effect of high electrical conductivity of Ti₃C₂Tx and high specific surface area of MoS₂ favoring gas adsorption. A variety of material analyzing methods will be used to elucidate the reasons behind the achievement of sensing performance by optimal decoration of MoS₂. For example, chemical bonding structures of MoS₂/Ti₃C₂Tx nanohybrids will be studied by X-ray photoelectron and Raman spectroscopies. Surface morphologies and microstructures of the hybrid materials will be analyzed by scanning electron microscopy and transmission electron microscopy.

**FF01.16.29**  
**Transferrable Ultra-Thin Organic Films for Molecular-Scale Interface Engineering**  
Shinyoung Choi, Nguyen Ngan Nguyen, Seong-Jun Yang, Kilwon Cho and Cheol-Joo Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Organic films with uniform, ultra-thin thickness can serve as building blocks to be assembled into more complex structures by sequential transfer processes. The approach provides organic interfaces engineered at the molecular-scale, which form the basis for discovery of novel organic materials and development of functional organic devices. However, transfer of such films often result in structural damages to the films, due to their weak mechanical strength. In addition, programmed organic interfaces easily deform by intermolecular diffusions. Here, we report several molecular thick C₆₀ and pentacene films with high spatial uniformity as prototypical electron acceptor and donor components, and transfer them layer-by-layer while maintaining structural integrity in the final structures. To obtain the structural stability, we integrate organic films with monolayer hexagonal boron films (ML-hBN), which act as both supporting layer for transfer and molecular diffusion blocking layer across organic interfaces. Layer-by-layer assembly of different organic films successfully generates composite films, including C₆₀/pentacene pn diode and C₆₀/pentacene vertical superlattice, where thickness and composition are modulated at the molecular-scale. Ultra-thin organic photodiodes and photoconductors have been demonstrated based on the precisely programmed organic interfaces and shown high performances.

**Nanomechanical and Nanoelectrical Mappings of Buried Defects in Lateral and Vertical Van der Waals Heterostructures**  
Marta Mucientes¹, Yuzhou Zhao², Melinda J. Shearer², Robert J. Hamers², Song Jin² and Oleg V. Kolosov¹; ¹Lancaster University, United Kingdom; ²University of Wisconsin–Madison, United States
Two dimensional (2D) transition metal dichalcogenides (TMDs) have generated strong interest between a wide scientific audience due to the variety of promising applications for nanoelectronics, photonics, sensing, energy storage, and opto-electronics, to name a few. In particular, tungsten disulfide (WS₂), tungsten diselenide (WSe₂) and molybdenum disulfide (MoS₂), individually or their combination to form vertical and lateral heterostructures, present unique mechanical, electrical and optical properties, being exceptional candidates for the fabrication of opto-electronic devices. The physical properties of these structures are strongly dependent of the quality of the materials and presence of defects, limiting somehow the performance in devices.¹

We have studied the subsurface defects with diverse Scanning Probe Microscopies (SPM) based in the Atomic Force Microscopy (AFM). The combination of the AFM with ultrasonic excitation of the sample or/and the cantilever allow the mapping of the mechanical properties with nanoscale resolution – namely, Ultrasonic Force Microscopy (UFM), Waveguide UFM (W-UFM) and Heterodyne Force Microscopy (HFM), respectively.² Similarly, by the electrical excitation of the sample, we can probe the dielectric properties and materials work function, using Dielectric Electrostatic Force Microscopy (D-EFM) and Kelvin Probe Force Microscopy (KPFM).

The preliminary results of the top surface nanomechanical maps of vertical heterostructures of WS₂ and WSe₂ with pyramidal shape, show clear contrast corresponding to missing planes in the buried layers, subsurface mis-orientation of the crystallographic axis and edge dislocations. To complete the study, the pyramids have been sectioned with the Beam Exit Cross-sectional Polishing (BEXP) permitting the direct scanning of the inner part of the 3D structures, identifying the layers and revealing inhomogeneities in the layer stack via local mechanical and electrical properties mapping. For lateral heterostructures of WS₂ and MoS₂ we use nanomechanical maps to reveal the unique mechanical behaviour creating ripples at the interface of the two materials, likely corresponding with the strain produced by the lattice mismatch.³

FF01.16.31
Double Flat Bands in Kagome Twisted Bilayers Eric Suarez¹, Roberto Hiroki Miwa² and Felipe Crasto de Lima²;
¹Universidad Tecnica Federico Santa Maria, Chile; ²Universidade Federal de Uberlandia, Brazil

We have studied theoretically how a generic bilayer kagome lattice behave upon layer rotation. Based on Density Functional theory calculations we developed a Tight Binding model with one orbital per site and found for low rotational angles and at low energies the same flat bands structure like in twisted bilayer graphene, moreover at high energies and due to the superstructure symmetry regions we found a characteristic three band dispersion of a kagome lattice, its width decreases for low angles confining them within a few meV, generating two sets of flat bands in different energy regions and localized in different spatial regions. The value of the magic angle is greater than in the rotated graphene bilayer which could result in a higher superconductivity temperature.

The kagome lattice arises in metal organic frameworks(MOF) where metals and organic ligands are the building blocks [1], a phenomenon as exotic as a quantum spin liquids was reported in spin 1/2 kagome-lattice antiferromagnet herbertsmithite[2].

Our tight binding parameters are based on a recent experimental measurement of a bilayer kagome compound Fe₃Sn₂ [3], the system is a soft ferromagnet with intrinsic anomalous Hall conductivity, the Dirac cones are separated by a gap of 30 meV as a consequence of the spin-orbit coupling.

One way to achieve larger magic angle is by increasing the relative value of the interlayer coupling, in MOF the effective coupling within the layer might be of the same order as the interlayer coupling, we explore also how this ratio might enhance the value of the angle at which the magic angle is obtained and eventually it might results in larger critical temperature.

Raman Micro-Spectroscopy with Integrated Rapid Temperature Control as a Characterization Tool for Studying Heterostructured Materials Craig Wall; Montana Instruments, United States

Tailoring 2D semiconductor heterostructures with specific bandgaps is a key aspect of leveraging new quantum materials for electronics and optoelectronics. The basic heterostructure assembly principle is simple: exfoliate, for example, a monolayer of MoS$_2$, put it on top of another mono- or few-layer crystal, c.a. WS$_2$, add another 2D crystal, and so on. The resulting heterostructure represents an artificial material assembled in a specified sequence with single layer precision, held together by van der Waals forces.

Raman micro-spectroscopy is used to characterize a variety of properties in 2D materials, including chemical, magnetic, electronic, symmetry, and layer orientation. Many interesting phenomena emerge across the 4K-500K temperature range. Often, new information about a sample can be obtained with temperature dependent measurements. We demonstrate efficient hyperspectral mapping of 2D materials with a micro-Raman spectroscopy and photoluminescence platform that maintains high spatial resolution and collection efficiency across the entire temperature range (4K – 525K). The system overcomes challenges associated with variable temperature sample drift by incorporating a low thermal mass sample stage, in-vacuum high NA objective, and coupling optics to a low astigmatism, broadband spectrograph.

The exciton recombination dynamics of stacked MoS$_2$-WS$_2$ heterostructures were previously studied at room temperature. The maximum of the valence band and the minimum of the conduction band are separated in the layers of WS$_2$ and MoS$_2$, respectively. The reported energy gap for MoS$_2$ is 2.39eV and for WS$_2$ is 2.31eV. The energy difference between the maximum valence bands of MoS$_2$ and WS$_2$ is about 350meV. Photoexcited free electron–hole pairs prefer to stay separated at layer interfaces. The excited electrons in WS$_2$ tend to accumulate in the conduction band of MoS$_2$ while holes generated in the valence band of MoS$_2$ tend to transfer to WS$_2$ at the interface. The interlayer radiative recombination of spatially separated carriers can lead to the extra peaks in the PL spectra. We observed the temperature dependence of the interlayer exciton in the hyperspectral mapping study which is at lower energy compared with pure monolayer MoS$_2$ and WS$_2$.

Growth of Nanorods of 2D Materials via a Novel Laser Treatment Technique Khaled Ibrahim, Inna Novodchuk, Kissan Mistry, Christopher Ling, Michael Singh, Michal Bajcsy, Joseph Sanderson, Mustafa Yavuz and Kevin Musselman; University of Waterloo, Canada

One-dimensional (1D) nanostructures such as nano-wires, -tubes, -rods and -fibers, have garnered great attention due to their excellent electrical, thermal, mechanical and optical properties and their suitability in a myriad of applications and devices. Applications of 1D nanostructures exist in solar cells$^{1,2}$, LEDs$^3$ and transparent conductors amongst other applications.

In this study, we demonstrate the previously unrealized ability to grow nanorods and nanotubes of 2D materials by femtosecond laser treatment of the respective flakes in solution. In as short as 20 mins, nanorods of tungsten disulfide, molybdenum disulfide, graphene, and boron nitride grow resulting in an up to 10-time increase in length. Due to the laser treatment, it was found that for some materials, notably the WS$_2$ particles reassemble to form new phases. Also resulting in the chemical modification of the nanorods with functional groups from the solvent atoms. The WS$_2$ untreated flakes are originally in the crystallographic 2H phase, the laser treatment reassemble and induces new primary bonds growing the particles into nanorods consisting of the 1T metallic crystallographic phase. Due to this transition, alongside the one-dimensional nature of the fabricated nanorods, the WS$_2$ nanorods display substantial improvements in electrical conductivity and optical transparency when employed as transparent conductors.

Room Temperature Magnetic Order in Air-Stable Ultra-Thin Iron Oxide

Jiangtan Yuan¹ and Jun Lou²;
¹Northwestern University, United States; ²Rice University, United States

Manual assembly of atomically thin materials into heterostructures with desirable electronic properties is an approach that holds great promise. Despite the rapid expansion of the family of ultra-thin materials, stackable and stable ferro/ferri magnets that are functional at room temperature are still out of reach. We report the growth of air-stable, transferable ultra-thin iron oxide crystals that exhibit magnetic order at room temperature. These crystals require no passivation and can be prepared by scalable and cost-effective chemical vapor deposition. We demonstrate that the bonding between iron oxide and its growth substrate is van der Waals-like, enabling us to remove the crystals from their growth substrate and prepare iron oxide/graphene heterostructures.

Defect Engineering in 2D Materials with Ion and Electron Beams

Paul Masih Das and Marija Drndic; University of Pennsylvania, United States

Large-scale manipulation and structural modifications of two-dimensional (2D) materials for nanoelectronic and nanofluidic applications remain obstacles to their industrial-scale implementation. Here, I will discuss how focused ion and electron beams can be utilized to engineer defects and tailor the atomic, optoelectronic, and structural properties of monolayer and heterostructure 2D materials such as graphene, phosphorene, hexagonal boron nitride, and various transition metal dichalcogenides (TMDs). A combination of aberration-corrected scanning transmission electron microscopy (AC-STEM), Raman spectroscopy, photoluminescence spectroscopy, and density functional theory (DFT) is used to study the characteristics of 0-dimensional (0D) defects and other low-dimensional nanostructures such as nanoribbons, antidot arrays, and nanoporous membranes. The results shown here lend the way to the scalable fabrication and processing of 2D nanodevices.

Large-Area Multiplexed Graphene Sensors for Detection of Ions in Electrolyte

Mantian Xue, Charles Mackin, Yiyue Luo and Tomas Palacios; Massachusetts Institute of Technology, United States

Graphene, an atomically thin material, is an excellent candidate for next generation sensing platform thanks to its unique electrical, optical, mechanical and chemical properties. Its all-surface structure gives it high sensitivity to the environment. However, it also makes graphene-based devices very sensitive to fabrication process. Small differences in graphene quality, such as surface contamination and defects, can lead to large variation in device behavior.

In this work, we developed a graphene-based sensor array functionalized with ion selective membranes (ISMs) that enables us to measure ion concentration in an electrolyte. With more than 200 functional devices per array, the system is able to detect ion concentration spanning over several orders of magnitude with a near-ideal Nernstian sensitivity, excellent selectivity, high reversibility and fast response time. The intrinsic variability in 2D material based sensor performance can be greatly mitigated by taking advantage of the large sample size and utilizing the redundancy in device response. Sensor redundancy helps to tight the 95% confidence intervals from ±50% to ±10%, while the reversibility can be increased from less than 80% to almost 95%.

This work uses an ion-selective functionalization based on a polyvinyl chloride based membrane with ionophores targeting specific ions, such as calcium, sodium and potassium. We chose these ions because their physiological importance. A material jetting 3D printer is used to print the ISMs with accurate control of the size and location. Several different ISMs can be deposited onto different regions of the sensing array, which allows for a multiplexed sensor array. By using statistical analysis techniques we are able to measure the concentration of each target ion within a complex background of interfering ions.

In summary, we developed a novel sensor platform that can simultaneously measure over 200 graphene-based multiplexed sensors to characterize the concentration of sodium, calcium and potassium ions in aqueous phase.
collecting data from a statistically significant sample size, this work presents a manufacturable and reliable technology that can be employed for a wide range of physiologic monitoring applications.

*Toward Disorder-Free Growth of Thin Metal Films on Graphene by Magnetron Sputtering*

Nikolaos Platsikas1, Olle Andersson1, John Arvanitidis2, Dimitrios Christofilos2, Ivan Shtepliuk1, Ivan G. Ivanov1, Rositsa Yakimova1 and Kostas Sarakinos1; 1Linköping University, Sweden; 2Aristotle University of Thessaloniki, Greece

Deposition of metal contacts on graphene is a crucial step for the fabrication of a wide array of novel optoelectronic and sensing devices. Magnetron sputtering is a state-of-the-art versatile technique for large-scale thin metal film synthesis. However, its inherent tendency for generating energetic species (both neutrals and ions) that cause ballistic defects and disorder on the surface upon which they form a film, renders sputtering incompatible with processes where graphene is used as substrate. The objective of this study is to establish the effect of sputtering conditions, during growth of thin Ag films, on the structure and electronic properties of graphene. Films are grown on monolayer graphene synthesized by SiC sublimation of C-face 4H-SiC and by CVD deposition on Cu foils. We use top-view SEM from which we establish that the produced Ag films exhibit a pronounced 3D growth morphology that can be attributed to the weak interaction between Ag atoms and graphene. We also employ micro-Raman spectroscopy and define the graphene crystalline quality and the point-defect density as a function of the deposition parameters. The energetic sputtered species cause disorder, evidenced by the appearance of the defect-related D-band and inhomogeneous broadening of the characteristic Raman peaks due to charge and local strain fluctuations. We also find that the effect of the energetic deposition flux on the pristine graphene structure and electronic properties becomes less pronounced with increasing sputtering pressure. These findings suggest that it may be possible to facilitate disorder-free growth of thin metal films on graphene by magnetron sputtering if deposition parameters (e.g., sputtering pressure, target-to-substrate distance, magnetic field configuration) are carefully adjusted in a way that minimizes the energetic input from the sputtering flux to the growing surface.

*First-Principle Investigation of Twisted Black Phosphorus*

Minwoong Joe, Yisehak Gebredingle and Changgu Lee; Sungkyunkwan University, Korea (the Republic of)

Black phosphorus is an intriguing material with intrinsic anisotropy induced by its unique puckered honeycomb structure. In bilayer or multi-layer black phosphorus, the system's anisotropy as a whole can be tuned by an interlayer twist angle, and thereby the material's electronic, optical, and mechanical properties. Thus, we here try to investigate the effect of interlayer twist angles or stacking orientations on twisted black phosphorus using first-principles calculations. The effects of twist angle on its band structure, phonon dispersion, mechanical property, etc. are presented. We discuss the mechanism of controlling electronic structures by twisting layers, and also, an effective way to handle the long-range Moire superlattice induced by incommensurate lattices in an arbitrary twist angle.

**FF01.16.39**
*Strain Engineering of 2D Materials for Integrated Photonic Devices*

Rishi Maiti, Chandraman Patil, Ti Xie, Haoyan Kang and Sorger Volker; George Washington University, United States

Triggered by the demands for high-performance computing requires much higher bandwidth density for inter-chip communication pushes the limit of device miniaturization. Hence, 2-dimensional (2D) materials have recently emerged as promising building blocks for photonics due to their number of fascinating features. Tuning of electronic and optical properties by engineering local strain is an exciting avenue for tailoring performance for 2D materials based integrated photonic device. Besides, continuous tuning of the strain, the ability to apply a spatially controllable strain by using a patterned substrate is even more crucial because it enables the realization of a graded bandgap semiconductor for the photonic integrated device. Here, we study the effect of large localized strain in the electronic band structure of a multilayer MoTe₂ by wrapping the 2D material around a non-planarized Silicon-on-insulator waveguide etched down to the buried oxide. Interestingly, induced tensile strain (4%) shifts the bandgap of MoTe₂ by about 0.8 eV obtained using DFT calculation, thus significantly increasing the absorption as compared to their pristine counterpart of bandgap (~1 eV). Here, the device is realized in a two-terminal in-plane electrode configuration without applying external gating, showing a high responsivity of (~0.5 A/W) and NEP of 90 pW/Hz0.5 at -2 V at 1550 nm. Our device demonstrates a response rate of ~35 MHz which is limited by the low
mobility (~1 cm²/Vs) of the MoTe₂. The integration of a few-layer MoTe₂ on Si MRR as active photodetector is envisaged to offer a potential pathway toward the realization of integrated on-chip interconnects for Telecommunication band.

**Enhanced Carrier Transport of MoS₂ through Metal-Semiconductor Interface Decorated by Monolayer h-BN**

Hemendra Nath Jaiswal¹, Maomao Liu², Simran Shahi², Sichen Wei¹, Fei Yao¹ and Huamin Li²; ¹University at Buffalo, United States; ²University at Buffalo, The State University of New York, United States

Two-dimensional (2D) monolayer molybdenum disulfide (MoS₂) has been demonstrated as an excellent semiconductor material for future nanoelectronics because of the suitable bandgap, good intrinsic mobility, thermal velocity, and mean free path etc. To fully explore the potential of monolayer MoS₂ for practical applications such as field-effect transistors, memories, photo-sensors, and solar cells, there is a critical need of metal-semiconductor contact engineering and optimization which can lead to the maximization of device performance. In this work, we exploited 2D monolayer hexagonal boron nitride (h-BN) as a decorating layer at the metal-MoS₂ interface, and demonstrated a significant improvement of the carrier transport through a quantum tunneling effect. Both monolayer MoS₂ and h-BN were synthesized by using two-zone chemical vapor deposition (CVD) method. The triangular domains of monolayer MoS₂ were synthesized directly on SiO₂/Si substrates and the continuous monolayer h-BN film was grown on copper foils. The field-effect transistor (FET) and transmission line measurement (TLM) devices were fabricated using electron beam lithography (EBL) and evaporation (10 nm Ti and 100 nm Au). Compared to the conventional MoS₂/Ti/Au contact where the thermionic emission is the dominating mechanism, the MoS₂/h-BN/Ti/Au contact shows the outstanding improvement of the carrier transport. For example, the on-current density was increased by two orders of magnitude, and the electron mobility was improved by ten times. These improvements can be attributed to the dominance of the quantum tunneling when the monolayer h-BN is inserted at the metal-semiconductor interface. Based on the temperature-dependent measurement, a lowering of the effective metal-semiconductor barrier height from ~60 to ~30 meV was induced by the monolayer h-BN decoration, and the reduction of the contact resistance was confirmed by the TLM technique. Our work has demonstrated the great potential of this novel contact engineering technique using the 2D monolayer insulator, which can be applied to other 2D materials and devices for broad applications.

**Asymmetry Behaviors on Bias Temperature Stress Instability of Multi-Layered MoS₂ FETs and Their Understanding via Extraction of Subgap Density-of-States**

Seung Gi Seo¹, Jin Heon Jeong¹, Seung Yeob Kim¹, Young Jun Byeon¹, Sungju Choi², Dae Hwan Kim² and Sung Hun Jin¹; ¹Incheon National University, Korea (the Republic of); ²Kookmin University, Korea (the Republic of)

For the newly emerging IoT sensors and display applications, low dimensional semiconductors such transition metal dichalcogenides (TMDs) can be one of appealing candidates beyond graphene because of their excellent electrical-switching-characteristics, together with novel mechanical, and optical properties. Among them, molybdenum disulfide (MoS₂) has been regarded as one of the most promising materials. Until to this date, in-depth knowledge on MoS₂ FETs in terms of electrical performance improvement, transport mechanism, back channel effects, etc have been accumulated through tremendous research activities. However, device reliability studies on MoS₂ FETs have been limitedly reported. Thus, systematic investigation on device instability of MoS₂ FETs under DC and pulsed mode operation and its comparison on instability behaviors, followed by understanding on the behind mechanism, are highly necessary in order to apply TMD FETs to next-generation display platforms which are required for ultra-high definition, mechanical flexibility, electrical stability, and others. Furthermore, for a quantitative understanding on gas adsorption effects on electrical performance of MoS₂ FETs, which are regarded as one of main factors for instability of TMDs, information on subgap density of states (DOS) in MoS₂ layers without (or with) hydrophobic polymer (CYTOP) encapsulation is one of pre-requisite parameters. On the other hand, in a recent past, trap information on MoS₂ FETs has been quantitatively analyzed by several techniques, whereas the previous reports for characterization of sub-gap traps for m-MoS₂ FETs were limitedly addressed; (i) Dₜ characterization via Terman method, (ii) shallow traps nearby conduction band (Eᵥ) via multi-frequency method, and (iii) deep level traps through hysteretic gate transfer characteristics, thereby entire characterization for sub-gap DOS was fundamentally limited by method itself and its characterization.

In this study, we investigated into device instability of MoS₂ FETs associated with series of key parameters such as
bias polarity, temperature, duty cycles, bias amplitude, and others. Asymmetry behaviors on bias stress instability under DC and pulsed mode operation were reproducibly observed and their mechanisms were systematically analyzed by using frame time dependency in pulsed mode operation, rationally supported by atomic and band models. Moreover, quantitative analysis on subgap states for MoS2 FETs before and after CYTOP encapsulation were performed by using optical charge-pumping capacitance-voltage spectroscopy. Based on extracted subgap DOS and their deconvolution with analytical model of acceptor (or donor) like states, all electrical parameters were systematically analyzed. Two times increase of field effect mobility ($\mu_F$) are strongly related with decrease of shallow-donor states ($N_{SD}$). In addition, significant improvement of subthreshold swing (SS) and hysteresis gap ($V_{HYST}$) are attributed to the reduction of tail states ($N_{TA}$), along with decrease in mid-gap states ($N_{MD}$). All systematic results in this work are highly anticipated to contribute to the understanding on device instability issues which are required for fulfilling the envisioned applications.

**FF01.16.42**

**Electronical Tuning of Complex Reflectivity with Graphene-Based Metasurface** Sangjun Han, Junhyeong Kim, Ju Young Kim, Juho Park and Min Seok Jang; KAIST, Korea (the Republic of)

In this work, we design a graphene-based metasurface for independent active modulation of amplitude and phase of mid-infrared light. This independent control over the phase and amplitude can be obtained by applying the alternating voltage to the two consecutive units of periodic graphene-gold multiscale structures (meta-atoms). In complex reflectivity plane, we are able to cover a large area of unit complex reflectivity square by only controlling the values of graphene Fermi energy in each set of meta-atoms.

The proposed structure can be analyzed with an effective surface admittance model [1]. For general multiscale structure with back-reflector, it is known that the reflectivity $r$ and the effective admittance of the metasurface $Y_S$ are related as

$$r = \frac{-Y_{Sub} - Y_0}{Y_{Sub} + Y_0 + Y_S},$$

where $Y_{Sub}$ and $Y_0$ are the admittance of the substrate and vacuum, respectively [1]. In this structure of alternating meta-atoms, the admittance of the pair (meta-molecule) is a serial connection of the half-admittances of each meta-atom $Y_{SI}$ and $Y_{S2}$: $Y_S = 2Y_{SI}Y_{S2}/(Y_{SI} + Y_{S2})$. The admittance of each meta-atom is predicted by a circuit model. The circuit model represents the effective conductivity of the meta-atom as a function of its structural parameters by taking the elements constituting the metasurface as corresponding circuit elements, and then calculating the admittance of the circuit connecting the elements. The gold bars array is represented by a serial connection of inductances and capacitances with the geometrical parameter of bars and slits. The array of graphene ribbons placed between the gold bars is treated with the effective admittance of the free-standing graphene ribbon array multiplied by the gain factor $P/g$, corresponding to the electric field amplification in the gap. In this way, we can approach the complex reflectivity of the metasurface from the viewpoint of its structural parameters, and optimize the whole structure. Further, by inducing the appropriate Fermi energy independently to each meta-atom of the metasurface, the reflected wavefront can be controlled in arbitrary manner (e.g. dynamic beam steering, focusing etc.)

**FF01.16.43**

**One-Dimensional MoS2NT-SWCNT van der Waals Heterostructures as Efficient Hole Transport Layer in Perovskite Solar Cells** Yang Qian1, Seungju Seo1, Haosheng Lin1, Yongjia Zheng1, Esko Kaupinnen2, Jing Kong3, Rong Xiang1, Il Jeon1, Yutaka Matsuo1,4 and Shigeo Maruyama1,5; 1The University of Tokyo, Japan; 2Aalto University, Finland; 3Massachusetts Institute of Technology, United States; 4Nagoya University, Japan; 5National Institute of Advanced Industrial Science and Technology, Japan

MoS2, along with other transition metal dichalcogenides (TMDCs) nanomaterials, have been demonstrated to be effective in photovoltaic (PV) devices with various functions and structures. Interestingly, the TMDC-based electronic devices can be either vertical or lateral, showing the potential of fabricating TMDC-based PV devices with different dimensionality. Recently, we have synthesized a new class of 1-dimensional (1D) van der Waals (vdW) heterostructures by chemical vapor deposition, in which MoS2 nanotube (MoS2NT) is wrapping around single-walled carbon nanotubes (SWCNT) to form a MoS2NT-SWCNT interface [1]. The application of this kind of 1D vdW heterostructures can allow us to fabricate PV devices with 1D dimensionality. In this research, we demonstrate the excellent hole-extraction ability of MoS2NT by applying MoS2NT-SWCNT to normal-type perovskite solar cells. The as-synthesized MoS2NT-SWCNT functions as both the hole transport layer...
and anode at the same time. Comparing with SWCNT, the wrapping of MoS$_2$NT around SWCNT improved the power conversion efficiency (PCE) by almost 20%, owing to the substantial enhancement of the fill factor. A PCE of 15.0% has been achieved after the application of spiro-MeOTAD. The 1D vdW heterostructures are beneficial by a closer physical distance between layers for a better hole-transport ability than 2D vdW heterostructures. In addition, the integration of different materials in one substance can also allow easier fabrication than layer-stacking, and thus reduce the size of the device and the amount of used materials. The successful application of MoS$_2$NT-SWCNT in perovskite solar cells are expected to ignite the application of 1D vdW heterostructures, as well as the application of SWCNT and TMDC based nanomaterials in PV devices.

SESSION FF01.17: Application of Contacts to 2D Materials
Session Chairs: Olga Kazakova and Hyeon Jin Shin
Thursday Morning, December 5, 2019
Hynes, Level 3, Room 312

8:00 AM FF01.17.01
Fabrication of 2D Lateral Metal/Semiconductor Junction via Selective Synthetic Integration of Transition-Metal-Carbide/Transition-Metal-Dichalcogenide Haeju Choi$^{1}$, Seunghyuk Choi$^{1}$, Chaeyeon Shin$^{1}$, Jaeho Jeon$^{1}$, Jin-Hong Park$^{1}$ and Sungjoo Lee$^{1,2}$; $^{1}$Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); $^{2}$Sungkyunkwan University, Korea (the Republic of)

For real implementation of 2D material-based nanoscale device integration, the construction of a manufacturable and highly stable metal/semiconductor building block is critically required. To develop practical 2D material-based electronic and photonic devices, the formation of 2D lateral metal/semiconductor junction structures can overcome fundamental technical obstacles such as high contact resistance and limitation of channel length scaling via conventional vertical junction structures. However, a formation method of large-scale 2D lateral metal/semiconductor junction structure with sufficient levels of controllability and quality has not been demonstrated. We herein propose the formation of a scalable 2D metal/semiconductor Mo$_2$C/MoS$_2$ lateral junction structure fabricated via selective synthetic integration of large-scale metal (Mo$_2$C)/semiconductor (MoS$_2$) junction. We demonstrate that centimeter-scale metallic 2D MXene (Mo$_2$C) can be synthesized from CVD-grown few-layer MoS$_2$ with chemical conversion using CH$_4$ and Cu catalyst. Further, a dimension-controlled Mo$_2$C/MoS$_2$ junction is fabricated by depositing a lithographically patterned SiO$_2$ masking layer. Results show that while chemical conversion to Mo$_2$C occurs in the uncovered MoS$_2$ part, the MoS$_2$ layer under the SiO$_2$ masking layer is protected from chemical conversion so that a scalable Mo$_2$C/MoS$_2$ heterostructure is integrated down to the nanometer scale, exhibiting excellent resistance of contact resistance of 2.1 kΩ μm. This proposed manufacturable and highly stable 2D material-integrated metal/semiconductor junction structure will provide a scalable building block for the implementation of 2D material-based nanoscale device integration.

8:15 AM FF01.17.02
Heterostructured Contacts to MoS$_2$ Enhance the Catalytic Efficiency of Hydrogen Production Joshua Pondick$^{1,2}$, Yu Zhou$^{1,2}$, Jose Silva$^{3}$, John M. Woods$^{1,2}$, David J. Hynek$^{1,2}$, Grace Matthews$^4$, Xin Shen$^{1,2}$, Barbara Brenna$^{5}$, Shu Hu$^{1,2}$, Moyses Araujo$^{3}$ and Judy Cha$^{1,2}$; $^{1}$Yale University, United States; $^{2}$Yale West Campus, United States; $^{3}$Uppsala University, Sweden; $^{4}$North Carolina State University, United States

Two-dimensional (2D) nanostructured transition metal dichalcogenides (TMDs) are promising candidates for catalyzing the hydrogen evolution reaction (HER). However, even though the free energy of hydrogen adsorption ($\Delta G_{\text{H}}$) is close to zero for many TMDs, experimental catalytic efficiencies have consistently fallen short of thermodynamic predictions. In order to investigate this disparity, the effect of the support substrate on the MoS$_2$-catalyzed HER was investigated. It has been demonstrated that both heterostructured contacts and the support
substrate can modulate the MoS$_2$-catalyzed HER, but it is difficult to isolate and identify the specific interfacial effects that influence the catalytic efficiency. To address this challenge, we utilized an electrochemical microreactor capable of isolating individual interfacial effects to probe the catalytic efficiencies of MoS$_2$ [1]. We show that heterostructured supports enhance the HER activity of monolayer MoS$_2$ [2]. This talk will examine two possible mechanisms to explain the modulation of the HER activities. The first mechanism is that highly conductive support substrates are better than dielectric substrates because they can effectively screen mirror charges that may form during HER. Indeed, MoS$_2$-WTe$_2$ and MoS$_2$-graphene heterostructures consistently outperformed MoS$_2$ supported on SiO$_2$ in agreement with our expectation. To further probe this mechanism, we placed MoS$_2$ on substrates with dielectric constants ranging from 4 to 300. The catalytic efficiency of MoS$_2$ decreased with increasing dielectric constant, supporting the idea that mirror charges can inhibit hydrogen production. However, the effect of substrates was proven minor compared to the effect of contact metals. Devices with Ni-graphite contacts significantly outperformed devices with Cr-graphite contacts regardless of the support dielectric constant. This suggests that the catalytic efficiency is largely determined by the second mechanism: charge injection. We attribute the increased activity of the Ni devices to lower contact resistance for electrons at the Ni-graphite interface than through the Cr-graphite interface. Thus, the enhanced HER from the MoS$_2$-WTe$_2$ and MoS$_2$-graphene heterostructures is attributed to the efficient charge injection into MoS$_2$ through large-area heterojunctions.

These results demonstrate the importance of interfacial design in TMD HER catalysts. The microreactor platform presents an unambiguous approach to probe interfacial effects in various electrocatalytic reactions.

**8:30 AM FF01.17.03**

**Conformal Wafer-Scale Formation of Patterned van der Waals (W, Mo)Te$_2$ Electrodes with Ideal Schottky Barriers**

Seunguk Song$^1$, Yeoseon Sim$^1$, Se-Yang Kim$^1$, Jung Hwa Kim$^1$, Inseon Oh$^1$, Woong Ki Na$^1$, Do Hee Lee$^1$, Jaewon Wang$^1$, Jinsung Kwak$^1$, Hyeonsik Cheong$^2$, Jung-Woo Yoo$^1$, Zonghoon Lee$^2$ and Soon-Yong Kwon$^1$; $^1$Ulsan National Institute of Science and Technology, Korea (the Republic of); $^2$Sogang University, Korea (the Republic of)

Beyond the silicon and compound semiconductor industries, two-dimensional van der Waals (2D vdW) materials have been predicted to be able to revolutionize electronics, photonics, and other industrial sectors since they possess many fascinating physical and electrical properties. However, 2D materials currently face challenges along the long-term road to commercialization, with increasing efforts being made to satisfy industrial needs. At this moment, the most critical issue for final 2D device performance is related to realizing good electrical contacts to 2D vdW semiconductors. In fact, most 3D (bulk) metals form non-Ohmic Schottky junctions to 2D vdW semiconductors, resulting in relatively high and bias-dependent contact resistances. Furthermore, the Fermi level at the metal-semiconductor junction (MSJ) is often pinned owing to several types of chemical interactions, and the Schottky-Mott rule generally provides incorrect prediction for the Schottky barrier height (SBH).

In this study, we not only performed the wafer-scale production of patterned transition metal (TM) ditellurides (e.g., WTe$_2$ or MoTe$_2$) on desired surfaces and positions with high electrical performance but also demonstrated the experimental formation of monolayer MoS$_2$ FETs containing 2D WTe$_2$/MoS$_2$ vdW MSJs with almost perfect interfaces. We have designed simple and efficient methods to grow high-quality, stoichiometric TM ditellurides with electrical performances comparable to those of mechanically exfoliated flakes. The fabricated 2D (W, Mo)Te$_2$/monolayer MoS$_2$ vdW MSJs with close-to-perfect interfaces are free from significant disorder effects and Fermi level pinning on the interface, and their SBHs largely follow the trend of the Schottky-Mott limit. For example, the measured SBH ($\approx$103.5 meV) of the WTe$_2$/MoS$_2$ interface was the lowest value experimentally observed for metal electrodes formed on monolayer MoS$_2$ and was very close to the theoretical value ($\approx$100 meV) calculated by the Schottky–Mott rule. Compared to the MSJs with conventional 3D metals, the fabricated 2D WTe$_2$/MoS$_2$ vdW MSJs exhibited a much improved electrical injection across the MSJs, which was attributed to the low SBH and depinning of the Fermi level at the interface. Employing position-controlled, patterned vdW contacts with ideal Schottky barriers provides the advantage of controlling the SBHs in a predictable manner. This ability to fabricate position-controlled, conformal vdW metals with different shapes affords new possibilities for the fabrication of multiple 2D nanoelectronics devices.
8:45 AM FF01.17.04
A New Metal Transfer Process for van der Waals Contacts to Vertical Schottky-Junction Transition Metal Dichalcogenide Photovoltaics Cora Went, Joeson Wong, Phillip Jahelka, Michael Kelzenberg, Souvik Biswas and Harry A. Atwater; California Institute of Technology, United States

Two-dimensional transition metal dichalcogenides are promising candidates for ultrathin optoelectronic devices due to their high absorption coefficients and intrinsically passivated surfaces. To maintain these near-perfect surfaces, recent research has focused on fabricating van der Waals contacts that limit Fermi-level pinning at the metal-semiconductor interface. Here, we develop a new, simple procedure for transferring metal contacts that does not require aligned lithography. Using this technique, we fabricate vertical Schottky-junction WS2 solar cells with template-stripped Ag bottom contacts, 15-nm-thick exfoliated WS2 absorber layers, and 20-nm-thick semitransparent Au transferred top contacts. Under laser illumination, we observe rectifying behavior and open-circuit voltage above 500 mV in devices with transferred contacts, in contrast to resistive behavior and open-circuit voltage below 15 mV in devices with evaporated contacts. Under one-sun illumination, we measure an open-circuit voltage of 256 mV, a short-circuit current density of 4.10 mA/cm², and a fill factor of 0.44. We calculate a power conversion efficiency of 0.46%, comparable to what others have observed in ultrathin transition metal dichalcogenide photovoltaics. Guided by device simulations that predict power conversion efficiencies close to 9%, we fabricate and characterize further-optimized devices with transparent top contacts and metal work functions that are better aligned to the multilayer WS2 conduction and valence bands. Our one-sun measurements and device simulation results indicate that this metal transfer process could enable high-specific-power vertical Schottky-junction transition metal dichalcogenide photovoltaics, and we anticipate that this technique will lead to advances for two-dimensional devices more broadly.

Ultra Clean van der Waals Contacts Using Indium Alloys on Two-Dimensional Semiconductors Manish Chhowalla; University of Cambridge, United Kingdom

We recently reported the realization of ultra-clean vdW contacts between three dimensional metals and single layer MoS2. Using scanning transmission electron microscopy (STEM) imaging, we show that the 3D metal and 2D MoS2 interface is atomically sharp with no detectable chemical interaction, suggesting van-der-Waals-type bonding between the metal and MoS2. We show that the contact resistance of indium electrodes is ~ 800 Ω-μm – amongst the lowest observed for metal electrodes on MoS2 and is translated into high performance FETs with mobility in excess of 160 cm²-V-s⁻¹ at room temperature without encapsulation. We have extended this work to other monolayer 2D semiconductors such as MoSe2, WSe2 and their p-n interfaces. We have also studied alloying of indium contacts with other metals to engineer the work function of the electrodes for facile electron and hole injection. I will describe our efforts on making good contacts on 2D semiconductors.

The Solution to the Solution—Colloidal Suspension of 3D Architectures of 2D Materials Jennifer G. DiStefano and Vinayak Dravid; Northwestern University, United States

For years, solution processing has enabled researchers to employ transition metal dichalcogenides (TMDs) in fields not accessible with traditional solid-state routes and rigid substrates. Scalable synthesis and exfoliation, chemical functionalization, and hybridization are particularly promising advantages of solution-based methods for TMDs. Colloidal suspension allows for facile assembly of TMDs, often of a desired size and thickness, onto arbitrary substrates. Exploratory biomedical applications, from diagnostics to therapy, have benefited from this unprecedented access to 2D semiconductors in solution and resultant functionalization possibilities. Solution-based hybridization between TMDs and complementary materials has enabled developments in electrocatalysis, sensing, and battery technologies, demonstrating the true breadth of diverse fields these techniques can impact. However, some of the most interesting TMD structures, including heterostructures, are barred from these modification and assembly opportunities because existing solution-based synthesis and exfoliation approaches are not compatible with complex geometries. Here we introduce a platform to successfully transfer artificial two-dimensional heterostructures synthesized with solid-state deposition to an aqueous solution. This essential transfer generates a stable solution where heterostructures can be functionalized for a variety of new applications or transferred to other substrates to create hierarchical assemblies.

Recently, we reported unique nanoparticle@TMD core-shell architectures (e.g. Au@MoS$_2$) and demonstrated their promising properties for electrocatalysis and optoelectronic devices. Subsequently, we have developed an approach to synthesize TMD core-shell heterostructures and utilize Au nanoparticles as functional vehicles to transfer these unusual structures into solution. We use a metal sulfurization process to synthesize Au@MoS$_2$@WS$_2$ structures on rigid substrates. High-resolution electron microscopy and Raman spectroscopy confirm the complete conversion to MoS$_2$ and WS$_2$ and high crystallinity of the TMDs. We then suspend these particles in water and demonstrate MoS$_2$/WS$_2$ heterostructures in solution. These core-shell heterostructures exhibit exceptional natural stability and monodispersity in solution, making them viable in many applications. Additionally, we leverage this colloidal suspension to chemically functionalize the core-shell particles and further expand application opportunities.

This presentation will also cover two of the broad future avenues enabled by this research approach. On one hand, the solution of core-shell particles itself can be employed via chemical functionalization or hybridization with other functional materials. For instance, biomedicine is one particularly ripe area for this application. These particles could be functionalized to carry chemotherapy drugs, or the TMD/plasmonic Au core hybrid could be leveraged for photothermal cancer treatment. On the other hand, this new platform allows one to conveniently transfer the particles to any substrate, including flexible substrates incompatible with high temperature synthesis. Directed assembly into artificial lattices or unique patterns will be achievable to fully exploit the interplay between the heterostructure shell and plasmonic core. Thus, by introducing a broad platform to create colloidal suspensions of artificial structures, this work opens the door for advanced engineering and utilization of TMD heterostructures.

3D Printed Microsupercapacitors from 2D Material Inks Cecilia Mattevi; Imperial College London, United Kingdom

Miniaturization over three-dimensions is very attractive for future on-chip technologies where device efficiencies need to be optimized over small footprints. This is a new challenge, as device miniaturization has been focused to achieve planar-geometries primarily.

Direct Ink Writing (Robocasting), is an additive manufacturing technique that brings the possibility of fabricating architectures with programmable design in the three-dimensions (3D) at different length scales. Here, we demonstrate 3D printed electrodes for microsupercapacitors and energy conversion systems from highly concentrated, water-based 2D atomically thin material inks using robocasting. The inks are composed by highly concentrated atomically thin sheets of transition metal chalcogenides either exfoliated from bulk powders or obtained via direct synthesis in solution. By tailoring the rheology of our formulated inks, printability has been achieved along with mechanical robustness of the printed architectures.

The printed architectures, from woodpile to interdigitated electrodes, are extended over a few mm in the three-dimensions and present electrodes widths as small as 100 μm. The 3D printed microsupercapacitors show leading areal capacitance and energy density as compared to planar microsupercapacitors, and stability in different electrolytes.
All-Printed Heterostructure Devices Made with Water-Based and Biocompatible 2D-Inks
Cinzia Casiraghi; University of Manchester, United Kingdom

Solution processing of 2D materials [1] allows simple and low-cost techniques such as inkjet printing [2,3] to be used for fabrication of heterostructure of arbitrary complexity. However, the success of this technology is determined by the nature and quality of the inks used. Furthermore, these formulations must be suitable for all-inkjet printed heterostructure fabrication - the remixing of different 2D crystal gives rise to uncontrolled interfaces, resulting in poor performance and lack of reproducibility of the devices. In this work we show a general formulation engineering approach to achieve highly concentrated, and inkjet printable water-based 2D crystal formulations, which also provide optimal film formation for multi-stack fabrication [4]. Examples of all-inkjet printed heterostructures, such as arrays of photosensors [4], logic memory devices [4], capacitors [5] and transistors [5, 6] will be discussed.

Towards Large Scale Manufacturability of (Mostly) Electronic Devices with 2D Materials
Juliana Radu, Inge Asselberghs, Cedric Huyghebaert, Dennis Lin, Benjamin Groeven, Steven Brems, Devin Verreck, Quentin Smets, Tom Schram, Goutham Arutchelvan and Surajit Sutar; imec, Belgium

2D materials hold the promise for many interesting applications in electronics. In this talk, we will evaluate their potential towards continued transistor scaling and provide materials targets which enable device performance comparable or surpassing that of scaled Si transistors. While transistor scaling for digital applications is the most coveted for application, MX2 materials have lower mobility than Si when deposited on wafer. Other applications in electronic circuits which do not require very high mobility have to be considered. We will approach this from the perspective of system and device co-optimization and discuss possible applications which require transits with very low leakage.

At imec, we are building a 300mm-wafer platform 2D materials which is being used to assess experimentally the manufacturability of devices with MX2 channel. In this context, we have demonstrated full-wafer (300mm) growth of MoS2 and WS2 by MOCVD and worked on transferring these materials from the growth wafer to a device wafer. We will describe the integration flow we have developed in the imec CMOS fab.

While progress in many aspects of device fabrication with MX2 materials is encouraging, several steps still lack fundamental understanding and methods to solve them. We will outline these outstanding problems and detail current status of where potential showstoppers appear.

Additive Manufacturing of Patterned 2D Semiconductor through Recyclable Masked Growth
Yunfan Guo and Jing Kong; Massachusetts Institute of Technology, United States

The 2D van der Waals crystals have shown great promise as potential future electronic materials due to their atomically thin and smooth nature, highly tailorable electronic structure, and mass production compatibility through chemical synthesis. Electronic devices, such as field effect transistors (FETs), from these materials require patterning and fabrication into desired structures.

Specifically, the scale up and future development of “2D-based electronics will inevitably require large numbers of fabrication steps in the patterning of 2D semiconductors, such as transition metal dichalcogenides (TMDs). This is currently carried out via multiple steps of lithography, etching, and transfer. As 2D devices become more complex (e.g., numerous 2D materials, more layers, specific shapes, etc.), the patterning steps can become economically costly and time consuming. Here, we developed a method to directly synthesize a 2D semiconductor, monolayer
molybdenum disulfide (MoS2), in arbitrary patterns on insulating SiO2/Si via seed-promoted chemical vapor deposition (CVD) and substrate engineering. This method shows the potential of using the prepatterned substrates as a master template for the repeated growth of monolayer MoS2 patterns. Our technique currently produces arbitrary monolayer MoS2 patterns at a spatial resolution of 2 μm with excellent homogeneity and transistor performance (room temperature electron mobility of 30 cm2 V−1 s−1 and on–off current ratio of 107). Extending this patterning method to other 2D materials can provide a facile method for the repeatable direct synthesis of 2D materials for future electronics and optoelectronics.

SESSION FF01.19: Fundamental Limits to Transport in 2D Materials

Approaching the Intrinsic Limit in Transition Metal Dichalcogenide van der Waals Heterostructures James Hone; Columbia University, United States

Studying the intrinsic behavior of 2D materials requires attention to both external and internal sources of disorder. This talk will first review the techniques used to create clean heterostructures with hBN to reduce environmental disorder. In graphene, ten years of progress has led to device performance now rivaling the highest-quality GaAs-based heterostructures. On the other hand, semiconducting transition metal dichalcogenides (TMDs) are also limited by atomic defects within the crystalline layers, which requires efforts in synthesis and characterization of high-purity crystals. This talk will present recent progress in synthesis of TMD crystals with dramatically lower defect density using a self-flux technique. Combining higher crystal quality and clean encapsulation allows observation of greatly enhanced optical properties, including near-unity photoluminescence quantum yield, and long excited-state lifetime in TMD heterostructures. In addition, electronic transport measurements show improved carrier mobility and reveal many new details in magnetotransport measurements, including observation of fractional quantum Hall states in monolayer TMDs. These high-quality crystals also allow studies of twisted bilayer TMDs, which show the emergence of many-body correlated states.

Sample synthesis is supported under NSF DMR-1420634
Studies of magnetotransport in monolayer WSe2 are supported under DOE SC-0016703
Studies of twisted bilayer materials are supported under DOE DE-SC0019443

2:00 PM FF01.19.02
Towards High-Mobility 2D Semiconductors Yuanyue Liu; The University of Texas at Austin, United States

One of the major challenges that limits the development of 2D semiconductors is the low mobility of electrons/holes. Here using Boltzmann transport theory with the scattering rates determined from first principles, which allows us to accurately calculate the intrinsic (phonon-limited) mobility, we will present the intrinsic mobility for a variety of 2D semiconductors, including MX2 and monoelement ones. Moreover, we will discuss how the mobilities are related with underlying physical properties, causing the mobility difference across different materials, and (if time allows) how the strain and thickness would alter the mobility.

Fundamental Limits of the Open Circuit Voltage in Ultrathin Transition Metal Dichalcogenide Photovoltaics Due to Band Tailing Joeson Wong1, Cora Went1, Ben L. Cotts2, Stefan Omelchenko1, Alberto Salleo2 and Harry A. Atwater3; 1California Institute of Technology, United States; 2Stanford University, United States

Band tails are ubiquitously observed at the band-edge of a semiconductor, often characterized by an exponential
decay in absorption below the band gap. Here, we characterize for the first time these band tail states in various ultrathin (<20 nm) transition metal dichalcogenide (TMDC) photovoltaic devices using photocurrent spectroscopy. We attribute the origin of these tail states to both intrinsic disorder within the TMDC (e.g. MoS$_2$, WS$_2$, MoSe$_2$, WSe$_2$) layer as well as the surrounding electrostatic environment in the form of a built-in field. Using our experimental measurements of the band tail states, we further analyze their implications on the fundamental limits of open circuit voltage in ultrathin TMDC photovoltaics using optoelectronic reciprocity relations. We find that in addition to the external radiative efficiency of TMDCs, band tail states may reduce the achievable open circuit voltage by over 100 mV due to increased recombination and therefore sets the maximum efficiency of ultrathin TMDC photovoltaics.

Anomalously Suppressed Lattice Thermal Conduction by Electron-Phonon Coupling in Tantalum Disulfide
Huili Liu$^{1,2}$, Chao Yang$^3$, Jiawang Hong$^3$ and Junqiao Wu$^{1,2}$; $^1$University of California, Berkeley, United States;
$^2$Lawrence Berkeley National Laboratory, United States; $^3$Beijing Institute of Technology, China

Charge and thermal transport in a crystal are carried by free electrons and phonons (quantized lattice vibration), the two most fundamental quasi-particles. Above the Debye temperature of the crystal, phonons mediated thermal conductivity ($k_L$) is typically limited by mutual scattering of phonons, which results in $k_L$ decreasing with inverse temperature, whereas free electrons play negligible role in $k_L$. We report an unusual case in a charge-density-wave single crystal, where $k_L$ is limited instead by phonon scattering with free electrons, resulting in a temperature-independent $k_L$. In this system, the conventional phonon-phonon scattering is alleviated by its uniquely structured phonon dispersions, while unusually strong electron-phonon (e-ph) coupling arises from its Fermi surface strongly nested at wavevectors where phonons exhibit Kohn anomalies. The finding reveals new physics of thermal conduction, offers a unique platform to probe e-ph interactions, and provides potential ways to control heat flow in materials with free charge carriers.

Thermal Conductivity of High-Quality Atomically Thin Boron Nitride and Its Thermal Expansion
Qiran Cai$^1$, Declan Scullion$^2$, Ying Chen$^1$, Elton J. Santos$^2$ and Luhua Li$^1$; $^1$Deakin University, Australia; $^2$Queen's University Belfast, United Kingdom

Heat management becomes more and more critical, especially in miniaturized modern devices, so the exploration of highly thermally conductive materials with electrical insulation and favorable mechanical properties is of great importance. Here, we report that high-quality monolayer boron nitride (BN) has a thermal conductivity ($\kappa$) of 751 W/mK at room temperature. Although smaller than that of graphene, this value is larger than that of cubic boron nitride (cBN) and only second to those of diamond and lately discovered cubic boron arsenide (BAs). Monolayer BN has the second largest $\kappa$ per unit weight among all semiconductors and insulators, just behind diamond, if density is considered. The $\kappa$ of atomically thin BN decreases with increased thickness. Our large-scale molecular dynamic simulations using Green-Kubo formalism accurately reproduce this trend, and the density functional theory (DFT) calculations reveal the main scattering mechanism. The thermal expansion coefficients (TECs) of monolayer to trilayer BN at 300 to 400 K are also experimentally measured, and the results are comparable to atomistic ab initio DFT calculations in a wider range of temperatures. Owing to its wide bandgap, high thermal conductivity, outstanding strength, good flexibility, and excellent thermal and chemical stability, atomically thin BN is a strong candidate for heat dissipation applications, especially in the next generation of flexible electronic devices.

**Hot Electron Transfer in Graphene/WS$_2$ Heterostructures**  
Chiara Trovatello$^1$, Giulia Piccinini$^{2,3}$, Stiven Forti$^{2,3}$, Filippo Fabbri$^{2,3}$, Antonio Rossi$^{4,5,2}$, Camilla Coletti$^{2,3}$, Giulio Cerullo$^1$ and Stefano Dal Conte$^1$; $^1$Politecnico University of Milan, Italy; $^2$Istituto Italiano di Tecnologia, Italy; $^3$Istituto Nanoscienze-CNR and Scuola Normale Superiore, Italy; $^4$University of California, Davis, United States; $^5$Lawrence Berkeley National Laboratory, United States

Stacking two-dimensional (2D) materials, like graphene (GR) and single layer transition metal dichalcogenides (1L-TMDs), has opened up unlimited possibilities to design and engineer new functional 2D van der Waals heterostructures (HSs).

Here we exploit ultrafast transient-reflection spectroscopy to optically investigate the charge transfer (CT) dynamics in a large area 1L-WS$_2$/GR HS, with an unprecedented temporal resolution, i.e. sub-20fs, and across a broad energy range spectrally covering both A and B excitons of WS$_2$ (1.8-2.5eV).

When the HS is excited with a photon energy of 2eV, above the optical gap of 1L-WS$_2$ (1.98eV), the differential reflectivity signal, i.e. $\Delta R/R$, is dominated A and B excitonic features of WS$_2$. On the other hand, if carriers are photo-injected in the HS well below the WS$_2$ bandgap, e.g. with 0.8eV photon energy, only graphene is actually excited. Nevertheless, the signal across A and B peaks appears immediately after excitation. This surprising result suggests an extremely fast CT from GR to WS$_2$. Indeed, when WS$_2$ alone is excited below bandgap with the same photon energy and fluence, no transient signal is detected.

The observed ultrafast charge transfer cannot be exclusively attributed to the direct excitation of new intermediate charge transfer states arising from the overlap of the graphene and the TMD bandstructures[1]. This is indicated by the excitation fluence dependence of the transient signal, which becomes strongly nonlinear at infrared excitation energies, revealing that the mechanism behind the observed ultrafast CT from graphene to the semiconductor is hot electron/hole transfer[2].

The timescale for the hot electron transfer is expected to be extremely short, below 50 femtoseconds[2]. The rise time of the A exciton dynamics is a direct estimation of the timescale for this process, and it is related both to the hot GR Fermi-Dirac distribution thermalization and the tunneling process, i.e. the time needed for hot electrons, exclusively excited in GR, to overcome the Schottky barrier and reach the semiconductor[3]. The extracted build-up of the A exciton transient signal, measured on the HS following a sub-20fs IR excitation at 1.3eV, is faster than 20 fs. This is the first direct measurement of the hot electron/hole transfer in time-domain.

Hot electron transfer is extremely promising for charge extraction at the HS interface, making this novel 2D HS suitable for the development of broadband and efficient low-dimensional photodetectors.

**4:00 PM FF01.20.04**  
**Spectroscopic Investigation of Electron Transfer from Monolayer MoS$_2$ to Organic Conjugated Polymers**  
Christopher Petoukhoff$^2$, Sofia Kosar$^1$, Ibrahim Bozkurt$^2$, Manish Chhowalla$^3$ and Keshav M. Dani$^1$; $^1$Okinawa Institute of Science and Technology, Japan; $^2$Rutgers, The State University of New Jersey, United States; $^3$University of Cambridge, United Kingdom

Organic/2D heterostructures have emerged as promising materials for ultrathin, large-area optoelectronic devices. Both organic and 2D semiconductors lack dangling bonds at their surfaces and interact via van der Waals forces, enabling their heterostructures to form ideal interfaces without the need for energy-intensive growth processes, such as molecular beam epitaxy. As such, ultrathin optoelectronic devices have been fabricated from organic/2D heterostructures including photovoltaics, photodetectors, and field-effect transistors, demonstrating large on-off ratios and anti-ambipolar behavior in the latter. Recently, organic conjugated polymer/2D heterostructures fabricated from the polymer, PTB7, and the 2D material, MoS$_2$, have demonstrated the photovoltaic effect with record values of the photovoltaic figures of merit normalized to the device active layer thickness. Despite this, devices fabricated from organic/2D heterostructures have shown relatively low internal quantum efficiencies, suggesting non-ideal charge transport throughout their devices. Investigating charge transfer dynamics across organic/2D semiconductor interfaces at fundamental timescales is an important part of understanding how to improve the low internal quantum efficiency of these devices.
Here, we employ photoluminescence and femtosecond transient absorption spectroscopies to study the charge transfer dynamics in large-area, organic conjugated polymer/MoS2 heterostructures. The heterostructures were formed between chemical vapor deposited monolayer MoS2 thin-films and 3 different conjugated polymer films: P3HT, PCDTBT, and PTB7. These 3 polymers have been used extensively as electron donors in high-efficiency polymer:fullerene organic photovoltaics, and each form Type-II heterojunctions with MoS2. Although electron transfer was expected to occur from the polymers to MoS2, we show that electron transfer occurs in the opposite direction: from MoS2 to each of the conjugated polymers via polaron pair states. We show that electrons are transferred from MoS2 to P3HT within 9 ps, and from MoS2 to PCDTBT and PTB7 in under 120 fs. Despite this, we demonstrate that the P3HT/MoS2 heterostructure is the most efficient because the transferred charges have an order-of-magnitude increase in their lifetimes, leading to enhancement in the photoluminescence from P3HT. We propose that the differences in the lifetime of transferred charges arises from the crystallinity of the conjugated polymer films.

Influence of Interfacial Morphology on Ultrafast Charge Separation in 0D/2D Mixed-Dimensional Heterojunctions

Suyog Padgaonkar, Mark C. Hersam and Emily Weiss; Northwestern University, United States

Mixed-dimensional heterojunctions (MDHJs) combine the characteristics of component materials such as the discrete orbital energies of zero-dimensional (0D) molecules and the extended band structure of two-dimensional (2D) semiconductors. While MDHJs have shown promise for optoelectronic applications – such as photodetectors because their performance exceeds that of the individual components – increased understanding of fundamental mechanisms and time scales of charge separation at the interface would drive improved design of these systems. Here, comparison between two different type-II organic/2D MDHJs comprised of copper (Cu) and free base (H2) phthalocyanine (Pc) and monolayer MoS2 elucidates the influence of interfacial morphology on charge separation lifetimes in these systems. In particular, time-resolved optical spectroscopy reveals two ultrafast charge transfer processes from selective excitation of each component material: sub-picosecond photoinduced hole-transfer and sub-320 fs photoinduced electron-transfer processes at the interfaces of CuPc/MoS2 and H2Pc/MoS2 MDHJs. In CuPc/MoS2 heterojunctions, charge separation lasts as long as 70 ns, which is a factor of 17 longer than that in H2Pc/MoS2 heterojunctions and a factor of 40 longer than that in previously reported transition-metal dichalcogenide-based heterojunctions. Polarized Raman spectroscopy shows that preservation of the charge-separated state is attributed to the face-on orientation of CuPc on the MoS2 surface, which templates stacking of CuPc molecules and facilitates hole migration away from the interface, whereas H2Pc molecules adopt a mixed edge-on and face-on orientation. This work highlights the role of molecular structure in determining the interfacial geometry and, ultimately, charge-transfer dynamics in 0D/2D heterojunctions and suggests principles for the rational design of other organic/2D MDHJs.

Unintentional n-Type Doping on Single Layer Nb-Doped MoS2 Observed by Scanning Nonlinear Dielectric Microscopy

Kohei Yamasue and Yasuo Cho; Tohoku University, Japan

Atomically-thin layered semiconductors as exemplified by few-layer MoS2 and WSe2 are an emerging class of materials with their potential use for semiconductor devices [1, 2]. In this context, dominant carrier distribution on these materials and devices is one of the key electronic properties for understanding their electrical characteristics and improving device performance. In fact, recently, an unintentional electron doping effect in MoS2 has been reported, which suggests the difficulty in fabricating intrinsic and p-type atomically-thin MoS2 [3]. This effect is attributed to surface electron accumulation due to the formation of sulfur vacancies on the surface of MoS2 and therefore becomes dominant in atomically-thin layers due to their high surface-to-volume ratio [3]. In order to investigate the transition of dominant carrier polarity on atomically-thin MoS2 layers, here we perform the nanoscale carrier distribution imaging on atomically-thin natural and Nb-doped MoS2 including single layer areas. By using a microwave-based scanning probe microscopy method called scanning nonlinear dielectric microscopy (SNDM) [4], we actually visualize unintentional n-type transition confined on single layer Nb-doped MoS2, even though Nb-doped MoS2 is nominally expected to be p-type in contrast to natural MoS2 with n-type dominant carriers. SNDM allows nanoscale dominant carrier distribution imaging through the detection of differential capacitance induced by small ac-bias voltage (so-called dC/dV imaging). As the polarity of dC/dV is inverted depending on the polarity of dominant carriers, we can identify n- or p-type on the local area below the tip. We have already succeeded in the detection of single layer MoS2 [5], because SNDM is exceptionally sensitive to tiny dC/dV. In this
study, we used novel intermittent contact SNDM with boxcar integration, which will be described elsewhere [6], to obtain higher S/N ratio than that in the conventional intermittent contact SNDM. The samples were natural and Nb-doped MoS₂ on SiO₂/Si substrates prepared by the mechanical exfoliation with so-called Scotch tape method. The measurement was performed in air at room temperature using a commercial scanning probe microscopy system (Bruker, Icon) integrated with a lab-made SNDM setup. As expected, for natural MoS₂, n-type contrast were seen even on few-layer MoS₂ including a single layer area. In contrast, we found that single layer Nb-doped MoS₂ showed unintentional n-type contrast, while multilayer areas were seen p-type. This unintentional electron doping effect was reproducibly observed on the single layer areas of other Nb-doped MoS₂ samples. In addition, unlike the multilayer areas, those with a few to several layer number often showed negligible dC/dV signal level. These results are reasonable if considering the counter doping effect depending on the surface-to-volume (S/V) ratio discussed in Ref. [5]. The effect does not manifest for multilayers with a low S/V ratio, but, for few-layers, it is balanced with Nb-doping, and then overcompensates in single layer areas with the highest S/V ratio. This implies the difficulty in p-type conduction on our as-prepared MoS₂ samples. The results here indicate that SNDM gives direct information on nanoscale carrier distribution on the areas with different stacking layers, which will provide a clue to controlling carrier types and doping levels in atomically-thin layered semiconductors.

Rigid-Lattice Moiré vs Atomic Reconstruction in van der Waals Heterostructures Matthew R. Rosenberger¹, Hsun Jen Chuang¹, Madeleine Phillips¹, Vladimir Oleshko², Kathleen McCreary¹, Saujan V. Sivaram¹, C. Stephen Hellberg¹ and Berend T. Jonker¹; ¹U.S. Naval Research Laboratory, United States; ²National Institute of Standards and Technology, United States

Van der Waals layered materials, such as transition metal dichalcogenides (TMDs), are an exciting class of materials with weak interlayer bonding which enables one to create so-called van der Waals heterostructures (vdWH). One promising attribute of vdWH is control over the twist angle between layers, which leads to the formation of moiré patterns that enable tuning of vdWH properties. In the case of TMD vdWH, moiré patterns have been used to explain unique optoelectronic behavior of these structures. However, the moiré theory used to explain the behavior of TMD vdWH have only considered the constituent layers as rigid lattices and have not allowed for atomic-level reconstruction, i.e. rearrangement of the atoms with the layers. The existence of atomic-level reconstruction would have a significant impact on the electronic and optoelectronic properties and would fundamentally change our theoretical understanding of these systems. Here, we present experimental proof of atomic-level reconstruction in twisted TMD vdWH, which is a significant departure from the rigid-lattice moiré theory. Using conductive atomic force microscopy (CAFM), we probe the nanometer-scale electronic behavior of twisted MoSe₂/WSe₂ and MoS₂/WS₂ heterostructures and show that, for twist angles around 1° or less, large domains of constant electronic behavior form rather than a continuously varying pattern of electronic behavior, as expected from conventional moiré theory. We find that the stacking arrangement (H-type or R-type) has a profound impact on the reconstruction behavior. We use transmission electron microscopy to corroborate the presence of atomic reconstruction, to demonstrate commensurate stacking within the reconstructed domains, and to demonstrate a transition from atomic reconstruction at small twist angles (≤ 1°) to a rigid-lattice moiré pattern for larger angles (≥ 3°). We use density functional theory (DFT) calculations to predict the low-energy stacking configurations of the heterostructures and to calculate the band structures of the low-energy stacking configurations. Agreement between CAFM and DFT enables us to assign stacking arrangements to the different reconstructed domains. Finally, we show that the difference in calculated bandgaps between heterostructures with H-type and R-type stacking agree with photoluminescence measurements of reconstructed heterostructures of both types. These results provide fundamental insight into the behavior of this exciting class of semiconductor heterostructure.

TiO₂ Nanowires/Ti₃C₂ MXene Based Multi-Functional Sensors with High Sensitivity and Ultrafast Response
Seong Jin Kim¹, Shuvra Mondal¹,² and Choon-Gi Choi¹,²; ¹Electronics and Telecommunications Research Institute, Korea (the Republic of); ²University of Science and Technology, Korea (the Republic of)

Ti₃C₂ MXene, a new class of two-dimensional transition metal carbides has attracted much attention as a sensing material due to its high surface-to-volume ratios and excellent electrical conductivity. Furthermore, the presence of surface terminated functional group such as oxide (-O) and hydroxyl (-OH) onto the Ti₃C₂ MXene provides reaction sites for water absorption. Recently, many studies have been investigated to understand the charge transfer mechanism when water molecules were sorption in MXene surface or intercalation between the MXene nanosheets for improving response speed and sensitivity. However, the electrical response to water vapor absorption that determines the performance of the humidity sensor can still be limited due to the high electrical conductivity of MXene. Therefore, it is required to study the novel MXene structure which can improve the sensor performance by maximizing the electrical charge while the water vapor or moisture is adsorbed on the film surface.

In this work, we synthesized TiO₂ nanowires/Ti₃C₂ MXene composites by facile solution process manipulating of concentration of NaOH solution. As a result, the density of TiO₂ nanowires increased in proportion to the concentration of NaOH solution and formed a network on the surface and interlayers of Ti₃C₂ MXene. The sensing performance of TiO₂ nanowires (NWs)/Ti₃C₂ MXene composites based humidity sensor was evaluated under relative humidity condition from 20 to 80 %. As a result, it showed a high sensitivity and fast response compared with pristine Ti₃C₂ MXene-based sensor. In addition, piezoresistive pressure sensor was fabricated by coating TiO₂ NWs/ Ti₃C₂ MXene on cotton fabric. Thereafter, the performance of the device evaluated over a wide pressure range of 0.33 to 63.1 kPa. As a result, our sensor showed high sensitivity of 2.5 kPa⁻¹ with excellent linearity. In addition, it exhibited an ultrafast response speed with a rise time of ~13 ms and decay time of ~17 ms. This study opens up a new avenue of two-dimensional layered hybrid materials for applications of advanced contact and non-contact electronic devices.

Effect of Gamma-Ray Irradiation on MoS₂ Investigated by Raman and X-Ray Photoelectron Spectroscopy
Burcu Ozden¹, Min Khalan², Minseo Park² and Choi Wonbong³; ¹Penn State Abington, United States; ²Auburn University, United States; ³University of North Texas, United States

Recently, molybdenum disulphide (MoS₂) has attracted great attention for diverse applications due to its material properties. It is thought that these material properties soon will make MoS₂ attractive for the development of radiation-hard electronics. Therefore, for the first time, we studied the effect of gamma-ray (γ-ray) irradiation on the crystal quality of a few-layered MoS₂ by using Raman and X-ray photoelectron spectroscopy techniques. The γ-ray irradiation dose of 120 Mrad was applied to 3.2, 4.5, and 5.2 nm thick MoS₂ films which were grown on Si by using a two-step synthesis method (sputtering of Mo, followed by sulphurisation). Before γ-ray irradiation, three active Raman modes (E₁g, A₁g) was detected. After γ-ray irradiation, the Raman peaks attributed to the E₁g and A₁g modes almost disappeared. The dramatic decrease in the S2p peak accompanied by an increase in the O1s peak and the change in the Mo3d3/2 binding energy from what is known for stoichiometric MoS₂ to that for native Mo oxide was observed in the XPS spectra. In conclusion, dramatic chemical changes in the MoS₂ films after irradiation is believed to be related to the fact that S vacancies are formed due to γ-ray irradiation, which subsequently transforms
MoS₂ to a native MoOₓ.

**A Semimetallic Two-Dimensional ZnSb with Remarkably High Hole Mobility**  
Wonchul Shin¹,², Chang Il Kwon¹, Jun Sung Kim¹ and In Chung¹,²; ¹Seoul National University, Korea (the Republic of); ²Institute for Basic Science (IBS), Korea (the Republic of); ³Pohang University of Science and Technology, Korea (the Republic of)

The discovery of exotic electronic properties of graphene has led to extensive research efforts to find new functional two-dimensional (2D) materials. For example, transition metal dichalcogenide (TMD) compounds are an excellent candidate for various electronic devices due to their thickness-tunable band gap. However, their relative low carrier mobility limits their applications. Recently, honeycomb-like monolayer materials composed of main group elements such as GeP³ and antimonene were reported to exhibit high carrier mobility. However, this property is only observable in epitaxially grown samples on specific substrates. Here, we present a new structure-type, metastable 2D ZnSb which exhibits remarkably high carrier mobility. The structure features unique two atom-thick Zn-Sb honeycomb layers stacked along the out-of-plane direction. This compound can be only achievable by topotactic chemical reaction we developed. Temperature-dependent electrical resistivity and Hall effect measurements on single crystalline 2D ZnSb show p-type metallic conduction with hole mobility of ~400 cm²V⁻¹s⁻¹ at room temperature. A new 2D ZnSb is readily cleavable to form a few layer-thick nanosheets by various irradiation techniques. This new phase shows completely different crystal structure and physical properties from a well-known three-dimensional semiconducting polymorph.

**FF01.21.04**  
**Ultras-Sensitive Graphene-Barristor Biosensor**  
Naebong Jeung¹, Jun-Ho Lee¹, Do-Hyun Park¹, In-Chul Choi¹, Hongjeong Yu², Hakho Lee² and Hyun-Jong Chung¹; ¹Konkuk University, Korea (the Republic of); ²Massachusetts General Hospital, United States

We present a new, highly sensitive biosensing approach using a graphene-based barristor [1]. The sensor is formed by interfacing graphene with semiconductor. The resulting Schottky barrier (between graphene and semiconductor) is highly susceptible to the device surface condition; binding of target biological molecules can turn on the device with very large signal gain. This mechanism makes the barristor far superior to conventional graphene FET sensors that are based on the charge-density modulation[2]. To prove the concept, we fabricated n-type barristor sensors and used them to detect DNA molecules. With target DNA binding, the height of the Schottky barrier increases, leading to the decrease in device currents. Even at very low DNA concentrations (~1 aM), we observed more than 40% changes in the device conductance. The technology may open up a new material and device concept for ultrasensitive biosensing.

**Mass Production of 2D ZnO Nanosheets Using Recyclable AAO Template**  
Jiyu Sun and Pu-Xian Gao; University of Connecticut, United States

Two-dimensional (2D) ZnO nanostructures are becoming more popular due to their properties such as nanometer-scale thickness, high surface to volume ratio, and good mechanical stability ¹. However, current strategies are usually limited to low production rate, complicated method, and high cost. Here in this study, we report a high-yield method to synthesize large-area ZnO 2D nanosheets by utilizing recyclable anodic aluminum oxide (AAO) template. ZnO nanosheets were synthesized by microwave-assisted hydrothermal synthesis method without using seeding layer, with a large lateral size and nanometer thickness. ZnO nanosheets could be obtained by a sonication process, with a yield of 3mg/cm² in 3 hours. XRD analysis indicated the formation of ZnO nanosheets exposed with (100) facets and the successful doping of Al. During electron microscopy imaging, an ultrathin morphology was observed with good wrinkling flexibility. Besides, due to the intactness of the template after nanosheet transferring using polymer, the AAO template can be cyclically utilized as the substrate for repetitive growth of ZnO nanosheets, which further reduces the cost and waste. Various application demonstrations are conducted based on this ZnO nanosheets, including gas sensor, thermochemical CO₂ hydrogenation, and photocatalysis. Owing to its ultrathin 2D morphology with abundant amounts of active sites and defects, a higher sensitivity and a short response time toward ppb–level gas detection may be obtained, and a higher conversion efficiency of CO₂ hydrogenation is achieved ²-³. High binding energies between gas molecules and oxygen vacancies existing in the exposed ZnO (100) facets lead to large surface reconstructions, which make a contribution to the gas sensing properties and CO₂ hydrogenation.
Furthermore, the highly exposed surface of nanosheets also facilitates gas sensing and catalysis performance. The demonstrated method here enables a new path to the high-yield synthesis of 2D ZnO for applications in energy-related field and beyond.

**Highly Efficient Luminescence from Large Scale TMDC by Minimizing Optical Loss**

Chansoo Kim, Seungju Seo, Beomseok Kang and Jeehwan Kim; Massachusetts Institute of Technology, United States

Since the discovery of graphene in 2004, two dimensional (2D) materials have led an intensive attention because of their unique physics and new device architectures. Nevertheless, there was limitation over having large-scale, monolayer 2D materials because it is extremely difficult to control the kinetic of 2D materials during the growth. Especially, it is mandatory to have monolayer of transition dichalcogenides (TMDCs) for optoelectronic applications as multilayer 2D materials have indirect band gap which involving phonon loss. In addition, since 2D materials themselves do not have sufficient external quantum efficiency (EQE), we cannot expect highly efficient luminescence from 2D material-based optoelectronics. Thus, it has been required to develop an alternative approach for 2D materials-based optoelectronics.

Here, we propose an interesting approach for highly efficient luminescence from large scale TMDCs by effectively engineering optical loss. Last year, we reported a new approach to make large scale, monolayer of the TMDC, called layer-resolved splitting. This approach enables us to have large-scale monolayer-by-monolayer stacking with pristine interface as it does not accompany any polymer residue and chemical contamination at the interface. Therefore, it minimizes the optical loss through interface interference. In addition, we successfully engineer additional optical loss by incorporating distributed bragg reflector (DBR) structures with TMDCs since DBR has broad reflection band and phase shift of DBR is close to zero. Thus, we can observe the improvement of photoluminescence in TMDC/DBR structure using layer-resolved splitting process. We strongly believe that this process will lead a new opportunity for highly efficient 2D material-based LED optoelectronic applications.

**FF01.21.08**

**Symmetry-Dependent Electron-Phonon Coupling in Black Phosphorus Revealed by Resonance Raman Spectroscopy**

Nannan Mao1, Xingzhi Wang2, Yuxuan Lin1, Liangbo Liang3, Jing Kong1 and William Tisdale1; 1Massachusetts Institute of Technology, United States; 2Boston University, United States; 3Oak Ridge National Laboratory (ORNL), United States

Crystals with low symmetry and low dimensionality have drawn tremendous fundamental and practical interest, since such a strongly quantum confined anisotropic system gives rise to many novel and complicated many-body interactions. Black phosphorus (BP), a two-dimensional elemental semiconductor, is a representative member of such low-symmetric nanomaterials. With the highly anisotropic electronic structure and phonon dispersions, black phosphorus has been an excellent platform for understanding the rule of symmetry related multi-particle interactions. Here, we investigated the electron-phonon coupling in few-layer and bulk BP using polarization-dependent resonance Raman spectroscopy with 16 laser lines. The in-plane \( A_\parallel \) mode, which shows larger intrinsic resonance effect than the out-of-plane \( A_\perp \) mode when excitation polarization is along the armchair direction, demonstrating symmetry-dependent electron-phonon coupling effect in BP. This understanding is further supported by the quantum perturbation theory and first-principles calculations on the anisotropic electron distributions. Moreover, the comparison of intrinsic resonance effects along two crystalline orientations allow us to resolve the existing controversies on the physical origin of Raman anomaly in BP and its dependence on excitation energy, sample thickness, phonon modes, and crystalline orientation.

**Ultraclean van der Waals Contact for Spintronic Devices**

Yan Wang, Guang Yang and Manish Chhowalla; University of Cambridge, United Kingdom
Graphene has been demonstrated to be promising for spintronic devices due to its intrinsically low spin orbit interaction\(^1\). Although long spin relaxation lengths (> \(2\mu\m\)) have been experimentally achieved with graphene, the degree of polarized carrier injection is still low (< \(10\%\)) due to scattering at the contact/graphene interface\(^2\). Ferromagnetic electrodes such as cobalt are most commonly used for injecting spin-polarized electrons into non-ferromagnetic graphene. Recently, atomic resolution scanning transmission electron microscope studies on metal/2D material interfaces have revealed that defects are created during metal deposition\(^3,4\). This has led the studies of inserting tunnel barriers such as h-BN\(^5\), MgO\(^6\), and TiO\(_2\)\(^7\) between Co and graphene layers for improving the spin injection efficiency. Here, we report results from our recent work on realizing ultra-clean van der Waals contacts using Indium electrodes for spintronics. Specifically, we use 3 – 10 nm indium to achieve defect-free contact, then deposit ferromagnetic Co layers on top. Annealing of the contacts leads to ferromagnetic In/Co alloy with defect free interface with graphene that can be used to inject spin polarized carriers with high efficiency.

*WSe\(_2\)/h-BN Heterostructure Memristor Devices Stacked by Quasi-Dry Transfer Process* Beom-Seok Kang, Chansoo Kim and Jeelwan Kim; Massachusetts Institute of Technology, United States

Memristors are a great promising candidate for a next-generation nonvolatile memory due to their small footprint, low power consumption, thus, suitable for handling tremendous data set such as learning neural-networks. At the early stage, memristor devices were fabricated with titanium dioxide (TiO\(_2\)) controlling movement of oxygen vacancies, nowadays, for improved performance and various applications, several materials such as organic polymer and ferroelectric thin film have been widely studied as been suggested as a switching medium. Recently, memristors utilizing two-dimensional (2D) layered material based memristors, which are atomically thin, flexible and easily heterogeneously integrated, for example, MoS\(_2\), MoTe\(_2\), h-BN have also shown their feasibility as they are atomically thin, flexible and easily heterogeneously integrated, successfully making 2D layered material them as a promising switching medium for atomically thin, flexible, and vertically stackable memristor.

In this study, we propose a memristor device architecture consisting of report WSe\(_2\)/h-BN heterostructure showing low leakage current, pristine interface, and, pristine interface, memristor devices. stable filament formation in switching mediums, which are key factors for stable memristor operation. Our main approach for them is engineering material combination with pristine interface. As h-BN itself has low leakage current properties and WSe\(_2\) itself has stable filament formation, we have found out that WSe\(_2\)/h-BN heterostructures have much large memory window (on/off ratio of \(\sim 10^4\)) and stable switching operation (over 100 times of repeatable cycling). Heterogenous material combination often generates interfacial issues, however, heterostructure on large area was successfully fabricated exploiting advantages of each materials; low leakage current of h-BN and repeatable switching of WSe\(_2\). These improved characteristics were also estimated with several devices fabricated in same process bawe could achieve high-quality interface by using our quasi-dry transfer process. We recently developed a quasi-dry transfer, allowing us large-scale 2D materials with pristine interface because the quasi-dry transfer does not accompany any chemical contamination at the interface during the process. Thus, we successfully engineer material combination with maintaining the properties of each material for stable switching behavior. We strongly believe that WSe\(_2\)/h-BN heterostructures by the quasi-dry transfer has a strong potential for stable memristors.
Optically Coupled 2D/Organic Synaptic Device for Simplified Weight in Neuromorphic Computing

Beom-Seok Kang1, Ji-Hye Lim2, Jin-Hong Park2 and Jeehwan Kim1; 1Massachusetts Institute of Technology, United States; 2Sungkyunkwan University, Korea (the Republic of)

Neuromorphic computing supported by synaptic devices, which mimics the structure and functions of neural networks at the hardware-level, is one of emerging candidates for the next generation cognitive computing. Although synaptic devices in artificial neural networks (ANN) feature small device footprints and reduced energy consumption, it has been challenging to find an optimal synaptic device for large-scale neuromorphic computing due to stochastic and unpredictable nature in conductance update. Also, for the synaptic device to be used as analog synaptic weight facilitating a simple multiply-accumulate (MAC) operation, it is required to have two synaptic devices to represent one weight since synaptic devices merely possesses positive conductance value, which can be expressed as weight = G+ - G-.

Here, we propose a 2D/Organic heterostructure synaptic device coupled with an optical source, which enables to solely represent each weight in neural networks without having two synaptic devices. Our key approach for the function is controlling reverse current by engineering i) symmetry of Metal-WSe2 contact and ii) input pulse characteristics and postsynaptic voltages. We have figured out that amount of photo-generated carrier diffusion is proportional to the symmetry of Metal-WSe2 contact. Less symmetric contact causes more asymmetric photo-generated carrier diffusion, making the reverse current and negative conductance possible. Also, direction of the diffusion from WSe2 to Metal is opposite to the direction of carrier injection from metal to WSe2, thus, balancing of them offers a way to control the polarity of conductance. By changing input pulses and postsynaptic voltage, we successfully balanced two types of carrier flows and gradually changed conductance states from negative to positive, which can be directly used as a weight without constituting conventional weight = G+ - G- cell. We believe that optically coupled 2D/Organic synaptic device will further revolutionize the current neuromorphic computing system in the way that it cuts the size of crossbar circuit in half and thus provides an energy-efficient platform for post von Neumann Computing.

Towards Large Scale MoTe2 Layers Grown by MBE

Zuzanna W. Ogorzalek1, Adam Kwiatkowski1, Krzysztof Korona1, Slawomir Kret2, Krzysztof Morawiec3, Johannes Binder1, Dariusz Wasik1, Jakub Polaczynski1, Bartłomiej Seredynski1, Janusz Sadowski1,2,3, Wojciech Pacuski1 and Marta Gryglas-Borysiewicz1; 1University of Warsaw, Poland; 2Institute of Physics PAS, Poland; 3Lund University, Sweden

MoTe2 belongs to transition metal dichalcogenides - materials, which have been intensively studied for the last few years. They provide a rare occasion to test relativistic physics with low energy excitations in condensed matter experiments. The unusual properties of the charge carriers, which are chiral, helical and have a linear E(k) dependence lead to many interesting physical phenomena such as chiral anomaly [1], extremely large positive magnetoresistance [2, 3, 4], or the planar Hall effect [1, 5]. The most commonly used methods to obtain MoTe2 layers, beside exfoliation from natural crystals [6] are the flux method [3, 4, 7] and chemical vapour transport [8]. Currently, Molecular Beam Epitaxy (MBE) technique comes into play [9, 10, 11, 12] giving the perspectives to combine different phases of MoTe2 and to grow heterostructures and hybrid structures.

In this paper we present the results of structural, optical and transport investigations of MoTe2 thin layers. The samples were prepared on Al2O3 and SI-GaAs [111B] substrates which both, at the appropriate growth temperature, allow us to obtain 2H and 1T’ polytypes of MoTe2 (as evidenced with Raman scattering) as well as other phases, e.g. Mo6Te6. Controlling the growth conditions allows to modify sample morphologies from regular 2D planes, through 3D precipitations to nanowires as studied in-situ with RHEED images, and ex-situ by TEM and SEM microscopy. Transport measurement were performed on large, millimeter-size Hall bars with metal (Ti/Au or In) contacts deposited via shadow masks. The resistance of the samples was measured in the temperature range 300 K – 1.5 K revealing either an increase of the resistivity for semiconducting samples or a very weak temperature dependence, showing significant disorder for the samples with the metallic phases. In the latter case, for high concentration (n ~ 1●1016 cm-2) several monolayer sample, the low value of carrier mobility (2 cm2/Vs) and a linear magnetoresistance up to 12 T revealed sample inhomogeneity. Furthermore, we have observed that the poor stability of the MoTe2 layers can be improved by different capping layers.

**Performance Study of van der Waals Density Functionals Using Group-IV Monochalcogenides**

NFN Sri Ranga Jai Likith and Cristian V. Ciobanu; Colorado School of Mines, United States

Within density functional theory (DFT), several methods have been developed in order to capture van der Waals interactions. Some popular density functionals used to study systems where van der Waals forces play an important role in determining the structure are the optB86b, optB88, PBE+D2, PBE+D3, PBE+TS, and PBE+TS+SCS functionals. In this study, we screen compounds of the form AX (where A: C, Si, Ge, Sn, Pb; X: S, Se, Te) in 6 different prototype van der Waals layered quasi-2D structures by first performing structural relaxation, then checking for dynamic stability for those compounds that remained quasi-2D after the relaxation, and then computing the piezoelectric tensor values (eij) for the dynamically stable structures. We perform this screening using each of the 6 van der Waals density functionals mentioned above, and thus, compare the performance and reliability of these functionals. Our results will aid future computational studies in choosing the best van der Waals density functional based on specific needs and resources at hand.

**FF01.21.14**

**Variable Temperature STM Study of Black Phosphorus**

Ben St Laurent, Hannah Bell, Christine Caputo and Shawna Hollen; University of New Hampshire, United States

While the high carrier mobility and tunable band gap of black phosphorus make it promising for device applications, a better understanding of native defects is needed for black phosphorus to reach its full potential. The native defects, which are primarily phosphorus vacancies, alter the electronic properties and expedite the degradation of black phosphorus in air. This poster will present a series of scanning tunneling microscopy experiments studying how the surface of black phosphorus changes with temperature. Varying the temperature for imaging allows us to investigate defect mobility in the lattice. The vacancies have been theorized to be highly mobile at room temperature, but become locked into place as the temperature drops. This study has also led to the observation of 5nm stripes on the surface. These stripes are periodic, and their prominence has a strong dependence on both temperature and tunneling bias.

**FF01.21.15**

**Hyperspectral Analysis of MoS2/WS2 Heterostructures**

Peter Lisker and Erik Einarsson; University at Buffalo, United States

Hyperspectral imaging is a powerful tool to connect spectral and spatial information. Raman spectroscopy is widely used to obtain rich information about 2D materials. Here we report on the combination of these methods. We grew transition metal dichalcogenide (TMD) heterobilayers of WS2 on top of MoS2 by chemical vapor deposition (CVD). We then used Raman mapping to create a hyperspectral image of the pristine heterobilayer, in which each pixel contains an entire Raman spectrum. Principal component analysis (PCA) of the hyperspectral data revealed subtle changes in the characteristic MoS2 E1g and A1g peaks, which can be used to characterize the number of layers. Based on our analysis, we identified MoS2 monolayer regions, WS2 monolayer regions, and MoS2/WS2 heterobilayers. This not only confirmed the direct growth of heterobilayers by CVD, but also revealed that WS2 preferentially...
grows on monolayer regions of MoS2, but not on multilayer regions.

**FF01.21.16**  
**Degradation Study of WSe2 via Raman Spectroscopy and Photoluminescence Imaging** Makarand R. Wadagave and Burcu Ozden; The Pennsylvania State University, United States

Semiconducting two-dimensional materials (2DMs) such as WSe2 (Tungsten Diselenide) have attracted significant attention due to their unique optoelectronic properties. However, such materials can be vulnerable to optical degradation under ambient conditions, yet a systematic study does not exist in the literature. The degradation study of WSe2 is essential to understand the applications of these materials in non-specialized operation conditions. In this study, we investigate the degradation of free-standing WSe2 due to humidity under ambient conditions by performing Raman spectroscopy and photoluminescence imaging over a 6-month period between June 2019 and December 2019. The findings of this study will provide fundamental insight into the degradation of WSe2 and inspire their application in optoelectronics under harsh conditions.

**FF01.21.17**  
**Simple Liquid Phase Intercalation and Exfoliation of MoO3 Rods into Nanosheets and Nanotubes and Conversion to MoS2** Pavithra B and Ravishanakar Narayanan; Indian Institute of Science, India

Two dimensional (2D) nano-materials are interesting due to their distinct properties like high specific surface area which make them suitable for catalytic and many other applications. One of the well-known layered oxides, MoO3 exists in stable orthorhombic a-MoO3 structure which involves stacking of MoO6 octahedra bilayers along the [010] direction. Electronic and optical properties of layered MoO3 can be tuned via ion or molecule intercalation between the layers, followed by exfoliation to form 2D nanosheets. A simple room temperature method for the exfoliation of MoO3 has been developed, which involves the intercalation of oleylamine. Starting from MoO3 rods, different systems and morphologies like MoO(3-x) – Oleylamine hybrid, MoO(3-x) nanosheets and MoO(3-x) nanotubes have been produced. α-MoO3 rods have been synthesized by the hydrothermal method as already reported. 2D-MoO3 layers have been realized via liquid phase exfoliation of Oleylamine intercalated MoO(3-x) hybrid. Following that, exfoliated sheets roll up to form nanotubes upon removal of Oleylamine. Transmission Electron Microscope (TEM) has been extensively used to understand the morphology and structure of initial rods, the intermediate stages of intercalation, hybrid structure, completely exfoliated MoO3 sheets and tubes. Structural and compositional information have been also obtained using Scanning Electron Microscopy, X-ray photoelectron spectroscopy, Raman spectroscopy and X-Ray Diffraction. The intercalation of Oleyamine into the Van der Waals gap of MoO3 rods results in the reduction of Mo to +5 state and creation of oxygen vacancies to produce MoO(3-x)–amine hybrid. The resulting sheets and tubes are also of non-stoichiometric, amorphous MoO(3-x). The amorphous MoO(3-x) sheets and tubes have been heated in ex situ in a furnace in both oxygen and inert atmosphere. MoO(3-x) recrystallizes to form orthorhombic, stoichiometric MoO3 at around 500°C in oxygen atmosphere. Electrochromic properties of amorphous MoO(3-x)–oleylamine hybrids were studied. Furthermore, Au/MoO3 hybrids have been obtained via the wet-chemical growth of ultrathin Au nanowires on the exfoliated sheets. We have converted the MoO3 rods into MoS2, a widely used catalytic material, by a comparatively low temperature method. Transmission Electron Microscopy study shows that the MoS2 spheres formed comprises of 4-8 ultrathin nanosheet stacked together. The mechanism of conversion from MoO3 to MoS2 has been understood by a series of time-dependent experiments. Since they contain a lot of exposed edges which are active towards catalysis, this material can act as a very good candidate as an electro-catalyst for H2 evolution reaction.

**FF01.21.18**  
**GeS Field Effect Transistor for High Temperature Applications** Srinivasa R. Tamalampudi1, Raman Sankar2, Ibraheem Almansouri3, Jin-You Lu1 and Matteo Chiesa1; 1Khalifa University of Science and Technology, United Arab Emirates; 2Academica Sinica, Taiwan; 3Laboratory for Energy and NanoScience (LENS), United Arab Emirates

Intrinsic crystal defects play a major role in tailoring the electrical and optical properties of two-dimensional (2D) materials. Here, we probe the impact of planar crystal defects on the electrical characteristics of germanium sulfide (GeS) field effect transistor (FET) at different operating temperatures varying from 300 to 575 K. Our results show that the measured mobility of the GeS field effect transistor was 0.04 × 10–3 cm2/(V s) at 300 K, and this value reached 58 × 10–3 cm2/(V s) at 575 K. It is important to note that the mobility of GeS FET at elevated temperatures
in this study is greater than the mobilities in the recently reported GeS photodetector studies. Furthermore, evidence that the threshold voltage ($V_{th}$) decreases and carrier concentration increases with increasing temperature in the GeS channel is provided. We demonstrate an Arrhenius-like relation of the carrier transport as a function of temperature, a behavior that we attribute to nearest-neighbor-hopping (NNH) conduction. The existence of planar defects is revealed using transmission electron microscopy (TEM) while density functional theory (DFT) analysis supports the hypothesis that the formation of localized energy states governs hopping conduction. This study reports hopping conduction at the temperature above 300 K for the first time, whereas previous investigations on 2D materials have reported a hopping mechanism in the low-temperature (<200 K) range. These observations give insight into the fundamental charge conduction mechanisms at high temperature in other 2D materials systems which are expected to aid in the development of applications for harsh environments.

**FF01.21.19**

**Wafer Scale Synthesis of Transition Metal Telluride Thin Films**

David Hynek$^{1,1}$, Ben Davis$^2$, John M. Woods$^{1,1}$, Milad Yarali$^{1,1}$, Joshua Pondick$^{1,1}$, Pengzi Liu$^{1,1}$, Sajad Yazdani$^{1,1}$, Yujun Xie$^{1,1}$, Lei Wang$^1$, Serrae Reed$^{1,1}$, Nicholas Strandwitz$^1$ and Judy Cha$^{1,1}$; $^1$Yale University, United States; $^2$Lehigh University, United States

Two-dimensional materials have attracted much attention over the past decade due to their unique van der Waals (vdW) interlayer bonding that gives rise to interesting physical phenomena that can be accessed through monolayer isolation and synthesis of heterostructures. Recently, transition metal tellurides of the form XTe$_2$ (X: Mo, W) have shown novel electronic properties, such as large magnetoresistance$^1$, superconductivity$^{2,3}$, quantum spin Hall states$^4$, and the predicted type-II Weyl semi-metal state$^{5,6}$, which are attractive for applications ranging from chemical sensing to quantum computing. One of the biggest challenges to vdW bonded materials is the lack of industrially scalable synthesis methods to create large scale, stable structures on substrates that are easily integrable in modern microfabrication processes.

Atomic layer deposition (ALD) is an industrially scalable technique that produces epitaxially grown films with uniform stoichiometry and thickness. In this work, ALD is used to deposit transition metal oxide films, which are then converted into wafer-scale transition metal tellurides using a vapor-phase annealing process. By controlling the reaction parameters and choice of substrates, we show that control over film morphology and phase can be achieved, leading to substantial improvements in crystalline quality. Additionally, we developed an *in situ* encapsulation layer for the synthesized transition metal tellurides and studied the effects of the encapsulation layers on growth kinetics and protection against oxidation.

**FF01.21.20**

**Slot Antennas for Graphene Mid-IR Photodetectors**

Jordan A. Goldstein and Dirk Englund; Massachusetts Institute of Technology, United States

Mid-infrared imaging has a wide range of applications, such as night vision, surveillance, and remote chemical sensing. However, the current options for mid-IR imagers leave much to be desired, with cooled detectors offering excellent performance at the cost of power, size and system complexity, while uncooled bolometers struggle with slow response times and low detectivity. Graphene is a promising alternative mid-IR sensitive optoelectronic material due to its broadband absorption, strong electrical response and wide process compatibility, but its low absorption for normally incident light poses a challenge in designing high efficiency devices. We propose to couple the graphene with metal slot antennas, compact resonators which capture specific wavelengths of light and significantly enhance the free space to graphene light coupling efficiency. Additionally, since the antennas’ footprints are much smaller than their absorption cross sections, multiple
antennas with different resonant frequencies can be placed in close proximity, allowing broadband and spectrally selective photodetection. Here we present simulations and a model confirming the validity of our approach as well as measurements of slot antennas demonstrating consistency between simulated and measured optical properties. We will also discuss how the antenna absorbers can be engineered into actual photodetectors as well as paths forward for integrating the technology with electronics. This research paves the way towards establishing graphene as a viable mid-IR sensing technology, improving upon the response time of bolometers and adding spectral selectivity while maintaining similar detectivities.

FF01.21.21
Synthesis, Crystal Growth and Characterization of Tetrel-Pnictide van der Waals Materials Justin Mark1,2, Brennan McBride1, Bingheng Ji1, Shannon Lee1,2 and Kirill Kovnir1,2; 1Iowa State University of Science and Technology, United States; 2Ames Laboratory, United States

Elemental P and As crystallize in layered structures; exfoliation of these structures using tape gave rise to novel 2D materials, phosphorene and arsenene. When pnictogens, such as P and As, are combined with light tetrels, Si and Ge, the resulting binary compounds are layered van der Waals materials. Strong covalent tetrel-pnictide bonding is found within the layer. The layers are terminated by the three-coordinated pnictogen atoms which have an electron lone pair pointed towards the electron lone pairs on atoms terminating neighboring layers. The repulsion of the electron lone pairs is responsible for the two-dimensional crystal structure with weak van der Waals type interactions between the layers. Strongly anisotropic bonding makes such materials not only easy to exfoliate but also stable against oxidation, unlike phosphorene-like materials. Strongly anisotropic and fascinating properties were predicted computationally and observed experimentally for this class of materials and their individual layers. Tetrel-pnictides have been shown to have several promising applications which include thermoelectrics, batteries, photovoltaics, optics, and superconductivity. To further expand the boundary of known tetrel-pnictide systems and their characterization, a deeper understanding of their synthesis and crystal growth is required. In this work we specifically focus on binary and ternary 2D tetrel-pnictide synthesis and characterization. Solid state synthesis involving elements, binary precursors, and metal flux has yielded several new 2D tetrel-pnictide phases, which exhibit complex structural motifs, inherently influencing their physical properties. Further complexity can be added to these structures through doping of framework atoms or cations in the layers, allowing for the tuning of desired properties.

FF01.21.22
Two-Dimensional MoTe2/Pentacene as Highly Efficient Type II Heterostructure Yu Jin Jang, Jin Cheol Park, Minh D. Tran, Meeree Kim, Hyoyoung Lee, Ji-Hee Kim and Young Hee Lee; Sungkyunkwan University, Korea (the Republic of)

Atomically-thin transition metal dichalcogenides (TMDs) have been recognized as a promising platform for the next generation photovoltaics on the basis of a tunable bandgap, large absorption coefficients, weak exciton-phonon coupling, and short distances for carrier extraction. However, photovoltaic efficiencies which have been practically obtained to date from various TMD heterostructures remained below 5% and this raises the question of a new design of two-dimensional (2D) heterostructures in terms of composition or configuration. Herein, we propose to construct a type II heterojunction between MoTe2 and pentacene as n- and p- type materials, respectively. Two semiconductors in the heterostructure produced excitons under illumination ranging from visible (Vis) to near-infrared (NIR) light and the staggered band alignment facilitated the charge separation at the interface. By carefully monitoring the ground state bleach (GSB) and photo induced absorption (PIA) signals of the heterostructure as a function of time with transient absorption spectroscopy (TAS), we found that the number of electrons and holes generated and extracted from the heterostructure was increased over the single materials and intervalley scattering occurring on longer timescales confirmed the charge transfer between two layers. This observation will provide a clue to the fabrication of 2D photovoltaic devices which breaks the efficiency limit.

FF01.21.23
Aligned Growth of Monolayer WS2 with Engineered Band Structure and Morphology Derived by Quartz Substrate Tianran Li, Jingwei Wang and Chun Cheng; Southern University of Science and Technology, China

Controlled growth of two-dimensional (2D) transition metal dichalcogenides (TMDCs) is important for the
applications in next-generation electronics and optoelectronics. Apart from the growth conditions, the growth substrate plays a crucial role such as in orientation regulation, band structure and morphology engineering. In this work, we report aligned growth of monolayer tungsten disulfide (WS₂) with engineered band structure and morphology on single crystal quartz substrate. The bandgap of epitaxial WS₂ was significantly expanded due to the built-in strain. By decreasing the temperature, the increased strain could further modulate the band structure and a direct-indirect transition in monolayer WS₂ could be achieved at liquid nitrogen temperature. Moreover, the unique lattice arrangement of quartz facilitates the anisotropic diffusion of precursor monomer and results in trapezoidal-like WS₂ which is confirmed by our density functional theory simulation. This work not only contributes to the controlled growth of TMDCs but also provide an effective approach to engineer the band structure and morphology of 2D materials.

Strong Carrier-Induced Electric Double Layer for Engineering Electronic Properties of Indium Selenide Field-Effect Transistors Chih-Yi Cheng¹, Wei-Liang Pai², Yi-Hsun Chen¹, Shao-Yu Chen¹, Raman Sankar², Fang-Cheng Chour², Chun-Wei Chen², Chi-Te Liang² and Wei-Hua Wang¹; ¹Academia Sinica, Taiwan; ²National Taiwan University, Taiwan; ³Monash University, Australia

Two-dimensional (2D) semiconductors feature high surface-to-volume ratio, offering an ideal platform for exploring unique surface and interfacial interactions [1]. An ionic liquid (IL) can be used in an electrostatic gating technique for effectively achieving high carrier density regime in 2D semiconductors by creating an electric double layer (EDL) at the semiconductor/IL interfaces [2-3]. The EDL arises when an IL gate voltage is applied and mobile ions accumulate at the interfaces, which attract charge carriers to the interface. However, it is rarely discussed whether the charge carrier confined in atomically thin 2D semiconductors can alter the electrostatic coupling at the solid/liquid interfaces. In this work, we systematically study the electrostatic coupling at the interface between the layered indium selenide (InSe) and the IL. We observe an anomalous temperature dependence of the transport behavior when the IL undergoes phase transition. Interestingly, the conductivity of the InSe devices interfaced with the IL enhances by a factor of 2 and the field-effect mobility reaches 1,200 cm²/Vs when the IL is around glass transition point (T_g). By the correlation of capacitance and transport behavior, we attribute the carrier density enhancement to a strong carrier-induced EDL when the ion motion greatly decreases around T_g. The observation of the distinct carrier-induced EDL in the InSe devices suggests novel functionalities to control the electronic transport in the 2D-semiconductor/IL hybrid systems.

FF01.21.25
Synthesis of MoS₂ on Epitaxial Graphene by Chemical Vapor Deposition Gabriel V. Soares¹,², Tais O. Feijo¹,³, João M. Lopes¹ and Claudio Radtke¹; ¹UFRGS, Brazil; ²PGMICRO-UFRGS, Brazil; ³Paul-Drude-Institut für Festkörperelektronik, Leibniz-Institut im Forschungsverbund Berlin, Germany

Stacking 2D crystals on the top of each other allows for the creation of van der Waals (vdW) heterostructures with new properties and functionalities[1]. As an example, MoS₂ (semiconductor) and graphene (conductor) can be combined to form metal-semiconductor junctions exhibiting an atomically thin Schottky barrier [2]. Moreover, the MoS₂/graphene structure can be used in hydrogen evolution reaction for clean energy applications [3]. However, before this material system can be implemented into different applications, it is mandatory to achieve its controlled synthesis at wafer-scale. For this, gaining an in-depth understanding of the mechanisms underlying 2D monolayer growth, as well as the effects of processing of the resulting heterostructure on its physico-chemical properties is crucial. The aim of this work is to investigate the basic mechanisms underlying the growth of MoS₂ by chemical vapor deposition (CVD) on epitaxial graphene (EG) on SiC, taking into account the influence of the number of graphene layers, and the MoS₂ growth temperature. MoS₂ was grown on EG templates which were synthesized via Si sublimation [4] on on-axis and off-axis SiC(0001) substrates. The use of SiC substrates with different miscuts permits to obtain different graphene coverage over the (0001) surface terraces (monolayer coverage for on-axis SiC; few-layer coverage for off-axis SiC). The MoS₂ growth is done in a CVD reactor using solid precursors of MoO₃ and S. Growth temperatures within the 500-700°C range with a fixed 40 min long temperature ramp were used.
Raman spectroscopy, Near edge X-ray Absorption Fine structure (NEXAFS), X-ray photoelectron spectroscopy (XPS), and atomic force microscopy (AFM) were used to characterize the MoS$_2$/EG/SiC(0001) samples. Interestingly, we will show that MoS$_2$ prepared on few-layer thick EG on off-axis SiC(0001) at different temperatures exhibits an improved surface morphology with the growth proceeding mostly in a layer-by-layer manner without the formation of 3D particles. The latter effect is usually observed when MoS$_2$ is performed on monolayer-thick EG, and it is probably related to a higher atomic corrugation of monolayer EG in comparison to few-layer EG. The EG corrugation as well as the MoS$_2$ crystalline structure for different samples were probed by NEXAFS measurements of the S(L) and C(K) edges. They were complemented by XPS analyses, which allowed to determine the chemical environment of C, Mo and S in the MoS$_2$/graphene heterostructures.

FF01.21.26
Rapidly Dissolvable Transient Field-Effect Transistors Based on Phosphorene Min-Kyu Song$^{1,1}$, Seok Daniel Namgung$^{1,1}$, Taehoon Sung$^{1,1}$, Jae hun Lee$^{2}$, Misong Ju$^{2}$, Ki Tae Nam$^{2}$, Yoon-Sik Lee$^{2}$ and Jang-Yeon Kwon$^{1,1}$;
$^{1}$Yonsei University, Korea (the Republic of); $^{2}$Seoul National University, Korea (the Republic of)

Transient electronics has received great attention as new generation of human implantable device that physically disappear after operation time in physiological condition. Many applications including biosensors, RF antennas and memories have been reported since its first demonstration in 2012. However, dissolution rate of silicon nanomembrane which has mostly been used as an active material in transient devices is quiet low ranging from a few days to weeks. In order to minimize physical damage caused by residue from dissolvable devices, dissolution time of the devices should be minimized. Phosphorene, atomically thin layers of black phosphorus, has been promised as a promising candidate for a new semiconductor material due to its outstanding intrinsic properties including high mobility and tunable bandgap. In addition, phosphorene is attractive for biomedical applications because of its nontoxicity of final degradation products, phosphoric acid. We found that phosphorene dissolves rapidly in physiological condition due to its high reactivity to water and oxygen. From this context, we suggested phosphorene as an active material for transient electronics. In this work, we fabricated biodegradable and biocompatible field-effect transistors based on phosphorene that rapidly disappears in biofluid within 36 hours. Combined use of phosphorene, peptide insulator, and molybdenum enables rapid dissolution of the devices. The devices exhibit high field effect mobility up to 468 cm$^2$V$^{-1}$s$^{-1}$ which is over 400 times higher than that of ZnO based field effect transistors and comparable to that of Si NM based field effect transistors.

We examined biodegradability of phosphorene using AFM and Raman spectroscopy. Dissolution rate of phosphorene was found to be 1.65 nm/hour in phosphate buffered saline (pH 7.4, 37 °C), which is about 8.8 times faster than that of Si nanomembrane in the same condition. Phosphorene with thickness of 30–40 nm disappears within 1 day due to its highly reactive nature to oxygen which has been regarded as a nettlesome barrier of phosphorene. Furthermore, we assessed the cytotoxicity of phosphorene by LIVE/DEAD viability assay to verify its feasibility to be applied in biomedical devices. After incubated with phosphorene, NIH 3T3 fibroblast cells showed viability of over 90 % up to phosphorene concentration of 50 μg/mL$^{-1}$. In conclusion, we not only realized the transient device that meets two criteria, fast dissolution and high performance, but opened new application possibility of phosphorene to bio implantable electronic devices platform.

FF01.21.27
Versatile Doping of Black Phosphorus and Functional Junction Structure Formation Jingyuan Jia and Tun Cao; Dalian University of Technology, China

Black phosphorus (BP) was recently rediscovered as being a layered two-dimensional (2D) semiconductor material that is potentially useful as the active material in future nanoscale devices. The electronic properties of atomically thin BP can be controlled by external gating or by chemical doping. Here, we demonstrate the versatile doping control of black phosphorus (BP) using an ionic liquid (EMIM:TFSI) as a surface charge acceptor for a wide range of electronic and optoelectronic device applications. BP following EMIM:TFSI doping achieves a high hole density of up to $10^{13}$ cm$^{-2}$ without impurity injection, which represents a degenerate doping level. Furthermore, this doping effect can be reversibly removed through immersion in isopropanol and the electrical performance of BP devices is
able to recover and approach the pristine state (cyclic process). Using a selective-area doping technique, both lateral junction structures and self-aligned source/drain BP field-effect transistors (FETs) are fabricated through a poly(methyl methacrylate) pattern method. The BP lateral junction devices show ideal rectifying behavior. Self-aligned BP FETs with channel lengths as low as 60 nm are presented, using a process similar to the conventional CMOS gate first process. Such FETs demonstrate the potential for fabricating nanoscale BP electronic devices.

**Controlled Synthesis of Vertically-Oriented MoS2 Flakes by Chemical Vapor Deposition—Morphological Evolution and Growth Mechanism**  
Talal Al Tahtamouni and Fadi Kamand; Qatar University, Qatar

Understanding the growth mechanism and morphological evolution is the key to control the growth of layered two-dimensional materials using chemical vapor deposition (CVD) approach. Herein, we report the CVD synthesis of vertically-oriented MoS2 flakes from the conventional precursors of MoO3 and S powder. Using different amounts of S powder in the CVD process, different morphologies and structures of MoS2 were obtained. A hypothesis based on two competing pathways of reactions is proposed to explain the growth mechanism and morphological evolution of the MoS2 nanostructures. In addition, catalytic activities of the vertically-oriented MoS2 flakes are tested for photoelectrochemical water splitting performance. Our results open the door to promote the process for the design of other transition metal dichalcogenide materials or complex structures in various applications.

**FF01.21.29**

**2D Transition Metal Dichalcogenides (TMDs) Nanopatterning by Block Copolymer Lithography**  
Taeyeong Yun, Inho Kim and Sang Ouk Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Structure engineering method is highly necessary for the various applications of 2D transition metal dichalcogenides (TMDs). We demonstrate edge-exposed 2D polycrystalline MoS2 nanomesh thin film through conventional block copolymer (BCP) nanopatterning. Metal nanomesh is deposited by e-beam evaporation on BCP template and then, MoS2 nanomesh thin film is directly fabricated through sulfurization of pre-deposited molybdenum nanomesh without any etching process. Our approach could be easily applicable not only to other metal sulfides and metal oxides but also to other structures of TMD thin film such as nanodots, nanorods array through various BCP nanopatterning. Because edge site of MoS2 is active for NO2 sensing, our edge-exposed MoS2 nanomesh represents 7-fold enhanced sensitivity to NO2 gas molecule compared to film structure as well as shows superior reversibility even under 80 % relative humidity environment. This structure engineering method could expand a novel applications of 2D TMD materials with optimal structure controllability.

**FF01.21.30**

**Dose-Dependent Proton Beam Irradiation Effect on WSe2 Ambipolar Field Effect Transistors**  
Jiwon Shin1, Kyungjune Cho1, TaeYoung Kim1, Jinsu Pak1, Jae-Keun Kim1, Seungjun Chung2, Woong-Ki Hong3 and Takhee Lee1; 1Seoul National University, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of); 3Korea Basic Science Institute, Korea (the Republic of)

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) have gained significant attention as one of the candidates for next-generation semiconductor materials due to their unique mechanical and electronic properties. For applications in various integrated devices, it is important to control the properties of 2D TMDs materials. In this work, the irradiation effect of high energy proton beams on tungsten diselenide (WSe2) ambipolar field-effect transistors(FETs) were investigated. We measured the electrical characteristics of the fabricated WSe2 FETs before and after the 10 MeV proton beam irradiation with different doses of $10^{12}$, $10^{13}$, $10^{14}$, and $10^{15}$ cm$^{-2}$. For low dose conditions ($10^{12}$, $10^{13}$, and $10^{14}$ cm$^{-2}$), the threshold voltages shifted to the negative gate voltage direction, and the current in the hole and electron accumulation regimes decreased and increased, respectively. However, the trends were opposite for the high dose condition ($10^{15}$ cm$^{-2}$); the threshold voltages shifted to the positive gate voltage direction, and the current in the hole and electron accumulation regimes increased and decreased, respectively. Also, we measured the physicochemical properties of the WSe2 flakes by X-ray photoemission spectroscopy (XPS) and Raman spectroscopy. There was no noticeable difference in XPS and Raman spectra on the WSe2 flakes before and after the proton beam irradiation. These phenomena can be explained by the combined effect of proton irradiation-induced traps and the applied gate bias condition. Specifically, irradiation-induced positive oxide traps in SiO2 dielectric play a role in enhancing electron accumulation and reducing hole accumulation in the WSe2 channel, whereas the irradiation-induced holes near the WSe2/SiO2 interface act as electron trapping sites, with enhancing
hole accumulation and reducing electron accumulation in the WSe₂ channel. This study may provide a method to control the electrical properties of WSe₂ FETs through proton beam irradiation. Furthermore, it is hoped that this study will contribute to a deeper understanding of the influence of high-energy proton beams on ambipolar WSe₂-based nanoelectronic devices and be helpful for the application of the TMD-based devices in harsh radiation environments such as space.

Selective Defect Formation in Hexagonal Boron Nitride by Boron Gettering Chemical Vapor Deposition

Irfan Haider Abidi¹, Zhengtang Luo² and Barbaros Oezylmaz³; ¹National University of Singapore, Singapore; ²The Hong Kong University of Science and Technology, Hong Kong

Luminescent defect-centers in hexagonal boron nitride (hBN) have emerged as a promising 2D-source of single photon emitters (SPEs) due to their high brightness and robust operation at room temperature. The ability to create such emitters with well-defined optical properties is a cornerstone towards their integration into on-chip photonic architectures. Here, we report an effective approach to fabricate hBN single photon emitters (SPEs) with desired emission properties in two isolated spectral regions via the manipulation of boron diffusion through copper during atmospheric pressure chemical vapor deposition (APCVD)—a process we term gettering. Using the gettering technique we deterministically place the resulting zero-phonon line (ZPL) between the regions 550-600 nm or from 600-650 nm, paving the way for hBN SPEs with tailored emission properties across a broad spectral range. Our ability to control defect formation during hBN growth provides a simple and cost effective means to improve the crystallinity of CVD hBN films, and lower defect density making it applicable to hBN growth for a wide-range of applications. Our results are important to understand defect formation of quantum emitters in hBN and deploy them for scalable photonic technologies.

Broadband Photodetector Based on MoS₂ Nanostructures—2D MoS₂/1D WS₂ and 2D MoS₂/3D Polyaniline for High Photoresponsive Properties

Manika Khanuja and Nahid Chaudhary; Jamia Millia Islamia, India

2D materials emerged as a new class of high-performance semiconductors for optoelectronics but with limited photoresponsivity. Herein, we have successfully synthesized pure MoS₂ nanosheets, MoS₂-Polyaniline (PANI) hybrid structure and 2D MoS₂/1D WS₂ heterostructure for their application in photodetector. The morphology was confirmed using Transmission Electron Microscopy (TEM) and Scanning Electron Microscopy (SEM) revealing nanosheets of MoS₂, hybrid structure of MoS₂-PANI and 2D/1D MoS₂/WS₂. The interlayer spacing of MoS₂ in MoS₂-PANI hybrid structure is increased from 0.68 nm to 0.75 nm. The samples were further characterized using X-Ray Diffraction (XRD), Fourier Transform Infrared Spectroscopy (FTIR), Uv-vis and Raman spectroscopy. The obtained samples were drop casted over silicon substrate followed by deposition of silver electrode to fabricate optical sensor. The fabricated optical sensors were studied at three different wavelengths of laser (λex): 635 nm (red), 785 nm (infra-red) and 1064 nm (near infra-red). The calculated photoresponsivity (Rp) of MoS₂ nanosheets was found to be 23.8 µA/W at laser wavelength of 635 nm (red), whereas MoS₂-PANI hybrid structure showed maximum (Rp) = 25 A/W at 785 nm (infra-red). The optical response of 2D MoS₂/1D WS₂ based photodetector showed (Rp) in a broadband range from the visible to the near-infrared (600-1065 nm, yield a (Rp) = 15 µA/W and high specific detectivity (D*) = 24 x 10⁶ jones at λex = 785 nm). The photoresponsive properties of all samples were also studied as a function of optical power density and follows the simple power law [1-2].

Three-Dimensional Architected Graphene Lattices from Additively-Manufactured Polymer Templates

Juveiriah M. Ashraf, Jing Fu, Kin Liao, Vincent Chan and Rashid K. Abu Al-Rub; Khalifa University of Science and Technology, United Arab Emirates

Two-dimensional (2D) materials offer unique properties as atomically thin layers and, when structured to be in a three-dimensional (3D) form, they exhibit exceptional material qualities. Graphene is one such material with
exceedingly novel properties with 3D porous graphene foams adding to their functionality. However, controlled synthesis of 3D foams from 2D materials into engineered structures is currently still a challenge. With the recent advances in many key technological fields, the need for lightweight and multi-functional materials is becoming highly imperative. Triply periodic minimal surfaces (TPMS) are edge-free cellular architectures with locally net zero curvature that divide a volume into two non-intersecting spaces. Their low density and yet high surface area have enabled them to be used as lightweight cellular materials, heat sinks, catalytic converters, and feed spacers. Integrating graphene into TPMS to form 3D architected lattices of the 2D material is expected to offer unprecedented thermal, electrical, and mechanical properties that could be exploited in a spectrum of engineering applications. Since processes like chemical vapor deposition (CVD) and atomic layer deposition (ALD) are highly substrate-, temperature- and shape-specific, it is difficult to synthesize 3D foams or coat complex lattice structures of TPMS with 2D materials like graphene using these techniques. For example, there is a minimum pore size needed to create free-standing graphene after removing the metal template used in CVD processes, otherwise the graphene foam collapses. Conformal or step coverage is also an issue in most physical vapor deposition (PVD) process like thermal evaporation. In this project, a facile, scalable and lab environment-friendly, synthesis method for novel 3D graphene foams has been developed using additively-manufactured polymer-based TPMS as the initial sacrificial template. Stereolithography (SLA) was employed to 3D print high resolution Gyroid (a type of TPMS) cubes of length 2 cm, which were dip-coated with graphene oxide (GO) solution followed by drying and thermal etching of the polymer scaffold. Scanning electron microscopy (SEM) and micro computed tomography (micro-CT) scans showed high shape retention of the complex TPMS architectures and low shrinkage after burnout of the polymer template, rendering the developed coating process to be used for structures of any morphology with a large range of pore sizes. Chemical reduction of the GO foams was done by adding one volume percent of hydrazine hydrate to the starting GO solution, and this was verified by an X-ray diffraction (XRD) peak at 20° along with a Raman response at 1358 cm\(^{-1}\) (D peak), 1591 cm\(^{-1}\) (G peak) and 2696 cm\(^{-1}\) (2D peak) which correspond to reduced graphene oxide (rGO). The 3D graphene foams have been tested for their thermal, electrical and mechanical properties, and evaluated for their electromagnetic interference (EMI)/shielding capability.

**Thickness-Dependent Optical Bandgap and Electrical Transport Properties in InSe Thin Films Grown by Pulsed-Laser Deposition** Dingheng Zheng, Junichi Shiogai, Kohei Fujiwara and Atsushi Tsukazaki; Tohoku University, Japan

The reduction of dimensionality leads to an emergence of exotic physical properties, which are absent in the bulk form of two-dimensional (2D) layered materials [1]. Up to now, many layered materials such as graphene and chalcogenides have been reported to exhibit interesting number-of-layers dependence of electronic structures and physical phenomena [2–4], providing a rich playground to explore possibility in optical or electrical device functionality at low dimensional limit.

Layered indium selenide (InSe) is one of the potential candidates for atomically-thin optoelectronic devices because of its high mobility originating from a small effective mass of electron and a wide variation of optical bandgap by thickness tuning as exemplified in mechanically-exfoliated flakes [5]. However, such thickness dependent optical properties of InSe have not been addressed in thin film form by applying deposition techniques. In this study, we have grown layered InSe thin films on insulating Al\(_2\)O\(_3\)(0001) and InP(111) substrates by pulsed-laser deposition (PLD). By taking advantage of the precise thickness controllability of PLD, systematic thickness dependences are investigated on optical bandgap and electrical transport properties [6]. With decreasing the film thickness of InSe on Al\(_2\)O\(_3\) from 145 to 1 nm, a systematic blue shift of absorption edges from about 1.4 to 3.3 eV is observed in optical transmittance spectra. Such blue shift can be ascribed to a band structure modification with bandgap broadening, as observed in an earlier report of photoluminescence studies in exfoliated flakes [5].

For the electrical transport measurements, InSe films grown on Al\(_2\)O\(_3\) show a large resistivity beyond the measurement limit. In contrast, the films on InP exhibit a \(n\)-type conduction. The sheet conductance of InSe on InP increases with increasing the films thickness, which we ascribed to an enhanced mobility from 230 cm\(^2\)V\(^{-1}\)s\(^{-1}\) at 1 nm to 730 cm\(^2\)V\(^{-1}\)s\(^{-1}\) at 146 nm. Our demonstration of the PLD growth of layered InSe thin films and their thickness dependent optical and electrical properties should establish a platform to investigate novel device functionalities beyond graphene by applying thin film growth technique to 2D materials.

After the discovery of the extraordinary properties of graphene, two-dimensional (2D) materials have attracted a growing interest due to their unique properties such as high surface area and charge carrier mobility. Different methods have been reported to prepare these materials, such as chemical vapor deposition, mechanical, chemical and electrochemical exfoliation. Most methods have disadvantages like having multistep and expensive process and using environmentally hazardous chemicals.

In this study, we used bipolar electrochemistry concept to design a cost-efficient, eco-friendly, single step, and controllable process for exfoliating and depositing 2D materials directly on conductive substrates. This method has been used for the formation of phosphorene, graphene oxide (GO), reduced graphene oxide (rGO) and their composites. Various materials characterization techniques have been used to study the properties of deposited materials. Electrochemical impedance spectroscopy, cyclic voltammetry, and galvanostatic charge-discharge tests have been carried out to evaluate the electrochemical performance of the materials as electrodes for double layer capacitors. The results showed high areal capacitance of 1.932 mF cm⁻² for rGO and 1.550 mF cm⁻² for phosphorene at a scan rate of 2 mV s⁻¹. From the frequency point of view, the capacitors showed very fast responses and cutoff frequency as high as 1820 Hz which is promising for being used in AC filtering applications. The materials synthesis technique and characterization will be addressed in details at the conference.

**Keywords:** Bipolar electrochemistry, graphene, phosphorene, exfoliation, supercapacitor, AC filter

**Laser-Sculptured Ultrathin Transition Metal Carbide Layers for Energy Storage and Energy Harvesting Applications**

Xining Zang; Massachusetts Institute of Technology, United States

Ultrathin transition metal carbides with high capacity, high surface area, and high conductivity are a promising family of materials for applications from energy storage to catalysis. However, large-scale, cost-effective, and precursor-free methods are lacking to prepare ultrathin carbides. Herein, we demonstrate a direct pattern method to manufacture ultrathin carbides (MoCx, WCx, and CoCx) on versatile substrates using a CO2 laser. The Laser-sculptured polycrystalline carbides (macroporous, 10~20 nm wall thickness, ~10 nm crystallinity) show high energy storage capability, hierarchical porous structure, and higher thermal resilience than Mxenes and other laser-ablated carbon materials. A flexible supercapacitor made of MoCx demonstrates a wide temperature range (-50~ 300 °C). Furthermore, the sculptured microstructures endow the carbide network with enhanced visible light absorption providing high solar energy harvesting efficiency (~ 72 %) for steam generation. The laser-based, scalable, resilient, and low-cost manufacturing process presents an approach for construction of multi-dimensional carbides and their subsequent applications.

**Keywords:** Laser-sculptured, ultrathin, transition metal carbides, energy storage, energy harvesting, solar energy harvesting, supercapacitor

**Interface Dynamics in Monolayer Transition Metal Dichalcogenides under Applied Bias**

Akshay A. Murthy, Teodor K. Stanev, Roberto d. Reis, Shiqiang Hao, Christopher Wolverton, Nathaniel P. Stern and Vinayak Dravid; Northwestern University, United States

Stemming from their intriguing optical and electronic properties, monolayer transition metal dichalcogenides (TMDs) and their heterostructures offer unique next-generation and flexible device architectures. These systems have been explored to construct atomically thin diodes, photovoltaic cells, and memory devices. Despite the performance and functionalities in these devices being largely dictated by interfacial charge transport, the microscopic origins of various realizable macroscopic properties in these systems remain unclear. Further, the eventual practical deployment of these devices requires monolayer TMDs to operate under prolonged applied bias, which raises some concerns over long-term stability and reliability. While pre and post-operational TEM analysis is useful for identifying structural flaws or non-uniformities, in situ TEM offers a pathway for gaining a mechanistic understanding of intermediary phenomena through direct imaging of the atomic structure when subjected to an
external stimuli. In this study, we explore the mass transport dynamics at monolayer MoS2 grain boundaries (GBs) as a function of a lateral electric field. Though these GBs offer significant potential for future memristive and light emitting structures, previous reports have also indicated that these interfaces serve as regions of localized heating and are prone to oxidation and overall damage. Because such deleterious aspects are quite disruptive to device performance, we seek to understand the localized thermal spikes and attempt to establish links between applied electric field and grain boundary-mediated atomic diffusion. The observance of this mass transport phenomena and the resultant formation of porous regions help explain the non-uniform heating profile previously exhibited along grain boundaries. Through ongoing work using this in situ biasing platform, we aim to probe various types of TMD interfaces in order to more accurately model the complex atomic scale interactions giving rise to measurable properties.

FF01.21.41
Graphene-hBN Barristor Spectroscope Tae-Young Jeong, Jun-Ho Lee, Hyun-Jong Chung and You-Shin No; Konkuk University, Korea (the Republic of)

Graphene is a zero-gap semiconductor whose Fermi energy can be adjusted by an applied electric field. When a semiconductor directly contacts with graphene, the graphene-semiconductor interface forms a Schottky barrier, which offers opportunities to control barrier height and subsequently flow of current. A barristor, utilizing these unique properties, is a device that enables a high On/Off ratio (e.g. switching ratio ~1000) by adjusting the Schottky barrier height, which has been highly challenging for conventional Graphene FETs (GFETs).

This study reports a Graphene/hBN/Metal vertical nanostructure on a SiO2/Si substrate. Conceptually, the incident light in visible frequencies with enough energy $E_{\text{incident}}$ on the Graphene/hBN junction can excite electron and hole carriers so that they can either tunnel through or overcome the given Schottky barrier. In experiment, we used an excitation laser with wavelength of 488 nm to provide the external energy on the vertical junction structure. Then we slowly varied the gate voltage and observed gradual decrease in the photocurrent. When the gate voltage reached a certain point, we observed the turn-off the photocurrent (i.e., current-off point). Using this current-off point as an indicator, we calculated the Fermi energy of graphene ($E_F$) at given gate voltage. When the lasers with different wavelengths (i.e., different energies) were used, we were also able to find different current-off point and subsequently the Fermi energies. The Fermi energy difference ($D_E$) between two experiment with different lasers was estimated (e.g., $E_F,488\text{nm}$ vs. $E_F,532\text{nm}$, $E_F,520\text{nm}$), which corresponds the energy difference the incident light. In this proof-of-concept experiment, we successfully demonstrated a new nanoscale spectroscopic device that can analyze unknown incident wavelengths.

FF01.21.42
Insights into Chemical Vapor Deposition of Hexagonal Boron Nitride (h-BN) via Thermodynamic Control for 2D Electronics Applications Ankit S. Rao, Abhishek Mishra and Srinivasan Raghavan; Indian Institute of Science, India

Hexagonal boron nitride (h-BN) has been established as the preferred substrate for nanodevices based on 2-dimensional (2D) materials owing to its atomically flat interface, excellent thermal conductivity and suitable dielectric characteristics. Thus, there is a fundamental requirement to manufacture wafer scale h-BN for large area applications and the most scalable method is chemical vapor deposition (CVD). The current approaches for CVD growth of h-BN are by and large empirical due to which there is lack of control over the deposition. Our research involves thermodynamic control of the B-N-H system by identifying the appropriate windows of process parameters for controlled growth of h-BN. The system consists of ammonia borane (BH3-NH3) as the precursor for CVD growth of h-BN over copper (Cu) substrate. Within the thermodynamic windows, the control over gas phase supersaturation would allow better kinetic control over crystal growth. Thermodynamic control is exercised over gas phase supersaturation by use of carrier gases such as hydrogen (H2) and argon (Ar) and by controlling the precursor flux via a simple vaporizer setup, which allows tuning of the supersaturation and partial pressures of the gases in the chamber.

We report control over grain size and number of layers, from multilayer films to monolayer to partially covered films with uniformity across a large area. We obtain high degree of control by regulating the supersaturation and tuning the gas phase chemistry via variation of the H2, Ar partial pressures and the precursor chemistry. The growth of h-BN layers is accompanied with undesired nanocrystalline BN (n-BN) particles due to the precursor chemistry and post-growth copper deposits which degrade the film quality and these particles show preferential nucleation at
defect sites. We observe a significant reduction in n-BN particles by reduction in the precursor partial pressure via change in the carrier hydrogen partial pressure, which indicates the effect of supersaturation on the surface chemistry. Also, preferential nucleation at location of defects is seen which can be attributed to the energetic potential difference at various sites of the surface which is of thermodynamic nature as the energy barrier for nucleation at different sites are finite at a supersaturation value. Thus, the effect of growth parameters on the quality of hBN film deposited via CVD is observed with change in partial pressures and flux of precursor. The quality of film significantly changes with change in gas phase chemistry all other parameters being same, and this can be attributed to the fact that partial pressure of reactants have an exponential effect on supersaturation. Thus, we report controllable and scalable growth of h-BN over large areas by implementing thermodynamic control.

**Case Study on the Stability of Exfoliated II-VI Layered Hybrid Materials**

Mengwen Yan¹, Sean Collins² and Jeremy I. Feldblyum³; ¹University at Albany, State University of New York, United States; ²University of Cambridge, United Kingdom

The successful isolation of two-dimensional (2D) materials such as graphene and MoS₂ has fueled the search for other van der Waals materials with distinct functional properties. However, reducing the dimensionality of these materials often leads to undesired structural and chemical degradation, especially in the presence of air. In this presentation, we provide a case study in the factors governing the structural and chemical stability of a new class of exfoliated 2D materials known as II-VI layered hybrids (LHs). II-VI LHs are 2D, quantum-confined semiconductors capped by organic ligands, which stabilize the bound, 2D inorganic layer. We show here that of exfoliated ZnSe(butylamine) and ZnSe(octylamine) are susceptible to oxidation, but in a manner highly dependent on a variety of factors including exfoliation conditions, ligand identity, and air exposure time. We show that appropriate selection of these parameters can kinetically stabilize these metastable 2D materials that are otherwise prone to degradation when exposed to ambient conditions.

**FF01.21.46**

**Dirac-Like Linear Bands in a Non-Honeycomb Lattice of a Surface Alloy**

Pampa Sadhukhan¹, Dhanshree Pandey²,³, Vinip Kumar Singh¹, Shuvam Sarkar¹, Abhishek Rai¹, Kuntala Bhattacharya⁴, Aparna Chakrabarti²,³ and Sudipta Roy Barman¹; ¹UGC-DAE Consortium for Scientific Research, India; ²Homi Bhaba National Institute, India; ³Raja Ramanna Centre for Advanced Technology, India; ⁴Indian Institute of Space Science and Technology, India

Since the discovery of graphene, fabrication of atomically thin two dimensional (2D) materials with nontrivial band topology has attracted enormous attention primarily because of their dissipationless conduction. This led to the discovery of a family of 2D quantum materials with exotic properties; for example, to mention a few are stanene, silicene, aluminene, borophene and phosphorene. In particular, the prediction of stanene, a buckled tin honeycomb layer, to be a quantum spin Hall insulator with Dirac cone-like linear energy dispersion and a large gap of 0.3 eV has stirred up efforts to realize it on substrates. Gold is an interesting substrate for stanene growth that also exhibits a Rashba spin-orbit split surface state. However, both experimental as well as theoretical studies of Sn growth on Au(111) show formation of Au-Sn surface alloy. Here, we first establish that surface alloying in Sn/Au(111) using core-level photoelectron spectroscopy, scanning tunneling microscopy and low energy electron diffraction. The composition and the surface symmetries of these surface alloys at room and elevated temperatures are AuSn with p(3x3)R150° at substrate temperature Tₛ= 300 K and Au₂Sn described by the matrix (2₁₁₃) at Tₛ = 400 K that transforms to (3√3x√3)R30° phase at 493 K. Angle resolved photoemission spectroscopy demonstrates unexpected occurrence of a linear band resembling Dirac cone at the zone-center of Au₂Sn surface alloy with the (2₁₁₃) surface structure. This band disperses linearly over a wide binding energy range starting from 1.5 eV at kₖ = 0.2Å⁻¹ to the Fermi level, where the two branches of Λ meet at the Γ point. It is also observed using a different photon energy of 23 eV (He Iβ) where the dispersion is very similar to that taken with 21.2 (He I) eV photon energy indicating that it is surface related. Moreover, as expected for a Dirac cone, it is unaffected by the variation of the azimuthal angle e.g. from the Γ-M direction to the Γ-K direction. The magnitude of the slopes (dEₚ/dkₖ) of the left and the right branches are essentially same, 6.9±0.1 and 6.9±0.1, respectively, and the calculated Fermi velocity turns out to be 1.05x10⁶ m/s, which is very similar to that of graphene (1x10⁶ m/s). Importantly, it is only for the (2₁₁₃) surface, the linear bands occur and the results of our density functional theory based calculations for different possible atomic arrangements to simulate these bands will also be discussed. Importantly, here the linear bands meet at the Fermi level at the Γ point in a non-hexagonal lattice in a surface alloy with Fermi velocity comparable to graphene, which
might have potential application is high speed electronic devices.

**Mechanical and Conductivity Study of the 3D Printed PBAT/PLA/Graphene Nanocomposites**

Da Hyun Choo¹, Zhehua Xiang², Xianghao Zuo³ and Miriam Rafailovich⁴; ¹Kent School, United States; ²Lawrence Woodmere Academy, United States; ³Stony Brook University, United States

The research focuses on ways to adjust the mechanical properties of polymers that can potentially replace non-degradable, petroleum based plastics using PBAT, PLA and H-5 graphene. PBAT and PLA are both biodegradable and highly expected with the improvements in thermal and electrical conductivities by adding graphene, in which 3D printing technique is adapted to orient the H-5 platelets into a uniform direction. In this study, the concentration of PBAT and PLA was kept as 3:1 while the graphene concentrations were changed from 8% to 20%. Mechanical properties such as impact toughness and tensile properties as well as the thermal and electrical conductivity were studied to show the performance of the blends. The results were compared with the previously hot-pressed samples with the same formulations.

The impact strength of the printed sample was observed comparable to the molded samples, while significant increases in the Young’s modulus, tensile strength and elongation at break were obtained for the printed samples during the tensile tests.

In thermal conductivity test, the testings were done in two directions: 3D print vertical direction and 3D print printing direction to compare with the molded samples. The results showed that the thermal conductivity depended a lot on the measuring direction. For the vertical direction, the thermal conductivity results were not as good as the molded ones. However, for the printing direction, the results were observed to be higher than the molded samples.

For the electrical conductivity test, both printed and molded samples initially showed extremely small conductivity. When the concentration of H-5 went to 16 percent, the value of printed samples went up to 339 s/m and approximately doubled when the concentration went to 20 percent, which is around 50 times higher than that of the molded samples.

SEM images were used to observe the graphene dispersions in the polymer blends matrix. The high magnitude images of the created nanocomposites showed that graphene particles demonstrate a constant direction, indicating the possibility of enhancement of the mechanical and electrical conductivity. From the TEM images, we can clearly see the regularized orientation of the graphene platelets, further proved the rearrangement of the directions of graphene platelets during the extruding process of 3D printing.

In conclusion, the mechanical and conductivity were enhanced during the 3D printing procedure and can meet the demands of electrical appliances. The results indicated the possibility of engineering biodegradable, high-performance polymeric materials.

**FF01.21.49**

**Transition Metal Enhanced Carrier Transport in Two-Dimensional Semiconducting Crystals**

Maomao Liu¹, Simran Shahi¹, Hemendra Nath Jaiswal¹, Sichen Wei², Fei Yao² and Huamin Li¹; ¹New York State University at Buffalo, United States; ²University at Buffalo, The State University of New York, United States

Two-dimensional (2D) semiconducting crystals such as transition metal dichalcogenides (TMDs) have been considered as promising semiconductor channel materials for future nanoelectronic devices. Theoretical models predict that among various semiconducting TMDs, WS₂ has the highest electron mobility and the best transistor performance including the highest on/off ratios and on-current densities. However, for the practical application such as complementary metal-oxide-semiconductor logic circuits, it is urgently needed to improve carrier transport efficiency along the in-plane channel and through the metal-semiconductor interface. In this work, we report a significantly improved carrier transport in few-layer WS₂ field-effect transistors (FETs) by exploiting transition metals as dopants and metal contacts. Cu was chosen due to its high diffusion coefficient and compatibility in MEMS/NEMS processing. Cu-doped WS₂ was synthesized by introducing Cu during the chemical transport interaction, and Cu-contact WS₂ devices were prepared by evaporating a 2-nm-thick Cu layer at the metal-semiconductor interface. Compared to pristine WS₂ FETs, both the Cu-doped and Cu-contact WS₂ devices show the outstanding increases in carrier mobilities, on/off ratios, on-current densities, transconductances, and subthreshold swings. The metal-semiconductor contact condition was also improved from Schottky to Ohmic due to an
outstanding reduction of the contact barrier height and thus the contact resistance. We also carried out a statistical study with over 20 devices for each kind, and the results were consistent and repeatable. Our work has demonstrated the great potential of applying transition metals to improve the carrier transport of semiconducting TMDs in various device applications.

Pristine and Metal-Doped Hexagonal Boron Nitride Films on Centimeter Scale by Atomic Layer Deposition
René Weißing, Daniel Stadler, Matthias K. Grosch, Anja Sutorius and Sanjay Mathur; University of Cologne, Germany

Hexagonal boron nitride (h-BN) with its atomically flat structure, excellent stability and large band gap energy (~ 6 eV) is an ideal insulator for 2D electronics. Fabrication of h-BN thin films is mainly limited to exfoliation of multilayer or bulk crystals, however the size of h-BN crystals are limited to few millimeters. Consequently, mechanical exfoliation and chemical transfer procedures typically deliver h-BN flakes of several tens of micrometers that come along with significant interfacial impurities, defects and low production capacity that limits the use of h-BN on large scale. Therefore, the vapor phase methods ALD and CVD are promising alternatives to grow h-BN monolayers and multilayers as demonstrated for several metallic substrates (e.g., Au, Cu, Ni, Co). Nevertheless, epilayer growth of unidirectionally aligned h-BN domains has been challenging due to excessive nucleation and 3-fold symmetry of h-BN lattice that results in twin boundaries. Therefore, we have developed vacuum-based processes to grow h-BN monolayers on centimeter scale Cu(111) substrates relevant for electronic applications. The synthetic access was achieved by two complementary half-reactions of B and N precursors (ALD) and via thermal decomposition and surface nucleation of single-source precursors such as amino boranes and borazine (CVD). We have recently investigated the growth of h-BN by CVD of solid ammonia-borane (BH3<-NH3) that sublimes at 100 °C and is thermally decomposed (dehydrogenated) on the substrate surface at elevated temperature (700-900 °C) to nucleate h-BN domains. Also, the CVD of borazine (B3N3H6) on Cu(111) showed the growth of large BN crystals that show a pronounced tendency of lateral diffusion to grow into coherent h-BN domains.

FF01.21.51
Molecular Routes to Two-Dimensional Metal Disulfides MS2 (M = Mo, W)
Veronika Brune, Matthias K. Grosch, Corinna Hegemann, Sanjay Mathur and René Weißing; University of Cologne, Germany

The ever-growing interest in van der Waals materials like two-dimensional transition metal disulfides (TMDSs) demands a matching supply of these materials. TMDS complexes containing group VI metal ions are attractive starting materials for 2D materials that offer great potential for low-power electronics, especially because of their favorable layered structures and promising electro-optical properties. For this we introduce an entirely novel class of molecular precursors: [MIV(SEtN(Me)EtS)2] (MIV = MoIV, WIV). Tungsten and molybdenum complexes of dianionic tridentate pincer type ligands (HSEt)2NMe produced air-stable monomeric disulfide complexes, [W(SEtN(Me)EiS)2] and [Mo(SEtN(Me)EiS)2], displaying W and Mo centers in distorted octahedral environment of 4 S and 2 N donor atoms. We then used these volatile and cleanly decomposing precursors in chemical vapor deposition for the creation of large area crystalline MoS2 and WS2 thin films. As-prepared films were subjected to atomic scale imaging and x-ray analysis to confirm the synthesis of phase-pure MX2 materials. New ligands presented in this work open up a new molecular route to precursor engineering for 2D transition metal disulfides and allow an efficient approach towards the synthesis of scalable van der Waals heterostructured materials.

FF01.21.52
N-Doped CVD-Grown MoSe2 Field Effect Transistors by Two-Step Doping Process
Seongin Hong¹, Haewon Cho¹, Junwoo Park¹, Jun Hong Park² and Sunkook Kim¹; ¹¹) School of Advanced Materials Science & Engineering Sungkyunkwan University, Korea (the Republic of); ¹²) School of Materials Science & Engineering Gyeongsang National University, Korea (the Republic of)

Two-dimensional (2D) layered transition metal dichalcogenides (TMDs) have been considered the next-generation semiconductor materials for potential sensor applications due to their intriguing mechanical, electrical and optical properties. Molybdenum diselenide (MoSe2), one of TMDs, has recently attracted attention for high performance photosensor applications owing to its superior photoresponsivity. In addition, since the bandgap of MoSe2 is smaller than it of MoS2, wide excitation wavelength range as well as excellent electrical conductivity can be obtained in
MoSe₂ field-effect transistors (FETs). However, chemical vapor deposition (CVD)-grown MoSe₂ FETs randomly exhibit n-type, p-type, or ambipolar characteristics due to the unexpected defect generated during the growth of MoSe₂ by uncontrolled growth condition. Here, two-step doping method with n-type doping effect was developed to achieve unipolar n-type MoSe₂ FETs and its long-term stability. After the two-step doping process on MoSe₂ FETs using oxygen plasma treatment (1st step) and Al₂O₃ layer deposition (2nd step), n-type, p-type and ambipolar MoSe₂ FETs are all converted to unipolar n-type MoSe₂ with enhanced electrical properties and stability. Field effect mobility of n-doped MoSe₂ was improved from 12.23 to 31.57 cm²V⁻¹s⁻¹, 3 times larger $I_{on}/I_{off}$ without any degradation for 21 days. The enhancement is attributed to fixed positive charges in Al₂O₃ layer and electrically-insulating oxidation on the top-surface of MoSe₂ by oxygen plasma treatment. The results suggest that the two-step methods will be a novel process to achieve n-type doping effect with high-performance and stability for various sensor applications.

**Tuning Band Splitting and van-Hove Singularities in Twisted-Bilayer Graphene Superlattices** Francisco Sanchez-Ochoa and Cecilia Noguez; Universidad Nacional Autónoma de México, Mexico

Twisted-bilayer graphene (TBLG) is a new kind of two-dimensional material where new physical phenomena arise because of the interlayer potential modulation as a function of the different relative orientations between layers. This arbitrary orientation in TBLG is characterized by the relative angle of rotation and the stacking pattern (AA, AB). The interlayer interaction could change the electronic band structure drastically as compared to one G layer. Here, we discuss the effective band structures calculated from the projection of supercell electronic-states on a G primitive cell. These effective band structures are obtained by unfolding the bands that are calculated using density functional theory [1]. The results show that the major changes in the electronic states of G are along the K-M path in the irreducible Brillouin zone of primitive cell; meanwhile, the other two paths Γ-K and Γ-M show a split of the π band for higher energies in the valence band. In the K-M path, we observe the appearance of electronic band gaps approaching the Fermi level when the angle between monolayers is small. These band gaps give rise to van Hove singularities in the density of states with a uniform distribution of discrete electronic states, like Rydberg-like series. These results provide the first theoretical evidence of the discretization of the band structure in a set of well-ordered electronic states and are in fair agreement with experimental observations [2–4]. These electronic states can be responsible for new conduction channels, which might be essential for the realization of new optoelectronic devices based on G [5,6].

**FF01.21.56**

**Chemiresistive Sensing of Ambient CO₂ by Metal-Organic Frameworks** Jinhu Dou and Mircea Dincă; Massachusetts Institute of Technology, United States

A growing demand for indoor atmosphere monitoring relies critically on the ability to reliably and quantitatively detect carbon dioxide. Widespread adoption of CO₂ sensors requires vastly improved materials and approaches because selective sensing of CO₂ under ambient conditions, where relative humidity (RH) and other atmosphere contaminants provide a complex scenario, is particularly challenging. This report describes an ambient CO₂ chemiresistor platform based on nanoporous, electrically conducting two-dimensional metal–organic frameworks (2D MOFs). The CO₂ chemiresistive sensitivity of 2D MOFs is attained through the incorporation of imino-semiquinonate moieties, i.e., well-defined N-heteroatom functionalization. The best performance is obtained with Cu₃(hexaiminobenzene)₂, Cu₃HIB₂, which shows selective and robust ambient CO₂ sensing properties at practically relevant levels (400–2500 ppm). The observed ambient CO₂ sensitivity is nearly RH-independent in the range 10–80% RH. Cu₃HIB₂ shows higher sensitivity over a broader RH range than any other known chemiresistor.
Characterization of the CO$_2$-MOF interaction through a combination of in situ optical spectroscopy and density functional theory calculations evidence autogenously generated hydrated adsorption sites and a charge trapping mechanism as responsible for the intriguing CO$_2$ sensing properties of Cu$_3$HIB$_2$.

**FF01.21.57**

**Electronic and Magnetic Properties of Vertically Aligned Bi-/Tri-Layered Graphene**  
Sekhar C. Ray; University of South Africa, South Africa

Saturation magnetization ($M_s$) of pristine bi-/tri-layered graphene (denoted as – FLG) is enhanced by over four (4) and thirty-four (34) times to $13.94 \times 10^{-4}$ and $118.62 \times 10^{-4}$ emu g$^{-1}$, respectively, as compared to pristine FLGs ($M_s$ of $3.47 \times 10^{-4}$ emu g$^{-1}$), via plasma-based-hydrogenation (known as graphone) and nitrogenation (known as N-graphene) reactions, respectively. However, upon organo-silane treatment on FLG (known as siliphene), the saturation magnetization is reduced by over thirty (30) times to $0.11 \times 10^{-4}$ emu g$^{-1}$, as compared to pristine FLG. Synchrotron based X-ray absorption near edge structure spectroscopy measurements have been carried out to investigate the electronic structure and the underlying mechanism responsible for the variation of magnetic properties. For graphone, the free spin available via the conversion of the sp$^2 \rightarrow$ sp$^3$ hybridized structure and the possibility of unpaired electrons from induced defects are the likely mechanism for ferromagnetic ordering. During nitrogenation, the Fermi level of FLGs is shifted upwards due to the formation of a graphitic like extra π-electron that makes the structure electron-rich, thereby, enhancing the magnetic coupling between magnetic moments. On the other hand, during the formation of siliphene, substitution of the C-atom in FLG by a Si-atom occurs and relaxes out the graphene plane to form Si–C tetrahedral sp$^3$ bonding with a non-magnetic atomic arrangement showing no spin polarization phenomena and thereby reducing the magnetization. Thus, plasma functionalization offers a simple yet facile route to control the magnetic properties of the graphene systems and has potential implications for spintronic applications.

**FF01.21.58**

**Monitoring the Low Doping Regime in Graphene—Comparison of Gated Raman Spectroscopy and Transport Measurements**  
Zhuofa Chen, Nathan Ullberg, Mounika Vutukuru, David Barton and Anna Swan; Boston University, United States

Identifying charge density fluctuations and impurities in graphene is vital for high-quality graphene-based devices. The benchmark method to determine the quality of a graphene-based device is the electrical transport measurement which requires labor-intensive and time-consuming device fabrication process. Existing optical methods using Raman spectroscopy only work for graphene with doping levels higher than $\sim 10^{12}$ cm$^{-2}$. These optical techniques include Raman G peak shift [1], Raman 2D peak shift [2], and 2D versus G frequency charge vector [3]. For high purity samples, e.g., suspended graphene, Boron nitride/graphene/Boron nitride heterostructures, and graphene deposited on octadecyltrimethoxysilane (OTMS), more precise optical methods still need to be developed to estimate the doping level of graphene. Here, we developed an optical probe that can evaluate the doping level and charge fluctuation in graphene in the range from $10^{10}$ cm$^{-2}$ to $10^{12}$ cm$^{-2}$ by using the split in the Raman 2D peak which appears at low doping levels.

Clean graphene samples were prepared on OTMS self-assembled monolayers. By comparing the Raman spatial mapping of the Raman 2D peak split with other Raman parameters (such as G peak frequency, G peak width, 2D peak frequency, 2D peak width, the 2D vs G frequency strain and charge vectors, and ratio of 2D over G peak intensity), the 2D peak split was found to have 10 times larger variation on graphene exfoliated on a OTMS treated substrate (charge density around $5 \times 10^{11}$ cm$^{-2}$), which means much higher sensitivity to charge variation.

In order to quantify the relationship between the 2D peak-split and doping level, we electrostatically biased the graphene to induce a known charge density while measuring the 2D Raman response. We fabricated Graphene Field Effect Transistors (GFETs) and measure the transport curve to find the reference charge neutrality point (CNP), the charge fluctuation and the mobility. The cleanest graphene devices on OTMS-treated substrates had an accidental doping of $3.6 \times 10^{11}$ cm$^{-2}$, a charge fluctuation of $2.2 \times 10^{11}$ cm$^{-2}$, and a mobility of $\sim 1.7 \times 10^4$ cm$^2$/Vs, as deduced from fitting two-point probe transport measurements. Electrostatically gated Raman measurements combined with transport measurements were used to correlate the 2D peak-split with the charge density on graphene with high precision. We found that the Raman 2D peak-split is inversely proportional to the charge density at low doping levels, i.e., a lower charge density results in a larger 2D peak-split [4]. The 2D peak-split can differentiate charge densities down to $2 \times 10^{10}$ cm$^{-2}$ per wavenumber of the 2D peak-split, two orders of magnitude higher precision than using G peak frequency and width, or the 2D versus G frequency charge vector [3].
In conclusion, we sought an optical probe (Raman spectroscopy) that can be used to evaluate the low charge density and the low charge fluctuations across a graphene sample without the fabrication or processing steps necessary for transport measurements. The Raman 2D peak-split was found to correlate with charge density with high precision (2×10^{10} \text{ cm}^{-2} \text{ per 2D peak-split wavenumber}). Our work provides a simple and non-invasive optical method to quantify the doping level of graphene from 10^{10} \text{ cm}^{-2} to 10^{12} \text{ cm}^{-2}, two orders of magnitude higher precision than previously reported optical methods. The 2D peak-split method provides a platform for estimating the doping levels and the quality of a graphene sample before building a high-quality graphene device.

Characterization of Interlayer Tunneling Junctions in Two-Dimensional Material Heterostructures via High-Throughput Computations

Adam Pfeifle1, Panchapakesan Ganesh2 and Marcelo A. Kuroda1; 1Auburn University, United States; 2Oak Ridge National Laboratory, United States

Following the isolation of individual graphene layers, several other two-dimensional (2D) materials have been discovered, including boron-nitride (BN), phosphorene, and transition metal dichalcogenides (TMDs) [1]. These 2D materials lack dangling bonds allowing for their seamless stacking to create multilayered heterostructures preserving their sharp interfaces [2]. The physical properties of these multilayer structures, including out-of-plane tunneling rates, may be tailored via composition and stacking order. As thousands of 2D materials have been isolated or predicted to be stable [3], the number of heterostructures that can be formed grows very rapidly. Here we develop methodology to characterize carrier transport in heterostructures formed with 2D materials. Our approach efficiently combines high-throughput first principles calculations and ballistic quantum transport. Our workflow generates vertical heterostructures with low-strain epitaxial mismatches between layers. Their geometries and electronic properties are obtained via first principles calculations within the density functional theory. Ballistic transport methodology based on the Landauer formalism employs representations of the electronic structure formed by projections of pseudo-atomic orbitals for efficient computations [4]. In particular, we analyze the modulation of the tunneling current as a function of strain perpendicular to the basal plane [5,6] for a variety of heterostructures based on graphene electrodes, and boron-nitride or transition metal dichalcogenides as tunneling barriers. Results are rationalized in terms of composition, stacking order and orientations. For the same number of layers, BN junctions exhibit larger tunneling currents than TMDs as its smaller thickness counterweights its larger band gap. We find, however, that the interlayer tunneling current of TMDs are more susceptible to mechanical strain than BN ones. We also compare results for the case of bulk electrodes and discuss virtues and limitations of approximations employed in this description. The results of this work may prove useful to the study of novel physical phenomena such as charge and spin transport in tunneling heterostructures based on 2D materials. This work has been partially supported by the NSF DMR-1848344.

Carrier Transport Dynamics in 2D Semiconductor High-Speed Photodetectors Exian Liu¹, Peijian Wang², Hao Zeng² and Jianbo Gao¹; ¹Clemson University, United States; ²State University of New York at Buffalo, United States

Despite that 2D semiconductors have promising optoelectronic and electronic applications, our fundamental understanding of its carrier transport dynamics is still in its infancy. In general, it remains challenging to unravel the carrier transport properties in devices since they are altered in the presence of defects/impurities or trap states. An ultrafast probe or high quantum efficiency device (the ratio between electrons collected to photon number), or both, are required to elicit carrier transport properties before significant carrier trapping into trap states and recombination occur.

In this work, we integrate black phosphorus and WS₂ in an ultra-high-speed photodetector structure with sub-25 ps response time to study the carrier transport dynamics. We elucidate the nature of transport mechanisms in different temporal regimes: pre-trapping and band-like transport in early time up to nanoseconds, followed by multiple trapping and release (MTR) hopping transport. In addition to demonstrating visible and infrared high-speed photodetectors, our study reveals the fundamental device physics, leading to device performance manipulation.

8:30 AM FF01.22.02
Highly Sensitive Broad-Spectrum Photodetector Fabricated with Integration of MoS₂ with Mo₂C Multi-Gratings Young Jae Kim¹, Jaeho Jeon¹, Chaeyeon Shin¹, Seunghyuk Choi¹, Jin-Hong Park¹ and Sungjoo Lee¹,²; ¹Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Broad-spectrum photodetection with high sensitivity through a single photodetector device is required for optical communications, wide-spectral switches, and memory storage applications. To achieve the highly sensitive photodetection in the wide spectral range, various 2D materials and heterojunction structures have been studied, however, limited absorption rate of 2D materials have still been retained as the critical huddle to achieve a sensitive photodetection in broad-spectral range. Herein, we propose a novel 2D hybrid structure consisting of semiconducting MoS₂ film integrated with metallic Mo₂C multi-gratings of various grating periods (400, 600, 800, and 1000 nm), which provides high responsivity (R > 10³ A/W) and distinctive photodetection (light-to-dark current ratio > 10²) over a broad spectral range (405 nm – 1310 nm). The grating of metallic Mo₂C produces plasmonic resonance, which provides hot carriers to the MoS₂ channel. By adjusting the grating period of Mo₂C (400 - 1000 nm), we can control the optimal photoresponse of light, from visible to NIR. The proposed photodetector with a novel 2D hybrid structure achieved a highly sensitive and broad spectral detectable photodetector devices and pave the way to achieving innovative future photodetector applications.

8:45 AM FF01.22.03
Ambient Effects on Photogating in MoS₂ Photodetectors Peize Han¹, Eli R. Adler¹, Yijing Liu¹, Luke St. Marie¹, Abdel El Fatimy¹,², Scott Melis¹, Edward Van Keuren¹ and Paola Barbara¹; ¹Georgetown University, United States; ²Ecole Centrale Casablanca, Morocco

Transition metal dichalcogenides (TMDs) have emerged as promising materials for optoelectronic applications due to their strong light absorption, their direct bandgap for semiconducting monolayers and their suitability for flexible substrates. Although photodetectors based on TMDs have shown remarkable performance, devices with high responsivity and detectivity are usually hindered by slow response times. Here we study the photogating mechanism yielding high responsivity in MoS₂ phototransistors and we show that, for wavelengths sufficiently short to create excitons in the MoS₂, light illumination causes desorption of gas adsorbates¹,².

The search for transformative materials beyond traditional covalent semiconductors, such as Si, has led to fast growing activities on new two-dimensional (2D) semiconductors and the exciting growing development of the metal chalcogenide indium selenide, InSe. This 2D crystal exhibits strong covalent atomic bonds in the layer plane and van der Waals (vdW) attraction between the layers, enabling the isolation of high-quality stable thin films down to the atomic monolayer thickness. The science and technology of 2D InSe represent a rapidly developing and vibrant field with breakthroughs emerging from both experiment and theory. InSe has a near band edge absorption that increases with decreasing layer thickness; high photoresponsivity from the infrared (IR) to the ultra-violet (UV) spectral range; a low mass conduction band electrons and high electron mobility even in atomically thin films, larger than in Si-based field effect transistors (FETs); high mechanical strength; a strain-sensitive band structure; a density of states with 1D van Hove singularities, etc. In this talk, I will present recent research on this new 2D system [1-5] and discuss emerging activities with prospects for digital electronics and photonics.

A variety of new two-dimensional (2D) van der Waals (vdW) crystals have recently been explored following extensive studies on 2D transition metal dichalcogenides (TMDs). Amongst them, noble metals-based 2D crystals such as 2D platinum (Pt) diselenide (PtSe₂) are particularly promising owing to their distinct advantages over conventional 2D TMDs offering higher carrier mobility, superior air stability, semiconducting-to-metallic transition, and lower growth temperature. Despite these projected property and manufacturing merits, much of their electrical properties have remained largely unexplored, significantly limiting their applications for electronic devices. For example, the strong metallic nature of 2D PtSe₂ layers projects a new type of metal/semiconductor Schottky junction based on 2D/3D vdW heterostructures of “mixed dimensionality” when they are interfaced with three-dimensional (3D) semiconductors. Herein, we report a new type of 2D/3Ds Schottky junction devices based on vertically-aligned metallic 2D PtSe₂ layers integrated on Si wafers. We directly grew 2D PtSe₂ layers of controlled orientation and transport characteristics via a low-temperature chemical vapor deposition (CVD) process and investigated 2D PtSe₂/3D Si Schottky junction properties. We found a comprehensive set of material parameters which decisively confirm the presence of excellent Schottky junctions, i.e., high rectification ratio (> 10³), small ideality factor (~1.9), and temperature-dependent variation of Schottky barrier heights. Additionally, we observed strong photovoltaic effects in the 2D PtSe₂/Si Schottky junction devices and extended them to realize flexible photovoltaic devices by direct growth of 2D PtSe₂ on thin (~20 µm) Si wafer. This study is believed to significantly broaden the versatility of 2D PtSe₂ layers in practical and futuristic electronic devices.
Transition metal dichalcogenides (TMD) exist in several polymorphs including 2H (usually semiconducting), and 1T/1T' (usually semi-metallic). Our theoretical calculations and experimental measurements show that TMDs are optically-dense and can feature a difference in near-infrared (NIR) refractive index greater than 1 between phases (delta n>1), which is comparable to established phase-change materials (PCMs). Martensitic phase-change behavior has been observed in TMDs and can be triggered non-thermally, and transformation strains are expected to be low due to the layered crystal structures. We suggest that TMDs may be useful as low-power, low-fatigue active materials to control light in integrated photonic circuits.

Among TMDs, sulfides are promising for photonics applications because they present the lowest optical loss and the highest material stability. Sadly, sulfide TMDs also have higher phase-change energy barriers than selenides or tellurides. This problem may be solved by designing sulfide TMD alloys that are thermodynamically-adjacent to phase boundaries. We use density-functional theory (DFT) and related methods to calculate free energy-composition diagrams at finite temperature for polymorphs in the MoS2-TiS2-ZrS2 system. Our calculations predict that the free energy of hypothesized phase-change alloys lies slightly above the convex hull. This highlights the need to process TMD alloys at low temperature, to avoid phase separation. Low temperature processing is also essential to integrated TMD films with integrated photonic circuits.

We fabricate large-area sulfide TMD pure-phase and alloy thin films by metal sputtering followed by sulfurization in H2S-containing atmospheres in a chemical vapor deposition (CVD) furnace. This two-step method combined with combinatorial sputtering enables rapid exploration of composition space and phase boundaries. By controlling CVD furnace gas conditions we are able to lower the processing temperature for large-area alloy thin films below 600 °C. We characterize the sulfide TMD alloy films by electron microscopy, Raman spectroscopy, and infrared spectroscopy. We measure the phase boundaries, quantify the extent of phase separation, and identify optimal compositions for photonics applications.

Giant Negative Electrostriction in CuInP2S6—Linking Theory and Experiments

The scientific interest in van-der-Waals (vdW) crystal CuInP2S6 originates from its many useful material properties such as ferroelectricity. The layered structure allows for easy exfoliation into ultrathin flakes and vDW interfaces can be utilized to create heterostructures with 2D materials such as MoS2 or graphene. Most notably, electrostrictive coefficients in this material have been found to be very large and negative, meaning that the crystal expands in an electric field oriented antiparallel to the spontaneous polarization in CuInP2S6. However, the magnitude of the electrostrictive coefficient and resulting piezoelectric response has been source of confusion. The Q33 and d33 extracted from XRD data using Landau-Ginzburg-Devonshire calculations are -3.2 m4/C2 and -85 pm/V, respectively, making the electromechanical output of CuInP2S6 comparable or even outperforming ferroelectric perovskites [1]. On the other hand, d33 extracted from density functional theory (DFT) as derivative of the polarization vs. stress yields only around -16 pm/V [2]. In this work we demonstrate how the boundary conditions of DFT, in particular clamping of lattice parameters are in agreement with experimental conditions in piezoresistance force microscopy (PFM) measurements on CuInP2S6 surfaces where similar d33 values are observed. In contrast, PFM on CuInP2S6 capacitors with µm sized top electrodes resembles an unclamped setup and shows piezoresponse in agreement with the predicted -85 pm/V. Having achieved excellent agreement, we have unraveled the intrinsic
origin of the negative electrostriction, which is linked to proximate chemical interactions between the vdW layers and the resulting anharmonicity of the potential well for polar Cu displacement.

Lithium Intercalation as a Reversible Structural Switch in WTe2: Philipp Muscher\textsuperscript{1,2}, William C. Chueh\textsuperscript{1} and Aaron Lindenberg\textsuperscript{1,2}; \textsuperscript{1}Stanford University, United States; \textsuperscript{2}SLAC National Accelerator Laboratory, United States

WTe\textsubscript{2} is a transition metal dichalcogenide (TMD) with remarkable structural properties, featuring broken inversion symmetry, quasi 1-dimensional W-W chains and out-of-plane distortions of the covalent layers. This so-called Td structure has been linked to WTe\textsubscript{2}'s unique physical properties such as its large, non-saturating magnetoresistance and its being a topological semimetal with type II Weyl points. Here, we demonstrate fast and highly reversible lithium intercalation into WTe\textsubscript{2} using an electrochemical platform with compositional control over a single flake. Our in-situ X-ray and optical studies, combined with DFT calculations, show that lithium intercalation is a powerful tool for tuning the properties of WTe\textsubscript{2}. In particular, Li\textsubscript{0.5}WTe\textsubscript{2} is a vastly expanded form of the initial structure with a polytype that is not otherwise observed in common TMDs.

11:15 AM FF01.23.04
Manipulation of Topological Properties in Weyl Semimetal Jun Xiao\textsuperscript{1,2}, Ying Wang\textsuperscript{3}, Philipp Muscher\textsuperscript{1}, Siqi Wang\textsuperscript{4}, Edbert Sie\textsuperscript{1,2}, Clara Nyby\textsuperscript{1,2}, Xiang Zhang\textsuperscript{1} and Aaron Lindenberg\textsuperscript{1,2}; \textsuperscript{1}Stanford University, United States; \textsuperscript{2}SLAC National Accelerator Laboratory, United States; \textsuperscript{3}University of California, Berkeley, United States

Quantum materials with novel phases of matter are the key building blocks of energy efficient quantum electronics and powerful quantum computation. Exploiting control of those materials is fascinating to achieve new functionalities and information algorithm in future quantum devices. Quantum nanomaterials like layered materials, has revealed many exotic properties such as extremely large magnetoresistance (MR)\textsuperscript{1}, type-II Weyl electron transport and diverging Berry curvature\textsuperscript{2,3}. On the other hand, the nature of layered materials leads to ultra large tunability of physical properties via external stimuli.

Here we report the manipulation of topological properties in Weyl semimetal based on layered materials. With such experimental control and various characterization means, we observed substantial modulation in optical and electrical responses. The observations indicate such changes are closely associated with the variation of topological property. Our findings highlight the potential for the realization of topological devices based on layered quantum materials.

11:30 AM FF01.23.05
Modulating the Functions of MoS\textsubscript{2}/MoTe\textsubscript{2} van der Waals Heterostructure via Thickness Variation Ngoc Thanh Duong\textsuperscript{1,2}, Minhee Yun\textsuperscript{3}, Seong Chu Lim\textsuperscript{1,2} and Mun Seok Jeong\textsuperscript{1,2}; \textsuperscript{1}Sungkyunkwan University, Korea (the Republic of); \textsuperscript{2}Institute for Basic Science, Korea (the Republic of); \textsuperscript{3}University of Pittsburgh, United States

The atomically thin and dangling bond-free 2D semiconducting transition metal dichalcogenides (TMDs) provides another alternative for the post-Si technologies. In the case of a Si device, the performance is predominantly dominated by doping, which changes the Fermi level, contact resistance, threshold voltage, and electrical conductivity. Fortunately, TMDs exhibit thickness-modulated band structures. Depending on the layer thickness, the position of the Fermi level changes, which implies that the effect of doping in the TMD can be observed by controlling the number of layers.

In this study, various functions have been realized in MoS\textsubscript{2}/MoTe\textsubscript{2} van der Waals heterostructures via controlling the thickness and carrier concentration of MoTe\textsubscript{2}. Thickness-dependent work function of MoTe\textsubscript{2} was confirmed by Kelvin probe force microscope (KPFM) measurement. The 2L MoS\textsubscript{2}/Few-layer (FL) MoTe\textsubscript{2} device could transform
from a $p-n$ forward diode into a Zener diode through the electrostatic gating effect. Moreover, the multi-layer MoS$_2$/multi-layer MoTe$_2$ device can be modulated between backward diode characteristic and forward diode characteristic with a rectification ratio up to $10^3$ at room temperature. Furthermore, many-valued logic (MVL) devices, which have more than three different logic states, are expected to provide higher efficiency than binary logic devices. MVL devices can help reduce the interconnection density and the number of transistors in logic circuits. For example, to create a ternary logic circuit, more than nine single transistors are used. In addition, we introduce a multi-valued inverter composed of 2L MoS$_2$/ FL MoTe$_2$ heterostructure showing three truth states (ternary inverter). In particular, our ternary inverter can be transformed to binary using simple laser irradiation. Our work also significantly benefits the electronics research, which follows the Moore’s law and beyond.

11:45 AM FF01.23.06
Atomically-Precise Moiré Fringes in 2D van der Waals Heterostructures of Graphene and Hexagonal Boron Nitride Sanjay K. Behura$^1$, Songwei Che$^1$, Phong Nguyen$^1$, Chen Wang$^1$, Rousan Debbarma$^1$, Michael R. Seacrist$^2$ and Vikas Berry$^1$; $^1$University of Illinois at Chicago, United States; $^2$MEMC LLC, United States

The van der Waals force-bound heterostructures of isostructural and isoelectronic graphene and hexagonal boron nitride (h-BN) offer a platform for fundamental phenomena evolving from the resultant Moiré superlattices. Such phenomena in two-dimensional (2D) planar sp$^2$ lattice stacks of graphene/h-BN or graphene/h-BN/graphene or h-BN/graphene/h-BN are sensitive to their atomic-scale assembly. Current techniques rely on physical or chemical transfer of both h-BN and graphene to build the 2D sandwich heterostructure circuits. These transfer-steps not only introduce the interfacial polymeric and metallic heteroatom impurities but also creates random or mis-aligned regions in the 2D-heterostructures. Here, we report Moiré fringes in the graphene and h-BN heterostructures developed through direct stacking of graphene and h-BN via a bottom-up all-chemical vapor deposition (CVD) strategy. Polycrystalline layer of h-BN is first synthesized via a surface chemical-interaction guided process on silicon-based gate-dielectric substrate. Then the graphene layer is grown via grain-boundary diffusion of catalytically produced carbon radicals through a polycrystalline metal film on h-BN. Finally, removing the thin metal film (and any graphene on it) results in graphene/h-BN heterostructures with a sharp, defect-free, and atomically-precise interfaces; as confirmed by scanning resonant Raman spectroscopy and X-ray photoelectron spectroscopy studies. The directly-grown, van der Waals bound graphene/h-BN heterostructures exhibit Moiré fringes with a periodic pitch of $\approx 10$ Å at a rotation angle of 16$^\circ$. Further, the low-temperature transport measurements reveal the charge carrier mobility of 100 cm$^2$V$^{-1}$s$^{-1}$, 2-orders of magnitude higher than the graphene/h-BN heterostructure produced via co-segregation process. Futuristically, this all-CVD direct-growth strategy will be a transformative approach for scalable production of van der Waals heterostructures to realize complex 2D circuitry and fundamental physics phenomena.

SESSION FF01.24: Fundamental Properties in 2D Material

Induced Atomic Ordering in Two-Dimensional Alloys Amin Azizi$^1$, Mehmet Dogan$^{1,2}$, Jeffrey D. Cain$^{1,2}$, Rahmatollah Eskandari$^1$, Xuanze Yu$^1$, Emily C. Glazer$^1$, Marvin Cohen$^{1,2}$ and Alex Zettl$^{1,2}$; $^1$University of California, Berkeley, United States; $^2$Lawrence Berkeley National Laboratory, United States

Semiconductor alloys enable fabrication of materials with continuously tunable properties such as lattice constant, bandgap, and carrier mobility, and has been a key strategy for property engineering throughout the history of semiconductor devices. However, it has long been an open question whether the atoms in the lattice of a multispecies alloy are randomly distributed or ordered in some way. The answer is fundamentally important, as the electronic, optical, thermal, and mechanical properties of alloys can be significantly affected by the presence of ordering. Ordering in semiconductor alloys has been studied, but most of the reports have been limited to reciprocal space, such as diffraction techniques. Two-dimensional (2D) materials provide an ideal playground to directly
visualize potential ordering in semiconductor alloys. However, 2D TMD semiconductor alloys reported to date have mostly been random. Here, we demonstrate experimental observation of atomic ordering in a monolayer semiconductor alloy and suggest a strategy to control ordering in 2D semiconductor alloys. Additionally, combined with theoretical calculations, we demonstrate how the induced atomic ordering can notably modify the bandgap of the monolayer alloy with respect to its random counterpart.

2:00 PM FF01.24.02
Defects and New Phases in Inorganic Two-Dimensional Materials—Insights from Multi-Scale Atomistic Simulations Arkady Krasheninnikov; Helmholtz-Zentrum Dresden-Rossendorf, Germany

As compared to bulk solids, large surface-to-volume ratio of two-dimensional (2D) materials makes many of them particularly prone to defect formation due to the interaction with the environment. At the same time, this opens new opportunities for post-synthesis introduction of impurities into these systems by, e.g., vapor deposition, development of new phases and thus tailoring their properties. In my talk, I will present the results of our recent theoretical studies of defects (native and irradiation-induced) in 2D systems obtained in close collaboration with several experimental transmission electron and scanning tunneling microscopy groups [1,2,4]. I will further discuss defect- and impurity-mediated engineering of the electronic structure of 2D molybdenum dichalcogenides by introducing transition metal atoms using ion beams and atom deposition at elevated temperatures [3]. Finally, I touch upon the intercalation of Li and other alkali metal atoms into bilayer graphene [4] and MoS₂ [5].

2:15 PM FF01.24.03
Extrinsic and Dynamic Edge States of Two-Dimensional Lead Halide Perovskites Letian Dou and Enzheng Shi; Purdue University, United States

As a new family of two-dimensional semiconductor materials, organic inorganic 2D halide perovskites have drawn significant attention in the past few years. Edges of 2D halide perovskites are found to exhibit unusual properties such as enhanced photoluminescence lifetime and reduced photoluminescence emission energy. In this talk, I will present the formation mechanism and the dynamic nature of edge states on the exfoliated 2D halide perovskites thin crystals. In contrast to other 2D materials, the edge states in 2D perovskites are extrinsic and can be triggered by moisture with a concentration of as low as ~ 0.5 ppm. High-resolution atomic force microscopy and transmission electron microscopy characterizations reveal the width of the low-energy states is ~ 40 nm wide. Temperature-dependent photoluminescence study suggests the edge states are a combination of several lower-energy states. Importantly, we demonstrate that the charge carriers on the dynamically formed edge states are not only long-lived, but also highly mobile and can be conducted along the edges effectively with high mobilities of 5.4-7.0 cm²V⁻¹s⁻¹. This work provides significant insights on the origin of the edge states in 2D perovskites and provides routes to manipulate their optical and electrical properties through controlling their edges.

Liquid-Mediated Strain Relaxation in 2D Materials Humberto Batiz Guerrero¹,² and Daryl Chrzan¹,²;¹University of California, Berkeley, United States; ²Lawrence Berkeley National Laboratory, United States

Due to its low dimensionality, properties in 2D materials are predicted to be more sensitive to strain than in their 3D counterparts. Specifically, in the case of few-layers transition metal dichalcogenides, the direct or indirect nature of the band gap, as well as its value, can be strain engineered [1]. Recently, a solvent evaporation-mediated decoupling process was demonstrated [2]. In this process, the strain within a WSe₂ grown on amorphous silica that arises from thermal expansion mismatch is released by the evaporation of an acetone droplet that initially covers the WSe₂ sample. A model for this strain release process is proposed and studied. The model assumes that the frictional forces
between the WSe₂ film and the substrate stabilize the strain within the film. As the droplet evaporates, the triple point, i.e. where the air, acetone, WSe₂ meet, is lifted from the substrate, thereby reducing the friction force and enabling strain relaxation. Taking into account the elastic, interfacial, and substrate-film interaction energies, a functional for the energy of the system is constructed and the differential equations governing the configuration of the system are derived, with the in- and out- of-plane displacements of the film being the relevant variables. A numerical approach is used to solve the resulting highly-nonlinear equations. The dynamics of the system are computed in an adiabatic manner. In this way, it is possible to gain insight about how the process could be enhanced. Theoretical understanding of a process that allows controlled strain release can potentially allow the processing of new devices with novel and interesting optoelectronic properties.

This work was supported within the Electronic Materials Program at LBNL by the Director, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division of the U.S. Department of Energy, under Contract No. DE-AC02-05CH11231.

2:45 PM FF01.24.05
Plasmon Free Surface Enhanced Raman Spectroscopy Using Metallic 2D Materials Xiuju Song¹²³, Yan Wang⁴, Fang Zhao⁵, Jieun Yang⁶, Wenjing Zhang⁷ and Munish Chhowalla⁸¹; ¹Rutgers, The State University of New Jersey, United States; ²Shenzhen University, China; ³The University of Manchester, United Kingdom; ⁴University of Cambridge, United Kingdom; ⁵Princeton University, United States

Two dimensional (2D) materials-based plasmon free surface enhanced Raman scattering (SERS) is an emerging field in non-destructive analysis. However, impeded by the low density of states (DOS), an inferior detection sensitivity is frequently encountered due to the low enhancement factor of most 2D materials. Metallic transition metal dichalcogenides (TMDs) could be ideal plasmon free SERS substrates because of their abundant DOS near the Fermi level. However, the absence of controllable synthesis of metallic 2D TMDs has hindered their study as SERS substrates. Here, we realize controllable synthesis of ultra-thin metallic 2D niobium disulfide (NbS₂) (<2.5 nm) with large domain size (>160 μm). We have explored the SERS performance of as-obtained NbS₂, which shows a detection limit down to 10⁻¹⁴ mol/L and an enhancement factor of up to ~10⁶. The enhancement mechanism was studied in-depth by density functional theory, which suggested a strong correlation between the SERS performance and DOS near the Fermi level. NbS₂ features most abundant DOS and strongest binding energy with probe molecules as compared with other 2D materials such as graphene, 1T phase MoS₂ and 2H phase MoS₂. The large DOS increases the intermolecular charge transfer probability and thus induces prominent Raman enhancement. To extend the results to practical application, the resulting NbS₂-based plasmon free SERS substrates were applied for distinguishing different types of red wines.

Using Computation to Resolve Discrepancies in the Reported Optical Properties of Two-Dimensional Black Phosphorous Thierry Tsafack, Stephen F. Bartolucci and Joshua A. Maurer; U.S. Army Futures Command, Combat Capability Development Command, United States
Two-dimensional black phosphorous, phosphorene, is an ideal candidate for flexible opto-electronics because it possesses a direct and tunable band gap, a high carrier mobility and a negative Poisson’s ratio. The band gap and photoluminescence emission maxima vary as a function of the number of phosphorene layers. Multiple experimental studies have reported a wide range of values for the photoluminescence emission maxima as a function of number of phosphorene layers. This disagreement limits our understanding of phosphorene’s optical properties, which are critical to many of the potential applications for this material. These discrepancies may be a result of oxidation altering the photoluminescent properties. To understand these differences, we have created computational models that allow us to understand the effects of oxidation and number of layers on the optical properties of phosphorene. Many-body perturbation theory in conjunction with both the Bethe-Salpeter-Equation (BSE) and the Green’s function screened potential (GW) have been used to derive absorption spectra that include excitonic and other many-body effects. These studies allow us to understand how oxidation level and layer number affect phosphorene’s absorption spectra, which, in turn, provides useful insights into phosphorene’s photoluminescence excitation and emission maxima.

2D Transition Metal Carbide (MXene) Thin Film for EMI Shielding and Heating Applications Chong Min Koo1,2; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Korea University, Korea (the Republic of)

MXenes are a family of 2D transition metal carbides, nitrides, and carbonitrides with the general formula Mn1XnTx (n = 1, 2, or 3; M = transition metal, e.g. Ti, Nb, Mo; X = C and/or N; T = surface termination, e.g. –OH, –F, –O). Unlike other 2D materials, MXenes offer an attractive combination of high electronic conductivity (~5000 S/cm), hydrophilicity, and processability. Transition metal carbide (MXene) have been considered as an effective EMI shielding material since we reported the outstanding EMI shielding effectiveness of MXenes (60dB at 10mm) in 2016. However, still it is lack of understanding EMI shielding behavior of MXene materials, especially, at the atom-scale thickness, because it is hard to make uniform atom-thick film. In this presentation, we present the EMI shielding behavior of MXene thin film with atom-level thickness, which was prepared through a self-assembly method. Monolayer-thick MXene film offers 20% shielding ability and a 24 layer film of 55 nm thickness demonstrates 99% shielding (20dB) and extraordinarily large specific shielding effectiveness per unit areal density (SSE/t = 3.89*106 dB cm2/g), revealing that MXene is very good for ultra-thin film shielding applications. Additionally, it will be demonstrated that, due to good shape-adaptability, easy processability and low sheet resistance, MXene thin films is very good for wearable heating device application.

3:45 PM FF01.25.02
Enhancement of the Superconducting Transition Temperature through the Formation of 2D Molybdenum Carbide/Disulfide Heterostacks Fu Zhang1, Yanfu Lu1, Wenkai Zheng2, Lavish Pabbi1, Kazunori Fujisawa1, Ana Laura Elias1, Eric Hudson1, Susan Sinnott1, Luis Balicas1 and Mauricio Terrones1, 1Pennsylvania State University, United States; 2Florida State University, United States

Two dimensional (2D) crystals beyond graphene exhibit promising functionalities in catalysts, optoelectronics and electronics. Recently, renascent transition metal carbides (TMCs, e.g. molybdenum carbide) show nontrivial superconductivity even when scaled down to few layers thin samples. Conjugation between 2D superconducting TMCs and semiconducting transition metal dichalcogenides (TMDs, e.g. MoS2) needs to be realized for the next-generation logic circuits. In this work, high quality superconducting 2D α-phase molybdenum carbide (Mo2C) flakes were synthesized on molten copper, and used to produce 2D molybdenum carbide/disulfide heterostructures having
atomically sharp interfaces through a gas phase reaction. Through aberration corrected transmission electron microscopy (AC-TEM) we found that the 2D molybdenum carbide crystal undergoes a series of structural phase-transitions between phases α-γ'-γ phases upon sulfurization. Hybrid systems, such as the γ'-phase, exhibit superconductivity with a higher critical temperature ($T_c$) than the original Mo$_2$C compound, transitioning into the metallic γ-phase upon increasing the sulfur content. This study demonstrates the stabilization of 2D γ-MoC and γ'-MoC$_{1-x}$ using Mo$_2$C as the precursor, and provides an alternative way to enhance the superconductivity molybdenum carbides via a phase-transition in the carbide (or nitride in future) systems. Such atomically sharp superconductor/semiconductor heterojunctions are critical for functional electronic components.

4:00 PM FF01.25.03
Characteristics of Gas Sensor Based on Molybdenum Disulfide/Graphene van der Waals Heterostructure
Shoji Maeda$^1$, Ryota Isu$^1$, Christopher J. Perini$^2$, Daiju Terasawa$^3$, Akira Fukuda$^3$, Masatoshi Koyama$^3$, Akira Fujimoto$^3$, Yoshiyuki Harada$^1$, Kazuto Koike$^1$, Mitsuaki Yano$^1$ and Eric M. Vogel$^2$; $^1$Osaka Institute of Technology, Japan; $^2$Georgia Institute of Technology, United States; $^3$Hyogo College of Medicine, Japan

Graphene and 2-dimensional (2D) materials such as transition-metal dichalcogenide (TMD) provide a wide range of unique electrical and optical properties. Such 2D gas-sensing materials possess structural advantages, for example, a high surface-to-volume ratio and the tunable functionality of the surface for decoration species. Therefore, they have attracted immense interest as new gas-sensing materials. In particular, the resistance of the device decreases when the n-type 2D sensing layer is exposed to reducing gases such as H$_2$. Besides, van der Waals heterostructures (vdWH) consisting of graphene and TMD [1] also are fascinating a lot of researchers working on 2D materials. A MoS$_2$/graphene vdWH is reported to show a significant change in resistance upon exposure to 1 ppm NO$_2$, originating from the modulation of the Schottky barrier height at the interface [2]. The purpose of our study is to synthesize large-area MoS$_2$ on SiO$_2$/Si substrate. Furthermore, we make the transistors and the vdWH consisting of graphene and MoS$_2$, which transduces gas-molecules adsorption on the surface and the interface into a change of the resistance.

In order to control the number of MoS$_2$ layers and grow large-area MoS$_2$, 1 nm Mo layer was deposited on SiO$_2$/Si substrates by e-beam evaporation. The Mo films were then directly sulfurized in a furnace at 900 degrees for an hour. The grown large-area MoS$_2$ films showed $E_{2g}^1$ Raman peak at 383.0 cm$^{-1}$ and $A_{1g}$ one at 406.9 cm$^{-1}$. This corresponds to a peak separation 23.9 cm$^{-1}$ of 3 layers MoS$_2$ [3]. We fabricated the MoS$_2$ transistors and examined the back-gate voltage and the drain one ($V_D$) dependences of the drain current ($I_D$). We confirmed the linearity of $V_D$–$I_D$ characteristics less than $V_D = 10$ V. Moreover, we extracted the field-effect mobility for a transistor with gate length/width = 100 μm /100 μm, but the value was much smaller than that of a previous study [4], resulting from the poor crystallinity of our MoS$_2$. However, this suggests our MoS$_2$ has a lot of adsorbed sites and is of advantage to adsorb more gas molecules.

We employed chemical vapor deposited (CVD) single-layer graphene and MoS$_2$/Graphene vdWH for gas-sensing. We put the devices on a sample stage heated at 200 degree C in a sealed test chamber and measured the resistance by flowing 1000 ppm H$_2$, 100 ppm NO and 100 ppm NH$_3$, respectively. NO gas becomes oxidizing NO$_2$ gas in the air. These flow rates of these gases and dry air gas were adjusted with a mass flow controller. In the case of CVD graphene, the change rate in resistance was just about 3 % for these gases. These results are corresponding to previous research [5]. On the other hand, the change rate in resistance of MoS$_2$/graphene vdWH was approximately 20% for H$_2$ and NO gases. Furthermore, by increasing the flow rate of the NO gas from 10 ppm through 100 ppm, a step-like change of the resistance was observed, and we confirmed the change of the resistance responded to the flow rate of NO gas. One of the mechanisms of gas adsorption for our vdWH is that MoS$_2$ acts as an adsorption layer and promotes the increase of hole concentration in graphene. Now we are making a lot of efforts to improve our vdWH and increase the Schottky barrier height, so that the resistance changes significantly by means of adsorbing gas molecules at the interface.

Two dimensional (2D) transitional metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS$_2$) have been demonstrated to be excellent semi-conductors for ultra-thin field effect transistors (FETs). However, the main challenge for improving the performance of FETs using 2D semiconductors is lowering contact resistance. Studies have shown that the creation of van der Waals contacts by dry transfer (graphene$^1$, hBN$^2$, metal$^3$) method can avoid damage to atomically thin TMD semiconductors caused by metal deposition. We recently reported the realization of ultra-clean van der Waals contact between Indium alloys and 2D materials$^4$. Here, we take advantage of the soft nature of indium to alloy it metals such as Au, Pd, Pt and Co to vary the work function so that both hole and electron injection is facilitated. We have measured the work function of the alloys using Kelvin force microscopy and correlated them with band offsets in WSe$_2$, MoSe$_2$, and mixture of WSe$_2$/MoSe$_2$ devices. Furthermore, we have systematically studied how annealing at different temperatures affects the alloy/semiconductor interface and FET performance.

Non-Linear Fluidic Transport in sub-2nm Channels—Towards Artificial Mechanosensitivity
Lyderic Bocquet1,2; 1Ecole Normale Superieure, France; 2CNRS, France

It is an exciting period for *nanofluidics*, the field exploring the transport of fluids at the nanoscales. Routes now exist to fabricate individual channels with nanometric and even sub-nanometric dimensions, while new instruments have also been invented to probe transport across these channels. And indeed, a number of quite exotic properties for water and ion transport have emerged since.

In this presentation I will discuss the emergence of strongly non-linear transport in ultimate confinement. I will report experiments exploring ionic transport under combined voltage and pressure driving: both in 2D channels made of van der Waals nanostructures, and in sub-2nm carbon nanotubes. In both types of channels, strong couplings between voltage-driven and pressure-driven transport are highlighted. I will show how such phenomena can be rationalized theoretically in terms of the coupled ion dynamics and flow transport, emphasizing on the key role of surface friction on ionic transport. Beyond I will further show theoretically how the classical equivalent of Coulomb blockade does emerge for ionic transport in 1D systems, via a fractional Wien effect.

These various phenomena lead to tunable ionic transport under specific stimuli, and they allow to envision the design of artificial mechano-sensitive response, similar to those observed in biological channels.

This work was done in collaboration with T. Mouterde, A. Poggioli, A. Marcotte, N. Kavokine, A. Niguës, A. Siria, from *Micromégas* team, ENS Paris, and with A. Keerthi, S. Dar, R. Boya and A.K. Geim, from Manchester University.

Nanofluidic Transport across Nanoporous Atomically Thin Graphene and Its Development as a Next-Generation Membrane
Rohit N. Karnik; Massachusetts Institute of Technology, United States

Nanoporous atomically thin membranes, wherein nanopores in two-dimensional materials provide pathways for rapid and selective fluidic transport, represent the ideal limit of an ultrathin membrane and have potential for improving the efficiency, selectivity, productivity, versatility, and chemical resistance for a variety of membrane separations. I will discuss our work on understanding mass transport and developing membranes that employ nanoporous single-layer graphene as the selective layer. Through controlled nucleation of defects via ion bombardment and oxidative etching, sub-nanometer pores are created in the otherwise impermeable graphene placed on a porous support. We discuss strategies for the design of defect-tolerant membranes and show that design of the porous support is critical to exploiting the selectivity of nanoporous graphene, which enables molecular sieving of gases across centimeter-scale nanoporous graphene membranes. We investigate the role of defects, illustrate methods to rapidly assess nanoscale defects in graphene, and demonstrate that the impermeability of graphene can be exploited to selectively seal defects and greatly improve its selectivity. Through these developments, we are able to realize centimeter-scale graphene membranes that show high selectivity between ions, molecules, and proteins for nanofiltration and dialysis, and ultrahigh permeance in organic solvent nanofiltration. We also demonstrate that the membranes exhibit high mechanical strength and are able to withstand applied pressures of 100 bar. These studies
illustrate the interplay between material structure and transport in nanoporous graphene and demonstrate its potential for the realization of next-generation membranes for water purification, bio/chemical separations, and other applications.

**9:15 AM FF02.01.03**

*Translocation of DNA through Ultrathin hBN/Graphene Nanoslits* Wayne Yang, Ashok Keerthi, Gangaiah Mettela, Andre Geim, Radha Boya, and Cees Dekker; 1Kavli Institute of Nanoscience, Delft University of Technology, Netherlands; 2The University of Manchester, United Kingdom; 3National Graphene Institute, United Kingdom

2D nanoslit devices, where the planes of two 2D materials such as hBN or graphene are separated by only a few nm, have attracted a lot of attention for their interesting water- and ion-transport behavior arising from their interesting confined geometry. Here, we investigate the passage of single DNA molecules through such nanoslits. These 2D nanoslits allow us to examine the entropic stretching behavior of DNA and its friction interactions of DNA with 2D materials as both are in close contact during translocation. Double-stranded (ds) DNA (which has a diameter of 2.2 nm) of 1-10kbp length in 2M LiCl salt is electrophoretically driven across a 2D nanoslit. The devices have a length of 1-2 microns, a width of 80-120nm and a height of only 3-6 nm. Upon entry into the channel, the dsDNA blocks the passage of ions leading to temporary current blockades – similar to nanopore translocations. Due to their small slit height, the entrance to the nanoslit presents a significant entropic barrier that the dsDNA must overcome in order to translocate into the slit. Shortening the dsDNA length allows the entropic barrier to be overcome and clear dsDNA translocations to be resolved. Increasing the bias voltage allows for an increased signal-to-noise ratio and well resolved dsDNA blockade current signals. Ongoing experiments are underway to investigate the role of interaction and friction between the surface of different 2D materials and the translocating biomolecules.

*Water Evaporation from Graphene Nanopores* Siyang Xiao, Quan Xie and Chuanhua Duan; Boston University, United States

Nanoporous graphene membrane has shown great potentials for various promising applications such as water desalination, biochemical separation, energy management and biosensing, owing to the atomically 2-D structure of graphene and the fast molecular transport across graphene. These features of graphene also make nanoporous graphene membrane most desirable as nanoporous membrane evaporators. The atomic thickness of graphene can minimize hydraulic resistance during evaporation and the ultra-high mechanical strength of graphene can provide excellent mechanical stability of the membrane. Therefore, nanoporous graphene membrane is expected to achieve the ultimate performance of nanoporous membrane evaporator. However, there are two major challenges that inhibit the development of nanoporous graphene membrane evaporators: 1) evaporation kinetics from single graphene nanopore remains unknown and consequently there are no rational optimization guidelines for graphene nanoporous membrane evaporators; 2) there is still no mature method to fabricate scalable graphene nanoporous membranes and integrate them as evaporators. In this work, we aim to solve the first challenge by experimentally studying evaporation from graphene membranes with single nanopores and provide insights for solving the second challenge. We used a hybrid nanochannel-nanopore design that we recently invented to conduct water evaporation measurements. This design has been proved to be able to achieve kinetic-limited evaporation regime, where evaporation flux is only limited by evaporation kinetics at liquid-vapor interface at nanopore mouth instead of liquid/vapor transport toward/away from the interface. Furthermore, such design is capable to accurately measure evaporation flux from individual nanopores. Our results show that water evaporation flux from graphene nanopores increases as pore diameter decreases, exhibiting a similar trend but higher diameter dependence than water evaporation from silicon nitride nanopores. The highest measured flux from a graphene nanopore with diameter of 73 nm is 2.1 mm/s at room temperature, corresponding to the heat flux of 480 W/cm², reaching 80% of
evaporation flux limit predicted by the classic Hertz-Knudsen theory. The enhanced evaporation from graphene nanoparticles compared to silicon nitride nanopores could be corroborated by a recent MD study which showed that the edge of graphene can facilitate evaporation due to the unique graphene-water interactions. Our findings provide new understanding of evaporation from graphene nanopores and consequently provide guidance for the design of nanoporous graphene membrane evaporators.

Field-Boosted Selectivity in Nanoscale Transport Ke Zhou and Zhiping Xu; Tsinghua University, China

Recent experiments have confirmed that nanoscale mass transport of gases, water and ions can be modulated by external stimuli such as pressure, temperature and the external electric field (EEF). Compared to pressure and temperature, the EEF can be applied in-situ, with remarkable stability and a wide range in amplitude control. Here, I will present two of our recent work focused on the controlled transport of hydrated ion and gas in nanochannels through the response in ionic motion under the EEF. We first demonstrate the enforcement of near-surface ion diffusion under an EEF, where their hydration shells are distorted while making contact with the surface. We find from molecular simulations a trapped/hopping scenario of diffusive ionic dynamics, where the diffusivity does not depend on their hydration radius but the corrugation of the free energy surface. As a result, the diffusion-specific selectivity can be elevated to ~10 at the expense of reduction in the mobility. The second theoretical study on the ionic liquids (ILs) confined in graphene oxide membranes suggests that the spatial distribution of cations and anions can be displaced under the EEF, modifying the absorption/desorption process and gas solubility in the composite membrane, leading to significantly enhanced gas selectivity. The findings are validated by experimental data, demonstrating separation performance that is superior to the upper bound of state-of-the-art membranes.

Selective Permeation of Low Dimensional Materials Hyung Gyu Park¹,²; ¹Pohang University of Science and Technology, Korea (the Republic of); ²Eawag (Swiss Federal Institute for Aquatic Science and Technology), Switzerland

Membrane technology promises to bring process intensification to various industrial processes such as chemical separation and resource purification. Membrane-participating processes can become more effective if selectivity, permeation and durability of membrane materials are improved. In this regard, mass transport phenomena under extreme confinement offered by low dimensional materials call for attention because understanding of their characteristics could help designing the membrane pores. Here, I present selective transport phenomena across 0D, 1D and 2D confined space that atomically thin orifices, nanotubes and 2D material lamellas provide, respectively. As the confinement dimension increases, mass permeation tends to decrease from ultimate permeation to fast transport to unimpeded diffusion, whereas chemical selectivity is prone to increase inherently. Nevertheless, one may tailor actual chemical selectivity through proper pore design and architectural modification. Thus obtained knowledge and pore architectures could lay the cornerstone of advancing membrane transport properties toward process intensification.

Electrochemical Nano-Fluidics Robert Dryfe, Pawin Iamprasertkun, Radha Boya, Ashok Keerthi and Gangaiah Mettela; University of Manchester, United Kingdom

The movement of electrolyte solutions within nanometer-scale channels is central to understanding nanofluidic phenomena. Ion transport within small (nm) scale pores is also key to electrochemical energy storage, where the energy storage process is dependent on ionic ingress into porous carbon materials [1,2]. Although very significant advances in the understanding of ion movement within electrically charged pores have been made [3], a key barrier is that porous carbon materials contain a complex distribution of interconnected pores of varying size, making it difficult to de-convolute specific size effects. A further connection between the fields of nanofluidics and electrochemistry arises because electrochemical control, based on the phenomenon of electrowetting, may be used to drive liquids into small channels [4]. We have been able to overcome this restriction by applying the nanochannel technology developed by Radha et al [5,6] in the electrochemical context, where one “wall” of the graphene channel
is used as an electrode. We are therefore able to observe the effects of differing ion sizes on electrical double-layer capacitance, additionally, the effects of such extreme confinement on electrochemical processes (both capacitive and Faradaic) can also be discerned.

Water Filling of Isolated Single-Walled Carbon Nanotubes—Cataloguing Dependence on Diameter and Etch Technique
Samuel Faucher, Natalie Northrup, Matthias Kuehne, Daichi Kozawa, Volodymyr Koman and Michael Strano; Massachusetts Institute of Technology, United States

Single-digit nanopores, or those with characteristic dimensions less than 10 nm, can induce dramatic changes in phase behavior and transport of the fluids they confine. Isolated single-walled carbon nanotubes (SWNT) form well-characterized nanopores and have been shown to contribute to anomalous water transport and phase behavior. Here, we introduce a scanning method using Raman spectroscopy that we use to rapidly determine the filled state of isolated SWNT. By scanning large numbers of carbon nanotubes, we show that substantial changes (~3 cm⁻¹) in the Raman radial breathing mode occur only in situations consistent with fluid filling, demonstrate the relative success of wet and dry etching in opening carbon nanotube ends, and discuss the diameter dependence of water filling. Specifically, the proportion of carbon nanotubes that fill increases dramatically with nitric acid treatment, while variations in filled proportion are strong but non-monotonic with carbon nanotube diameter.

Two-Dimensional Materials Get Electrified in Water—Ab Initio Simulations of the Surface Reactivity of Graphene, h-BN, Their Heterostructures and Graphene Oxides in Water
Benoit Grosjean¹, Felix Mouhat¹, Anton Robert¹, Francois-Xavier Coudert², Rodolphe Vuilleumier¹ and Marie-Laure Bocquet¹; ¹CNRS and ENS Paris, France; ²PSL University, France

Currently basal planes of 2D materials like graphene (G) and hexagonal boron nitride (BN) are considered inert towards covalent addition chemistry in aqueous conditions. However recent ionic transport experiments have unveiled a considerable electrification of the water-BN surfaces [1], with a contrasting response for its water-Graphite homologue [2]. This surface charging was conjectured to originate in the differential hydroxide adsorption at the surface of these twin materials, but the considerable challenge of simulating the elusive hydroxide ion in liquid water has precluded a proper explanation up to now.

In this talk I will first show by means of ab initio simulations that 2D materials do strongly interact with the hydroxide ion from water. As a key ingredient, our ab initio simulations involve the description of the quantum nature of both the layered material and liquid water, corresponding to Ab Initio Molecular Dynamics (AIMD). A full quantum treatment is indeed required to explore the targeted interfacial chemical reactivity of liquid water, in particular to properly include dynamical proton transfers between H-bonding water molecules, a process denoted as the Grotthuss mechanism. We highlight a strong (covalent) chemisorption of the OH⁻ anion on boron-nitride, while the OH⁺ ion is only physisorbed on the graphene layer. Furthermore in its physisorbed state, the OH⁻ species retains a large surface mobility thanks to the Grotthuss mechanism, here confined at the graphene interface [3]. Building on these findings, we extended our exploration of liquid water at graphene-hBN heterojunctions. Counterintuitively, our ab initio simulations of liquid water do show that liquid water does dissociate on such borders [4], leading to the spontaneous formation of an adsorbed OH⁻ ion, while the proton is liberated in the liquid.

Finally I will extend the scope of water reactivity to activated 2D materials, like graphene oxide surfaces [5]. Our ab initio results point in particular a strong dynamical reactivity of the epoxide functions.

These different results are expected to impact strongly the ionic transport across such stacked graphitic membranes.
In spite of their difficulty, quantum insights open unprecedented avenues for the use of intertwined 2D materials for nanofluidics.[6]

Ionic Mobility Engineering in Sub-Nanometer Graphitic Channels  Massimo Spina, Nathan Ronceray, Mordjann Hind Soulammas, Kittipitch Yooprasertchuti and Slaven Garaj; National University of Singapore, Singapore

Nanochannels based on carbon materials have been intensively studied in the last decade because of their promising application in nanofiltration and the novel physical phenomena arising between graphitic surfaces at the nanoscale. More recently, atomically-smooth graphitic channels with sub-nm heights have been fabricated and used to investigate the physics of ions and water molecules in slits comparable to the smallest ion sizes.

In this work, we investigated ionic flow in atomically-smooth graphitic channels with height ranging from 7Å to 35nm. We show that the mobilities of ions in such confinements do not scale with hydration shell in a simple fashion, and we further explored the role of the surface charge, physical confinement and chemical interactions. Engineering ionic mobilities within the graphitic channels, we could induce strong current driven by the salinity gradient. Such osmotic power generators – driven by mobility engineering, rather than surface charge – are more resilient on the variation of chemical environment and show orders of magnitude increase in osmotic power density compared to commercial membranes.

Carbon Nanotube Porins—A Versatile Biomimetic Platform for Studying Nanofluidic Transport Phenomena  Aleksandr Nov., 1,2 Lawrence Livermore National Laboratory, United States; 2University of California, Merced, United States

Controlling molecular transport on a molecular scale is important for applications ranging from membrane separations, to bioelectronic interface design. Living systems move ions and small molecules across biological membranes using protein pores that rely on nanoscale confinement effects to achieve efficient and exquisitely-selective transport. Carbon nanotube porins—pore channels formed by ultra-short carbon nanotubes assembled in a lipid membrane—can exploit similar physical principles to transport water, protons, and small ions with efficiency that rivals and sometimes exceeds that of biological channels. I will discuss the role of molecular confinement and slip flow in these pores and show how it can enhance water and proton transport efficiency and influence the mechanisms of ion selectivity in these pores. Overall, carbon nanotube porins represent simple and versatile biomimetic membrane pores that are ideal for studying nanoscale transport phenomena and building the next generation of separation technologies and biointerfaces.

2:00 PM FF02.02.02
Fast Ion Diffusion in Carbon Nanotube Channels  Steven F. Buchsbaum, Melinda L. Jue, Chiatai Chen, Eric R. Meshot, Sei Jin L. Park, April Sawvel, Edmond Lau, Tuan Anh Pham, Kuang Jen Wu and Francesco Fornasiero; Lawrence Livermore National Laboratory, United States
Many simulations and experiments have investigated pressure-driven fluid flow in carbon nanotubes (CNTs) and demonstrated enormous transport rates through these channels. Comparatively little attention has been given so far to concentration-driven transport in CNTs despite its importance in a large variety of fields. While a few studies assumed bulk/hindered diffusion for small molecules through nm-wide CNTs, other simulations have predicted self-diffusion coefficients several times larger than in the bulk, and NMR experiments supporting these claims are beginning to emerge. These large uncertainties in the magnitude of the diffusion rates through CNTs have hampered their full exploitation in nanofluidic devices.

To obtain a precise quantification of the diffusive flow in CNTs, we have fabricated membranes with a large but known number of single-walled carbon nanotubes (SWCNT) as fluid transport pathways. Contrary to previous membrane systems, this platform enables us to minimize uncertainties in the calculation of the per-pore flow rate. A series of stringent control experiments confirms that these membranes are defect free and that transport occurs only through SWCNTs. Once corrected for the boundary layer resistance at the membrane/fluid interface, our measurements indicate that the transport diffusivity of small ions in single-walled carbon nanotubes is about an order of magnitude faster than in the bulk. The dependence of the flow enhancement on the ion chemico-physical properties is also discussed. These results suggest that CNT membranes could enable dialysis process with unprecedented efficiency, shed further light onto the unique transport properties of graphitic channels, and enable a more accurate design of CNT-based fluidic systems for a broad range of applications.

Leveraging Large-Scale Electronic Structure for Multi-Scale Models of Confined Solutions Mengyi Wang, Zhongyue Yang and Heather J. Kulik; Massachusetts Institute of Technology, United States

Water exhibits unique properties under confinement that are distinct from properties of bulk water. Atomistic modeling can provide valuable insight into differences in nano-confined (e.g., by nm-scale carbon nanotubes) water and salt solutions. However, accurate, first-principles modeling of molecular interactions is necessary to predict emergent properties. To better understand the graphene-water interface in such systems, we performed ab initio molecular dynamics on representative confined systems. We investigate the nanoscale solvation behavior of selected ions on coronene and circumcoronenes as finite graphene models. We investigate the degree of charge transfer between the ion and water with range-separated hybrid density functional theory as well as how that charge transfer fluctuates during dynamics. We also investigate how defects alter these dynamics and solvation in model systems.

Unraveling the Role of Many-Body Polarization Effects on the Thermodynamic and Transport Properties of Nanoconfined Water Inside Carbon Nanotubes Rahul Prasanna Misra and Daniel Blankschtein; Massachusetts Institute of Technology, United States

Extremely fast water transport and high ion selectivity in smaller-diameter carbon nanotubes (CNTs) have raised the prospect of the practical use of CNTs in membrane-based applications. Several experimental and molecular dynamics (MD) simulation studies have reported that the CNT wall behaves like a nearly frictionless surface, which results in a significant enhancement of the water flow rate through CNTs. The extent of water flow enhancement is typically quantified using the concept of a slip length, which mathematically represents the extrapolated distance relative to the wall of the CNT where the water velocity goes to zero. Although previous MD simulation studies have laid a solid foundation to uncover the molecular mechanisms responsible for the large slip lengths of water inside CNTs, the precise dependence of the slip length on the CNT diameter, chirality, and metallicity still remains unknown.

In this talk, we will discuss our results on the slip flow of water through 0.8 nm – 2 nm diameter CNTs, obtained
using classical MD simulations. The classical MD simulations are carried out using quantum mechanically-derived polarizable force fields [1] to model water-CNT interactions. Our theoretical framework can accurately model the anisotropic polarizability tensors of CNTs, including self-consistently modeling the water-CNT polarization energy, which was neglected in previous MD simulation studies. By carrying out classical MD simulations, we investigated the dependence of the water density and friction coefficient on the CNT diameter and chirality. We find that contrary to common intuition, water behaves like a compressible fluid in nanoconfinement such that many-body polarization effects result in a pronounced enhancement in both the density and the structuring of water molecules confined inside CNTs. We also obtain an anomalous maximum in the water friction coefficient for ~ 1 nm diameter CNTs, which is in good qualitative agreement with previous experimental studies which have reported pronounced water ordering and freezing-point elevation inside such narrow CNTs. Further, by carrying out MD simulations using different water models, we will highlight the roles of water-CNT and water-water interactions on the water friction coefficient inside CNTs. Finally, by carrying out MD simulation studies which have utilized a Lennard-Jones potential to model the water-CNT interactions, our findings highlight the necessity to utilize polarizable force fields to more realistically model the CNT/water interface.

2:45 PM FF02.02.05
Enhanced Electrokinetic Energy Conversion with Macroscopic Vertically Aligned BNNT Membranes
Semih Cetindag1, Aaditya Pendse2, Robert F. Praino3, Sangil Kim2 and Jerry W. Shan1; 1Rutgers, The State University of New Jersey, United States; 2University of Illinois at Chicago, United States; 3Chasm Advanced Materials, United States

Recent nanofluidic experiments with single or few nanopores in graphene, molybdenum disulfide and hexagonal boron nitride have shown unique fluidic transport properties and the potential for electrokinetic energy conversion with unprecedented power densities. In such nanopores, the high-surface charge makes possible a diffusio-osmotic mechanism for ion-selective transport, distinct from the Donnan exclusion that is typical of conventional membranes. In particular, experiments with single boron nitride nanotubes (BNNTs) have reported large surface charge in aqueous solution, and osmotic power densities up to several kW/m² when extrapolated to macroscopic membranes. However, no such macroscopic BNNT membranes have ever been fabricated, and their performance at large scales and pore densities is unknown. Thus, we seek to devise scalable means to manufacture such large-area nanotube membranes, and to investigate their fundamental mechanisms and performance for ion selectivity and electrokinetic energy conversion.

Here, we describe the fabrication of the first-ever macroscopic vertically aligned- (VA-) BNNT membranes, and our study of their ion-selectivity mechanism and osmotic-power-generation performance. The membranes are fabricated with a unique solution-based technique in which BNNTs are aligned and concentrated in a liquid oligomer with an external field, and then locked in place by in-situ polymerization. With this scalable fabrication technique, we have made VA-BNNT membranes of size 1-10 cm² and having tube densities of $10^6$-$10^8$ BNNTs/cm² and open pore densities on the order of $10^7$ pores/cm². We show that, due to the high surface charge in their pores, the BNNT membranes are highly cation-selective even when the Debye length is smaller than the inner radius of the nanotubes. Moreover, the membranes exhibit energy-conversion efficiencies of 30%, and have osmotic power densities (based on open pore area) comparable to and even exceeding that of single BNNTs, up to 7,500 W/m² at pH 11 and 1 M:1 mM KCl molarity difference. To elucidate the mechanisms for ion selectivity and osmotic-power generation, we compare the membrane performance for different salts and for few-wall and multi-wall BNNTs of different diameters. Notably, these scalably fabricated VA-BNNT membranes, with relatively large yet highly selective pores, have enhanced electrokinetic-energy-conversion performance, and may enable efficient energy harvesting from salinity gradients, as well as efficient desalination and other separations via a different mechanism than conventional membranes.

3:30 PM *FF02.02.06
Observation and Spectral Assignment of Family of Hexagonal Boron Nitride Lattice Defects Daichi Kozawa¹, Ananth Govind Rajan¹, Sylvia Xin Li¹, Takeo Ichihara¹, Jamie Warner², Daniel Blankschtein² and Michael Strano¹; ¹Massachusetts Institute of Technology, United States; ²University of Oxford, United Kingdom

Atomic vacancy defects in single unit cell thick hexagonal boron nitride are of significant interest because of their photophysical properties, including single-photon emission, and promising applications in quantum communication and computation. The spectroscopic assignment of emission energies to specific atomic vacancies within the triangular lattice is confounded by the exponential scaling of defect candidates with the number of removed atoms. Herein, we collect more than 1000 spectra consisting of single, isolated zero-phonon lines between 1.69 and 2.25 eV, observing 6 quantized zero-phonon lines arising from hexagonal boron nitride vacancies. A newly developed computational framework for isomer cataloguing significantly narrows the number of candidate vacancies. Direct lattice imaging of hexagonal boron nitride, electronic structure calculations, and subsequent boric acid etching are used to definitively assign the 6 features. Systematic chemical etching supports the assignment by demonstrating the sequence of growth of successively larger vacancy centres from smaller, which include a single B vacancy and a 16-atom triangular defect. These features exhibit a range of emission lifetimes from 1 to 6 ns, and phonon sidebands offset by the dominant lattice phonon in hexagonal boron nitride near 1370 cm⁻¹. This assignment should significantly advance the solid-state chemistry and photophysics of such vacancy emitters.

4:00 PM FF02.02.07
Ion Solvation and Transport in Carbon Nanopores—Predictions from First-Principles Simulations Tuan Anh Pham, Cheng Zhan and Eric Schwegler; Lawrence Livermore National Laboratory, United States

Carbon nanopores underpin a large array of materials systems and technological applications, including supercapacitors and water desalination. In these devices, understanding of the ion behavior is essential for predicting and optimizing the performance; however, many mechanistic details remain enigmatic. These include transport and solvation properties of the ions, and how they are governed by the degree of confinement and interfacial interactions. Here, we employ first-principles simulations to unravel key features of the solvation structure of several common ions at the interface with graphitic interface, and under confinement within graphene slit pores as well as carbon nanotubes (CNTs). We find that polarizable ions generally exhibit a stronger adsorption at graphitic interfaces, and these effects are found to be significantly enhanced under confinement. In addition, we find that confinement significantly influences ion selectivity and transport, i.e., ions with a small radius are found to yield a notably larger energy barrier to reach the pore entrance. These results points to the complex interplay between confinement and specific ion effects, which has broad implications in optimizing nanopores for ion selectivity and energy storage. Comparison with available experimental data will also be discussed.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

4:15 PM FF02.02.08
Forced Convection Heat Transfer of Air Along the Longitudinal Direction of Aligned Multi-Walled Carbon Nanotube Channels Wonjae Jeon¹, Taehun Kim¹, Sung-Min Kim¹ and Seunghyun Baik¹,²; ¹Sungkyunkwan University, Korea (the Republic of); ²Institute for Basic Science (IBS), Korea (the Republic of)

Fast mass transport through carbon nanochannels has been extensively explored. However, only a few studies have investigated convective energy transport through nanochannels. The no-slip and temperature-jump conditions compete each other in nanoscale convection heat transport [1]. The fast mass transport provides an interesting opportunity to explore nanoscale convection heat transfer. Here, we report the experimental investigation of convective heat transport of air through the vertically-aligned multi-walled carbon nanotubes (VAMWNTs) [1]. The unit cell flow channel was defined as an interstitial space among four adjacent nanotubes (hydraulic diameter = 84.9 nm). The air flow was in the transition and creeping flow regime with two orders magnitude higher flow rates than the prediction of Hagen-Poiseuille theory [1]. Due to the ultrahigh microwave absorption cross-section of long nanotubes [2], rapid, selective, and volumetric heating of the VAMWNTs was realized by providing a constant heat flux using the single-mode microwave (2.45 GHz) heating system [1]. The convective heat transfer coefficient and Nusselt number were experimentally obtained [1]. The heat transfer coefficient was relatively small partly due to the temperature jump and small Reynolds number. However, the heat transfer coefficient increased significantly as
Reynolds number increased. Furthermore, the surface area available for heat transfer could be increased by 4 orders of magnitude using the aligned nanotube structure [1]. Overall, a large number of nanochannels in a given cross-section of heat sinks may enhance the total heat flow rate significantly [1]. A recent progress in our lab will also be introduced. References: [1] Nanoscale, 10, 23103 (2018) [2] J. Phys. Chem. C, 118, 13757 (2014)

4:30 PM FF02.02.09

**New Water Structure in a Geo-Inspired Nanotube and Interrelated Dynamics** Geoffrey Monet¹, Erwan Paineau², Gilberto Teobaldi³, Stéphane Rols¹ and Pascale Launois⁴; ¹Université Paris Saclay, France; ²CNRS, France; ³STFC, United Kingdom; ⁴ILL, France

Interfaces, as well as water structuration at interfaces, have a major influence in nanofluidics. Hydrophilicity and charge of the interfaces are key parameters [1,2]. Here, we would like to introduce nanochannels that are extremely interesting but less well-known than those based on carbon or on boron nitride for instance. These are imogolite-like nanotubes, inspired from alumino-silicate imogolite nanotubes discovered in soils as early as 1962 [3]. They are synthesized by soft chemistry and they are monodisperse in diameter and in chirality [4]. Their hydrophilic inner surface can be rendered hydrophobic by replacing hydroxyl groups by methyl ones [5] and their surface charge is also tunable [4, 6]. Such properties obviously make imogolite-like nanotubes ideal model systems for fundamental studies about nanoconfinement. Imogolite-like nanotubes are also becoming appealing for a wide range of potential applications, from filtration to depollution of water [7].

Here, we focus on geo-inspired alumino-germanate imogolite-like nanotubes (Ge-INT) with nominal formula GeAl₂O₃(OH)₄, which are synthesized by our team at Orsay and whose atomic structure has been recently determined [4, 8]. By carrying out inelastic neutron scattering (INS) experiments coupled to ab-initio molecular dynamics simulations, we reveal a unique structure of the water layer adsorbed inside Ge-INT [8]. Water molecules form an ordered triangular lattice on the inner surface of the nanotube, each molecule having three H-bonds with germanol groups on the surface. To the best of our knowledge, this structure differs from that of any kind of two-dimensional water, either on planar surfaces [9] or on curve surfaces of nanochannels. Detailed analysis of the vibrational density of state measured by INS shows that the dynamics of INT and water are strongly interrelated, a fully original result with respect to the available experimental literature about water in one-dimensional or two-dimensional nanopores. For instance, enhanced diffusion of water in CNTs due to phonon-induced oscillation friction has been predicted from molecular dynamics simulations [10] but it has not been complemented by experimental evidence. A new, well-defined translation vibrational mode of water molecules with respect to the nanotube wall is finally observed. Due to the peculiar bonding of water molecules with germanol groups, the evolution of the mean square displacement of water molecules as a function of temperature in Ge-INT is found to differ markedly from the ones measured for CNT [11] which are associated with frictionless water slip [12, 13]. Notably, the dynamics of INT-confined water remains harmonic from 10K to 300K, with no phase transition towards a liquid state up to room temperature.

4:45 PM FF02.02.10

**Measurement of the Single Molecule in a Nano Cage Based on Graphene Transfer** Fei Zheng; Southeast University, China
Nanopore sensing based on the blockage of ionic current caused by the steric hindrance of nanoparticles translocation has shown the promise in the detection of a single molecule and its morphology. However, due to the fast translocation velocity of nanoparticles and complicated fold morphology, it is hard to distinguish one from several molecules in the nanopore and achieve the concrete morphology. Here, we present the method to detect single DNA molecule precisely with a special nanoliter-sized cage. The fabrication of this cage is based on the transfer of thin graphene on the nanopore membrane which is laid on the Si chip. On both sides of the cage are two nanopores, one in the graphene membrane and the other in the silicon nitride membrane. The preparation method for the former nanopore is dielectric breakdown and the counterpart for the latter one is the drilling of the focus ion beam. The length of the cage depends on the depth of the silicon nitride membrane which can be manipulated by etching or drilling methods. The graphene nanopore is 10 nm and the silicon nitrogen nanopore is 100 nm, which form a current circuit in series. Attributed to the difference in size, the resistance of the graphene nanopore is relatively larger, which means the potential drop across the 10 nm nanopore can be of two order of magnitude larger than that across the 100 nm nanopore. Hence, the DNA molecule will translocate from the bulk solution to the nano cage through the graphene nanopore under sufficient electrophoresis force but will not escape from the 100 nm nanopore owing to the weak potential drop. The single molecule will be trapped in the nano cage unless a reverse voltage is applied. This method can extend the duration of blockage event and increase the accuracy of detecting single molecule. According to the value of current drop, the morphology of the single molecule can be confirmed. This method and the structure of nano cage will promote the research in the field of single molecule detection and provide inspirations for nanopore sensing.

**FF02.03.02**

**Investigation of Nitrogen Doping Effect on Electrokinetics at Graphene-Water Interface**

Takeru Okada¹, Golap Kalita², Masaki Tanemura², Ichiro Yamashita³, Fumio S. Ohuchi⁴, Meyya Meyyappan⁵ and Seiji Samukawa¹;
¹Tohoku University, Japan; ²Nagoya Institute of Technology, Japan; ³Osaka University, Japan; ⁴University of Washington, United States; ⁵NASA Ames Research Center, United States

Energy harvesting has been widely recognized as an important issue. Among the novel energy-harvesting methods, liquid-flow-induced electricity generation stands out as a mechanically non-degradable strategy that targets a variety of natural body of water as a viable energy source, such as river, currents in ocean, rain, etc. The energy harvesting by flowing water on graphene has been studied. The physical view proposed to date is still not deterministic, however, surface conditions are key factors for the understanding of the mechanism and maximizing the performance. In our strategy, the surface conditions include electrical potential at the liquid-solid interface and wettability of graphene, both of which can be tuned by heteroatom doping. In this paper, we discuss the contribution of the bonding state of nitrogen atoms in graphene. In addition, the role of the surface condition of graphene on flow-induced electricity generation is investigated.

We studied two type of nitrogen-dopant atoms with specific bonding state in graphene, thus graphitic and pyridinic nitrogen. Graphitic nitrogen is located at in-plane of graphene and pyridinic nitrogen atoms are located either above point defect or the edge due to geometrical limitation. The power generation was investigated using CVD graphene and deionized water droplets by manually dropping the droplets (0.1 ml). Both pyridinic and graphitic nitrogen dopants enhance voltage generation by water-flow. On pristine graphene, a single water droplet induces approximately 80 mV (0.89 μW). In contrast, the voltage induced at both types of nitrogen-doped graphene is approximately three times greater in magnitude (~240 mV). However, the output power from pyridinic nitrogen is almost zero because of much larger resistance increase by doping compared with graphitic nitrogen. The geometric constraints of the pyridinic nitrogen degrade graphene’s electrical conductivity. Therefore, it is found the graphitic nitrogen dopant is superior for power generation (1.3 μW) [1].
The enhancement of voltage generation by nitrogen doping is explained as follows. The electronic state of the nitrogen-doped sites is considered to have an important role. Nitrogen doping of carbon in various applications acts as an electron donor by providing the unshared electron pair of nitrogen in graphene. The local charge of graphitic nitrogen is positive and that of the surrounding carbon atoms is negative. This is explained by the electron transfer from nitrogen atom. The inside of the droplet sitting on top of graphene is affected by the negative charge on the graphene surface, leading to potential formation at the interface. The induced negative charge reduces electric double layer at the interface, resulting in the formation of steep potential \[2,3\].

In summary, we have investigated the effect of graphene doping on flow-induced power generation between graphene and water interface and found that the nitrogen-doped graphene shows enhancement of power generation. The surface charge of the nitrogen-doped graphene reduces the electric double layer thickness, resulting in the formation of a steep potential, which contributes to higher power generation.

**Ion Transport through 2D-Channels of Graphene Oxide Membranes with sub-nm Interlayer Spacing**

Jongwoon Kim, Seung Eun Lee and Chang-Soo Han; Korea University, Korea (the Republic of)

Over the past decade, ion sieving using carbon-based materials such as carbon nanotube, graphene and graphene oxide has been attracted attention in water purification and ion filtration. Among them, graphene oxide (GO) membranes have recently emerged as promising candidate in the industry due to their excellent mechanical property, inexpensive synthesis, controllable selectivity and easy processing. Especially, they naturally have sub-1nm interlayer spacing comparable to the dimension of molecules or ions, which is crucial factor for ion sieving. Since the ions and molecules are sieved out according to the interlayer spacing, it is important to narrow the interlayer spacing to enhance the filtration efficiency. Herein, we fabricated thermally reduced graphene oxide (rGO) membrane with different interlayer spacing ranging from 3.7 Å to 8.0 Å in a dry state. GO membranes have inherent property to swell in water, which enlarge the interlayer spacing by several angstroms in water. We found that the minimum spacing to allow the water molecules to permeate the channels was 5.7 Å. Once the GO membrane immersed in water, the interlayer spacing increased to 9.6 Å. While the untreated GO membrane with interlayer spacing of 8.0 Å in dry state (13.8 Å in water) have no selectivity in ion permeation, we found that the anions, such as SO\(_4\)\(^{2-}\) and Fe(CN)\(_6\)\(^{3-}\), was totally rejected to permeate through the thermally reduced GO membrane with interlayer spacing of 9.6 Å. On the other hand, the permeation of cations was exponentially decreased with the hydrated diameter of cations. We found that sub-nanometer interlayer spacing of reduced GO membrane can physically sieve the ions, and negatively charged oxygen-functional groups rejected the multivalent anions.

**Strain Engineering of Graphene Oxide Membranes for Nanofluidic Transport**

Catherine E. Machnicki, Kyung-suk Kim, Derek Stein and Ian Y. Wong; Brown University, United States

Molecular transport through atomically-thin, layered 2D materials is associated with unique physicochemical phenomena not observed in bulk solution. In particular, ion and water transport are affected by extreme confinement, and exhibit behaviors analogous to those observed in nanofluidic channels. Moreover, the surface chemistry of carbon nanomaterials such as graphene (oxide) results in distinct interfacial interactions, which may be further engineered by mechanical strain. Such controlled modulation of surface topography, colloquially referred to as wrinkling, could affect local electronic structure and chemical interaction by manipulation of lattice structure. The coupling of ionic and molecular transport with strain engineering in 2D material architectures could be leveraged for desalination, energy storage, molecular sensing and energy conversion. However, our fundamental understanding of physicochemical transport properties within strained 2D material nanofluidics remains limited. Here, we utilize strain engineering to modulate both in-plane and out-of-plane molecular transport within multilayered 2D material assemblies. We show that metal ions can intercalate between 2D materials, increasing the interlayer spacing. Furthermore, multilayer GO papers permit water and oxygen transport, but are impermeable to organic molecules, even when unfolded at large area strains. These mechanochemical mechanisms may enable new fundamental
insights into molecular transport under extreme confinement, as well as stretchable and wearable devices.

FF02.03.07
Nanofluidics in Smectite Clays Leide P. Cavalcanti\textsuperscript{1,2}, Heloisa N. Bordallo\textsuperscript{3}, Kenneth Knudsen\textsuperscript{4} and Jon O. Fossum\textsuperscript{2}; \textsuperscript{1}ISIS Neutron Source, United Kingdom; \textsuperscript{2}Norwegian University of Science and Technology, Norway; \textsuperscript{3}University of Copenhagen, Denmark; \textsuperscript{4}Institute for Energy Technology, Norway

New physical effects have been shown to be possible in “ultrasmall confined spaces” \cite{1} such as higher viscosity or higher mobility among others. Here we present clay minerals as possible materials for the study of nanofluidics. Clays are nano-silicate layered materials with structural properties that can be modified and controlled for intercalation and transport of foreign molecules in their 2D nanospace. Intercalation of water in smectite clays occurs naturally and has been extensively studied with a wide range of techniques, among them neutron \cite{2} and X-ray scattering \cite{3}. Water dynamics in smectite clay interlayers has been studied extensively. Recent experiments and simulations have shown that CO\textsubscript{2} can intercalate and flow in smectite clay interlayers provided from external bulk gaseous, liquid or supercritical CO\textsubscript{2} \cite{4}. We have demonstrated that under certain conditions of pressure and temperature, fluorohectorite smectite clays are able to capture a large amount of CO\textsubscript{2} in this way, depending on the type of charge compensating cation residing in the interlayer \cite{5,6,7}. We have investigated fluorohectorite clays with three different cations (Na\textsuperscript{+}, Ni\textsuperscript{2+} and Li\textsuperscript{+}), suggesting the formation of a stable CO\textsubscript{2} complexation with the clay interlayer cation. Thus, clays could also be used as a model for nanofluidics of CO\textsubscript{2}.

Adsorption Transparency of Supported Graphene Morteza H. Bagheri\textsuperscript{1}, Rebecca T. Loibl\textsuperscript{1}, Yingchun Jiang\textsuperscript{1}, J. Anibal Boscoboinik\textsuperscript{2} and Scott N. Schiffres\textsuperscript{1}; \textsuperscript{1}Binghamton University, United States; \textsuperscript{2}Brookhaven National Laboratory, United States

The effect of graphene conformal mapping on the wetting of a surface remains a controversial topic. Many groups have studied the wetting transparency of graphene coated surfaces by measuring the water contact angle on the surface, however, airborne contamination due to the exposure of the surface during contact angle experiment can alter the hydrophilicity/hydrophobicity of the surface. Here, we explore this controversy by comparing the interaction of water molecules with a surface through measurement of the adsorption energy of the water molecules on the surface with and without graphene coatings. We find that the isotherms of water adsorbing on graphene are strongly influenced by the substrate, with the surface energy only being reduced by 10\% for Pt and Al and 30\% for Au

FF02.03.09
Developing the Performance of Devices for Nanopore Single Molecule Sensing of Biopolymers Brian Sheetz; University of Rhode Island, United States

Nanopores are nanoscale diameter holes in thin film membranes. They can deliver single-molecule sensing that provides concentrations while also profiling material properties of analytes from single molecules, to (bio)polymers such as DNA, proteins and sugars, and nanoparticles. Nanopores can be formed easily by controlled dielectric
breakdown (CDB) to match their size to the single nanometer to tens or hundreds of nanometers size of analytes. Passage of a molecule through a pore immersed in electrolyte is achieved by application of a voltage across the membrane. Detection of this molecular passage is most commonly done by Resistive Pulse Sensing (RPS)—measuring the change in pore resistance caused by the presence of an analyte in the pore. The magnitude of the resistive pulse is determined by parameters such as the molecular size and charge density. Detection is inherently single-molecule, without the need for chemical labelling steps. Nanopore DNA sequencing has leveraged this sensitivity to native molecular structure and properties. We have extended this basic DNA sequencing concept to motivate the development of nanopores for profiling a much more variable set of biopolymers, oligo- and polysaccharides. With more than 100 naturally occurring monomers and with more variable charge than DNA—and with the added complication of branching—a more sophisticated set of nanopore tools and sensing mechanisms is required. We have begun to undertake this development, which spans preliminary measurements of a diverse and challenging array of biopolymers to correlate known molecular properties to nanopore signal patterns. We will discuss development of alternative fabrication strategies for the core nanopore element, device-design considerations including microfluidics integration, and how to exploit a wider range of electrokinetic phenomena than had been pioneered for nanopore DNA sequencing. In addition, we will discuss issues in streamlining signal processing. These topics will be presented in the context of developing nanopore science for glycomics.

FF02.03.10
Permeation Characteristics of Graphene Oxide Membrane Fabricated and Modified in Various Methods
Seung Eun Lee and Chang-Soo Han; Korea University, Korea (the Republic of)

Recently, a tremendous amount of attention has been paid to the technology of desalination and air purification to solve the problem caused by severe water shortage and air pollution. Membrane separation method is one of the key technologies to solve this problem due to its energy-saving and environmentally friendliness. In this field, Graphene oxide (GO) membrane is a prominent candidate with its exceptional properties of selective separation and high permeability as to specific ions or molecules. It also has the potential to overcome the limitations of traditional membranes due to its excellent mechanical properties, chemical stability and easy fabrication process. GO membrane forms a dense structure formed by layered flakes, so that it obtains a sieving-effect. Moreover, selective permeating and rejecting effect is also obtained with its intrinsic properties. However, at the same time permeation through numerous defects is one of the major permeation paths, so the precise mechanism is not known yet. In this study, using GO membranes fabricated and modified by various methods, we tried to clarify the permeating mechanism by observing the change of properties of membranes and the permeation of ions and molecules. GO films were characterized using SEM, AFM, XRD, XPS and Raman. With these results, we observed the correlation between the properties of GO membrane and permeation characteristics and tried to figure out of the possibilities to commercialize.

SESSION FF02.04: Ultra-Thin Nanopores and Nanoporous Membranes I

8:15 AM FF02.04.01
Highly Anion Selective Single-Layer Graphene and Boron Nitride
Mustafa Caglar1, Bertram T. Brown1, Inese Silkina1, Oliver Burton1, Vitaly Babenko1, Stephen Gilbert2, Alex Zettl2, Stephan Hofmann1 and Ulrich Keyser1;
1University of Cambridge, United Kingdom; 2University of California, Berkeley, United States

In the growing climate emergency the world finds itself in, sources of clean water and energy will be of critical importance in the near future. Efforts towards achieving this goal have been aplenty but a wholesome solution has yet to emerge. The potential of 2D materials are immense in this field given their thinness, mechanical strength and alterable surface chemistry. Most notably, anion selective 2D membranes - allowing passage of anions - are absent from literature. Membranes that are able to filter selectivity for both anions and cations are needed for applications ranging from blue energy to desalination. We present highly cation and anion permeable graphene and hexagonal boron nitride prepared with minimal overheads, achieving salt rejection ratios of up to 500. We characterise our
membranes using HRTEM in order to elucidate some of the mechanisms for this selectivity. By using Goldman-Hodgkin-Katz (GHK) fitting we extract permeability factors, demonstrating degrees of selectivity. Anion filtration is achieved through the use of multivalent ions but the effect is recreated in monovalent species using a low concentration background of multivalent ions. This means that as grown chemical vapour deposition (CVD) membranes could be used as highly ion selective and high flux membranes, extrinsically controlling the ability to filter for anions or cations as needed.

8:30 AM *FF02.04.02
Voltage Gated Inter-Cation Selective Ion Channels from Graphene Nanopores Joseph S. Bunch¹, Lauren Cantley¹, Jacob Swett², David Lloyd¹, David Cullen¹, Ke Zhou³, Peter Bedworth², Scott Heise², Adam Rondinone³, Zhiping Zhu⁴ and Steve Sinton²; ¹Boston University, United States; ²Lockheed Martin Space, United States; ³Oak Ridge National Laboratory, United States; ⁴Tsinghua University, China

With the ability to selectively control ionic flux, biological protein ion channels perform a fundamental role in many physiological processes. For practical applications that require the functionality of a biological ion channel, graphene provides a promising solid-state alternative, due to its atomic thinness and mechanical strength. Here, we demonstrate that nanopores introduced into graphene membranes, as large as 50 nm in diameter, exhibit inter-cation selectivity with a ~20x preference for K⁺ over divalent cations and can be modulated by an applied gate voltage. Liquid atomic force microscopy of the graphene devices reveals surface nanobubbles near the pore to be responsible for the observed selective behavior. Molecular dynamics simulations indicate that translocation of ions across the pore likely occurs via a thin water layer at the edge of the pore and the nanobubble. Our results demonstrate a significant improvement in the inter-cation selectivity displayed by a solid-state nanopore device and by utilizing the pores in a de-wetted state, offers an approach to fabricating selective graphene membranes that does not rely on the fabrication of sub-nm pores.

Transparent Proton Transport and Nonlinear Water Transport through Two-Dimensional Nanomesh Material Sheng Meng; Chinese Academy of Sciences, China

Molecular sieving is of great importance to proton exchange in fuel cells, water desalination, and gas separation. Two-dimensional crystals emerge as superior materials showing desirable molecular permeability and selectivity. Here we demonstrate that the experimentally fabricated graphyne membrane shows superior proton conductivity and perfect selectivity thanks to its intrinsic nanomesh structure. The trans-membrane hydrogen bonds across graphdiyne serve as ideal channels for proton transport. The free energy barrier for proton transfer across graphdiyne membrane is ~2.4 kJ/mol, nearly identical to that in bulk water (2.1 kJ/mol), enabling “transparent” proton transport at room temperature (Fig. 1). This results in a proton conductivity of 0.6 S/cm for graphdiyne membrane, four orders of magnitude greater than graphene and ten times larger than commercial proton exchange membrane nafion. Considering its ultimate pore size of 0.55 nm, graphdiyne membrane blocks soluble fuel molecules and exhibits superior proton selectivity. These advantages endow graphdiyne a great potential as proton exchange material in fuel cells, sensors and other applications. If time allowed, results about water transport and water photosplitting on 2D materials will be also discussed.

Optimal Transport and Colossal Ionic Mechano-Conductance in Graphene Crown Ethers Subin Sahu¹,², Justin Elenewski¹,², Christoph Rohmann¹,² and Michael Zwolak²; ¹University of Maryland, United States; ²National Institute of Standards and Technology, United States

Directly interrogating the mechanism of ion transport in sub-nanoscale pores is challenging. Thus, typically computational approaches are employed to help shed light on the processes contributing to ion translocation, which are many: steric hindrance due to van der Waal repulsion, dehydration, strong electrostatic interactions due to confinement and a reduced dielectric constant, the structural fluctuations of the pore and flexibility of the membrane, etc. Biological ion channels, for example, balance electrostatic and dehydration effects to yield large ion selectivities alongside high transport rates. These macromolecular systems are often interrogated through point mutations of their pore domain, limiting the scope of mechanistic studies. In contrast, we demonstrate that graphene crown ether pores afford a simple platform to directly investigate optimal ion transport conditions, i.e., maximum
current densities and selectivity. Crown ethers are known for selective ion adsorption. When embedded in graphene, however, transport rates lie below the drift-diffusion limit. We show that small pore strains – 1 % – give rise to a colossal – 100 % – change in conductance. This process is electromechanically tunable, with optimal transport in a primarily diffusive regime, tending toward barrierless transport, as opposed to a knock-on mechanism. Measurements of mechanical current modulation will yield direct information on the local electrostatic conditions of the pore. These observations suggest a novel setup for nanofluidic devices while giving insight into the physical foundation of evolutionarily-optimized ion transport in biological pores.

9:45 AM FF02.04.05
Ion Specific Adsorption under Nano-Confinement—Molecular Dynamics Simulations and a New Continuum Model Peiyao Wang, Dan Li and Zhe (Jefferson) Liu; The University of Melbourne, Australia

Ion partition in nanopores, such as averaged in-pore ion concentration and ion distribution, is critical for many electrolyte related applications, for example, energy storage devices, water treatment, and biology-inspired sensor. A comprehensive model that can quantitatively describe the ion partition under nano-confinement conditions is highly desirable for us to go beyond the trial-and-error experiments to achieve quantitative prediction and design for the next generation of the electrolyte related applications. However, it remains a fundamental challenge, especially in the case of ion-specific effect.

In this talk, we will present molecular dynamics (MD) simulations and a new continuum model to describe the ion partition in nanopores with ion-specific effects quantitatively. Our model system is sodium tetrafluoroborate (NaBF₄) aqueous electrolyte (0.8 M) in graphene nanoslits (varying from 1.0 nm to 4 nm). The Na⁺ and BF₄⁻ ions exhibit different dispersion interaction with graphene surface, leading to a strong specific BF₄⁻ adsorption at graphene surface. Our MD simulations systematically studied how the nano-confinement effects in graphene nanoslits could affect the ion concentration and distribution. The ion concentration in graphene slits exhibits a non-monotonous variation to slit size. The ion distribution profiles in the slit also demonstrate significant dependence on slit size.

Aiming to develop practical device design tools at a large length scale, we also developed a quantitative continuum model to describe the ion-specific adsorption under nano-confinement condition. We modified the classic Poisson-Boltzmann (PB) equation by incorporating the ion-surface effective potential, the electrostatic correlation, and the steric correlation interactions. A new model for steric correlation interaction is proposed, which takes account of the solvent structures in the graphene nanoslits. Our model quantitatively reproduces our MD simulation results very well. Our new continuum model could serve as a general approach for quantitative description of ion local distribution in nanoslit with ion-specific effect. It would be much more efficient than the MD simulations to describe the ion-specific adsorption inside complex porous structures. Besides, it could also lay a ground for the development of continuum models to quantitatively describe the charging dynamics in nanoporous materials.

10:00 AM BREAK

10:30 AM *FF02.04.06
2D Materials FET's for Bio-Sensing Nagendra B.M. Athreya, Mingye Xiong and Jean-Pierre Leburton; University of Illinois at Urbana-Champaign, United States

The last two decades have experienced rapid technological developments in the search of cheap and high accuracy devices for fast bio-molecular identification. In the realm of DNA and protein sequencing, there has been an increasing interest in the use of nanopores in solid-state materials because of their distinct advantage over biological pores in terms of flexibility in pore design and mechanical strength. Two-dimensional (2D) solid state materials such as graphene and Molybdenum di-sulphide (MoS₂) in particular have attracted attention because of their atomically thin layered structure and electrically active characteristics, predisposing them to offer single base resolution and simultaneously multiple modalities of detecting biomolecular translocation. 2D nanopore devices promise seamless integration with semiconductor electronics and are poised to revolutionize a variety of technologies such as genomics, point-of-care diagnostics and digital data storage to name a few.

The past year has witnessed significant activity to experimentally realize nanopore Field Effect Transistors (FETs)
and understand the fundamental sensing mechanism in such devices. Currently, the dominant consensus from theoretical calculations has involved the electrostatic modulation of the FET current due to the translocating biomolecules. In this talk, we review and provide insights into this sensing principle by modeling the electron flow through 2D material nanopore FETs. We describe a method to systematically characterize nanopores FETs by contrasting the changes in the FET behavior before-and-after nanopore drilling and DNA translocation. We outline measurable predictions of high-resolution FET based sensing of DNA-protein complexes and damaged DNA. We compare these FET signals to the corresponding ionic current signals calculated from all-atom Molecular dynamics simulations. Further, we also outline possible techniques to improve the detection SNR by augmenting pore and device design with statistical signal processing algorithms. Finally, we propose a scalable device design of nanopore FETs to detect and identify translocations of single-biomolecules in a massively parallel scheme.

11:00 AM *FF02.04.07
Nanoporous Graphene Membranes for Gas Separation—From Ion Gating to Molecular Tumbling De-en Jiang; University of California, United States

Although a single-layer graphene membrane with nanopores can separate gases with high selectivity by molecular sieving, the pore size is difficult to control at sub-angstrom resolution. Here we discuss two approaches to mitigate this issue via molecular dynamics simulations. First, we demonstrate that a monolayer of ionic liquid on the porous graphene allows anions to gate the pores of significantly larger in size than the gas molecules while still achieves high selectivity. Second, we propose a novel design based on the bilayer nanoporous graphene membrane which allows the effective pore size of the membrane to be continuously tunable by the offset between the two single layers. We find that skinnier and shorter molecules tumble through the elliptic-cylinder-shaped nanopore of the bilayer membrane, leading to higher entropic selectivity.

11:30 AM FF02.04.08
Gas Permeation and Separation across Selectively Etched Nanoporous Graphene Membranes Karl-Philipp Schlichting and Dimos Poulikakos; ETH Zurich, Switzerland

Gas molecules permeating across nanopores of two-dimensional materials experience the least possible resistance due to the atomic thickness of the material. However, pristine two-dimensional materials, such as graphene, are impermeable even to the smallest gases making it unsuitable for gas separation applications. The potential of two-dimensional materials for gas separation can consequently only be harnessed if the material is perforated in a precise and controlled manner. In this work, we present a novel synthesis route of nanoporous graphene membranes with a facile and dry chemical etching approach. The pore growth is initiated in a first step within the graphene lattice selectively at previously introduced atomic defects. The second process step consists of dry etching graphene selectively at the lattice defects, resulting in well-controlled, parallel pore growth yielding membranes with narrow pore size distributions. The resulting membrane performances are investigated in the context of gas separation applications and demonstrate similar selectivity but orders of magnitude higher permeance compared to other perforation techniques of two-dimensional materials.

11:45 AM FF02.04.09
Effects of Surface Trapping and Contact Ion Pairing on Ion Transport in Graphene Nanopores Jian Ma, Kin Li, Zhongwu Li, Jingjie Sha, Yunfei Chen and Lijian Zhan; Jiangsu Key Laboratory for Design and Manufacture of Micro-Nano Biomedical Instruments, School of Mechanical Engineering, Southeast University, China

Nanoporous graphene have attracted much attention in nanofluidics due to their high permeation and low resistance to ions or molecules. They have been widely used in biomolecules sensing, material separation, and energy conversion. With the help of the surface charges on the rim of nanopores, the nanopores have strong ionic selectivity, which provides a perfect platform for seawater desalination with a low-energy cost, and for energy conversion with high efficiency. The major challenge is how to fabricate nanoscale pores on pristine graphene as it cannot be permeated by all atoms including the hydrogen atom in the world. Here we presented an efficient way to produce high-density nanopores on graphene membranes with tunable size in the sub-nanometer range by plasma etching. Besides the pore size, the nanopore density is also controllable through adjusting the exposure time of the sample to argon or oxygen plasma. The plasma-treated graphene membranes can selectively transport protons, Na+ and Cl− ions. Density function theory calculations uncover that the sp2 and vacancy-type defects construct different energy barriers for different ions, which allow the defected graphene membrane to selectively transport ions.
In order to understand the mechanism of the ionic transport in graphene nanopores, we applied molecular dynamics (MD) to investigated the dynamic process of ion transport in graphene nanopores. With the advantage of the simulations, the duration time for each ion passing through the nanopore was analyzed. It is found that the formation of the contact ion pair plays a critical role in reducing the ion mobility inside a nanopore without surface charges. The mobility for both cations and anions decreases with the reduced pore size because it is easier to form the contact ion pairs inside the neutral nanopore with a smaller diameter. Inside a charged nanopore, besides the contact ion pair formation, the surface charges also play a significant role in reducing the counterion mobility through surface trapping. It is uncovered that the mobility of Na$^+$ ions increases first and then decreases with the surface charge density, while Cl$^-$ ions have the opposite trend. A modified first-passage time model is proposed to take into account the ion pair formation and the trapped ions inside a nanopore, which provides a clear picture in describing ion transport through a nanopore.

SESSION FF02.05: Ultra-Thin Nanopores and Nanoporous Membranes II
Session Chairs: Joseph Bunch and Rahul Raveendran Nair
Wednesday Afternoon, December 4, 2019
Hynes, Level 3, Room 309

1:30 PM *FF02.05.01
Theory of Nanofluidics in Ultrathin Nanopores Narayana R. Aluru; University of Illinois at Urbana-Champaign, United States

Structure, dynamics and transport of fluids in ultrathin membranes/nanopores can be vastly different from their macroscopic counterparts. For example, water transport through carbon nanotubes has been shown to exhibit flow rates which are many orders of magnitude larger compared to those obtained from classical theories. While classical theories are fast, they do not account for the microscopic mechanisms that are important in ultrathin membranes. Quantum and atomistic simulations can provide good accuracy, but they are limited in the length and time scales that can be dealt with. In this talk, we will present multiscale theories to describe fluidic behavior in ultrathin membranes. First, we will discuss multiscale approaches to calculate fluidic properties such as structure, interfacial friction, viscosity, permittivity, slip, etc. in ultrathin membranes. We will show that these properties can be vastly different when compared to their bulk counterparts. Second, we will discuss the development of nanofluidic theories incorporating microscopic physics and show that these theories can predict water flow rates which are consistent with experimental measurements. Finally, we will discuss the physics of electrical double layers (EDLs) and show that the structure and dynamical properties of ions and water in EDLs of ultrathin membranes can be different from those in larger pores/channels.

2:00 PM FF02.05.02
Rapid Water Transport in Carbon Nanomembranes Yang Yang1,2, Petr Dementyev1, Niklas Biere1, Daniel Emmrich1, Patrick Stohmann1, Riko Korzet2, Xianghui Zhang1, André Beyer1, Sascha Koch1, Dario Anselmetti1 and Armin Gölzhäuser1; 1Universität Bielefeld, Germany; 2Imperial College London, United Kingdom

A major challenge in developing 2D membranes is to create a high density of sub-nm sized channels in the material. Carbon Nanomembranes (CNMs) are 2D films fabricated by crosslinking of self-assembled monolayers. This work will present a ∼1.2 nm thin CNM made from terphenylthiol (TPT) precursors that combines high water permeance with high selectivity. TPT CNMs only allow water and helium to pass through, but stop most gases and liquids. In particular, water across with an extremely high permeance of $\sim 1.1 \times 10^{-4}$ mol m$^{-2}$ s$^{-1}$ Pa$^{-1}$, 2,500 times faster than helium. Scanning probe microscopy revealed that these membranes consist of sub-nm channels with an areal density of $10^{19}$ m$^{-2}$. If assuming all channels are active for mass transport, we found a single-channel permeation coefficient of 66 water molecules s$^{-1}$ Pa$^{-1}$, as high as that observed for channels in carbon nanotubes and aquaporin proteins which support a single-file transport of water molecules. This suggests that the fast water flow through TPT CNMs is attributed to a dense network of sub-nm channels and a coordinated water movement per single channel. This encourages the potential use of these membranes for water purification. The versatile and flexible fabrication process also brings the possibility of tailoring CNM functions for usage in different separation systems.

**2:15 PM FF02.05.03**

**MXene Nanopores as Novel Solid-State Biosensors** Mehrnaz Mojtabavi¹, Armin VahidMohammadi², Wentao Liang³, Majid Beidaghi² and Meni Wanunu¹;¹Northeastern University, United States; ²Auburn University, United States; ³Kostas Advanced Nano-Characterization Facility, United States

Nanopore biosensor platforms, namely solid-state and biological nanopores, have been developed over the past two decades as label-free sensors of single molecules and biopolymers (DNA, RNA, and proteins). While biological pores are typically self-assembled and form a natural channel that penetrates an organic membrane, such as a lipid bilayer, in solid-state nanopores, pores are synthetically fabricated by focused electron beam ablation or by dielectric breakdown of an ultrathin solid-state membrane. Thus, solid-state nanopores are more tunable for arbitrary sizes and geometries, and further, the robust framework and mechanical stability of synthetic membranes offers the ability to perform experiments under harsh conditions (e.g., hydrostatic pressure, extreme pH, denaturing conditions, etc.).

The advent of two-dimensional (2D) materials (graphene, MoS₂, WS₂, and BN, for example) as support membranes for solid-state nanopores, offers in principle the highest detection resolution of any pores, because the thickness of these pores is about one atom thick. To further investigate the potential of 2D materials as nanopore support membranes, we have studied novel solid-state nanopores based on new 2D materials known as MXenes. MXenes are an emerging family of 2D transition metal carbides and nitrides with a general formula of $M_{n+1}X_nT_x$ (i.e. $T_iC_2T_x$), where $M$ is a transition metal, $X$ represents carbon or nitrogen ($n=1$, 2, and 3), and $T_x$ indicates different functional groups (O, OH, F) present on MXene surface. Sensing, energy storage, and water purification are among the various applications that MXenes have shown promise towards, owing to their controllable composition and surface tunability. Our initial results have shown that MXenes provide high mechanical robustness, long-time stability, and low-noise ion current recordings that are suitable for single molecule detection. Through further improvement in the fabrication process of MXene membranes, as well as harnessing of some unique MXene characteristics, we show here how MXene membranes could potentially overcome some challenges that relate to limited resolution, such as access resistance limitations, that other solid-state and biological nanopores are facing.

van der Waals Layered Materials towards Room-Temperature Magnetic Semiconductors Young Hee Lee¹,², Seok Joon Yun¹ and Dinh Loc Duong¹;¹Sungkyunkwan University, Korea (the Republic of); ²Institute for Basic Science, Korea (the Republic of)

The ferromagnetic state in van der Waals two-dimensional (2D) materials has been reported recently in the monolayer limit. Intrinsic CrI₃ and CrGeTe₃ semiconductors reveal ferromagnetism but the Tc is still low below 60K. In contrast, monolayer VSe₂ is ferromagnetic metal with Tc above room temperature but incapable of controlling its carrier density. Moreover, the long-range ferromagnetic order in doped diluted chalcogenide semiconductors has not been demonstrated at room temperature. The key research target is to realize the long-range order ferromagnetism, Tc over room temperature, and semiconductor with gate tunability. Here, we unambiguously observe a ferromagnetic hysteresis loop together with magnetic domains above room temperature in doped V-doped WSe₂, while maintaining the semiconducting characteristic of WSe₂ with a high on/off current ratio of five orders of magnitude.
The understanding of strongly-correlated quantum matter has challenged physicists for decades. Such difficulties have stimulated new research paradigms, such as ultra-cold atom lattices for simulating quantum materials. In this talk I will present a new platform to investigate strongly correlated physics, based on graphene moiré superlattices. In particular, I will show that when two graphene sheets are twisted by an angle close to the theoretically predicted ‘magic angle’, the resulting flat band structure near the Dirac point gives rise to a strongly-correlated electronic system. These flat bands exhibit half-filling insulating phases at zero magnetic field, which we show to be a correlated insulator arising from electrons localized in the moiré superlattice. Moreover, upon doping, we find electrically tunable superconductivity in this system, with many characteristics similar to high-temperature cuprates superconductivity. These unique properties of magic-angle twisted bilayer graphene open up a new playground for exotic many-body quantum phases in a 2D platform made of pure carbon and without magnetic field. The easy accessibility of the flat bands, the electrical tunability, and the bandwidth tunability though twist angle may pave the way towards more exotic correlated systems, such as quantum spin liquids or correlated topological insulators.

Keynote: Molecular Transport through Two-Dimensional Capillaries

Andre Geim; University of Manchester, United Kingdom

I will review our group’s work on the molecular transport properties of angstrom-scale channels fabricated by der Waals assembly of 2D crystals. These channels can be viewed as if individual atomic planes were extracted from a bulk crystal leaving behind two edge dislocations with an empty space in between. Gas, water, ion and proton transport have been studied in capillaries down to one atom in height.

SESSION FF02.08: Angstrom-Scale Nanochannels and Lamellar Membranes I

Role of Hydration Shell in Engineering Ionic Mobility inside Å-Scale 2D Channels

Solleti Goutham, Ashok Keerthi, Ankit Bhardwaj, Michael Shiggins, Gangaiah Mettela, Andre Geim and Radha Boya; University of Manchester, United Kingdom

Two-dimensional (2D) materials have received widespread popularity over the past decade. Particular in the field of nanofluidic studies by reducing the dimensions from micro to sub-nano scale1 system led to emergence of new fluidic phenomena. In the view of fundamental science passive ion transport under the strong confinement will provide basic information about water-ion-material interaction. Under the strong confinement, various parameters such as hydration shell, orientation of water molecule, surface charge influence the movement of solvent and solute through nanochannels. The hydration shell of ion is of great significance to understand ion permeation and it plays a crucial role in biological and aqueous chemical systems2,3. We explore ions with increasing radii and study the influence of hydration shell on ionic transport in such confinement. Here our measurements of ion-transport through
Å-scale sized channels allow us to study the ion mobility to discern the hard versus soft ball behaviour of ions. Surprisingly we found that similar hydrated diameter size ions show asymmetric mobility behaviour. Our observations may help to enhance the cutting-edge technology in the fields of ion separation, energy conversion and novel fluidic devices.

8:30 AM *FF02.08.02
Tunable Graphene-Based Membranes Rahul Raveendran Nair; University of Manchester, United Kingdom

Permeation through nanometre-pore materials has been attracting unwavering interest due to fundamental differences in governing mechanisms at macroscopic and molecular scales, the importance of water permeation in living systems, and relevance for filtration and separation techniques. Latest advances in the fabrication of artificial channels and membranes using two-dimensional (2D) materials have enabled the prospect of understanding the nanoscale and sub-nm scale permeation behaviour of water and ions extensively. In particular, graphene oxide (GO) membrane containing 2D graphene capillaries shows unique permeation properties such as ultrafast permeation of water and molecular sieving. In my talk, I will discuss our recent results on molecular and ionic permeation properties of GO membranes and its prospect for several applications.

9:00 AM *FF02.08.03
Two-Dimensional Nanofluidics Jiaxing Huang1 and Jun Gao2; 1Northwestern University, United States; 2University of Twente, Netherlands

Electrolytes exhibit drastically different properties when confined in nanochannels. For example, in bulk solution, cations and anions simultaneously move along opposite directions to generate ionic current. However, in channels narrower than the Debye length of the electrolyte (a measure of how far electrostatic effects can persist), the surface charges on the inner walls repel ions of the same charge and attract the counterions, making them the dominating charge carriers. Such unipolar ionic transport can enhance ionic conductivity up to several orders of magnitudes. Nanochannels that enable such transport can be fabricated in bulk materials, but such “top-down” methods are rather expensive and difficult to scale up. The construction of nanofluidic channels with the 2D sheets, a “bottom up” approach, can be done simply by casting or filtration of 2D sheets dispersed in solution, as first demonstrated with graphene oxide sheets. The surface properties and the spacing of the 2D nanochannels can be conveniently controlled by modifying the starting sheets. A number of 2D materials are already available for this purpose.

The exfoliation-reconstruction strategy not only breaks down the experimental barrier of entry to study nanofluidics, but also offers a number of unprecedented opportunities. For example, one can also draw an analogy between the 2D nanofluidic films and extrinsically doped semiconductor wafers, because they both have a planar geometry and only one type of dominating charge carriers. Looking ahead, one can potentially use these lamellar films as “ionic wafers” to create ionic devices or even circuits mimicking the functions of their electronic counterparts. While the hard semiconducting wafers have to be patterned by lithography, these flexible ionic wafers can also be patterned by alternative methods such as Kirigami-like cutting techniques to define the functional elements. Some problems that should be addressed in the field will also be discussed.

9:30 AM FF02.08.04
Enhanced Water Flow through Angstrom-Channels Ashok Keerthi and Radha Boya; The University of Manchester, United Kingdom

Water conduction through porous materials and membranes plays a significant role in nature as well as water purification technologies. Flow through confined channels with dimensions below few nanometers displays a drastic enhancement in the observed water velocities. Most of these studies were with carbon surfaces (e.g., carbon nanotubes) and the enhanced flows were primarily attributed to frictionless transport of water molecules on atomically flat graphitic surface. Nevertheless, with another atomically flat material namely hexagonal boron nitride (hBN), a structurally similar but electronically dissimilar analogue of graphite, we test the water flow velocity. We investigate the link of the hydrodynamic flow to the surface friction and electronic properties of the confining materials, which remains unclear to date. Using precise angstrom scale capillaries made up of graphite and boron nitride walls, we study the water flow through them and address the effect of electronic properties and surface friction. We employ precision gravimetry to study the water flow quantitatively. Unlike graphite capillaries, which show slip
enhanced water flow, hBN capillaries showed at least two orders of magnitude lower water flux. While the velocities of water inside graphite capillaries reach up to 1 metre/second, for hBN capillaries the velocity can reach hardly 0.007 metre/second. Both the surfaces are atomically flat and even structurally similar. What contributes to this massive difference? We probe the possible reasons one by one. We have examined in detail the effects which can contribute to slip flow on two structurally similar atomically flat surfaces of graphite and hBN.

9:45 AM FF02.08.05
Molecular Dynamics Simulations on Ion Transport through Angstrom-Scale Channels Fengchao Wang; University of Science and Technology of China, China

Structural and dynamic properties of ions confined in nanoslits are crucial to understand the fundamental mechanism underlying a wide range of chemical and biological phenomena. Recently, angstrom-scale channels were fabricated using 2-dimensional materials assembled into devices with controllable size, atomically smooth inner walls, and little surface charge, which provide us a new platform to study ion transport under strong confinement. In particular, this new confining geometry allows the size exclusion effect to be unambiguously decoupled from other mechanisms. Here, we investigate ion transport through two-dimensional slits using molecular dynamics simulations. K+ and Cl– show similar ion mobilities in a bulk aqueous solution, whereas they exhibit a remarkable difference when transporting through an angstrom-scale channel. Our molecular dynamics simulations uncover that such discrepancy originates from the subtle differences in their hydration structures and preferable locations across the channel. Opposite charge causes different water dipolar orientations around ions, mediating the distance and tribological interactions between hydrated ions and channel’s walls. Hydrated Cl– ions experience a remarkable larger friction force inside the channel and consequently a smaller mobility compared with K+ ions. Ion transport also shows clear size effect. As the slit size approaches the ultimate scale, dehydration at the entry impedes the ionic conductance significantly, and even induces a complete ion rejection. We demonstrate that energy barriers required to accomplish the ion permeation can be theoretically connected to the partial dehydration process. The proposed model is further validated by simulations. Our results offer insights into the atomistic details of ion permeation, which may also shed light on developing effective ways for water filtration and desalination.

10:30 AM *FF02.08.06
Graphene Oxide Membrane with Angstrom Channel Size for Selective Separation of Ions, Water and Gases Jongwoon Kim, Seung Eun Lee and Chang-Soo Han; Korea University, Korea (the Republic of)

Graphene oxide (GO) has been promising candidate material for separating water, ions and gases. Previous researchers have done great efforts to understand how GO membrane filtrates the ion and water molecules. The capability to separate the matters depends on the adsorption, diffusion and sieving diameter of the membranes. The transport mechanism through GO membrane with less 1nm interlayer spacing (wet state) becomes very complex to figure it out, because three effects should be considered. Using GO membrane with Angstrom channel size, separating results of ions, water and gases are presented and the plausible mechanisms are discussed.

11:00 AM FF02.08.07
Dipolar Graphene-Based Laminar Membranes Marcos V. Surmani Martins1,1, Seunghyun Hong2 and Slaven Garaj1,1,1; 1National University of Singapore, Singapore; 2King Abdullah University of Science and Technology, Saudi Arabia

Dipolar graphene-based interfaces are yet to be considered for the latest generation of ionic sieving membranes, while having remarkable potential related to their enhanced charge interactions, water acceptability and suppressed nonspecific adsorption of complex molecules on the solid-liquid interface (fouling). Such membrane bears resemblance to zwitterionic macromolecules that retain both positive and negative groups, which make them highly hydrophilic and electrokinetically stable at a broader range of pH and ionic strengths when compared to other conventional families of macromolecules or materials.

In this work, we investigated the ionic transport in dipolar laminar graphene oxide (GO)-based membranes, harboring both positive amid and negative covalently bonded charge groups. By controlling the content of different oxygen carrying groups, the overall ionic permeability can be tuned. Even with an enhanced hydrophilicity of the
membrane, the membranes with higher degree of reduction showed ionic permeability values lowered by an order of magnitude. Moreover, a peculiar reversed ionic selectivity among mono- and divalent ions is observed, giving us general insight into molecular interactions within GO membranes. The scalability of these membranes, combined with their chemical stability, as well as antifouling properties make them strong candidates for applications such as, biochemical separation processes, desalination and osmotic power generation.

SESSION FF02.09: Ultra-Thin Nanopores and Nanoporous Membranes III

1:30 PM *FF02.09.01
Nanosculpting Two-Dimensional Materials—From Antidots and Bandgap Tinkering to Nanopores and DNA Sequencing
Marija Drndic; University of Pennsylvania, United States

Atomic-defect engineering in 2D materials provides new opportunities from condensed matter physics to molecular filtration. Introducing atomic and nm-scale vacancies in 2D materials changes their electrical and optical properties (for example the bandgap, as in antidot lattices). When 2D materials are suspended, vacancies make the membranes permeable to ions and molecules in liquid or gas phases, allowing transport studies at atomic scales. While Ohm’s law works well to describe ion current flow through nm-size holes, for sub-nm holes comprised of a handful of missing atoms, one measures non-linear current-voltage curves. Sub-nm holes allow the passage of smaller water molecules but block the larger hydrated salt ions which can be exploited for efficient water desalination. Raman and photoluminescence spectroscopy combined with aberration-corrected TEM, together with molecular-dynamics and DFT calculations, provide a comprehensive approach to characterize the holes and transport through them. Raman peak shifts can be used to quickly determine the density of vacancies, once those have been initially calibrated with electron microscopy data.

2:00 PM *FF02.09.02
Controlling Ionic and Molecular Transport through Porous 2D Membranes
Ulrich Keyser and Stephan Hofmann; University of Cambridge, United Kingdom

Thin membranes made from systems like graphene are emerging as essential building blocks for applications ranging from desalination, osmotic power production to molecular sensing. Here, we elucidate the physical interactions that govern transport of ions and macromolecules in these systems. Our quantitative measurements based on diffusion of positive and negative ions across porous 2D membranes of graphene and hexagonal boron nitride (h-BN) prove their cation selectivity in a wide pH range. The Goldman-Hodgkin-Katz equation allows us to extract the ion selectivity from current−voltage characteristics of graphene and h-BN monolayers separating reservoirs of different salt concentrations. Systematic measurements varying the Debye screening length as well as the type of ions and pH demonstrate that negative surface charge gives rise to cation selectivity. In addition, we show that the cation selectivity can be reversed into anion selectivity by the chosen ionic species. Surprisingly, h-BN and graphene membranes show very similar characteristics. The extrinsic nature of the selectivity enables to create efficient...
power conversion for streaming currents. Finally, we will discuss our recent measurements on the transport of macromolecules like DNA through pores in graphene and hBN and efforts to measure the force during translocation using optical tweezers.

2:30 PM FF02.09.03
Two-Dimensional Nanopore DNA Sequencing by Diffusion Current Measurements Wei-Lun Hsu¹, Yuji Nakagawa¹, Daisuke Egusa¹, Soumyadeep Paul¹, Ya-Lun Ho¹, Jean-Jacques Delaunay¹, Zhen Gu², Yi-Lun Ying², Yi-Tao Long²,³, Eiji Abe¹, Yoshihiro Iwasa¹ and Hirofumi Daiguji¹; ¹The University of Tokyo, Japan; ²East China University of Science and Technology, China; ³Nanjing University, China

Nanopore technology using biological pores embedded in a lipid bilayer has emerged as a rapid and inexpensive alternative to conventional DNA sequencing methods. In a similar vein, artificial solid-state nanopores possessing the advantages of mechanical strength, modifiable geometry and stable chemical properties over the biological nanopores are expected to be more favorable for biomolecule detections. However, thus far the development of solid-state nanopore technology has encountered gigantic obstacles in both spatial and temporal resolutions hindering the fulfillment of practical sequencing applications. Comparing with the gap between each DNA nucleotide (~3.4 angstroms), the thickness of conventional silicon nitride membranes is approximately two orders of magnitude greater. In this regard, two-dimensional materials nanopores have been recently employed attempting to improve the spatial resolution, whose thicknesses coincide with the distance between each nucleotide (e.g. the thickness of a monolayer molybdenum disulfide is 6.5 angstroms). Nevertheless, although these ultrathin nanopores conceptually promise high spatial resolution, the reduction of the pore length concurrently brings up two major issues: (i) the augmentation of Joule heating effects in which the imposed electric field magnitude is inversely proportional to the pore length. In consequence, the superheated solution inside the nanopore not only can give rise to the denaturation of DNA molecule properties but deteriorates the signal-to-noise ratio due to the additional thermal noise; and (ii) the presence of transport-induced-charge effects resulting in a lack of translocation events at low applied electric field but excessive translocation speed at high applied electric field yielding poor temporal resolution.

Here, we propose a novel and simple approach to effectively resolve above issues originated from the external electric field. Instead of tracing the conduction current variation, we replaced the external electric field with a solute concentration difference across a 3 nm monolayer molybdenum disulfide nanopore and detected the diffusion current variation during the diffusiophoretic translocation events of 20-mer ssDNA molecules. In this diffusion current system, Joule heat generated from the conductive ionic flux and transport-induced-charge effects due to the nanopore ion concentration polarization were simultaneously avoided. As a result, we successfully obtained four levels of current signals which are considered as the evidence of four types of nucleotides on the DNA molecules. These promising results revive opportunities for direct DNA sequencing using solid-state nanopores.

3:15 PM *FF02.09.04
Light-Enhanced Blue Energy Generation Using MoS2 Nanopores Aleksandra Radenovic; Ecole Polytechnique Federale Lausanne, Switzerland

Back in 2016 [1] we reported the first measurement of osmotic power across 2D membranes, and they were an important demonstration that nanomaterials may indeed represent a revolution in this domain, with direct application envisioned for renewable energy and small portable sources of energy. Power densities achieved in MoS2 nanopore outperformed the “conventional” thicker solid-state pores by orders of magnitude and make the whole concept of using 2D-pores extremely attractive. To reach the full potential, the osmotic power generator had to operate in an alkaline environment (pH 11), pH levels that are far from the values found in estuaries. High pH was required to increase the surface charge of the MoS2. Early on, we understood the importance of the surface charge in the power generation of 2D membranes and we explored ways how to improve the performance of osmotic power generation. In this work, we demonstrate that the osmotic power can be increased five-fold using light. To enhance and modulate surface charges we have used low power densities of light (~1-3 W/m2), that should be attainable in real-world applications where the sun can act as the photon source. To exploit MoS2 photoexcitability, we selected laser sources operating at 475nm and 643nm, with photon energies above the bandgap of single-layer MoS2. Also, we investigate the role of the pore sizes and surface charges on the osmotic power generation. By introducing a
formalism based on the Dukhin number \cite{2}, we can decipher the contributions to the osmotic power from the pore and surface conductions. At the high surface charge densities, the osmotic potential in small pores is reduced, since the dominant contribution originates from the surface condition. The main message of our work concentrates on the elegant way how the two most abundant energy sources can be efficiently married in the same device paving a way for next generation of tandem blue energy/solar devices based on 2D materials.

3:45 PM FF02.09.05
Scaled-Up Fabrication of MoS2 Freestanding Membranes for Nanopore-Based Biomolecule Detection
Mohammad Amin Alibakhshi, Anthony Vargas, Zhuoyu Zhang and Meni Wanunu
1; 1Northeastern University, United States; 2Nankai University, China

Two-dimensional (2D) Materials such as graphene,\cite{1-4} molybdenum disulfide (MoS2),\cite{5-7} and tungsten disulfide (WS2)\cite{8} have gained attention as alternatives to the protein nanopores for DNA sequencing applications, and as promising candidates for harvesting osmotic gradients for blue energy.\cite{9} From a device standpoint, such measurements are not viable unless a reliable scaled-up fabrication method of the 2D freestanding membranes is available.\cite{10} In addition, reducing the low frequency noise of these devices is critical for sensitive measurements of biomolecules.\cite{6} Among the 2D materials, MoS2 has gained special attention due to its less hydrophobic nature as compared with graphene. Moreover, we have previously shown that unlike graphene, MoS2 membranes can directly grow on apertures using chemical vapor deposition (CVD) method, which eliminates the time-intensive membrane transfer process.\cite{6} Here, we take advantage of this technique and demonstrate scaled-up fabrication of high quality MoS2 membranes on apertures. The apertures with diameters in the range of 50 nm to 200 nm were fabricated in silicon nitride membranes in 4-inch wafers using electron beam lithography. By fine-tuning the growth conditions we have been able to grow freestanding MoS2 membranes on apertures in 4-inch wafers with over 60% yield, which enables fabrication of hundreds of devices in a single CVD run. Understanding the temperature profile in such a large diameter CVD tube is essential in successful growth of the MoS2 crystals. Our computational fluid dynamics simulation points to strong temperature gradients and density-driven flows that develop in the tube, which constrain the conditions under which growth occurs on the target wafer. By addressing this problem we have been able to reliably reproduce high-quality growth over large areas. We used a transmission electron microscope to drill nanopores in the freestanding membranes for conductance and noise measurements. The rms noise of the ionic current at 100 mV applied bias and 1MHz bandwidth was recorded to be typically less than 250 pA. Further, as the voltage increases the noise further increases, with large contributions from low-frequency components. Our wafer scale direct 2D materials growth method, combined with automated nanopore fabrication, for example, by feedback-controlled dielectric breakdown,\cite{11} can address the device fabrication requirements for performing challenging single-molecule sensing of biomolecules.

References
Ionic transport in atomic-layer materials has demonstrated stimulating phenomena rising from its molecular interaction caused by spatial confinement parallel to that observed in biological proteins. Exploration of steric hinderance in ionic salt molecules is made possible thanks to the various device fabrication capabilities with 2D materials. In our study, we fabricate an array of nanoporous defects in TMDs ranging from single-atom to few-nm defects using ion irradiation and investigate the ionic-transport behavior of these devices. In addition, we create individual single-atom defects using advanced aberration-corrected scanning transmission electron microscopy (AC-STEM) to understand wetting behavior and therefore surface-charge density of the individual single-atom defects in monolayer TMDs. In this talk, I will cover the device fabrication of single-atom to few-nm defects and the governing effects of non-linearity observed in ionic current-voltage relationship through these defects.

Hybrid Nanopore—Integration of MoS$_2$ and OmpG for Single Nucleotide Sensing at Picomolar Concentration

Payel Sen, Hiofan Hoi and Manisha Gupta; University of Alberta, Canada

Solid-state nanopores have been used as small molecule sensors due to its steady pore current [1]. Analytes can be detected by their translocation-based ionic blockade current through the nanopore. Biological pores have structural precision and high sensitivity to chemical and electronic modifications, but lack the necessary structural strength for good repeatability and stability of sensing which can be provided by the solid-state nanopores [1]. The drawbacks for both systems can be overcome by integrating the biological pore with the solid state pore to create a hybrid nanopore [2]. This can be achieved by insertion of a biological pore into a solid state nanopore. In this research, we have used both Silicon nitride, SiN$_x$ and Molybdenum disulphide, MoS$_2$ (2D material) as membranes for solid state pores. MoS$_2$ thickness can be controlled to monolayer and hence the pore thickness can be controlled very precisely. This lower thickness translates to a higher resolution for molecular sensing. Here, we have used OmpG, a barrel protein having an outer diameter of 3.3 nm and inner diameter of 2 nm, for the biological pore. Single OmpG pore is pulled through by applying a bias to the solid state nanopore and it is prevented from going through the pore by choosing a correct size (3.5-4 nm diameter) solid state pore, fabricated of either SiN$_x$ (50 nm thick) or MoS$_2$ (Monolayer: 0.65 nm thick) pores to form hybrid pores. One of the major advantages of OmpG nanopore is its capability of insertion in solid state pore without a guiding DNA. Additionally, the flexibility of its external loops can be fine-tuned, thus offering a good control over detection specificity. 40 pM solution of single stranded DNA oligos (each having 30 mixed nucleotides) were pulled through 2.5 nm solid state SiN$_x$ and MoS$_2$ pores and 4 nm (outer diameter) hybrid SiN$_x$ and MoS$_2$ pores, and their translocation statistics was compared. Both solid state and hybrid nanopores created using SiN$_x$ and MoS$_2$ along with OmpG were used for studying DNA translocation. In case of solid state nanopores, MoS$_2$ has the advantage of retarding nucleotide translocation by 26-fold as compared to SiN$_x$. This improves the signal to noise ratio (SNR) to 11.2 for MoS$_2$ as compared to 1.86 for SiN$_x$. MoS$_2$ also demonstrates a 12-32% of deviation around the average translocation current value for a particular nucleotide, hampering precise identification of individual species, especially those having low density. An improvement in current deviation to 2-5% is observed using the hybrid nanopores. Monolayer MoS$_2$ demonstrated a 2-8 fold reduction in deviation compared to solid state monolayer MoS$_2$, while preserving an SNR greater than 10. Hybrid monolayer MoS$_2$/OmpG pore therefore is seen to sense individual DNA nucleotides from its picomolar concentration solution with 3-7 times improved resolution than SiN$_x$ nanopore systems and greater than twice the specificity shown by solid state monolayer MoS$_2$ nanopores. Current blockade values, signal-to-noise ratio, standard deviation of current and detected single nucleotide count will be reported for solid state and hybrid SiN$_x$ and MoS$_2$ pores.

References
Dielectric breakdown (DBD) of solid-state membranes in solution has been proved to be a powerful method for fabricating nanopore, attracting plenty of research interests in solid-state nanopore sensing. Sub-2nm nanopores that are hard to process by FIB, TEM and laser can be fabricated with very high reliability and reproducibility by the DBD method, which enable the detection of the sizes and structures of small molecules. However, the position of fabricated nanopore via DBD method was stochastic.

Here in, we report a fascinating method called tip-controlled breakdown (TCBD) for fabricating single or multiple nanopores by combining atomic force microscopy (AFM) and DBD approach. During the fabrication process, a conductive AFM tip is firstly brought into contact with a graphene membrane positioned above an electrolyte reservoir filled with potassium chloride solution. Then, a voltage pulse is generated from AFM built-in voltage module to produce a local electrical field at the end of the AFM tip. Nanopores would form precisely beneath the tip due to the local electrical field effect with a complete suppression of multiple pore formation compared with DBD approaches. The diameter of nanopores was under control of voltage pulse frequency and amplitude. The experiments show that sub-2nm nanopore was fabricated with the voltage no more than 5V. Potassium chloride concentration, voltage pulse frequency and amplitude have been investigate to optimize the TCBD method. Our results demonstrate that the approach greatly accelerates the electric breakdown process, leading to an average pore fabrication time on the order of tens of milliseconds, at least two orders of magnitude shorter than achieved by classic DBD approaches. With this fast pore writing speed, over 100 pores can be fabricated within half an hour on the same membrane. Stable ionic-current blockades were observed when DNA passed through the nanopores created on the graphene membranes by TCBD approach.

Finally, combining the nano position advantages of AFM and the simplicity/low-cost of the DBD approach, the TCBD has been demonstrated to be a highly efficient, reliable and reproducible nanopore fabrication method. We anticipate TCBD has the potential to become a nanopore fabrication technique which, integrated into an optical/magnetic setup, could be used as a high-throughput and multichannel characterization technique.
graphene as wall coating. To this end, Molecular Dynamics (MD) simulations are conducted to study water flow through uncoated and coated polyamide nanoslit pores with different heights. We perform a characterization of the interfacial properties and evaluate the impact that the polymeric matrix has on water structure. The force fields employed to model the species are validated measuring the water contact angle and comparing values against experimental results. Using Non Equilibrium MD Simulations (NEMD), Poiseuille-like flow is studied. The flow is achieved by imposing body forces corresponding to values of 2.93, 5.87, 11.75 bar/nm. Viscous heating is transmitted to and conducted through the walls as in a real system. From the MD trajectories, we compute shear stress, density, temperature and velocity profiles across the channel. Using these observables, we analyze the correlation between local water structure, flow enhancement and slip length. The velocity profiles in the coated polymeric pore exhibit a parabolic shape with substantial wall slippage. Hence, our results indicate that water interactions with the underlying polyamide have a significant influence on the water flow rates in the pores. We compute flow enhancements ranging from 62 to 116 for the cases with coated pores. Equilibrium MD simulations (EMD) are performed to calculate the fluid-solid interfacial friction by using the Green-Kubo relation. The values of the friction coefficients calculated are 594 and 14.3 (kN s)/m² for uncoated and coated nanoslits. We find that the flow enhancements computed from NEMD are in line with the friction coefficients computed from EMD. Our results show that graphene coatings can enable drag reduction in polymeric nanopores. The insights reported in this study may serve as a guide in designing strategies to achieve low friction transport of water solutions in nanostructured pores. These strategies will allow the development of more efficient LOC platforms and membranes for molecular sieving and nanofiltration.

8:30 AM *FF02.10.02
Understanding the Free Space and Mass Transport in 2D Nanochannels Baoxia Mi, Sunxiang Zheng and Zhongying Wang; University of California, Berkeley, United States

Ultrathin membranes formed by stacking two-dimensional (2D) nanosheets, including graphene oxide (GO) and MoS₂ hold unique separation capabilities that enable their applications in the filtration of aqueous solutions as well as organic solvents. However, the separation capability of a layer-stacked membrane can be significantly affected by its natural tendency to swell in solutions by absorbing molecules into 2D nanochannels and forming an enlarged interlayer spacing (d-spacing). In this study, the d-spacing of a layer-stacked GO and MoS₂ membranes was experimentally quantified when the membranes were soaked in aqueous or organic solutions. We found that solvents with high dipole moments tends to cause significant swelling of GO, while non-polar solvents such as hexane and toluene only cause subtle swelling. To understand such unique swelling behavior, the solubility parameter of GO was experimentally determined to mathematically describe the affinity between GO and the testing solvents. Separation performance of the GO membrane in different organic solvents were tested to understand the mass transport in confined GO nanochannel. The layer-stacked GO membrane could achieve > 90% rejection of small organic dye molecules (e.g., rhodamine B and methylene blue) in ethanol and acetone without crosslinking due to insignificant swelling. Additionally, it was found that solvents with different polarity demonstrate very different transport resistance.

9:00 AM *FF02.10.03
Multilayered Graphene Membranes—New opportunities for Nanoionics Dan Li and Zhe (Jefferson) Liu; University of Melbourne, Australia

We have previously developed a soft chemistry approach to fabricate multilayered graphene membranes (MGMs) with their interlayer distance tuneable from 10 nm down to sub-nanometers [1]. In this talk, I will demonstrate how MGMs can provide a unique platform for nanofluidics, and particularly nanoionics research. My talk will include: (1) How experiments and simulations can be combined to quantify the nanostructure of the MGMs for nanoionics research [2]; (2) How supercapacitor and membrane experiments can be coupled to modulate ion diffusion through nano-confined electrical double layer; (3) How MGMs can serve as a model electrode to enable quantitative understanding of the ion transport in nanoporous for predictive design of capacitive energy storage devices.

Realigning Nanochannels in Conventional Graphene Oxide Films to Achieve Enhanced Permeability and Controlled Release
Muchun Liu and Robert H. Hurt; Brown University, United States

There is great interest in exploiting van der Waals gaps in layered materials as continuous nanofluidic channels. Multilayer graphene oxide (GO) films with selective transport properties have been used for water desalination, oil-water separation, gas separation and pervaporation applications. Conventional GO membranes are often limited in practice by low permeability since the intersheet nanochannels align perpendicular to the desired overall transport direction, leading to highly circuitous fluid pathways that are orders of magnitude greater than the membrane thickness.

Here we demonstrate a novel approach to fabricate stable GO membranes with vertically aligned nanosheets spanning the membrane in the Z-direction. Compressive texturing of planar GO films tilts the nanosheets and nanochannels to near vertical directions, which are then stabilized imbedded in low-permeability polymer matrices and thin sectioned. The resulting membranes provide direct access to the entrances of intersheet nanochannels at both the top and bottom surfaces to create well-defined Z-directional fluid pathways whose length is on the same order as the micron-scale membrane thickness.

The compressive wrinkling and crumpling of graphene oxide films can also be used to control the release rates of molecular intercalants pre-loaded into GO gallery spaces. Experimental studies on rhodamine B dye, used as a model, show diffusive release rates in the rank order: planar > 1D wrinkled > 2D crumpled films. This type of fluidic-space manipulation should allow the intelligent design of 2D-material-based technologies such as time-release drug eluting coatings.

9:45 AM FF02.10.05
Potential Dependant Ionic Sieving through Functionalized Laminar MoS2 Membranes
Wisit Hirunpinyopas, Eric Prestat, Mark A. Bissett and Robert Dryfe; The University of Manchester, United Kingdom

Laminar MoS2 membranes show outstanding potential for practical applications in energy conversion/storage, sensing, and as nano-fluidic devices. The re-stacking of exfoliated MoS2 creates nanocapillaries between the layers of MoS2 nanosheets. These MoS2 membranes have been shown to possess a unique combination of ionic rejection properties, high water permeation rates, and long-term solvent stability, with no significant swelling when exposed to aqueous or organic solvents. Chemical modification of MoS2 membranes has been shown to improve their ionic rejection properties, however the mechanism behind this improvement is not well understood. In this work, we elucidate the ion-sieving mechanism by the study of potential-dependent ion transport through functionalized MoS2 membranes. The ionic permeability of the MoS2 membrane is transformed by chemical functionalization with a simple naphthalene sulfonate dye (sunset yellow) and with a resultant attenuation of permeability by at least an order of magnitude, compared to the pristine MoS2 membranes and permeability reported for graphene oxide and Ti3C2Tx (MXene) membranes. The effects of pH, solute concentration, and ionic size/charge on the ionic selectivity of the functionalized MoS2 membranes are also reported. Understanding the mechanism of ionic sieving within functionalized MoS2 membranes will enable future applications in electro-dialysis and ion exchange for water treatment technologies.

Nanoconfined Ionic Liquid in Nanoslites for Selectively Gas Separation
Xinsheng Peng; Zhejiang University, China

Separating CO2 from other light gases is believed to have extremely practical significance and economic benefits due to the strong demand from the industrial processes and the green-house effect. Conventional adsorption and low temperature distillation have their intrinsic drawbacks while membrane separation shows great potential. However, the trade-off between the high selectivity and permanence is still a great challenge. In this report, we prepared a high-performance CO2-phlic membrane, two-dimensional nanosheets supported ionic liquid membrane, by confining [BMIM][BF4] into the nanochannels of laminated graphene oxide membrane. The strong interaction
between graphene oxide and [BMIM][BF₄] stratifies the cation and anion of [BMIM][BF₄], and the layered anion facilitates CO₂ transportation. The resulted membrane has an excellent performance with CO₂ high permeance and good selectivity of CO₂/H₂, CO₂/CH₄, and CO₂/N₂ respectively. Moreover, it has high temperature resistance, long-term durability and high-pressure stability, which shows great potential in CO₂ separation. In addition, we found that external electric field could further facilitate selectively CO₂ transportation through nanoconfined ionic liquid.

Mass Transport Enhancement in Modified Graphene Oxide Membranes  
Jae Eun Shin, Ji Soo Roh, Farhad Moghadam, Been Namkoong and Ho Bum Park; Hanyang University, Korea (the Republic of)

Graphene oxide (GO) has a heterogeneous nanostructure consisting of sp²-graphitic regions and sp³-oxidized regions. In general, the sp² domains of GO have hydrophobic nature, whereas sp³ domains represent hydrophilic nature. Oxygen moieties in GO act as a spacer to enlarge the interlayer distance between individual GO sheets within GO membrane. In general, the amount of oxygen moieties in GO sheets reaches above 80%, which acts as a hindrance for even small gas molecules, eventually leading to low gas permeability. To enhance the gas permeability in GO membranes, the sp² domains in GO sheets were precisely adjusted in this study. Commonly, sp²/sp³ ratio can be tuned by reducing GO using chemical, thermal, and electrochemical methods. However, these methods lead to much disadvantages of remaining chemical additives, structural deformation, difficulty in mass production. Above all, the sp²/sp³ ratio would not be precisely controlled using conventional reduction methods. Although the mild reduction methods have been reported to overcome these problems, there have been no systematic membrane studies using GO sheets with different sp²/sp³ ratio. Here we report a mild hydrothermal treatment to precisely control the graphitic regions in GO and also tune its electrical and molecular transport properties. The change in hydrothermal conditions, such as thermal temperature and time, significantly affects the gas separation performance as well as water and salt transport of the modified GO membranes. The high-resolution TEM images of hydrothermal treated GO membranes showed that this mild hydrothermal treatment leads to the gradual increase of sp²-graphitic regions and minimize the formation of structural defects during the reduction. Besides, the change in electrical conductivity as a function of sp² domain was correlated with gas permeability as well as water transport through the modified GO membranes, and also was elucidated using percolation theory. Then, we prepared the membrane using hydrothermal treated GOs to measure the gas permeability and selectivity, water permeability, and salt permeability and salt rejection. This work demonstrates the separation performance enhancement of GO membranes by redesigning the structure of GO and reveal the transport mechanisms through each domain in the modified GO membranes.

Nanoparticle Diffusion in Confined Liquid Observed by Graphene Liquid Cell Transmission Electron Microscopy  
Sungsu Kang¹², Minyoung Lee¹ and Jungwon Park¹²; ¹Seoul National University, Korea (the Republic of); ²Institute for Basic Science, Korea (the Republic of)

Nanoparticles are generally stabilized by ligands whose dimension is comparable to that of nanoparticle core. The surface ligands endow nanoparticles with unique physical and chemical properties which can modify collision dynamics and diffusive motion of nanoparticle when suspended in a confined medium. Here, we directly tracked trajectories of Au nanoparticles smaller than 5 nm in solution by graphene liquid cell transmission electron microscopy, and found that different modes of diffusion exist in the medium. Dynamics of the nanoparticles in graphene liquid cells display Brownian motion with stark deviation from the Stokes-Einstein equation. Detailed analyses of nanoparticle displacements exhibit that their distribution does not follow a Gaussian distribution, implying the existence of structural heterogeneity in liquid confined by graphene sheets. We also reveal that expansion of nanobubbles induces the superdiffusive motion of the nanoparticles at the bubble interface.

11:45 AM FF02.10.09
Fabrication of Sub-Nanometer Pores on Graphene Membrane for Ion Selective Transport  
Han Qi; Southeast University, China

The ability to sieve ions through nanopores with high throughput addresses significant importance in seawater desalination and other separation applications. In this work, it is demonstrated that plasma etching process provides an efficient method to produce high density nanopores on graphene membranes with tunable size in sub-nanometer.
Besides the pore size, nanopore density is also controllable through adjusting the exposure time of the sample to the argon or oxygen plasma. The plasma treated graphene membranes can selectively transport protons, Na\(^+\) and Cl\(^-\) ions. Density function theory calculations uncover that sp\(^3\) and vacancy-type defects construct different energy barriers for different ions, which allow the defected graphene membrane to selectively transport ions. Our study indicates that oxygen plasma etching can be used as a very convenient and efficient method for fabricating monolayer filtration graphene membrane with tunable sub-nanometer pores.

**TUTORIAL**  
Aggregation-Induced Emission

Sunday Morning, December 1, 2019  
Hynes, Level 2, Room 206

Aggregation-induced emission (AIE) is an influential concept proposed in 2001 for describing a photophysical phenomenon, in which non-emissive molecules in solutions are induced to emit strongly when their intramolecular motion is restricted in aggregate or solid state. The conceptualization of AIE not only breaks the common belief of aggregation-caused quenching, but also provides new mechanistic insights on light emitting process of luminogenic aggregates and illuminates the path to the exploration of practically useful luminescent materials for optical, electronic, energy and biomedical applications, such as organic LEDs, solar cells, sensing, imaging and image-guided cancer therapy, etc. The AIE effect can be utilized in all applications involving aggregates.

The tutorial aims to bring the attendees updated information on the fundamental AIE research and the state-of-the-art applications of AIE luminogens. It is also designed for the experienced AIE researchers to reinforce their knowledge on the scopes of development of new generation of AIE materials, understanding of AIE mechanisms and exploration of advanced technological applications. Eight top experts from seven counties will deliver lectures and consulting sections, providing a unique platform for the attendees to learn from the professionals and foster dynamic and scientific exchange via exciting cross-disciplinary discussions. The tutorials will be conducted using interesting illustrations and simple languages, which will greatly benefit junior researchers and graduate students.

Two-Dimensional Mesoporous Superlattices of Silica Cages Tangi Aubert$^{1,2}$, Kai Ma$^1$, Kwan W. Tan$^{1,3}$ and
Mesoporous silica based materials and their derivatives in the bulk, as films, and as nanoparticles have attracted a lot of attention for their application potential across different areas, e.g. in catalysis, energy, and nanomedicine. Extensive research efforts have resulted in the continuous discovery of new structures, from quasicrystalline to hierarchical structures. Among these materials, cage-type silica mesoporous materials are of particular interest for their facile pore accessibility and versatile functionalization opportunities. The formation of these advanced materials derives from the self-assembly of silica nanocages as the building blocks, following a cage-based crystallization mechanism. However, fundamental understanding of how order emerges on the way from a single cage to a 3D bulk material remains limited.

We recently developed a series of low-dimensional silica structures, with in particular the discovery of isolated pentagonal dodecahedral silica cages formed around single surfactant micelles [1,2]. Dodecahedral cages constitute the elementary building blocks in a large variety of naturally occurring and synthetic materials, including DNA and RNA cages, clathrates as well as mesoporous silica. These motifs are thus found across a wide range of length scales, in organic as well as inorganic materials. We therefore saw in this discovery an opportunity to investigate the early stages of the growth mechanisms at play in micelle directed self-assembly processes that lead to the formation of cage-type mesoporous silica with well-defined crystallographic structures.

Following a similar strategy as for the formation of nanocrystals superlattices, we assembled silica cages at an interface between two immiscible solvents. By carefully varying the synthesis conditions, we could assemble 2D superlattices with high control over the morphology, going from monolayers to multilayers of cages. While in a monolayer with honeycomb structure the silica cages do not show any orientational order relative to each other, this orientational correlation increases with increasing layer number leading to complex clathrate type structures in silica cage multilayers. Expanding the superlattices beyond 3-4 layers of cages further evidenced a relaxation of the 2D confinement, driving the assembly towards more favorable bulk structures. Thus, with this approach we can observe the emergence of the crystallographic registry as a result of the concerted self-assembly of surfactant micelles directing the silica 3D network.

Since these 2D superlattices can be coherently fabricated over macroscopic film dimensions, the resulting membranes may be of interest for a number of applications. By adopting concepts from 2D electronic materials, tuning the structure, composition and angle between heterostacks of silica cage superlattices is now paving the road for the design of advanced functional and hierarchical superstructures, with potential separation or catalytic properties not accessible via conventional bulk material syntheses.

Facet-Controlled Synthesis and Aggregation of Hematite Nanoparticles Yining Wang1,2, Xin Zhang1, Meizong Zong1, Zhening Wang1, Junwu Zhu2 and Kevin Rosso1; 1Pacific Northwest National Laboratory, United States; 2Nanjing University of Science and Technology, China

Hematite with its high earth-abundance and low biotoxicity is considered to be one of the most promising candidates as a catalytic substrate in various new energy devices. In particular, controlling hematite morphology to expose certain high-energy facets appears to be a promising route to performance improvements. In this study, we describe additive-free synthesis protocols that yield diverse uniform nanoparticle morphologies by controlling the concentration of iron ions and hydrothermal temperatures. Increasing the concentration of iron ions and decreasing the hydrothermal temperature was found to systematically inhibit growth along the c-axis and facilitate growth along the b-axis, leading to the formation of bipyramids with \{111\} facets. Hematite nanostrings were achieved by the assembly of nanocubes with \{104\} facets and a secondary growth process. Growth by nanoparticle aggregation was investigated in detail sing powder X-ray diffraction (pXRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), Raman spectroscopy, and atomic force microscopy (AFM). These findings may pave the way to production of chemically pure and morphologically well-defined hematite nanoparticles, and to economically advance their practical application in energy devices.

Water Adsorption Induced Organization of MgO Nanocubes into 1D and 2D Structures Oliver Diwald1, Gilles R. Bourret1, Daniel Thomele1, Michel Bockstedte1 and Johannes Bernardi2; 1University of Salzburg, Austria; 2TU Wien, Austria

Water adsorption and thin water film formation on unsupported metal oxide nanoparticles can lead to structural and microstructural transformations that arise from different processes like water-assisted self-assembly of particles or dissolution/ recrystallization processes. This presentation deals with examples where structure-property relationships have been established for MgO nanocubes and their transformation behavior in different water containing environments. We will show that water vapor can induce the self-organization of the nanocubes into regularly staggered one-dimensional structures.[1] The transformation evolves via an initial alignment of the MgO cubes, the formation of intermediate elongated Mg(OH)2 structures, and their annealing induced reconversion into 1-D structures. In the presence of water vapor the particles spontaneously orient themselves to form staggered MgO nanocube assemblies, where the cubes are offset from each other. Ab initio Density Functional Theory (DFT) modelling identifies surface energy changes associated with the cube surface hydration and hydroxylation to promote the uncommon particle assembly.[2] It will be shown how simple process steps like water adsorption via the gas phase or dissolution-recrystallization processes in condensed water can be utilized as valuable routes to generate anisotropic mesostructures. The here presented transformation mechanisms occurring inside and outside an aqueous bulk solution may pave novel routes for inducing texture in ceramics. Moreover, they point to a great test bed for new surface science concepts where the emergence of associated local structures can accommodate important new functionalities which are beneficial for catalytic activity and microstructure evolution.

9:00 AM *FF03.01.04
Unraveling Phase Transformation Pathways of Ferric Oxyhydroxide Nanocrystals in Aqueous Solution Kevin Rosso; Pacific Northwest National Laboratory, United States

Fe(III)-(oxyhydr)oxide nanocrystals are an emerging basis for cost-effective catalytic substrates, as well as a dominant class of reactive minerals in soils and sediments. In both contexts, developing a molecular-level understanding of crystallization processes that control particle phase, size, and morphology is critical. However, in aqueous solutions near ambient conditions this remains complicated by the challenge of following rapid initial precipitation, yielding the poorly crystalline metastable phase ferrihydrite (Fh), and then the slower mass transfer pathways transforming it into more stable nanocrystals such as lepidocrocite (Lp), goethite (Gt), and hematite (Hm). The slowness of the latter is linked to both the low aqueous solubility of Fe(III), which restricts the dissolution/reprecipitation pathway, and the low solid-state diffusivity of lattice iron, which restricts the topotactic pathway. Particle-based assembly has been proposed in some cases, but alone this cannot accomplish transformation without also recruiting one or both of these two slow pathways. Importantly, addition of only micromolar concentrations of Fe(II) accelerates the Fh phase transformation by several orders of magnitude.

Here we overview new observations that help unveil principles governing pathway selection and rate, and the catalytic effect of Fe(II). We report a comprehensive experimental/computational study of Fh transformation into Lp/Gt nanocrystals at circumneutral pH, with and without aqueous Fe(II), resolved at the iron site occupancy level. In the absence of added Fe(II), Fh aged over two years was periodically characterized using in situ mXRD with detailed line shape analysis, electron microscopy, and synchrotron Fe L-edge and O K-edge XAS/XMCD spectroscopy quantitatively analyzed using MRCI ab initio calculations. The results are compared to DFT calculations of relative phase stabilities and activation energies for solid-state diffusion of iron along topotactic channels. Tetrahedral Fe(III) is clearly resolved minor component of freshly precipitated Fh, diminishing concomitantly with increasing octahedral Fe(III) and decreasing net magnetic moment until the first appearance of Lp and Gt nanocrystals at ~100 d. Calculated iron diffusion activation energies although as low as 1 eV per unit cell are still too high to support topotactic transformation. Microscopic characterization is well aligned with dissolution/reprecipitation; no compelling evidence for particle-mediated transformation was found. In the presence of Fe(II), an observed ~1000x rate acceleration appears to arise from facile interfacial electron and iron atom exchange that effectively increases the activity of labile Fe(III) at Fh surfaces, resulting in rapid nucleation of Lp and Gt nanocrystal products. Both non-redox and Fe(II)-catalyzed transformation therefore can be explained on a uniform footing via dissolution/reprecipitation. The collective findings suggest the importance of transient Fe(III) species stabilized at interfaces controlling the kinetics of transformation and, in turn, nanocrystal outcomes.
Dynamically Evolving Hierarchical Structure in Clays
Michael Whittaker¹,², Benjamin Gilbert¹ and Jillian Banfield²; ¹Lawrence Berkeley National Laboratory, United States; ²University of California, Berkeley, United States

Clay minerals like montmorillonite (MMT), composed of highly anisotropic layers less than one nanometer thick and up to microns wide, are the most abundant inorganic nanomaterials on earth. Particles comprise negatively charged MMT layers separated by discrete molecular layers of water and solvated cations, creating a porous matrix that controls the fate of water, carbon dioxide, nutrients, and pollutants in myriad natural settings. Here, we show evidence of highly dynamic and coupled interactions between clay layers that are accessible through thermal fluctuations, which lead to unexpected particle arrangements and pore structures that are not predicted by current theories.

Stacks of layers exhibit aspects of plastic crystallinity in which the barriers to rotation of an individual layer are on the order of 0-5 kT per unit cell. This results in size-dependent short-range order between neighboring layers whose persistence length depends on the hydration energy of the interlayer cation and its concentration in solution. In the presence of mixed electrolytes, particles phase-separate into compositionally distinct particles with different hydration states. A free energy difference of approximately 4 kT per unit cell allows two populations to reach metastable equilibrium through the exchange of both cations and MMT layers. These dynamically rearranging particles exhibit a panoply of topological defects that contribute to the hierarchical structuring of particle aggregates. Non-ergodic evolution of the system dynamics over time produces new structures that continuously emerge over timescales spanning many orders of magnitude. This new perspective on the dynamic structure of MMT reveals potentially general aspects of colloidal interactions in layered materials, and will help improve predictions of ion exchange and fluid transport and retention in many natural systems.

SESSION FF03.02: Aggregation-Induced Emission I

AIEgen-Based Bioprobes for Biomedical Applications
Dan Ding; Nankai University, China

We report a quantum dot-sized organic dot with aggregation-induced emission (AIE) characteristics as a promising cell tracker for noninvasive long-term tracking of adipose-derived stem cells (ADSCs) in living mice. We demonstrate that the AIE dots possess high fluorescence, strong photobleaching resistance, low in vivo toxicity, excellent retention in living ADSCs and negligible interference on the ADSC pluripotency and secretome. The AIE dots also exhibit far superior in vitro cell tracking capability as compared to the widely used commercial cell trackers of PKH26 and Qtracker 655. The in vivo studies using an ischemic hind limb-bearing mouse model reveal that the AIE dots can precisely and quantitatively report the fate of ADSCs and their therapeutic effect in vivo for 6 weeks. Moreover, we have also synthesized a far-red/near-infrared fluorescent AIEgen-based nanodot, which can efficiently generate reactive oxygen species (ROS) under light irradiation. It is found that the AIEgen-based nanodots are able to visualize tumor tissues and assess tumor margins during surgery in a tumor-bearing mouse model. More importantly, upon tumor removal followed by irradiation of the incision site with light, the AIE nanodots in the residual tumors will generate ROS, which has been demonstrated to successfully suppress the residual tumors and reduce the risk of tumor recurrence after debulking surgery.
Designing Fluorescent 2D Nanocrystals through Self-Assembly of Sequence-Defined Peptoids Chun-Long Chen; Pacific Northwest National Laboratory, United States

Two-dimensional (2D) materials have attracted intense interest due to their unique structures and novel properties for applications in molecular separation, sensing, catalysis, and biomedicine. Despite the unique advantage of the 2D nanostructure in development of functional optical crystals, 2D nanomaterials, such as graphene, graphene oxide and transition metal dichalcogenides, have limited intrinsic optical properties and surface chemistries that restrict them as efficient optical crystals for applications. For example, none them have been directly used as probes for single particle tracking within biological systems.

We recently developed a new class of highly stable and self-repairing 2D nanomembranes (2DNMs)\(^1\) from sequence-defined peptoids—a type of protein-mimetic that was invented to mimic the recognition capability of proteins and peptides. These free-standing 2DNMs are highly stable and exhibit a number of properties associated with cell membranes, including thicknesses in the 3.5 - 5.6 nm range, spontaneous assembly at interfaces, and the ability to self-repair. We further demonstrated that a broad range of functional groups can be incorporated and patterned within 2DNMs through large side-chain diversity and/or co-crystallization approaches. In this presentation, I will present our recent progress in the design and synthesis of fluorescent 2D nanocrystals by self-assembly of sheet-forming peptoids conjugated dye molecules. We demonstrated a fine tuning of optical properties of these 2D nanocrystals by varying the dye density and chemistry. The high crystallinity of these 2DNMs enabled a long-range ordering of dye molecules within 2D crystals to achieve unique optical properties, such as high photostability and quantum yield, for applications in biological imaging and molecular sensing.

Modular Design of Peptide-AIEgens or DNA-AIEgens Bioprobes for Biosensing Applications Fan Xia and Zaiyu Wang; China University of Geosciences, China

Fluorophores probes are widely used in fields of bioimaging in cells, tissues, or animals and monitoring multiple biological processes in the complex environments. Such sensitive imaging properties allow scientists to make a direct visualization of pathological events and cellular targets. Conventional fluorescent molecules have developed for several decades and achieved great successes, however, their emissions are often weakened or quenched at high concentration or in aggregate state that might result from aggregation-caused quenching (ACQ) effect and reduce the efficiencies of their applications.

In contrast to ACQ effect, aggregation-induced emission (AIE) molecules exhibit strong fluorescence in aggregated states and possess various advantages such as low background, high sensitivity and accuracy, long-term tracking ability, and strong resistance to photo-bleaching. Therefore, those AIE fluorophores are employed as unique fluorescence molecules and excellent modular blocks for the biosensing applications in the field of ions, amino acid, carbohydrates, DNA/RNAs, peptide/proteins, cellular organelles, cancer cells and bacteria.

11:30 AM *FF03.02.04
Self-Assembly Based on AIEgens for Image-Guided Anticancer Therapy Wenjing Tian; Jilin University, China

Aggregation-induced emission luminogens (AIEgens) have attracted concentrated attention in bioimaging due to large stokes shift, fine biocompatibility and good photobleaching resistance. Recently, AIE nanoparticles, as a brand new anti-cancer treatment, can simultaneously achieve dual functions of tumor imaging and treatment, which are promising for clinical medicine. Herein, we successfully co-assembled AIEgens with an antitumor paclitaxel to form Co-NPs for cell imaging and antineoplastic activity. Besides, self-assembly nanostructured AIE photosensitizers with red light emission and high fluorescence quantum yield were prepared for photodynamic therapy. Furthermore, in order to investigate the relationship between molecular structure and photosensitization, we designed and synthesized two types of AIE photosensitizers (PSs) with asymmetrical Donor(D)-Acceptor(A) structure and
symmetric A-D-A structure. We found that the singlet oxygen yield could get double promotion by the A-D-A molecule design. It suggested that the designed materials were promising as PSs for potential clinical applications.

Towards Colorful, Switchable Enamine-Based Materials Olof Ramstrom1,2; 1University of Massachusetts Lowell, United States; 2Linnaeus University, Sweden

In this presentation, ways to harness the powers of enamines will be described. Different stabilized enamines have been developed and applied to configurational switching, metal coordination, and constitutional dynamics through transamination. By controlling the dynamic features, turn-on luminescence effects could be obtained both on the molecular level and when applied to materials. The results show that controllable, enamine-based materials show potential for sensing and imaging applications.

2:00 PM *FF03.03.02
Coordinating AIEgen—Single Molecular Platform Leading to Diversified Emission Yun Yan; Peking University, China

Controlling the emission color of AIEgens is very promising in creating functional luminescent materials. This is usually achieved by modifying the chemical structure of the AIEgens, which is very complicated and are often not very efficient. We show that by attaching a coordinating moiety to the AIEgen, multiple emission can be achieved by simply changing the coordinated metal ions. The metal coordination may bring up changes to (1) the conformation of the AIEgen;(2) the energy gap between HOMO and LUMO of the coordinating AIE molecule; (3) binding affinity to different chemicals. As a result, the emission color and the function of the AIE molecule can be facilely tuned by variation of the coordinating metal ions. Compared to organic synthesis, the coordination strategy is very facile and efficient. We show that by using coordinating AIEgen, we are able to obtain tunable emission and achieve one-on-multiple recognition of important chemicals.

2:30 PM FF03.03.03
Self-Assembly, Superhydrophobic Surface Formation, Solid State Emission and Mechanofluorochromism from Phenothiazine Derivatives Sivalingam Suganya and Edamana Prasad; Indian Institute of Technology Madras, India

Design of organic molecules exhibiting emission in the aggregated state is increasingly getting attention in the field of materials chemistry. Self assembly of low-molecular-weight gelators (LMWGs) in a particular solvent environment leads to the formation of luminescent gels with 3D nanostructures. Similarly, particular way of stacking by small organic molecules leads to solid state emission. If the self-assembling organogel/small molecules bear hydrophobic alkyl chains, it could be possible to develop superhydrophobic surfaces through self-assembly. Further, self-assembling systems can exhibit mechno responsive switchable fluorescence in solid state, which has wide applications in optoelectronics, sensors, memory chips and security papers. Herein, we present the synthesis and characterization of solid state emitting phenothiazine based organogel linked with poly (alkyl ether) dendron (S1) and small molecule connected with pyridine ring (S2). The hydrophobic alkyl chain present in S1 was effectively utilized to fabricate the superhydrophobic surface with a water contact angle of 157°. Further, small molecule S2
displayed a special kind of mechanofluorochromism (MFC) from cyan blue (480 nm) to green emission (535 nm) with an unusual crystal-to-crystal phase transitions. Upon photoexcitation, $S_1$ and $S_2$ exhibited twisted intramolecular charge transfer (TICT) and aggregation induced blue shifted emission. Further, single point energy calculations using Density functional theory (DFT) authenticate the MFC behavior of $S_1$ and $S_2$. The details of the work will be presented.

3:30 PM *FF03.04.01
In Situ Nanoelectrical, Electrochemical and Electromechanical Characterization of the Liquid/Solid Interface with Atomic Force Microscopy
Thomas Mueller, Bede Pittenger and Peter De Wolf; Bruker Nano Surfaces, United States

While in situ atomic force microscopy (AFM) studies have traditionally focused on nanoscale topographic or mechanical characterization, additional information would greatly benefit in situ studies of biocompatible devices, complex hierarchical materials and energy materials to name a few. Here we present the development of atomic force microscopy modalities for in situ and in operando electrical, electrochemical, and electromechanical studies with nanometer resolution at the electrified solid-electrolyte interface. This work builds on the recent development of an insulated nanoelectrode probe with small active Pt apex, which enables high resolution studies, as shown in the simultaneous acquisition of local EC and conductivity information at electrified solid/liquid interfaces of nanoparticle-catalysed photocathodes for water splitting. [1, 2] The range of in situ characterization is further expanded with the new Data Cube AFM modes which provide hyperspectral data comprising voltage and surface distance spectra at every pixel of the image. In particular, Data Cube SECM mode records an approach curve at every pixel thus aiding quantitative modeling of SECM signals. Further, we will show that the variable surface dwell time enables nanocontact EC studies such as local surface EC potential measurement. [3, 4] In general, Data Cube electrical modes provide comprehensive data for ex situ and in situ studies, and the opportunity to extract new kinds of maps through physical modeling of the point spectra or algorithms such as principal component analysis.

Finally, we will present in situ studies of bio-electromechanics with piezo force microscopy (PFM). Despite great interest for biomedical applications, such studies have so far been few other than pioneering work by Kalinin et al. [6, 7] and few other groups. [8] Challenges include the need for chemical compatibility, presence of parasitic electrochemical reactions, capacitive charging from electrical double layers, and de-localized electric field in conductive liquid environments, making the use of physiological conditions impractical. We will show that the use of the nanoelectrode probe mitigates these factors enabling acquisition of PFM data in conductive liquid. [9, 10] Here the use of Data Cube PFM mode not only provides added information about the contact resonance, it also provides higher sensitivity, pushing the PFM detection limit to higher ionic strength.

In Situ Tracing the Evolution of Protein 2D Nanostructures at Solid-Liquid Interface Shuai Zhang1,2, Harley Pyles1, David Baker1 and James J. De Yoreo2; 1University of Washington, United States; 2Pacific Northwest National Laboratory, United States

Among biomolecular composites in nature, the macromolecular-inorganic hybrid biomaterials, like bone, enamel and nacre, have the outstanding physical and biological properties. Several artificial bio-composites with the programmed macromolecular-inorganic interfaces, which are inspired by the native ones, have been reported. However, the in-situ visualizations of the synthesizing/assembly processes, with spatial resolution in nanoscale and temporal resolution in second are still rare. That makes the entropy term and kinetic possibilities are inaccessible in many cases. Hence, the dynamic information in the design and synthesis is often ignored.

In this talk, I will present the in-situ study of the evolution of 2D protein matrices (DHR-micaN)1, on the mica surface by in-situ high-speed atomic force microscopy. By tuning the electrolyte type, protein concentration, protein size and intra-protein interactions, the protein molecules can stay as the isolated monomers, condensed liquid, and the anisotropic 2D liquid crystal with smectic order. At [KCl] above 1M, the order develops from an initial 2D liquid phase through the formation of fluctuating clusters. The mica substrate also has certain role to confine the protein nanostructures aligning along pre-defined direction. Those findings have not been previously recorded, and 2D liquid crystal with smectic order had been considered as a non-existent phase in some theoretical analyses. Numerous lines of evidence imply that, besides the programmed protein-mica and protein-protein interactions, the entropic interactions, like the release of interfacial water from the surface and the proteins, also play a critical role in the assembly process.

4:15 PM FF03.04.03
Building Two-Dimensional Materials One Row at a Time—Avoiding the Nucleation Barrier Jiajun Chen1,2, Enbo Zhu3, Juan Liu4, Shuai Zhang1,2, Hendrik Heinz4, Yu Huang3 and James J. De Yoreo1,2; 1University of Washington, United States; 2Pacific Northwest National Laboratory, United States; 3University of California, Los Angeles, United States; 4University of Colorado-Boulder, United States

Assembly of 2D patterns on crystal surfaces has been widely investigated to reveal the structural and energetic relationships between the substrate and overlying architecture. Progress has been achieved in understanding and controlling their assembly, yet little is known about the mechanism by which they nucleate. Understanding the dominant pathways and formation kinetics would enable precise control over phase and morphology during synthesis of 2D materials. In our study, short peptides were selected for their ability to bind on MoS2 (0001). We studied nucleation and growth of 2D films of these peptides directly with in situ AFM and compared our results to molecular dynamics simulations. We find the peptide arrays exhibit an epitaxial relationship to the underlying hexagonal lattice, but assemble row-by-row from dimeric growth along three equivalent directions. The nuclei are ordered from the earliest stages. Although the final crystals are 2D, due to the 1D nature of the constituent rows, there is no critical size, and the nucleation rate varies linearly with concentration and is finite for all concentrations above the solubility limit. Our results verify long-standing but unproven predictions of classical nucleation theory in one dimension while revealing the key interactions responsible for ordered assembly.

4:30 PM *FF03.04.04
Supramolecular Heterostructures—Expanding Molecular Self-Assembly into 3D Vladimir Korolkov; Oxford Instruments-Asylum Research, United States

The self-assembly of two-dimensional supramolecular networks is a well-known route to control the spatial organization at the nanoscale and beyond as well as bringing new chemical functionality on the surface. With a very few exceptions, these supramolecular networks are, in almost all cases, limited to monolayer thickness. The controlled growth of sequential layers, creating an organic layered structure, has so far been much more limited. Specifically, the additional functional control, which may be achieved through the formation of heterostructures realized by placing one supramolecular layer on another and resulting in growth into the third dimension perpendicular to the substrate, has not been widely explored for these systems.

Here we report on our recent progress in engineering and characterizing organic van der Waals materials –
supramolecular heterostructures (SH) with atomic force microscopy (AFM) [1–2]. SHs are layered organic materials that are stabilized by hydrogen bonds in plane and by van der Waals interactions and/or dipolar interactions between layers. They can be formed by, for example, growing sequential layers of bi- and mono-component two-dimensional supramolecular arrays stabilized by hydrogen bonding. The heterostructures are formed on layered materials such as hexagonal boron nitride (hBN), graphite or black phosphorus by depositing layers of cyanuric acid/melamine (CA.M), 1,2,4,5-Tetrakis(4-carboxyphenyl)benzene (TCPB), trimesic acid (TMA) and terephthalyc acid (TPhA) and other molecules.

AFM has confirmed a clear epitaxial arrangement between the layers of the heterostructure, although each layer can exhibit distinct symmetries, for example hexagonal (CA.M) and TMA, square (TCP), linear (TPhA), rhombic (TCPB) arrangements.

We analyze SHs under ambient conditions using Cypher AFM and demonstrate the routine acquisition of images with 0.1 nm resolution.

The work will present examples of single molecule and sub-molecular resolution. In the latter case, we will discuss the opportunities and challenges in achieving and interpreting ultrahigh resolution AFM images of molecules in the ambient for the purpose of their unambiguous identification.

should exist: one is a non-equilibrium structure and the other is an equilibrium one. It was confirmed that the transition from PC ZnO to non-PC ZnO accompanied valence shift and structural changes. The XANES absorption edge is sensitive to valence states. In the case of mixed-valent manganates and phase mixtures, Mn^{2+}, Mn^{3+}, and Mn^{4+} were clearly determined by the shift of Mn-K absorption edge. The energy shift was 10 eV between Mn^{2+} and Mn^{4+}. Since the electronic circumstances are different between ZnO and manganates, it is not straight to determine the Zn valence in the same way as manganates. The Zn valence in ZnO powder is 2. At least, it could be claimed that the Zn valence increased to 2+δ under UV irradiation.

Photochromic ZnO nanoparticles were synthesized by using VHF plasma enhanced CVD. The changes in Zn valence and local atomic structures were investigated by XANES and EXAFS. The absorption edge energy (E_0) and the local atomic structure significantly changed under UV irradiation and heat treatment. The Zn valence of PC ZnO was 2+δ. The coordination number N and Debye-Waller factor σ^2 of PC ZnO retained under heat treatment at 420K; at 570 K, N and σ^2 drastically changed and PC ZnO transformed to non-PC ZnO. The transition from PC ZnO to non-PC ZnO accompanied valence shift and structural changes. It was concluded that PC ZnO has a non-equilibrium phase in terms of crystallinity.

This research was supported by the ALCA and A-STEP programs of Japan Science and Technology Agency. This research was partially supported by JSPS KAKENHI Grant Number JP15K04603 and JP26390098. A part of this work was performed under the Cooperative Research Program of “Network Joint Research Center for Materials and Devices”. X-ray measurements were done at Kyushu Synchrotron Light Research Center.

FF03.05.02 Ultra-Dense (~20 Tdot/in^2) Nanoparticle Array from an Ordered Supramolecular Dendrimer Building Block Containing a Metal Precursor Kiok Kwon^1, Bong Lim Suh^2, Kangho Park^2, Jihan Kim^2 and Hee-Tae Jung^2; ^1Korea Institute of Industrial Technology, Korea (the Republic of); ^2Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The creation of an ultra-dense, highly periodic nanoparticle array from a soft building block is one of the most important issues in the fields of material science and nanotechnology. To date, ordered structure made from block copolymer (BCP) have been primarily used as templates for fabricating highly periodic nanoparticle arrays with high areal densities. Herein, we demonstrate for the first time the use of a supramolecular dendrimer assembly for the formation of a highly ordered nanoparticle array with a high areal density of ~20 Tdot/in^2, four times larger than that of the currently reported BCP-based nanoparticle arrays. By the simple thermal annealing of a supramolecular dendrimers containing a metal precursor between two flat, solid substrates, a hexagonal array of small gold nanoparticles (with a diameter of ~1.6 nm and center-to-center distance of ~5.3 nm), oriented normal to the bottom, was achieved. Density functional theory calculations demonstrated that the gold cation strongly bound with high binding energy to the head group of the dendrimer with a tapered shape. This structure served as a building block for self-assembly into a stable cylindrical structure. The findings obtained in this study provide a new paradigm for creating highly periodic, ultra-dense nanoparticle arrays by using a supramolecular assembly. It is important to note that we studied only one dendrimer, which possessed a hexagonal cylindrical structure, while numerous other dendrimer materials, which have a large diversity in terms of phase, size, and chemistry, exist in nature. We anticipate that this study will lead to the creation of a large family of supramolecular dendrimers that can be utilized as soft templates for creating periodic, ultra-dense nanoparticle arrays.

FF03.05.03 Wet Corrosion Process—A Simple and Versatile Method to Fabricate K-Doped Titanium Oxide Nanostructures So Yoon Lee^1; ^1Shibaura Institute of Technology, Japan; ^2KU Leuven, Belgium

Up to date, nanostructured Ti-based materials have attracted considerable attention due to their unique and diverse physico-chemical properties and potential for diverse applications. Among them, nanostructured potassium (K) incorporated Ti-based oxide materials (KTiO_x) have received particular attention due to their wide range of interesting applications, e.g. in photovoltaic cells, batteries, photochromic and electrochromic devices.
photocatalysis, gas sensors, biomaterials, owing to their remarkable structural and physical properties. However, so far one of the main bottlenecks for diverse applications has been the nanostructures fabrication, which generally involves complicated process, low reproducibility and high cost for chemical modification. Since the physical properties can be greatly affected by the size and morphology of the nanostructures as well as the precise incorporated K amount, several processes had to be combined, exacerbating these drawbacks. This drawback strongly limits their fast implementation in potential applications. Hence, elaborating a process that allows easy synthesis and a simple tuning of the desired morphology and properties via a single-step process is currently one of the key issues in this research field.

We used the wet corrosion process (WCP) which was developed in my previous research to Ti metal plates. In this work, we extended our studies to different Ti-based metal substrates and systematically investigated, for the first time, the characteristics of the resulting KTiOx, depending on the initial Ti content prior to WCP. The results clearly indicate direct correlation of the nanostructures fabrication with the Ti content in the initial material. Moreover, optical properties of the KTiOx could be correlated with their structural properties. Understanding the direct relationship between the Ti content of the initial metal and the condition of WCP to control the structural and physical properties makes it possible to produce the KTiOx on demand, for various applications.

Ti-based materials are currently considered as one of the most promising candidates for multifunctional semiconductor photocatalysts. We have investigated the photocatalytic performance of KTiOx fabricated by WCP. This result can be very interesting for photoinduced catalysis.

We fabricated nanostructured KTiOx via WCP using the Ti, TAV, and TN substrates. Systematically the relation between the Ti content of the initial metal and the condition of WCP was studied, with the conclusion that these parameters strongly control the morphology and physical properties of the generated nanostructures. One-dimensional nanostructures could be obtained within a specific window of the process condition: Ti and TAV metals which contain more than 90% Ti yielded elongated nanostructures of K-incorporated titanium oxide after treatment with 10–20 mol/L-KOH solution. In contrast, TN metal with about 50% of Ti content required a KOH treatment with >20 mol/L-KOH solution indicating that the process window shifted to higher concentration. For all samples the morphology evolution as a function of the WCP condition was similar, but the precise Ti content of the initial material determined the amount of incorporated potassium as well as the KOH concentration at which elongated nanostructures were produced. In detail, we focused on Ti series to estimate the photocatalysis application.

Structural and crystalline properties of KTiOx were studied by means of X-ray diffraction, scanning and transmission electron microscopy. Chemical composition was determined by X-ray fluorescence and energy-dispersive X-ray analysis. Photocatalytic performance was investigated by studying the degradation of methylene blue, cardiogreen, and azorubine red dyes upon UV irradiation. The negatively charged crystalline KTiOx nanostructures with high surface area showed significantly higher photocatalytic degradation compared to their KTiOx counterpart.

FF03.05.05

Crystallization Pathway-Controlled Microstructural Evolution of Magnetite Mesocrystals

Bum Chul Park1,1,
Jiung Cho2,
Myeongsoo Kim1,
Min Jun Ko1,
Lijun Pan1 and Young Keun Kim1;
1Korea University, Korea (the Republic of); 2Korea Basic Science Institute, Korea (the Republic of)

Mesocrystals consisting of assemblies of smaller crystallites have received much attention because of their crystallization pathway beyond classical theory and emergent functionalities that are not present in the individual components. Of various materials, magnetite (Fe3O4) exhibiting soft magnetism has been extensively studied and utilized broadly in electronics and biomedicine for decades. Because the magnetic properties of Fe3O4 mesocrystals depend on the crystallite and particle sizes, it is necessary to understand how they are determined during the crystallization process. However, the crystallization mechanism of Fe3O4 has been addressed phenomenologically by observing just a part of the entire crystallization pathway; thus, the details of the crystallization mode remain unclear.

In this study, we suggest that nonclassical and classical pathways are concurrently involved in the formation of clustered mesocrystalline Fe3O4 nanoparticles (c-Fe3O4 NPs), and the microstructure is affected by which pathway governs the reaction overall. We note that different ferric (oxyhydr)oxide polymorphs appear separately as intermediates on each pathway and can be chemically controlled. In early stages of the reaction, we observe a nonclassical pathway on which c-Fe3O4 NPs grow by oriented attachment of primary particles that form directly from lepidocrocite. In a late stage of the reaction, we observe a classical pathway on which Fe3O4 NPs form by stepwise transformation of lepidocrocite, goethite, and Fe3O4, in that order. We present the kinetics of each pathway as a Johnson–Mehl–Avrami–Kolmogoroff (JMAK) model that describes the isothermal transformation process.
Based on this understanding, we can control the diameter and crystallite size of c-Fe₃O₄ NPs independently according to the content ratio of chemicals in a broad range. Finally, we report successful experimental implementation of the crystallite size effect on the coercivity curves as a function of diameter. Because c-Fe₃O₄ NPs represent a crystallographically ordered aggregate of spheres, we can discuss the collective coercivity behaviour, which is hard to observe in single NPs.

FF03.05.07

Two-Dimensional Metal Oxide Free-Standing Films by Self-Assembly of Nanoparticles at the Air-Water Interface for H₂S Sensing Pavithra B, Neha Sakhuja, Subhajit Kundu, Navakanta Bhat and Ravishanakar Narayanan; 1Indian Institute of Science, India; 2University of Minnesota Twin Cities, United States

Simple, scalable and inexpensive method for the synthesis of metal oxide thin films is highly demanded for the emerging applications especially in the field of sensing and nanoelectronics. We demonstrate an effective method for synthesizing polycrystalline thin films of metal oxides using a unique reaction design at the air−liquid interface. We have exploited this interface reaction design to synthesize SnO₂ and PdO thin films and engineered their properties by varying the reaction parameters. These free-standing sheets have been synthesized by one step hydrothermal reaction at the interface with surfactant-free method. The thin films formed at the interface have a lateral dimension in centimeter. A possible growth mechanism is proposed. The metal oxide particles formed in the bulk of the solution move to the interface and get trapped to form a continuous, polycrystalline film to minimize the energy of the system. Transmission Electron Microscopy (TEM) has been basically used to understand self-assembly of the particles. TEM study shows that the films are formed due to the self-assembly of oxide nanoparticles (~30 nm in size) trapped at the interface; hence are polycrystalline. X-ray diffraction, Scanning Electron Microscopy and Atomic Force Microscopy measurements have been carried out to understand the structure, morphology and thickness of the films. These films are highly stable at elevated temperatures. The properties of these thin films can be manipulated simply by changing the reactant concentration and other reaction parameters like temperature and time of reaction. We have explored thickness tunability by varying the precursor concentration which in turn affects optical and electronic properties; hence the sensing behavior. SnO₂ films showed astounding gas sensing performance towards H₂S by demonstrating 25 ppb (S = 19.3%) as the lowest limit of detection at 150°C. The sensor can operate reliably in the range of 25 ppb to 6 ppm (S=25621%) H₂S. H₂S is known to be exhaled in “Bad Breath” (also known as Halitosis). It is considered as “normal” in the range of 80–160 parts-per-billion (ppb), “weak” in the range of 160–250 ppb, and “strong” if exhaled in concentrations greater than 250 ppb. Hence, sub-ppm detection of H₂S can aid in disease diagnosis at early stage. The highly sensitive and selective detection of this sensor makes it a potential candidate for breath-based diagnostics. This class of materials synthesized in two-dimensional morphology is extremely interesting for fundamental studies as well.

FF03.05.08

Fabrication of 3D Hierarchical Structured β-Ga₂O₃ Film via Advanced Laser Sintering Method Jong Wan Ko, Jiyong Park, Jae Hyang Lee, Dong-Hyun Kim, Yong Son and Jeong Hun Lee; Korea Institute of Industrial Technology (KITECH), Korea (the Republic of)

Monoclinic β-Ga₂O₃, which has a direct wide bandgap (Eg = 4.9 eV at room temperature), has tremendous potential as an electronic device material due to its excellent physicochemical properties including chemical stability, high mechanical properties, and thermal stability. In particular, the high breakdown voltage of monoclinic β-Ga₂O₃ and its transparency in the visible light region are suggesting promising applications in many fields such as power semiconductor, electromagnetic wave shielding, ultraviolet shielding agents, gas sensors, field effect transistors, and solar cells. In previous studies, monoclinic β-Ga₂O₃ was used as a single crystalline wafer grown by the edge-defined film-fed growth (EFG) method, and as a form of thin film fabricated by various vacuum deposition methods such as magnetron sputtering, pulsed laser deposition (PLD), molecular beam epitaxy (MBE), metal-organic vapor phase epitaxy (MOVPE), metal-organic chemical vapor deposition (MOCVD) and sol-gel method. However, the EFG method can obtain β-Ga2O3 with high purity, but it requires a lot of energy in the process. β-Ga₂O₃ in the form of the thin film can be manufactured with a precise pattern, but it has disadvantages that require high-vacuum deposition equipment. These two traditional approaches have limitations on the extended use of monoclinic β-Ga₂O₃.

Recently, as the 3D printing technology in the metal and polymer fields has developed remarkably, it has brought innovation in the manufacturing field. For example, airplane parts made with powder bed fusion (PBF) type 3D printing technology can be manufactured in a lightweight structure that could not be manufactured by conventional
methods. This allowed us to improve fuel efficiency and profitability. In our work, the process screening platform was established for the fabrication of 3D hierarchical structured monochoric $\beta$-$\text{Ga}_2\text{O}_3$ using customized PBF-type 3D printer. We also developed the controlled process management system by facilitating process variables including the viscosity of $\beta$-$\text{Ga}_2\text{O}_3$ paste, one-step layered thickness, laser experimental conditions (power, scan direction, scan speed), and atmospheric condition. The sintering behavior of nano-sized $\beta$-$\text{Ga}_2\text{O}_3$ particles and hierarchical structure evolution of $\beta$-$\text{Ga}_2\text{O}_3$ layers were investigated. The analytical results (XRD, XPS, UV-vis absorbance, surface roughness, domain size, etc.) revealed that higher sintering activity led to the increased densification reaction resulting in larger domain size and fewer contents of the pore. Establishment of the optimization process of monoclinic $\beta$-$\text{Ga}_2\text{O}_3$ manufacturing by our laser sintering method ensures promising adaptability of PBF type 3D printing technology for ceramic materials.

FF03.05.09
Highly Efficient Radiation Shielding of Bismuth Nanoparticle Modified Textile Yiting Zheng and Ming Su; Northeastern University, United States

This abstract reports a new method that cotton textile modified with bismuth nanoparticle can block x-ray radiation effectively within hundreds of micro-meter thickness. Bismuth nanoparticle is grafted on the nanocellulose which is a bridge to crosslink nanoparticle on the textile. The homogenous dispersion of nanoparticles on textile fiber surface is attributed to this spatially distributed modification, which enhances the shielding efficiency to 90% for 500 mm nanoparticle modified cotton textile. The fact that the relationship between shielding rate and thickness agrees well with the Beer-Lambert law, facilitates the prediction of shielding rate in specific application. Given its low cost, light weight, structure conformability and wearability, bismuth nanoparticle modified cotton textile will find its use in a wide range of fields related to personal radiation protection.

FF03.05.10
Novel Hierarchical YBO3 :Eu Crystals Synthesized by Folic Acid Assisted Hydrothermal Process Shan Li, Yingzi Ge, Hongkun Deng and Xianwen Zhang; Hefei University of Technology, China

YBO3:Eu crystals with flower-like hierarchitecture are readily synthesized through a folic acid assisted hydrothermal process using polyborate precursors in the aqueous solution. It was found that the pH value, borate/yittrium ratio and the mass of folic acid take effects on the morphology and photoluminescence emission intensity of YBO3:Eu crystals. The product with the small flower-like hierarchitecture was obtained under the conditions of pH value at 9, borate/yittrium ratio at 2 and the mass of folic acid at 0.44g, showing the strongest photoluminescence intensity. Such a hydrothermal route using folic acid as a capping agent may provide a green and effective method for fabricating useful and complex 3D architectures of LEDs phosphors.

FF03.05.11
Hybrid Structures as Building Blocks for the Production of Advanced New Materials Gabriel D. Rocha, Marcelo A. Martinho, Marco Aurelio L. Cordeiro and Edson R. Leite; CDMF, Brazil

Polymer nanocomposites containing small fractions of nanoparticles (NPs) have the ability to produce materials with higher mechanical properties due to the combination of properties of the inorganic NPs (e.g., stiffness, thermal stability) and polymer (e.g., flexibility, ductility and processability). The mechanical properties of these nanocomposites are linked to the dispersion of NPs in the matrix. Thus, an excellent dispersion of the nanoparticles is the main hindrance in the processing of nanocomposites. One of the most promising strategy for overcoming this challenge is the use of self-assembly (SA) of hybrid structures, as macromolecules grafted on NPs, providing a simple and rapid method for constructing orderly structures with several degrees of complexity[1]. On the other hand, despite the progress in controlling the equilibrium structure of grafted NPs, these nanocomposites exhibit a low tensile strength fragility that limits the control of physical properties over macroscopic areas. This behavior is even more critical for nanocomposites with high quantity of NPs. In face of this scenario, this study aims to provide fundamental insights into the hybrid structures as a building blocks for new materials with tailored physicochemical properties, notoriously with high ratio hybrid structures/polymer matrix. Based on this, Polyethylene Glycol (PEG) at different molecular weights (PEG Mw = 3000 and PEG Mw = 6000) was used as grafting polymer on Magnetite ($\text{Fe}_3\text{O}_4$) NPs, which were synthesized in a single step-route[2]. By improving organic interactions within the hybrid structures, thin films samples with superior mechanical behavior were produced by controlled evaporation of the grafted NPs colloid, consolidation by uniaxial pressure and mild thermal treatment. All these steps were analyzed by...
Scanning Electron Microscopy (SEM) (F50 Inspect) and Transmission Electron Microscopy (Tecnai F20), where it was possible to identify the myriad of hybrid structures organization, interactions and fracture behavior. The films were also characterized by dynamic mechanical test, and through the data was possible to get some insights into the relationship of storage modulus and loss modulus with NPs size, shape, PEG density on the surface of NPs, PEG chain size, and interactions between NPs-PEG/PEG-NPs. Then, this study demonstrates the potential of hybrid structures as building block for the development of advanced materials by correlating fundamental mechanical behavior with structure assembly and the interaction within the organic grafted molecules.

**FF03.05.12**

**Preparation and Application of AIE Fluorescent Polymers for Semiconductor Laser Illumination**

Yue Ru and Chenxi Hu; Beijing Research Institute of Chemical Industry, China

Solid-state light, such as light-emitting diodes, organic light-emitting semiconductors, polymer light-emitting diodes, etc., have the advantages of small size, high luminous efficiency and long life, which are used to replace traditional lighting sources. Nakamura Shuji, Isamu Akasaki and Hiroshi Amano won the 2015 Nobel Prize for their high-efficiency Light Emitting Diode (LED). In a short period of time, LED lighting has developed into a lighting source with a market penetration rate of 31%. The market size of China alone has reached more than 200 billion yuan. However, LED has certain limitations as an illumination source. The problem of “efficiency drop” has always limited the wide application of white LEDs.

In these years, the emergence of laser diode (LD) technology has further expanded the types of new lighting sources. Compared with the LED light source, the LD light source has the following characteristics: (1) The electro-optical conversion efficiency is high. In the work of An Zhenfeng et al. [6], an LD component with an efficiency of 71% is prepared by optimizing the device structure, and usually LED The electro-optical conversion efficiency is generally about 20%; (2) the volume is smaller, the volume of the LD component is usually one percent of the LED component, and has greater advantages in terms of weight reduction and design; (3) the LD light source does not have a problem of "significant efficiency drop", and the device operation is not unstable due to working time and operating temperature. Therefore, LD light source instead of or auxiliary LED light source is expected to become a new direction of solid-state light source development.

When the LD light source is used as a white light illumination source, it is also necessary to refer to the synthesis method of the white LED light source. The commonly used methods include two categories: (1) the three primary color method (three primary color method), and the so-called three primary color method refers to the use of red, green, and blue. The LD light source of the same color emits light at the same time, and the three colors are mixed to obtain white light ; (2) the fluorescence conversion method, the LD light is irradiated on the material having photoluminescence property, and the emitted fluorescence is mixed with the original light of the light source. After getting white light. Usually use ultraviolet or blue light as the excitation source, and yellow and red phosphors as the fluorescent material.

Fluorescence conversion method is more advantageous in terms of cost and safety, and is more suitable for production as an industrial product. Therefore, the preparation of LD device by fluorescence conversion method has become a hot spot for research and enterprise development. However, most of the fluorescent conversion materials used in current laser illumination devices contain rare earth metals, which are costly and limit the further application of laser illumination devices.

In our work, a fluorescent polymer with Aggregation-Induced Emission (AIE) is prepared as a fluorescent conversion material, and the effects of different processes on its light conversion effect are explored. Controlled emission from cyan to red can be achieved through pH regulation, which is based on the principle that pH can effectively control spatial conjugate by altering the aggregation of carboxylic acid groups and hydroxyl groups The results show that using this material as a fluorescent conversion material, white light is produced after blue laser excitation, its CIE 1931 coordinates (0.365,0.335), color temperature 4177K, belongs to the neutral white area. which is expected to replace the existing fluorescent materials for semiconductor lasers.
Ohnuki\textsuperscript{1}, Shinya Yoshioka\textsuperscript{1}, Miki Sakai\textsuperscript{2} and Yukikazu Takeoka\textsuperscript{2}; \textsuperscript{1}Tokyo University of Science, Japan; \textsuperscript{2}Nagoya University, Japan

Recently, the spherical photonic crystal called a photonic ball has attracted attention [1-4]. It consists of the primary structure, which is a periodic array of colloidal particles, and the secondary structure of the spherical shape. The wavelength of reflection exhibits the red shift when the primary particles become large. An interesting optical property has been reported for photonic balls with colloidal particles larger than 350 nm\textsuperscript{1}: a ring-shaped iridescent reflection can be confirmed on the peripheral region of the photonic ball when observed using an optical microscope. On the other hand, photonic balls macroscopically have a specific color when observed by the naked eyes, despite the iridescence observed under the microscope.

The reflection mechanism of the peripheral region is divided into two opinions; one is the grating diffraction which originates from regularly arranged colloidal particles on the surface of the photonic ball [2, 3], and the other is Bragg diffraction caused by lattice planes of the face-centered cubic (fcc) [4]. The former idea can explain the iridescent reflection, but not the specific color when observed with the naked eye. However, the latter idea explains the specific color only.

Further, the reflection on the peripheral region does not form a perfect ring; there are non-reflective dark regions. The areas of the non-reflecting regions largely depend on the numerical aperture of the objective lens. With the numerical aperture increase, the reflective areas expand. For example, using an objective with the numerical aperture 0.90, the non-reflecting area disappears, and the complete ring-like reflection appears on the peripheral region.

In this study, we propose a theoretical model to explain the above complicated optical properties of the photonic ball. In this model, the reflection of Bragg diffraction by the fcc lattice planes coexists with the reflection of the grating diffraction that consists of surface particles [5]. It is confirmed that the wavelength fulfilling the interference condition of Bragg diffraction of the (220) planes simultaneously satisfies that of the grating diffraction. In addition, detailed observations with optical and electron microscopes revealed a distinctive structural difference between the reflective and non-reflective regions: the in-plane arrangement of colloidal particles on the surface is different with respect to the radial direction of the ball between the two regions. From detailed experiments and theoretical calculations, we have found that the non-reflective region does reflect light, but into a highly oblique direction which cannot be observed under the optical microscope using the objective lens with a low numerical aperture.

We have also investigated the angular dependence of the reflection, and found that the photonic ball exhibits very low iridescence macroscopically. This is because of the unique reflection mechanism where both the Bragg and diffraction grating are important. From this low iridescence, the photonic ball can be a suitable candidate for the structurally colored pigment.

Red/NIR-Emitting AIE Platform Based on Phenothiazine Junyi Gong\textsuperscript{1}, Xiangzhi Song\textsuperscript{2} and Ben Zhong Tang\textsuperscript{1}; \textsuperscript{1}Hong Kong University of Science and Technology, Hong Kong; \textsuperscript{2}Central South University, China

Nowadays, most of aggregation-induced emission luminogens (AIEgens) with donor (D) - acceptor (A) structures are based on propeller-shaped triphenylamine (TPA) as electron donor. After years of development, TPA-fused AIEgens are comprehensively developed with hundreds of papers published in past few years. Although there're many similarity between phenothiazine and TPA, AIEgens based on phenothiazine is much fewer than TPA based AIEgens. In this contribution, we designed and synthesized 11 PTZ derivatives through Knoevenagel Condensation. Almost all the PTZ dyes are emissive at red spectral region, above 600 nm. In addition, PTZ10 and 11 were found emissive at the NIR region with high fluorescence quantum yield in the solid state (~5 \%). Since PTZ doesn't have any rotatable elements like normal AIEgens, we investigated the exact driving force for the AIE behaviour of the PTZ dyes through quantum mechanics computation and single crystal analysis, from which the restriction of intramolecular vibration was proved to be the AIE mechanism. Moreover, we used PTZ6 which has fairly a high fluorescence quantum yield (~20 \%), to selectively track the lipid droplets of HeLa cells with vert high contrast,
demonstrating a high application potential of the PTZ dyes.

**Non-Aromatic Annulene-Based AIE System via Aromaticity Reversal Process**
Zheng Zhao, Zaiyu Wang, Jacky Wing Yip Lam and Ben Zhong Tang; The Hong Kong University of Science and Technology, Hong Kong

Aggregation-induced emission (AIE) is a photophysical phenomenon correlated closely with the excited state intramolecular motions e.g. rotation and vibration. Although AIE has attracted increasing attention due to their significant applications in biomedical and optoelectronics, an in-depth understanding of the excited state intramolecular motion and elucidation of the origin of the intramolecular motion are yet to be fully developed. Here we found that the non-aromatic annulene derivative of cyclooctatetrathiophene (COTh) shows typical AIE phenomenon in spite of its rotor-free structure. The underlying mechanism was systematically investigated through photoluminescence (PL) spectra, time-resolved absorption spectra, theoretical calculations, circular dichroism (CD) and circular polarized luminescence (CPL) spectroscopy as well as by pressure-dependent fluorescent spectra, which indicated that the aromaticity reversal from ground state to the excited state served as a driving force for inducing the excited state intramolecular vibration, leading to the AIE phenomenon. To our knowledge, this is the first time that aromaticity reversal is demonstrated as a reliable strategy to develop novel vibronic AIE systems. And this work also provides a new viewpoint to understand the excited state intramolecular motion behavior of lumiongens.

**FF03.05.16**

**An AIEgen with Anion-π+ Interactions for Selective Wash-Free Imaging and Photodynamic Killing of Bacteria**
Chenchen Liu, Qiyao Li, Jacky Wing Yip Lam and Ben Zhong Tang; The Hong Kong University of Science and Technology, Hong Kong

Recently, a new aggregation-induced emission (AIE) system with anion-π+ interactions was first developed and demonstrated a novel strategy to develop inherent-charged AIE luminogens (AIEgens). AIEgens with charges possess unique advantages, such as enhanced biocompatibility and subcellular targeting ability resulted from electrostatic interactions between biomacromolecules and AIEgens. Therefore, they are expected to find wide biological applications. Unfortunately, the introduction of charges to AIEgens often suffers from complicated synthetic route, tedious purification and low yield. Herein, a new AIEgen, namely TTPABQ, with anion-π+ interactions was designed and obtained via one-pot synthesis. TTPABQ possesses a high specificity to bacteria and high photostability. It can image both Gram-positive and negative bacteria in a wash-free manner. This greatly simplify the imaging process. Furthermore, TTPABQ can also work as a promising photosensitizer to kill bacteria through efficient generation of reactive oxygen species upon white light irradiation.

**Less is More—AIEgen Derived Core@Shell Nanoparticles for Multimodality Tumor Imaging and Synergistic Therapy**
Xuewen He; The Hong Kong University of Science and Technology, China

Multifunctional nanomaterials integrating the prominent feature of each single functional moiety offer a great potential in multimodality tumor imaging and synergistic treatment. The traditional strategy for achieving multifunctional nanoplatforms adopting one-by-one combination of different constituents, suffers from the problems of complicated structural design, sophisticated purification and natural incompatibility between several functionalities. Herein, a novel “less is more” strategy is presented to realize multifunctionality within a simple silver core/AIE (aggregation-induced emission) shell nanoparticle. Surprisingly, apart from their intrinsic AIE fluorescence (FL) and noble-metal based computed tomography (CT) properties, an extra interface with excellent photothermal (PT) and photoacoustic (PA) functions was in situ generated between the core and shell part. As a result, multifunctional nanoparticles integrated with FL, PA, CT, radiotherapy (RT) and photothermal therapy (PTT) properties were achieved and performed excellently in correlated tumor imaging and synergistic therapy.

**Fluorescence Sensing of Cr(VI) by Functionalized Polyquinolines Synthesized from Metal-Free Multicomponent Polymerization**
Yubing Hu and Ben Zhong Tang; The Hong Kong University of Science and Technology, China

Development of polymerization methodology to afford polymers with unique structures and advanced
Functionalities is of considerable academic significance and technological implication. Among various multicomponent reactions, the A3-coupling of aldehyde, alkyne and amine has been established as a convenient and atom-economical method to construct nitrogen-containing heterocycles. To construct novel functional polymers with well-defined structure, our group has been working on the exploration of polymerization methodology from alkyne monomers for decades. However, there is still a plenty room for improvement. For example, the development of metal-free polymerizations is highly desirable due to the high cost and biological toxicity of metal catalyst residues. It is hence desirable to develop metal-free efficient polymerization of alkynes to avoid such problems. Herein, a facile and highly efficient approach towards functionalized polyquinolines was designed and developed by formic acid-catalyzed multicomponent polymerizations of alkynes, arylamines and glyoxylates. Conjugated polyquinolines were formed in situ with high molecular weights ($M_w$ up to 16 900) in nearly quantitative yields (up to 97.5%). Fluorescence tunable polyquinolines were achieved by altering the electron-donating substituents of the alkyne derivatives. The incorporation of luminogens into the polymer backbone rendered the resulting polymers with various aggregation-induced fluorescence behaviors. The tetraphenylethene-containing polyquinolines demonstrated to be a sensitive and highly selective fluorescence sensor of Cr(VI). Compared to other metal ions including K+, Na+, Mg2+, Al3+, Fe3+, Co2+, Ni2+, Cu2+, Pb2+, Ag2+, Cd2+, Hg2+ and Cr3+, the fluorescent sensing of Cr(VI) was more specific with an emission quenching ratio of over 20-fold. After a series of mechanism studies, the fluorescence quenching effect of Cr(VI) was proved to induced by inner filter effect. Such a non-irradiation energy conversion manner ensured the flexible and straightforward technique for the detection of Cr(VI).

**Ratiometric Detection of Mitochondrial Thiol with a Two-Photon Active AIEgen** Yuan Gu and Ben Zhong Tang; HKUST, China

In clinical studies, thiol measurement in the whole blood is of diagnostic and prognostic significance. In addition, the detection of mitochondrial thiol is very important for investigating cellular functions or dysfunctions. Here, a ratiometric aggregation-induced emission luminogen (AIEgen) called TPE-PBP for thiol detection was developed by introducing a para-dinitrophenoxy benzyl pyridinium moiety to tetraphenylethylene. TPE-PBP exhibits excellent biocompatibility, high photostability, and large two-photon absorption cross-section. TPE-PBP emits red fluorescence in PBS buffer without thiol. Upon addition of thiol, there is a gradual blue shift of TPE-PBP’s emission with ratiometric fluorescent response because of cleavage of the dinitrophenyl ether bond by thiol followed by the self-immolation of the para-hydroxybenzyl moiety to produce a less-conjugated AIEgen. The *in vitro* quantification of thiol is enabled by the linear ratiometric fluorescence response with a very low limit of detection. Considering the high sensitivity and good selectivity towards thiol detection, TPE-PBP was also utilized to detect thiol in the blood. Furthermore, mitochondrial thiol *in vitro, ex vivo* and *in vivo* were quantitatively mapped by TPE-PBP using fluorescence microscopy under one- and two-photon conditions.

**FF03.05.20**
**Aggregation-Induced Delayed Fluorescence** Zujin Zhao; South China University of Technology, China

Purely organic luminogens with thermally activated delayed fluorescence (TADF) can harvest singlet and triplet excitons to afford high electroluminescence (EL) efficiencies for OLEDs. However, most TADF emitters have to be dispersed in host matrix to prevent aggregation-caused quenching (ACQ). The doped OLEDs of TADF emitters often encounter a knotty problem of severe efficiency roll-off as lumiance increases, which defers practical application of TADF emitters in industry. In our group, we are working on the luminogens with aggregation-induced emission (AIE), which are free of ACQ. Recently, we develop a series of novel luminogens with aggregation-induced delayed fluorescence (AIDF), which can facely solve the aggregation-caused emission quenching and/or exciton annihilation problems of current TADF emitters. They are composed by an electron-withdrawing carbonyl core and various electron-donating groups, such as phenoxyzine, phenothezine, 9,9-dimethyl-9,10-dihydroacridine, carbazole and so on. They exhibit weak emissions without delayed fluorescence in solutions but strong emissions with prominent delayed components upon aggregate formation or in neat films, exhibiting the typical AIDF characteristics. The nondoped OLEDs based on the neat films of these AIDF luminogens exhibit lowered turn-on voltages and increased lumiance (> 100000 cd m⁻²) with respect to the doped OLEDs. Thanks to the excellent exciton utilization (~100%), the nondoped devices furnish remarkable EL efficiencies of up to 72.9 cd A⁻¹, 81.8 lm W⁻¹ and 22.6%, and negligible efficiency roll-off at 1000 cd m⁻². To the best of our knowledge, these devices are the most efficient and stable nondoped OLEDs reported so far.

**Tracking Entry Process of Biofunctional AIEgens into Cells and Mapping Their Distribution in Organelles**

Wei He, Parvej Alam, Tszy Kin Kwok and Ben Zhong Tang; The Hong Kong University of Science and Technology, Hong Kong

Benefiting from high aggregated-state emission, superior photostability and low cytotoxicity, a variety of AIE luminogens (AIEgens) have been designed as fluorescent bioprobes for cell imaging. The entry process of AIEgens into cells has been rarely investigated although it is of fundamental importance. Herein halogen-labeled AIEgens with specific organelle targeting properties have been comprehensively designed for tracking their entry process into cell and their distribution inside the cells. Cooperatively with confocal fluorescent imaging, the techniques of time of flight secondary ion mass spectrometry (ToF-SIMS) have been applied to analyze the distribution of AIEgens during the process of bioimaging. This study will not only provide new strategies for designing biofunctional AIEgens but also bring new insight for understanding the cell entry process of AIEgens.

**Photonic Bandgap-Induced Light Extraction of Perovskite-Embedded Copolymer Particles**

Seung-Jea Lee¹, Jin Woo Choi², Santosh Kumar¹, Chang-Lyoul Lee¹ and Jae-Suk Lee¹; ¹Gwangju Institute of Science and Technology, Korea (the Republic of); ²Korea Institute of Materials Science, Korea (the Republic of)

LED with narrow full-with at half maximum (FWHM) has been studied to realize natural color mimetic displays. Due to relatively broad FWHM of organic-LEDs, perovskites have been suggested as an alternative. Even though perovskites have narrow FWHM, low stability hindered the usage of perovskites in LED fields. Color filters, such as photonic crystals, have been applied to narrowing the FWHM of emitting light based on the optical resonance at the edge of the photonic bandgap. However, angle-dependency of the photonic bandgap has been a big obstacle that should be overcome. Herein, organic-inorganic hybrid perovskite-embedded copolymer particles are prepared via self-emulsion polymerization (SEP) to increase the stability of the perovskite and improve the angle-dependency of the photonic bandgap. PbBr₂-embedded copolymer particles firstly prepared then the particles are self-assembled to polycrystalline photonic crystals. The embedded precursors are converted to perovskite using vapor-assisted solution process (VASP). The stability of the perovskite was enhanced due to the encapsulating polymers. Photoluminescence intensity increased ~12% and FWHM of the emission narrow down to ~13 nm due to the resonance effect of the photonic bandgap. Moreover, angle-dependency of photonic bandgap has been improved due to the polycrystalline structure of photonic crystals.

**Organic Polymorphs—Different Molecular Packing Induced Different Room Temperature Phosphorescent Properties**

Weilong Che¹, Yujun Xie¹ and Zhen Li¹,²; ¹Institute of Molecular Aggregation Science, Tianjin University, China; ²Wuhan University, China

The development of organic room temperature phosphorescent (RTP) materials is accompanied by opportunities and challenges. The relationship between polymorphisms and RTP properties has attracted much attention as the different molecular packings of one molecule in solid state, which exhibits significant different optical and electronic properties. Herein, we report an organic molecule BBP-BO with unique polymorphic emission properties. Two kinds of BBP-BO crystals were obtained, crystal A exhibit bright photoluminescence (PL) with a quantum yield of 11.25%, which is higher than that of crystal B (6.85%). Interestingly, Crystal A shows a distinct RTP phenomenon with a long lifetime of 17.92 ms@492 nm, but Crystal B has a relatively weak RTP phenomenon with
short lifetime of 3.49 ms@492 nm. Crystal structures analysis shows that the different optical properties of the two crystals are related to the molecular packing mode. The further exploration how molecular packing affect RTP property is essential for designing and synthesizing novel RTP materials.

**Theoretical Revelation and Experimental Confirmation of the Mechanism of Aggregation-Induced Emission in Organic Materials**  
Qian Peng; Institution of Chemistry, China

Better understanding of the mechanism of aggregation-induced emission can help develop novel AIE systems and exploit novel applications. Here, we have disclosed the microscopy mechanism of AIE by systematically investigating the excited-state electronic transition property, nuclear vibrational modes, the radiative and nonradiative decay rate constants, and the fluorescence quantum efficiency using the thermal vibration correlation function rate theory coupled with quantum chemistry calculations.[1] For typical AIEgens with the nature of \((\pi, \pi^*)\), we have put forward that the block of the nonradiative decay channels recovered strong emission in aggregate.[2] The nonradiative decay channels refer to the molecular vibration modes with large electron-vibration coupling value. We have found the rotational, twisting, bending and stretching vibration modes can be largely restricted in aggregate, resulting in the decrease of the nonradiative decay rate. For some hetero-AIEgens, we have proposed that the conversion from dipole-forbidden \((n, \pi^*)\) or \((\sigma, \pi^*)\) state to dipole-allowed \((\pi, \pi^*)\) state happen to induce strong emission when going from solution to aggregate. [3] Then, we have proposed some strategies to probe and verify the mechanism using the resonant Raman spectrum, isotopic effect, pressure effect, and the nanoparticle size effect and so on. Some of them have been fully confirmed by the experiments. Furthermore, the molecular design principles are raised and many unusual AIE fluorophors are designed theoretically and synthesized experimentally. [4]

**Transformation of Waste Printed Circuit Boards (PCBs) to Value-Added Nano-Materials for a Wide Range of Applications: A Holistic View**  
Rasoul K. Nekouei, Farshid Pahlevani and Veena Sahajwalla; University of New South Wales, Australia

Every year a huge volume of electronic wastes (e-waste) are being discarded with an increasing trend due to the technological and scientific advancements. To many countries, this kind of waste is to be a major concern since various kind of materials including metals (basic and pernicious metals), polymers and ceramics are entangled elaborately and too hard to be separated readily. PCBs are considered as one of the main splits of e-wastes containing around 35% metals. The metallic portion includes Cu, Zn, Sn and Fe, making this waste stream valuable as a secondary source of raw materials after separation and purification. In this research, we focused on the metallic portion of waste PCBs to turn them into value-added nano-materials practical application including nano-fluids, wastewater purification and water splitting. The projects step is as below:

1. In the first step, we focused on presenting a feasible and novel process to enhance the amount and purity of metallic portion of the waste PCBs without further chemical or/and physical. Two milling stages including knife mill and ring mill were applied to increase the liberation degree followed by a physical flotation process using bromoform fluid for beneficiation and enrichment. To recognize the composition and metal content in each classification, the classified (using sieve shaker) powders were characterized in each stage. Eventually, the mixture
of all powder was characterized in terms of its thermal behavior and composition of exhausting gas to estimate its threat for the environment.

2. In this step, we used the classified waste PCBs as a source of initial alloying powders to synthesize a homogenous nano-structured Cu-Zn-Sn-Fe-Ni alloy via mechanical alloying. This nano-structured powder is commonly used in a range of applications where the heat transfer and conductivity play a vital role such as nanofluids or additive manufacturing. To characterize the properties of powders, various characterization methods were utilized including XRD, XPS, FESEM, EDS, HRTEM, STEM, UV–Vis and optical microscopy. Finally, as a potential application, a nanofluid solution was prepared and characterized using pH and conductivity measurements.

3. In the next step, we tried to leach all remaining metals to a solution just in one leaching step using HNO₃. One of the objectives of this stage was to minimize the leaching time, amount of acid applied and energy consumption. To achieve these targets, a multi-variant multi-response statistical method was used to optimize the leaching efficiency of major metals content. Lastly, to understand the composition and importance of the residue, the solid residue of leaching was characterized.

4. In this stage, SnO₂ quantum dots were unexpectedly formed as spontaneous precipitation with a very slow kinetic rate from the last step leaching solution. The precipitation was triggered without the use of any chemicals or surfactants. It also occurred selectively as a by-product without influencing the solubility of other metal-containing ionic species. Then, the precipitation mechanism in the solution and the measurement of the surface area and other characteristics of the QDs were identified. After calcination, the SnO₂ QDs were applied to wastewater treatment to remove methylene blue (MB) as dye pollution.

5. In the last step, the solution containing Cu²⁺, Zn²⁺, Ni²⁺, Al³⁺, and Pb²⁺ ions was exposed to three ion exchange resins (Amberlite IRA 743, Lewatit TP 208 and Lewatit TP 260) to extract and separate the metallic ions of heavy metals. In addition to the optimization of resin load, contact time and solution temperature, the thermodynamics and kinetics of the adsorption were calculated to prove the accuracy and reliability of the experiments. The preferred locations of adsorbed ions on resin beads were traced and analyzed by electron microscopy. Finally, a stripping process was applied to examine the desorption selectivity and enhance recycling efficiency.

**Molecular Face-Rotating Polyhedra Constructed through Restricting Phenyl Flipping of AIEgen** Hang Qu, Zheyu Huang, Xue Dong and Xiaoyu Cao; Xiamen University, China

Chiral cage compounds are important because they exhibit extending functions such as chiral recognition and circularly polarized luminescence. Generally, two strategies have been established to construct chiral cages: by using chiral precursors, or based on the chirality at metal centers. Inspired by mathematics, we have reported a strategy to generate emergent chirality of organic cages by assembling achiral two-dimensional truxene building blocks into chiral octahedra through dynamic imine chemistry.

Tetraphenylethylene (TPE) and Pentaphenylpyrrole (PPP) are well-known aggregation-induced emission chromophores (AIEgen) and exhibits two rotational patterns in its propeller-like P or M configurations, respectively. Through dynamic covalent chemistry, the chiral molecular Face-Rotating Polyhedra (FRP) were constructed from restricting phenyl flipping of TPE or PPP. Accompanied by the generation of chirality, strong fluorescence also emerged during cage formation. In the study of FRP, we provide the strategies to predict the shape of FRP and the number of isomers. This study provides insight into construct chiral cages by the rational design through graph theory, and might facilitate further design of cages and other supramolecular assemblies from aggregation-induced emission active building blocks.

**Chiral Molecular Face-Rotating Sandwich Structures Constructed through Restricting the Phenyl Flipping of Tetraphenylethylene** Xiao Tang; Xiamen University, China

Chiral tetraphenylethylene (TPE) derivatives, as well known AIE chromophores, have great potential in chiral recognition and circularly polarized luminescence. However, they were mainly constructed through introducing chiral substituents at the periphery of the TPE moiety, which required additional chemical modifications and limited the variety of chiralities of products. We constructed a series of chiral face-rotating sandwich structures (FRSS) through restricting the phenyl flipping of TPE without introducing any chiral substituents. In FRSSs, the TPE motifs display P or M configuration which resulted in complex pattern arrangements and a variety of chiralities. Interestingly, only four isomers, as two pairs of enantiomers, were found in the assemble system and two of them are thermodynamic products. And we also found that non-covalent repulsive interactions in vertices caused the
facial hetero-directionality of FRSs, and the hydrogen bonds between imine bonds and hydroxy groups induced excited-state intramolecular proton transfer (ESIPT) emission of FRSs. In addition, the fluorescence intensity of FRSs decreases with the addition of trifluoroacetic acid. Our study provides new insights into the rational design of chiral assemblies by means of AIEgens, such as TPE and its derivatives, through restriction of intramolecular rotation (RIR), which can be applied in luminescent materials, chiral molecular recognition or asymmetric catalysis.

Testing the Stability of Molecular Imprint Biosensors Emma Walsh¹, John Jerome², Jessica Semel², Kelvin Linskens² and Miriam Rafailovich²; ¹Newtown High School, United States; ²Stony Brook University, The State University of New York, United States

Previously it was shown that molecular imprinting (MI) technology can be used to produce biosensors with the potential for use in point-of-care diagnostics for detection of Zika virus, pancreatic cancer, polio and other antigens, etc. [1]. MI biosensors utilize a self assembling monolayer (SAM) of hydroxy-terminated alkanethiol chains on gold-coated silicon chips. The SAM crystallizes around the target analyte. Once crystallized, the monolayer retains the shape of the analyte allowing it to sensitively and selectively bind the target analyte. The analyte is measured using a simple potentiometric readout. These sensors are easy to implement and only require a simple potentiometer for detection. Hence they can be especially useful in third world areas where advanced sensing instrumentation is lacking. The sensor chips require sterile laboratory conditions for imprinting, but they can be used at point of care, which may be remotely located. In order to reach these areas, it is important to optimize the method of storage and shipping the imprinted detector.

MI sensors were fabricated as previously described [1] using hemoglobin as the target analyte and incubated at room temperature in the desiccator for up to a week while our control chips were tested fresh, without incubation. Following 72 hours of incubation, MI biosensor detected the analyte (hemoglobin) with almost no loss of sensitivity as compared to freshly prepared control sensors. However by 120 hours of incubation the biosensor no longer demonstrated a linear response to increasing concentrations of target analyte indicating that the SAM was unstable under test conditions. These data suggest that the thiols used in SAM are sensitive to moisture present under atmospheric conditions, and hence should always be stored in vacuum unless they are used within the day that they are imprinted. It is encouraging that the chips did not show deterioration within the first 72 hours when stored in a rough vacuum, similar to the one used in food storage applications, hence they could be vacuum packed and shipped overnight to the point of care. Further work is in progress to improve the vacuum conditions and extend the lifetime of the chips.

Light-Directed and Responsive Colloidal Crystals Engineered with DNA Jinghan Zhu, Haixin Lin, Youngeun Kim and Chad A. Mirkin; Northwestern University, United States

Colloidal nanocrystals are promising building blocks for the construction of hierarchical 2D and 3D components for use in optical, electronic, magnetic, and therapeutic devices. Therefore, multiple assembly techniques (e.g., entropic, depletion, electrostatic, biorecognition) have been developed to engineer hard or soft nanoparticle-based crystalline
materials. DNA-mediated crystallization, which uses DNA-grafted nanoparticles as “artificial atoms” to generate hierarchically ordered superlattices (e.g. soft colloidal crystals), has advantages over other assembly techniques because the nanoparticle core “atom” identity (nanoparticle size, shape, and composition) can be tuned independently of the DNA “bonds” (sequence, strength, length, and density). However, it still remains a challenge to pattern DNA-functionalized colloidal crystals into specific shapes while retaining crystallinity. Herein, we report on the light-induced patterning of colloidal crystals engineered with DNA. Light-responsive colloidal crystals are synthesized by incorporating azobenzene-tethered DNA as bonding elements. Here, the photo-isomerization of azobenzene molecules between the trans- (visible light) and cis-form (UV light) directly translates into a change in the DNA hybridization interactions, resulting in a reversible switching between nanoparticle binding and non-binding states. We thus utilize such light-controlled assembly and disassembly to selectively remove nanoparticles that are located outside of a desired pattern. Specifically, we assemble a crystalline thin film of DNA-grafted nanoparticles and then apply UV-light to controllably dehybridize certain DNA strands which enables their dissolution leaving behind the desired pattern. The light-responsive printing of DNA-functionalized colloidal crystals marks a significant step towards fabricating advanced “smart materials” that can be dynamically manipulated via different types of stimuli on-cue.

Nanocrystal Superlattices and Derivatives for Energy Applications Angang Dong; Fudan University, China

The self-assembly of colloidal nanocrystals (NCs) into superstructures provides an efficient bottom-up pathway for constructing new functional materials. Among various superstructures, NC superlattices represent an entirely new class of solid-state materials with unique collective properties and wide applications. However, conventional NC superlattices are inappropriate structural motifs for energy applications due to the impeded molecular accessibility of NCs by foreign species. In pursuit of widening the range of applications of NC superlattices, it is desirable to develop new architectures that enable full access of NC constituents while simultaneously facilitating mass transport properties. Herein, I will focus on low-dimensional, hierarchical NC superlattices with rationally designed structures and mesoscale morphologies toward high-performance energy storage and conversion. I will also spend half of the time to cover NC superlattice derivatives, especially ordered graphene-like frameworks, which are emerging as a new class of mesoporous carbon materials. By exploiting the versatile surface chemistry and self-assembly behaviors of colloidal NCs, a rich array of mesoporous graphene-based materials can be designed, which show great promise as material platform for energy applications.

8:30 AM *FF03.06.03
Programmable Metamaterials through Colloidal Crystal Engineering with DNA Chad A. Mirkin; Northwestern University, United States

Metamaterials exhibiting desirable optical phenomena require the precise assembly of nanoscale building blocks with positional and orientational control. Colloidal crystal engineering with DNA offers the ability to chemically program the structure of nanoparticle-based materials with sub-nanometer precision in three dimensions. This structural control enables the design and discovery of new materials with previously unattainable functionalities and the determination of key structure-property relationships. DNA-programmable assembly can be applied to the field of optical metamaterials to dramatically expand the range of architectures that can be synthesized by chemists and explored by theorists. Through the convergence of bottom-up DNA assembly with top-down lithographic approaches, colloidal plasmonic nanoparticles of different sizes, shapes, and compositions can be precisely placed in two and three dimensions on a surface to form optically active superlattices. Additionally, exploiting DNA’s native responsiveness to chemical stimuli provides dynamically reconfigurable superlattices that are particularly interesting as metamaterials. These large-area superlattices, which would be difficult, if not impossible, to synthesize with any other currently available top-down or bottom-up technique, enable the use of colloidal nanoparticles as metamaterial building blocks and provide a platform to investigate and design new types of light-matter interactions in nanoparticle-based metamaterials.

9:00 AM *FF03.06.04
Interfacial Structure, Interparticle Forces and Assembly Dynamics During Oriented Attachment of Nanocrystals James J. De Yoreo1,2, Guomin Zhu2,1, Lili Liu1, Jaehun Chun1, Maria Sushko1, Xin Zhang1, Sebastien
Kerisit¹, Jennifer Soltis¹, Gregory Schenter¹, Christopher J Mundy¹,² and Kevin Rosso¹; ¹Pacific Northwest National Laboratory, United States; ²University of Washington, United States

Crystallization by particle attachment is a widespread phenomenon in synthetic and natural environments. In mineral systems, this process exhibits diverse styles ranging from oriented attachment of like phases to mis-oriented aggregation of disparate phases followed by coarsening to single crystals. While descriptions of these systems must share a commonality with continuum-based DLVO-type theories for simple colloids, mineral systems present additional complexities, including face-specificity of dielectric properties, structured nanoscale interfaces, and solvent-responses of a comparable length scale. To understand the relationship between nanocrystal structure, interparticle forces and assembly dynamics, we are investigating nanocrystal assembly of titanium, iron and zinc oxides. For ferrihydrite (FeOOH) and ZnO, in situ TEM demonstrates that direction-specific forces align diffusing particles prior to contact and that attachment occurs on lattice matched faces via a sudden jump to contact. Direct AFM-based measurements of the forces between both TiO₂ and ZnO surfaces reveal orientation dependent attractive interactions exhibiting the symmetry of the underlying lattice. MD simulations indicate a combination of hydration and dispersion forces orient the particles and that barriers caused by hydration layers, cannot be overcome by simple Brownian forces in the absence of fluctuations of the layers. Classical DFT simulations suggest these barriers are greatly reduced and attractive forces increased through ion correlation interactions. Addition of organic ligands, like oxalate, to the ferrihydride system produces a dramatically different pathway and outcome: Nanoparticles of hematite (Fe₂O₃) nucleate sporadically from the ferrihydrite and, once formed, are covered with oxalate and drive all new hematite particles to nucleate within about 1 nm of the interface, after which they jump to contact. The oxalate inhibits growth and coarsening of the particles, leading to spindle-shaped aggregates of crystallographically aligned particles with a fixed and constant aspect ratio. Thus the random assembly process seen in the pure ferrihydrite system is replaced with one that is deterministic due to interface-driven nucleation.

9:30 AM *FF03.06.05
Marrying Top-Down Fabrication and Bottom-Up Assembly of Colloidal Nanocrystals to Construct Devices
Cherie R. Kagan; University of Pennsylvania, United States

We combine top-down fabrication and bottom-up assembly processes to construct artificial, meta-molecules, materials, and devices with unconventional physical properties from colloidal, metal nanocrystal (NC) building blocks. Lithographically-defined, size- and shape-engineered topographical templates are used to direct the capillary assembly of NC metamolecule oligomers. We map the evolution in optical response as we increase the number of nearest neighbor shells in close-packed spherical NC assemblies, and as we construct trimers of nanorods that assemble along the edges of equilateral triangles to form open structures.¹ ² The triangular arrangement of nanorod trimers supports strong magnetic plasmon modes in their open interior, and circumferential displacement of the nanorods generates a chiroptical response under unidirectional oblique illumination. We also combine nanoimprint lithography with solution-based deposition of NCs to form superstructures for large-area, active metamaterials. By chemically exchanging the long ligands used in NC synthesis with more compact ligand chemistries we control interparticle distance.³ This ligand-control of distance allows us to tailor a dielectric-to-metal phase transition seen by a 10¹⁰ range in DC conductivity and a dielectric permittivity ranging from everywhere positive to everywhere negative across the whole range of optical frequencies. We realize a “diluted metal” with optical properties not found in the bulk metal analog, presenting a new axis in plasmonic materials design. Using this approach, we demonstrate strong, near-infrared optical absorbers that transduce light to heat.⁴ We also demonstrate quarter-wave plates with extreme bandwidths and high polarization conversion efficiencies in the near- to-mid infrared.⁵ Finally, we exploit the distinct chemical and mechanical properties of NC assemblies, in comparison to bulk materials, to create 2D, lithographically-defined NC/bulk bimorphs, which upon ligand exchange, transform to create functional 3D architectures.⁶

10:30 AM *FF03.06.06*  
**Chiral Inorganic Nanostructures and Long-Range Correlations in Particle Assemblies** Nicholas A. Kotov  
University of Michigan, United States

Early observation of strong circular dichroism for individual nanoparticles (NPs) and their assemblies have developed into a rapidly expanding field of chiral inorganic nanostructures. The chiral inorganic nanostructures encompass sophisticated constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from Ångströms to microns. Many of them are formed spontaneously from polydispersed building blocks, which enables their structural and functional engineering over a broad range geometries and optical properties. This talk will address (1) the mechanisms of chirality transfer in inorganic materials, (2) the origin of the uniquely high values of optical anisotropy, (3) the fundamental challenges of multiscale chirality observed in nanostructures, and (4) physicochemical differences/similarities with chiral supramolecular, liquid crystal, and biological systems. The analysis of phase diagrams for the assembly of chiral NPs affords understanding essential role of long-range correlations between NPs and a possibility of critical phenomena in the assembly at nanoscale that can lead to exceptionally complex assemblies from polydispersed nanocomponents exemplified by chiral hedgehog particles. The parallels with biominalized skeletons of coccoliths help understanding the need for chiral asymmetry in live matter. Simplification of the chiral assembly processes also helps accelerating the development of technologies based on chiroplasmonic, chiroexcitonic, and chiromagnetic effects observed for the individual NPs and their assemblies exemplified by the polarization vision mimicking that of some organisms.

11:00 AM FF03.06.07  
**Connecting Energetics to Dynamics in Oriented Attachment Using Real-Time Observations** Lili Liu¹, Elias Nakouzi¹, Jaehun Chun¹, Christopher J Mundy¹, Maria Suslik¹ and James J. De Yoreo¹,²  
¹Pacific Northwest National Laboratory, United States; ²University of Washington, United States

Although one-dimensional nanostructures of ZnO have been suggested to form via oriented attachment (OA), the detailed mechanism underlying this process remains unresolved as no direct observations of ZnO OA have been reported. Here we use *in situ* liquid phase (LP)-TEM to directly observe and investigate dynamic aspects of ZnO nanorod formation by OA. Detailed analysis on translational and rotational motions of ZnO particles, tracked in real time, demonstrates that aggregation-coalescence via OA event was the primary mode of ZnO particle growth, and in some cases produced chain-like ZnO nanostructures. While the particle interactions with molecular granularity suggest a qualitative difference between ZnO OA and near-OA events, our study shows that the attachment event is notably influenced by dynamic nature associated with the particle motions such as abnormal particle diffusivity and quasi-2D nature under confinement. Our study suggests a complementary aspect to obtain better understanding of the OA, as well as the current viewpoint mainly focusing on energetic considerations.

11:15 AM FF03.06.08  
**Understanding the Growth Mechanism of Anisotropic ZnO Nanorod Formation** Sukesh K. Tumram and Rajdip Bandyopadhyaya  
Indian Institute of Technology Bombay, India
Nanostructured Zinc oxide (ZnO) has great importance in many areas, such as catalysis, sensors, cosmetics and biomedical applications. In literature, ZnO nanorods (NR) are the most widely studied nanostructure. However, the mechanism of their growth into the final rod-shape is not well understood. In the present work, we have synthesized ZnO NR and studied its temporal growth mechanism, using zinc chloride as a precursor and hexamethylenetetramine (HMTA) as a reducing agent. It has been reported that, HMTA degrades into ammonia and formaldehyde at a certain temperature which subsequently provides hydroxyl ions and helps in the ZnO nanostructure formation. Hence, to understand the role of temperature, NR synthesis has been done at various temperatures, namely 65, 75, and 85 °C. It was observed that, the time required for NR formation decreased with increased in temperature, which was confirmed by nanostructure morphology at different reaction time-points. Length to diameter aspect ratio (AR) of NR is found to vary from ~1 to ~9, from the initial to final time-point (180 min). It correlates well with using ICP-AES, the utilization of Zn2+ ion in NR formation which increases with higher temperature (< 20 %, 20 % and 55 % at 65, 75, and 85 °C respectively at 180 min).

To capture the evolution of ZnO NR formation, intermediate samples were characterized by scanning electron and transmission electron microscopy. Initially, a new crystal structure- a hollow “nanocone” (NC) crystals of ZnO (AR ~1) was observed. Further, these crystals find a perfect crystalline match and self-organize with a neighboring NC, which results in the formation of a binary NC pair. Latter these pairs each grow in 1-D direction only, leading to the hexagonal ZnO NR. The NCs may have high intrinsic surface energy, which makes them find and attach to a similar crystalline surface of another NC, together forming NC pair. We have observed that this NC pair now acts as a base for NR formation because growth is occurring, only at both the ends along the length of the NC. Characterization techniques such as XRD and XPS have been done for analysing crystal size, phase formation and oxidation state respectively, for intermediate products. Synthesized ZnO NRs are presently being used in the degradation of pharmaceutical wastes in water.

Keywords: ZnO, Nanocone, Nanorod

11:30 AM *FF03.06.09
Noncovalent Self-Assembly and Formation of Active Nanostructures Hongyou Fan; Sandia National Laboratories, United States

Nanocrystals (NCs) exhibit unique size- and shape-dependent physicochemical properties arising from low dimensional quantum confinement effects and have been successfully used as building blocks for the fabrications of 2- and 3-dimensional NC arrays for the development of ‘artificial solids’ (or metamaterials) with new collective optical and electronic properties derived from the interaction or coupling of different NCs in an assembly. NC surface chemistry plays a key role in control of microstructures of the NC arrays such as mesophase. Here we report our recent progress in development of surfactant-assisted micelle confined noncovalent self-assembly and synthesis of active nanostructures. This approach is simple, general, and can be used to synthesize highly ordered nanostructures with different sizes and shapes. Through using varied surfactants and building blocks, this method provides a unique opportunity for subsequent self-assembly through hydrogen-bonding, π-π stacking, charge interactions, etc. and formation of highly ordered nanocrystal arrays with controlled mesophase, orientation, and material forms (film, powder, particle).

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.
Intrinsic Analysis of Transition Processes from the Lowest Triplet Excited State of Heavy Atom-Free Conjugated Molecular Crystals with Persistent Room Temperature Phosphorescence Shuzo Hirata; The University of Electro-Communications, Japan

Persistent room-temperature phosphorescence (RTP) under ambient conditions is attracting attention due to its strong potential for applications in bioimaging, sensing, or optical recording because materials with persistent RTP can be utilized for high contrast emission imaging independent of autofluorescence using small and cost effective photo-detectors. To extract efficient persistent RTP, the control of the radiative rate from the lowest triplet excited state ($T_1$) ($k_p$), the nonradiative rate of intramolecular vibrational relaxation at room temperature (RT) from $T_1$ ($k_{nr}(RT)$), and the triplet quenching rate at RT caused by interactions with the ambient surroundings ($k_q(RT)$) is crucial. In the last five years, $k_{nr}(RT)+k_q(RT)$ have been suppressed in a variety of heavy atom-free conjugated crystals under ambient conditions, which has allowed electrons in $T_1$ to partly access the persistent RTP pathway with small $k_p$. However, for complex conjugated crystalline systems a key strategy to suppress $k_{nr}(RT)$ and $k_q(RT)$ as well as increase $k_p$ for the efficient persistent RTP is not found yet.

Here, we investigate electronic structures controlling $k_p$, $k_{nr}(RT)$, and $k_q(RT)$ of heavy atom-free conjugated molecular crystals showing persistent RTP. For the analysis of $k_q(RT)$, high resolution optical microscopy analysis showed that, despite a favorable molecular stacking, aromatic crystals with persistent RTP are characterized by small diffusion length and significant small values of the diffusion coefficient of triplet excitons. Quantum chemical calculations reveal a large overlap between the lowest unoccupied molecular orbitals but very small overlap between the highest occupied molecular orbitals (HOMOs). Inefficient electron exchange caused by the small overlap of HOMOs prevents triplet excitons from diffusing over long distances and consequently from quenching at defect sites inside the crystal or at the crystal surface, contributing to minimization of $k_q(RT)$. For $k_{nr}(RT)$, analysis using vibrational spin–orbit coupling (SOC) at RT indicates that the large decrease of $k_{nr}(RT)$ hardly decreases before and after crystallization for the heavy atom-free conjugated crystals. Cooperative analysis using the high resolution microscope as well as the quantum chemical calculation indicated that the large decrease of $k_{nr}(RT)+k_q(RT)$ is caused by not the decrease of $k_{nr}(RT)$ but the small decrease of $k_q(RT)$ owing to the small diffusion of triplet excitons at RT. For overall electronic structures to access the persistent RTP, the localization of HOMO due to moderate charge transfer (CT) conjugated structure or π-degeneracy of three dimensional highly symmetric conjugated structures might be a key. The HOMO localization sometimes induces moderate CT character in transitions between high-order singlet excited states ($S_m$) and the ground state ($S_0$) as well. Stronger SOC between the moderate CT characteristics of the $S_m$–$S_0$ transitions and local excited characteristics of the $T_1$–$S_0$ transition contribute to the large increase of $k_p$ independent of $k_{nr}(RT)$.

This is first overall analysis of $k_p$, $k_{nr}(RT)$, and $k_q(RT)$ of heavy atom-free conjugated molecular aggregates. This knowledge of electronic characteristics, $k_p$, $k_{nr}(RT)$, and $k_q(RT)$ of conjugated molecular crystals will be important for realizing efficient persistent RTP from a variety of conjugated molecular crystals.

2:00 PM *FF03.07.02* Fluorescent Polymersomes with Aggregation-Induced Emission Min-Hui Li; Chimie ParisTech, PSL University Paris, CNRS, France

Synthetic amphiphilic polymers have been developed since last decades for the purpose of forming self-assembled polymer vesicles (polymersomes) which mimic the structures of lipid vesicles (liposomes) and the properties of cells in some extent. Polymersomes are much more stable, more robust and less permeable than liposomes due to the high molecular weight of polymers. They show high loading capacity for both hydrophobic molecules entrapped in the membrane and hydrophilic ones encapsulated in the inner aqueous compartment. Another interesting feature of polymersomes is that their properties can be finely adjusted by the rich chemical design of the amphiphilic building blocks. Stimuli-activatable functions, fluorescence-generating moieties and targeting groups can be introduced to make smart polymersomes which are currently studied as a means of drug delivery and biomedical imaging. Our group has focused, since several years, on the tailor-design of smart polymersomes based on biocompatible and biodegradable building blocks. In this communication, I will present fluorescent polymersomes with aggregation-induced emission (AIE), which are made of polycarbonates, polyesters, polyurethanes, and N-substituted poly(amino acid)s containing AIEgens. Some of these AIE polymersomes are also stimuli-activatable and can be opened under CO$_2$- and pH-stimulation. We aim to develop innovative approaches to cell/tissue imaging and controlled drug delivery with *in situ* bio-distribution tracing.

**Novel Dinuclear Ir(III) Complexes Based on Schiff Base as AIEgens and Their Applications** Dongxia Zhu; Northeast Normal University, China

A series of dinuclear Ir(III) Schiff base complexes have been synthesized and shown to exhibit both aggregation induced emission (AIE) and piezochromic luminescence (PCL) behaviour. We employed highly flexible Schiff base ligands to construct an AIE-active molecule with strong intermolecular interactions between the aryl rings in the aggregated or crystal state. The multifunctional dinuclear Ir(III) complexes are applied in second-level anti-counterfeit trademark, data encryption device and reversible monitoring device for volatile organic compounds.

**Synthesis of COF and MOF Colloids in Confined Bioinspired Conditions** Carlos Franco Pujante1, David Rodriguez San Migue1, Felix Zamora2 and Josep Puigmarti-Luis3; 1ETH Zurich, Switzerland; 2Universidad Autónoma de Madrid, Spain

Covalent Organic Frameworks (COFs) and Metal-Organic Frameworks (MOFs) are versatile porous materials with promising applications in a vast number of fields. Nevertheless, the high temperatures and the hazardous solvents required for the synthesis of these materials, among the poor solubility of the starting building blocks in the reaction media have provided a poor control over the size of the crystalline domains generated and in the morphology of COF/MOF crystals. These factors have limited the processability of COF and MOF hindering the integration in functional devices, as well as preventing their use in bio-systems. Therefore, great efforts are made in the field to understand and control the growth of COF and MOF crystals at length scales spanning from the nano- to the micrometer scale.1-3 Inspired by the confined spaces employed in living systems to constrain the crystallization processes, here we report for the first time a methodology for preparing stable aqueous colloidal solutions at room temperature of crystalline COF and MOF nanoparticles. This procedure allows downsizing these porous-materials beyond the previously reported limits, being able to, for example, synthesize MIL 100(Fe) nanoparticles under 20 nm. Additionally, thanks to their nanosized shape, we demonstrate the possibility to process these materials into a variety of micro- and millimeter-sized structures. We have demonstrated that by controlling the aggregation of the colloids, two-dimensional freestanding films and three-dimensional shapes can be accomplished. Among to improve their bioavailability, these results will undoubtedly open new possibilities for the implementation of COFs and MOFs into functional devices.

**Aggregation Induced Emission (AIE) of Cyclometalated Iridium Complexes—Applications for Highly-Selective Sensing of Anions and Neutral Molecules** Martin R. Bryce; Durham University, United Kingdom
Cyclometalated iridium complexes are of considerable interest due to their high photoluminescence quantum yields (PLQYs) at room temperature, physicochemical stability and long (several microseconds) PL lifetimes leading to their widespread applications in organic light-emitting diodes (OLEDs), as light-emitting electrochemical cells (LECs), biological labels, chemosensors for inorganic ions, data recording and security protection devices.

We will report that efficient Aggregation Induced Phosphorescence Emission (AIPE) of an ionic di-Ir(III) complex occurs when the counterion is exchanged specifically by perchlorate in aqueous media. As a result, a rapid, highly selective “turn-on” phosphorescent response to perchlorate is observed in aqueous media. X-ray crystallography, transmission electron microscopy and theoretical calculations support the photophysical data and the sensing mechanism.[1] We have also synthesized mono-iridium(III) complexes which possess aggregation-induced emission enhancement (AIEE) and detect the explosive 2,4,6-trinitrophenol (TNP) selectively with high quenching constants in aqueous media. The sensing mechanism has been systematically investigated by mass spectrometry, \(^1\)H and \(^19\)F NMR spectroscopy and X-ray crystal structure analysis. A hydrogen bonding interaction between TNP and the ancillary ligand of the Ir complex explains the high selectivity for TNP compared to other nitro-aromatics.[2]

Diffusional Behavior of Cu Nanocluster on Amorphous Carbon Surface Che-Wei Chang1, Guan-Rong Huang2 and Yu-Chieh Lo1; 1National Chiao Tung University, Taiwan; 2National Center for Theoretical Sciences, Taiwan

Growth of metallic nanowires is of practical importance for manufacturing integrated circuits in semiconductor industries. Copper (Cu) nanowires recently have been considered one of the promising materials in commercial application because of its superior electric/thermal properties. Experimental researches have shown that Cu nanowire growing on amorphous carbon (a-C) substrates is productive, but to our best knowledge the microscopic mechanism of how a-C film morphology affects Cu cluster diffusion remains to be unclear. Our molecular dynamics (MD) simulations of Cu cluster diffusion with a time scale of 300 ns laid down a prior knowledge for nanowire growth engineering, and showed that Cu nanoclusters with diameter of 1 was locally-diffused rather than globally-diffused on a 2.0 g/cm² a-C film. This suggested that the substrate roughness is crucial to the diffusion behavior. To further clarify the mechanism, we carried out the MD simulations with different cluster sizes, diffusion paths, and surface roughness. Through trajectory analysis of MD simulations, the relation among diffusion coefficients, cluster sizes and surface roughness was built, and showed that increasing surface roughness on a-C film may localize the trajectory of Cu cluster and reduce its size dependence on Cu cluster diffusion. Therefore, our simulation results may draw a new direction in nanowire growth engineering for controlling the diffusion pattern of Cu cluster by tuning the surface roughness of a-C substrate.

8:30 AM *FF03.08.02
Oriented Attachment—An Alternative Mechanism for the Growth of Nanostructures Younan Xia; Georgia Institute of Technology, United States

I will present a number of examples, in which oriented attachment of nanoscale building blocks rather than atomic deposition is responsible for the formation of noble-metal nanostructures with well-defined and controllable morphologies or shapes. Typical morphologies include nanocubes, wavy nanowires lined with planar defects, and dendritic nanostructures. The key requirement is the formation of a large number of nanoscale building blocks at the very beginning through homogeneous nucleation and the initiation of colloidal stability due to depletion of stabilizer from the surface of the building blocks. Due to the inclusion of planar defects, such nanostructures are attractive catalytic materials for a range of reactions and applications.

9:00 AM *FF03.08.03
Atomically Precise Metal Nanoclusters—From Synthesis to Assembly Rongchao Jin1 and Xin Zhang2; 1Carnegie Mellon University, United States; 2Pacific Northwest National Laboratory, United States

A major goal in nanoparticle synthesis is to control nanoparticles with atomic precision and reveal their total structures (i.e., core plus surface ligands). This talk will present some breakthroughs in metal nanoparticle research, including the atomically precise synthesis via solution chemistry and total structure determination by X-ray crystallography, as well as the assembly/crystallization of nanoparticles into hierarchical macroscale structures. By controlling nanoparticles with atomic precision, one can now reveal the long sought-after total structures of nanoparticles at the atomic level, such as the 1 nm Au25(SR)18, 1.7 nm Au133(SR)52, 2.2 nm Au246(SR)80 and Au279(SR)84 nanoclusters (where, SR = thiolate). These perfect nanoparticles (i.e. uniform structures and no defects) serve as model systems for addressing many fundamental questions that were previously difficult or impossible to tackle, such as the origins of chirality, periodicities in nanoparticle growth, structural isomerism, metallic-to-nonmetallic transition, single-atom level doping, atomic-level details of self-assembly, and many other mysteries at the nanoscale. The attainment of atomically precise nanoparticles will offer exciting opportunities in future studies on functional materials.

9:30 AM FF03.08.04
Size-Dependent Dynamic Structures of Gold Nanoparticles in CO Yang He1, Jin-Cheng Liu2, Langli Luo3, Jun Li4, Scott X. Mao4, Chongmin N. Wang1, Yang-Gang Wang5, Junfa Zhu6 and Yingge Du1; 1Pacific Northwest National Laboratory, United States; 2Tsinghua University, China; 3Tianjin University, China; 4University of Pittsburgh, United States; 5Southern University of Science and Technology, China; 4University of Science and Technology of China, China

Particle structural stability and mobility on the substrate critically affects their catalytic performances and
aggregation propensity. Here, by using atomic resolution in-situ environmental transmission electron microscopy, we reveal size-dependent structure dynamics of single gold (Au) nanoparticles on ceria in CO oxidation environment at room temperature. While large Au nanoparticles remain rigid in the catalytic working condition, ultrasmall Au clusters lose their intrinsic structures and become disordered, featuring vigorous structural rearrangements and formation of dynamic low-coordinated atoms on surface. *Ab initio* molecular-dynamics simulations reveal that the interaction between ultrasmall Au cluster and CO molecules leads to the dynamic structural response, demonstrating that the shape of the catalytic particle in the relative environment may totally differ from the shape under the vacuum condition. The present observation provides insight on the origin of superior catalytic properties of ultrasmall gold clusters. In addition, we also demonstrate the substrate effect on the mobility of Au nanoparticles. Surface steps on ceria can pin the motion of Au clusters; while Au nanoparticles readily moves and aggregates on amorphous SiO₂ substrate.

9:45 AM  FF03.08.05
**Quantum State Manipulation of Atomically Precise Gold Nanoclusters for Self-Assembled Nanomaterials**
*Tatsuya Higaki*, Meng Zhou and Rongchao Jin; Carnegie Mellon University, United States

Particle-based crystallization (PBC) is a useful approach to build up nanomaterials with desired functionality by controlling the properties of metal nanoparticles as building elements. Atomically-precise gold nanoclusters have gained broad interest as the building unit for functional nanomaterials because of their unique quantum state and related intriguing properties. These nanoclusters exhibit non-metallic electronic structure unlike bulk or plasmonic nanoparticle of gold, and their electronic structure is very sensitive to the size and structure of nanoclusters, even to the atomic level of difference. Recent advances in controllable synthesis allow chemists to tailor the size/structure of nanoclusters with atomic precision, providing new opportunities to control the functionality at single atom level. Further improvement of the tailoring method is expected through the investigation of some fundamental questions regarding the quantum state of nanoclusters. For example, the question on the transition from non-metallic to metallic state still remains elusive due to the difficulty in atomically precise preparation of nanoclusters near the transition size region (i.e., ~2 nm). The answer to this central question has been eagerly pursued because the exploration near the critical size can give us further insights into the formation of metallic bond and the origin of surface plasmons. The critical factors to tailor the non-metallic properties also have been investigated toward the general rule on the unprecedented size dependence of the nanoclusters’ functionality. In this presentation, I will discuss the successful identification of the transition from non-metallic to metallic state for Au nanoclusters at atomic level of precision, as well as the critical factors to atomically control the non-metallic properties below the transition regime. I will first talk about the synthesis and optical properties of atomically precise Au₂₇₉(SR)₈₄. Further characterization by ultrafast spectroscopy revealed metallic state of the Au₂₇₉ particle based on its laser power dependent dynamics, which is in contrast with the nonmetallic state of the previously reported Au₂₄₆(SR)₈₀. The abrupt transition with merely 33 metal atom difference is unprecedented, and it goes against >50 years of theoretical prediction of smooth transition.

I’ll also talk about atomic tailoring of Au nanoclusters to manipulate their non-metallic properties. I have synthesized Au₃₀(SR)₁₈ with an exotic crystalline phase: hexagonal close-packed (hcp) structure. The excited state dynamics of hcp-Au₃₀ is studied by ultrafast spectroscopy, and compared with other two nanoclusters with different crystalline phases: body-centered cubic (bcc) Au₃₈S₂(SR)₂₀ and face-centered cubic (fcc) Au₃₆(SR)₂₄. The observed lifetimes of hcp-Au₃₀ and bcc-Au₃₈ are 1 ns and 4.7 μs, respectively, demonstrating that controlling the crystalline phase of Au nanoclusters has significant effects on the excited state lifetime with three-orders-of-magnitude alteration.

The discovery of the non-metal to metal transition and the crystalline phase effect has provided critical insights into the quantum state of gold nanoclusters at atomic level. Further studies toward the direction will guide one to the strategy to engineer the functionality of nanomaterials by quantum state manipulation for applications in optoelectronic, catalysis, and biomedicine, as well as quantum computing.

**Manipulating Fluid Behavior for Material Assembly and Crystallization**  
*Yan Li*; Peking University, China

Solution process is often used in the assembly and crystallization of molecular or ionic substance and clusters. We developed several strategies making use of the behaviors of the liquid fluids to control the assembly and
crystallization. Both the temperature gradient and composition gradient were used to manipulate the Marangoni flow of the solution. By using a top-heating-bottom-cooling (THBC) setup, a steady Marangoni flow with a single vortex was created in the thin liquid film on solid substrates to facilitate the patterning of materials. By dropping dispersions of nanomaterials in water soluble organic solvents on the surface of water, Marangoni flow formed spontaneously and pushed the nanomaterials outside to form a thin film floating on water. We also studied the behavior of water-insoluble organic droplets on water surface. The three phase contact lines are tunable and thus the self-division process of the droplets was manipulated, which were further used to assemble materials. We show with the above examples that fluidics is a powerful tool in controlling the solution-based crystallization and assembly.

11:00 AM FF03.08.07
Formation and Self-Assembly of Graphene Nanoribbons and Nanosheets in Metals with 3D Epitaxy Lourdes G. Salamanca-Riba¹, Xiaoxiao Ge¹, Christopher Klingshirn¹, Oded Rabin¹ ¹, Manfred Wuttig¹, Daniel Cole² and Christopher M. Shumeyko²; ¹University of Maryland, United States; ²U.S. Army Research Laboratory, United States

Composites consisting of carbon nanostructures, such as graphene and carbon nanotubes, and metals are desirable for power transmission lines, interconnects and heat transfer applications due to the combination of excellent charge carrier mobility, thermal conductivity and mechanical strength of the carbon nanostructures and the high density of electrons in the metal. There have been metal/nanocarbon composites made by different methods, such as, chemical vapor deposition, friction stir, ball milling, and plasma spraying that have produced materials with enhanced hardness and tensile strength. However, in many instances the electrical and thermal conductivities of the metal/nanocarbon composites deteriorate. In the case of aluminum and its alloys, for example, very frequently these fabrication methods give rise to the formation of Al₄C₃ which is the culprit in the worsening of the electrical and thermal properties of the metal. We are using electrocharging assisted process (EAP) to assemble graphene nanoribbons inside a liquid metal. EAP consists of the application of a high DC current to a mixture of liquid metal and carbon particles. The current in the EAP pulls out atoms from the carbon particles which assemble into C-C chains that eventually form ribbons. The ribbons become crystalline with the same structure as graphene nanoribbons forming a 3D network in the matrix of the metal. The EAP not only crystallizes the ribbons into graphene structures but the ribbons become nucleation sites for the metal during solidification. Raman scattering, TEM and XPS show that the carbon nanostructures have primarily sp² bonding, they have a preferred orientation with the crystalline lattice of the metal and a nanocarbon crystallite size that increases with duration of the applied current. Al-C nanocomposites prepared with the EAP have shown 5 % increase in electrical conductivity as well as increase in the local stiffness, as measured by nanoindentation, compared to the pure Al alloys. Molecular dynamic simulation shows that graphene nanoribbons block the propagation of dislocations in the aluminum. Current AFM also indicates an increase in the local current from these samples compared to the parent aluminum alloy. Funded by DOE EERE under Award No. EE0008313.

Multi-Component Colloidal Constructs Designed through Self-Assembly of Defective Colloidal Molecules Mehdi Zanjani and Nishan Parvez; Miami University, United States

Engineering various types of structures through self-assembly of colloidal particles is a powerful approach in material design and processing. While simple colloidal building blocks, such as spherically symmetric particles, provide a number of well-known structures, more complex building blocks are needed to create novel structures with desired functionalities and tunable properties. Multicomponent building blocks such as colloidal molecules can provide a versatile platform for engineering new structures. However, in many cases, the synthesized colloidal molecules may end up suffering from ‘defects’ that are generally deemed to be an undesirable characteristic for multicomponent building blocks.

In this study, we use computational techniques to identify, investigate, and exploit self-assembly paradigms that are made possible through the use of defective colloidal molecules. Specifically, we study how defective units, which are typically missing one or two particles compared to the regular units, can be taken advantage of in order to build finite-size constructs that would otherwise be inaccessible. We further demonstrate different types of ordered superstructures that can be assembled through engineered directional interactions between defective and regular colloidal molecules. We use Molecular Dynamics (MD) and Brownian Dynamics (BD) simulations to study the thermodynamics and kinetics of self-assembly, and investigate the phase behavior of the resulting colloidal
constructs as a function of building block size and shape. This study will generate an understanding of different possibilities for self-assembly of defective multi-component colloidal building blocks and provide guidelines for future experimental studies to target new material design approaches.

11:30 AM *FF03.08.09
Self-Assembly of Anisotropic Nanocrystals Ou Chen and Yasutaka Nagaoka; Brown University, United States

Anisotropic nanocrystals with defined surface patchiness represent a unique class of building objects for constructing high-order architectural nanomaterials. When utilizing in assembly, on the one hand, anisotropic nanocrystals can display strong asymmetric interactions induced by the patchiness that may complicate the formation of ordered structures compared to the assemblies of isotropic building blocks. The same asymmetric interactions, on the other hand, can not only result in novel translational orderings, but also induce correlations between the atomic orientations of HNCs upon crowding, thus possibly dictate and control the atomic lattices within the assembled superstructure. In this talk, I will use several types of anisotropic 'patchy' nanocrystals as examples to demonstrate how they assemble into the unprecedented superstructures through the directional interactions among the building blocks under an enthalpy-driven condition. Both translational periodicities and orientational ordering of the final superstructural materials will be discussed. The dominating driving forces lead to the obtained architectures will be identified through molecular dynamics computer simulations and experimental results.

SESSION FF03.09: Aggregation-Induced Emission IV
Session Chairs: Mingdi Yan and Xin Zhang
Wednesday Afternoon, December 4, 2019

1:30 PM *FF03.09.01
Antimicrobial Nanoaggregates and Nanoclusters Mingdi Yan; University of Massachusetts Lowell, United States

The increasing prevalence of drug resistance to the majority of existing antibiotics has generated a pressing global healthcare crisis. Certain highly resistant bacteria have acquired multiple mechanisms against all available antibiotics including the drugs of last resort. We are developing new strategies to combat antimicrobial resistance, for example, nanoantibiotics in the form of nanoaggregates or nanoclusters. In one study, we developed a modular synthesis of fluoroquinolone derivatives which are propeller-shaped. Upon precipitation into water, these compounds readily assembled into amorphous nanoaggregates that displayed enhanced luminescence. Furthermore, the nanoaggregates exhibited up to 2 orders of magnitude enhancement in the antibacterial activity. In the second example, our recent work on antimicrobial gold nanoclusters will be discussed. We have shown that the cluster structure has a profound impact on the antibacterial activity of the nanoclusters. Additionally, by modulating the ligand structure and composition, Gram-negative activity against Pseudomonas aeruginosa was enabled.

2:00 PM FF03.09.02
Robust Serum Albumin-Responsive AIEgen Enables Latent Bloodstain Visualization in High Resolution and Reliability for Crime Scene Investigation Zhaoyu Wang, Ben Zhong Tang and Chenchen Liu; The Hong Kong University of Science and Technology, Hong Kong

Bloodstains provide admissible information for crime scene investigators. The ability to resolve latent bloodstains that are commonly found in real scenarios is therefore pivotal to public security. Here, we report a facile approach for invisible bloodstain visualization based on the click reaction between serum albumin and tetraphenylethene maleimide (TPE-MI), an aggregationinduced emission luminogen (AIEgen). Compared to the widely adopted methods based on the harsh catalytic oxidation activity of hemoglobin, this working principle benefits from the specificity of the mild catalyst-free thiol–ene click reaction that improves the reliability and resolution. In addition, the mild conditions preserve DNA information and bloodstain patterns, and the excellent photophysical properties of the AIEgen afford high sensitivity and stability (>1 yr). Such an excellent performance cannot be achieved by

Final Program 1/13/2020  1578
conventional AIEgens and aggregation-caused quenching luminogens with similar structures. TPE-MI outperforms the benchmark luminol-based technique in visualizing latent bloodstains as showcased in two mock crime scenes: spattered blood track and transfer blood fingerprint. This disclosed method is an advancement in forensic science that could inspire future development of technology for bloodstain visualization.

2:15 PM FF03.09.03
New Emissive Organic-Inorganic Hybrid Nanomaterials Based on Organic Fluorophores Grafted onto Nanocrystals Using Aggregation Induced Emission Effect Olivier Margeat1, Pierre-Antoine Bouit2, Jörg Ackermann1 and Muriel Hissler2; 1CINaM-CNRS, France; 2ISCR, France

Light emitting materials are nowadays important compounds in various applications and for many of them the developments of emissive organic molecules have opened new opportunities for future technologies.[1] However, even though organic materials show strong emission, their solution-processing remains challenging and morphology control as nanoparticles suffers from large distributions over size and shape.[2] A possible way to enhance the emission of organic fluorophores and to control the size of solution-processable emissive nanoparticles at the same time is their grafting onto inorganic nanoparticle surfaces. In order to avoid the classical aggregation-caused quenching (ACQ) effect [3] when high concentrations of organic ligands are present on nanoparticle surface, the opposite effect, namely aggregation-induced emission (AIE) [4] is a promising approach to generate strong light emission. Indeed, in this case, the high concentration helps to freeze the motion of the molecules to reduce the non-radiative deactivations. In this work, we thus present the synthesis of AIE nanohybrids prepared via the grafting of organic AIE ligands onto high band gap semiconductor nanoparticles. These organic-inorganic core-shell systems are composed of ZnO nanospheres as core and AIE ligands as shell. The design of the efficient AIE fluorophores is based here on hydroxy-oxophosphole luminophores, which can easily be grafted on metal oxide semiconductors. The structure-properties relationships leading to the highly emissive properties have been investigated. Thanks to theoretical calculations and XPS analyses, we could show that the electronic coupling between the ligands and the ZnO nanoparticles leads to partial charge transfer from the ligand to the ZnO core. Additionally, we showed that the grafting of these phosphole ligands onto ZnO nanoparticles introduces first a strong emission enhancement by the suppression of the hydroxyl resonator of the hydroxy-oxophosphole function that is electronically coupled to the emitting pi-system. Furthermore, the restriction of intra and inter molecular motions, through cluster formation (in solution) or highly emissive thin film processing, is found to introduce a second emission enhancement due to AIE effect. Preliminary tests in LED configuration using these AIE nanohybrids as emissive layer were obtained, that could demonstrate the potential of this new class of nanomaterials to be used as electroluminescent material by taking the advantage of combining both the AIE effect and the transport properties of the inorganic scaffold.

2:30 PM BREAK

3:30 PM *FF03.09.04
Face-Rotating Polyhedra Xiaoyu Cao; Xiamen University, China

In nature, protein subunits on the capsids of many icosahedral viruses form rotational patterns, and mathematicians also incorporate asymmetric patterns into faces of polyhedra. By taking inspiration from nature and mathematics, we used pseudo-chiral truxene (Tr) and triazotruxene (TAT) derivatives as building blocks to construct a series of molecular polyhedra with rotational patterns on faces, which we term as Face-Rotating Polyhedra (FRP). FRP represent a special form of molecular chirality. The relative stability of these polyhedra enables separation by chiral HPLC and full characterization. We also investigated the assembly process and the kinetics of interconversion of the polyhedra by a combination of chiral HPLC, CD, MS and NMR. Tetraphenylethylene (TPE) and its derivatives, as well-known AIE chromophores, have been extensively studied due to their broad applications in many fields. TPE unit exhibits either M or P configuration in its propeller
structure when the free rotation of phenyl rings was hindered, making it a possible building block for FRP. We assembled TPE units with triamine to construct cubes or sandwich-like assemblies with “emergent” chirality and fluorescence. This study provides strategies to construct FRP by means of AIEgens, which can be applied in luminescent materials, chiral molecular recognition or asymmetric catalysis.

Tetraphenylcyclopentadiene-Based Hyperbranched Polymers—Convenient Syntheses From One Pot “A4 + B2” Polymerization and High External Quantum Yields up to 9.74% in OLED Devices Yujun Xie1 and Zhen Li1,2; 1Institute of Molecular Aggregation Science, Tianjin University, China; 2Wuhan University, China

Through the A4 + B2 type Suzuki-Miyaura coupling reaction, hyperbranched polymers CP1, CP2, and CP3 were easily prepared, which exhibited high luminous efficiency in solution, neat film, and solid state as well as good thermal stability. When fabricated into organic light-emitting diodes (OLEDs) with mCP as host, the device based on CP1 demonstrated the good EL performance with external quantum efficiency (EQE) up to 6.36%. While the bipolar TADF host of CzAcSF was utilized instead of mCP, the driving voltage (at luminescence of 10 cd m-2) decreased from 5.7 to 4.4 V, and the EQE further increased to 9.74%, which was the highest EQE reported for hyperbranched polymers.

4:15 PM FF03.09.06
Multiscale Morphological Visualization of Semi-Crystalline Polymer by a Polymorphic AIE Marker Michidmaa Khorloo; Hong Kong University of Science and Technology, Hong Kong

Crystalline morphologies exist in many synthetic and natural macromolecules and are believed to play an essential role in biological phenomena and materials science. Despite the high performance of fluorescence imaging in spatial morphology characterization in life science, high-contrast mapping across different microstructures in solid polymers is challenging. In this work, we demonstrated a strategy to impart aggregation-induced emission (AIE) and polymorphic characteristics in a single luminescent system, whose polymorphic crystalline states with distinct emission are generated selectively in amorphous and crystalline phases of a polymer to light up the whole morphology. High compatibility between the AIEgen and polymer matrix allows the sensitivity of the AIEgen to be visually shown as different emissions. Consequently, information of the polymer morphology (crystalline and amorphous phases) is transformed into distinct fluorescence colors, allowing a single AIE molecule as a fluorescent marker for multiscale visualization of polymer morphologies in terms of amorphous and crystalline phases distribution, quantitative polymer crystallinity measurement, and spatial morphological arrangement. The proposed strategy provides a correlation between microscopic morphologies and macroscopic optical signals, opens an avenue of fluorescence imaging in materials science.

4:30 PM FF03.09.07
Aggregation-Induced Enhancement of Phosphorescence via Molecular Self-Assembly in Small Molecule Platinum Acetylides William Mullin; Tufts University, United States

The development of rational design principles for electronic materials is crucial to ensure efficient device performance and favorable optical properties. Small molecule phosphors are becoming increasingly important for OLEDs, optical sensing, and display technology. Heavy transition metals such as palladium and platinum enhance spin-orbit coupling of chromophores by mixing the energy levels of the singlet and triplet states, allowing for faster
intersystem crossing and a population of excited triplet states. Solid-state phosphorescence, however, is susceptible to aggregation-caused quenching (ACQ) through non-radiative processes, which significantly diminish phosphorescent quantum yield of neat solids. Herein, we present progress on an approach to ameliorate this problem by utilizing structural components of the molecules themselves to suppress chromophore aggregation and prevent ACQ. Specifically, we demonstrate aggregation induced enhancement of phosphorescence using a series of ester substituted phosphorescent platinum acetylides. Perfluorinated arene pendant groups on these chromophores encourage coplanar aromatic stacking interactions between adjacent molecules, insulating excited chromophores from non-radiative quenching typically associated with aggregation of phosphors. Fluorinated compounds show strong solid-state phosphorescence, which we attribute to fluoroarene-arene stacking interactions that prevent inter-chromophore aggregation, as demonstrated through their X-ray crystal structures. In contrast, non-fluorinated compounds show very little solid-state phosphorescence, a consequence of cofacial chromophore aggregation. This work highlights the potential broad utility of the non-covalent stacking interactions of fluorinated arenes in the development of solid state phosphors.

SESSION FF03.10: Particle Aggregation IV

Analysis and Control of CeO2 Mesocrystal Formation in Continuous Hydrothermal Synthesis System Takaaki Tomai1, Andrzej-Alexander Litwinowicz2, Akira Yoko3, Gimyeong Seong4, Seiichi Takami5, Shunsuke Asahina6, Xiaodong Hao7 and Tadafumi Adschiri2; 1Tohoku University, Japan; 2Nagoya University, Japan; 3JEOL, Japan; 4Shaanxi University of Science & Technology, China

Mesocrystals formed from assembled nanoparticles with ordered alignment have attracted much attention as promising materials in various engineering fields, such as photocatalysis, energy storage, and optical/magnetic application including metamaterials. Hydrothermal method with flow-type reactor can produce not only nanoparticles, but also mesocrystals, continuously [1]. However, the mesocrystal structure/size is difficult to control because the structural formation mechanism of the secondary structure of nanoparticles has not been clarified. In this study, to investigate the mesocrystal formation process, we conducted time-resolved experiments in the order of seconds using flow-type hydrothermal reactor [2]. We employed L-glutamic-acid-modified CeO2 nanoparticle as the building block of mesocrystal. The cerium nitrate solution with L-glutamic acid was pumped into the flow-type reactor, continuously, and mixed with preheated water at a T-shaped mixer. The temperature and pressure in the reactor tube was maintained at 548 K and 25 MPa. The reaction time was varied by altering the length of the reactor tube. In the hydrothermal reactor, the precursor reacts to form the L-glutamic-acid-modified CeO2 nanoparticles and the produced nanoparticles assemble by the L-glutamic acid as a glue to form mesocrystals. The snapshots of the produced materials during formation process of mesocrystal were obtained by HRTEM and XRD observations for the clusters synthesized from 0.7 s to 8.0 s. Here, we found that the primary nanoparticles in the loose agglomeration order themselves to form a cubic CeO2 mesocrystal. At a reaction time of 0.7 s, the truncated octahedral CeO2 nanoparticles (ca. 20 nm) aggregated in spherical shape (ca. 72 nm) with polycrystal structure. However, the structure of the cluster changed from spherical to cubic in less than 8.0s. The diffraction pattern of the cubic clusters gives a crystalline structure resembling that of a single crystal by rearrangement of the primary building blocks. These formation dynamics can be regarded as the analogy to the conventional crystalline particle formation. In the case of crystalline particle formation, nucleation occurs from monomers via non-crystalline droplet, followed by crystal growth with monomer diffusion to the crystal surface. In the case of the mesocrystal formation in this system, non-ordered agglomeration of primary nanoparticles firstly formed, followed by orientation of primary nanoparticles and mesocrystal growth with primary particle attachment. Consequently, the agglomeration of nanoparticles can be regarded as nucleation, and the orientation and growth can be regarded as the crystal growth, which can be seen in the conventional crystalline particle formation.

Based on the idea that nanoparticles behave like monomers in conventional particle formation, we conducted size
control of mesocrystal. In conventional particle formation, the nanoparticle concentration and the solvent properties affects the nucleation and crystal growth, determining particle size. For example, using the same flow-type hydrothermal reactor, the unmodified CeO$_2$ nanoparticles became smaller with lower precursor concentrations and the addition of ethanol as antisolvent. On the other hand, in the case of mesocrystal formation from L-glutamic-acid-modified CeO$_2$ nanoparticles, the mesocrystal size also decreased with the decrease in the precursor concentration and with addition of the ethanol, antisolvent.

8:15 AM FF03.10.02
**Understanding the Formation of PbSe Honeycomb Superstructures by Dynamics Simulations** Giuseppe Soligno and Daniel Vanmaekelbergh; Utrecht University, Netherlands

PbSe honeycomb superstructures, recently obtained by the self-assembly of PbSe nanocrystals (NCs) at fluid-fluid interfaces [1], have attracted a great interest since their predicted optoelectronic properties should combine the virtues of graphene with those of semiconductors [2]. However, their formation mechanism is still far from understood [3].

With a new coarse-grained molecular dynamics model we are able to reproduce the self-assembly of PbSe NCs in honeycomb and other observed 2D superstructures [4]. Our results shed light on the superstructure formation dynamics by identifying and quantifying the key parameters that drive the NC self-assembly into one or another superstructure. In particular, we show how the obtained NC superstructure depends on an intricate interplay between the interface-adsorption forces experienced by the NCs at the fluid-fluid interface and short-range electrostatic forces between the NCs. We also show indications that our model can be applied to study the formation and stability of defects in the self-assembled superstructures.

8:30 AM *FF03.10.03
**Real Time Imaging of Dynamic Behavior of Individual PbSe Nanocrystals During Superlattice Phase Transformations** Haimei Zheng$^{1,2}$; $^{1}$Lawrence Berkeley National Laboratory, United States; $^{2}$University of California, Berkeley, United States

PbSe nanocrystals have attracted considerable attention because of their potential applications in solar cells, light emitting diodes and field effect transistors. Monodisperse nanocrystals form superlattices with emergent collective properties. Although there have been intensive studies on PbSenanocrystal superlattices, how individual nanocrystals change and how they interact with each other during superlattice transformations are largely unknown. Direct observation with high spatial and temporal resolution using transmission electron microscopy (TEM) provides the opportunity to address these questions. We developed high-resolution carbon-film liquid cells, which allow to directly observe PbSe nanocrystal superlattice transitions using TEM. A monolayer of hexagonal superlattice of oleate-capped PbSenanocrystals is used as the starting materials. During its transformation into a square lattice due to ligand displacement, we observed an unexpected phenomenon that PbSe semiconductor nanocrystals can drastically change shape depending on the chemical environment. For example, ethylenediamine (EDA) induced oleate removal increases the nanocrystal dipole-dipole interactions, triggering the large shape changes and rapid nanocrystal fusion. After the ligands are removed, PbSe nanocrystals experience drastic directional shape deformation when the spacing between two nanocrystals reaches 2–4 nm. Moreover, the deformation can be completely recovered when two nanocrystals move apart or it can be retained when they attach. We have also performed the superlattice phase transition in pure ethylene glycol (EG) and found nanocrystals maintain their original shape during self-assembly, the resulting superlattices are more uniform and less defective.
The large deformation, which is responsible for the structural defects in the epitaxially-fused nanocrystal superlattice, likely arises from inter-nanocrystal dipole–dipole interactions. This has been further testified by our molecular dynamics (MD) simulations.

Direct Imaging of Layer-by-Layer Growth in a Colloidal Nanoparticle Superlattice Qian Chen; University of Illinois at Urbana-Champaign, United States

Layer-by-layer growth has been a hallmark of atomic crystallization to produce flat films of semiconductors or alloys for device applications, where a new surface layer starts to develop only after the preceding layer is complete. Here we show the direct imaging of nanoparticles crystallizing in a layer-by-layer fashion to large-scale superlattices with flat surfaces, utilizing the protocols we have developed in low-dose liquid-phase transmission electron microscopy (TEM). Single-particle tracking of the real-space, real-time TEM movies not only elucidates the structure and surface morphology of the superlattice during growth, but also enables the measurement of key parameters associated with layer-by-layer growth that are otherwise inaccessible. Coupling the in-situ observation with molecular dynamics simulation, we reveal the energetic origin of the layer-by-layer growth in our system by mapping the free energy landscape. Changing the pairwise interparticle interaction leads to other atomic crystallization pathways to occur in the same system, including roughening transition and coalescence. These atom-mimicking crystal growth pathways have hardly been realized in micron-sized colloids, suggesting a fundamental importance of the length and time scale associated with nano-sized building blocks.

9:30 AM FF03.10.05
Synthesis of Cuboctahedral CeO2 Nanoclusters and Their Assembly in Cuboid Nanoparticles by Oriented Attachment Using Selective Ligand Desorption Edson R. Leite1,2, Içamira C. Nogueira3, Elson O. Longo2, Juan Andres4 and Santiago Maya-Johnson2; 1Centro Nacional de Pesquisa em Energia e Materiais (CNPEM), Brazil; 2Federal University de Sao Carlos, Brazil; 3Federal University of Amazonas, Brazil; 4Universitat Jaume I, Spain

Controlled and predictable growth through oriented attachment (OA) mechanism is still a challenge. Here, we describe a simple approach to control the OA process through selective ligand scavenging from the {100} facets of CeO2 nanoclusters. Aggregates of these nanoclusters smaller than 10 nm with controlled cuboid shape were obtained. For the synthesis of the cuboctahedral CeO2 nanoclusters, we developed a solvent-controlled synthesis approach based on a nonhydrolytic sol-gel process and used an ester aminolysis reaction to control ligand scavenging from the {100} facets. First-principle calculations allowed us to understand and interpret, at the molecular level, the effects of shape control on the growth process. Fine-tuning of the desired morphologies can be achieved by controlling the values of the surface energies, which leads to the formation of morphologies that the classic growth process does not allow. The methodology described in this work, for the controlled assembly of CeO2 nanoclusters, may be relevant for the investigation of self-assembly processes of other metal oxides as well as for other types of inorganic nanoparticles in future work, which means that it brings new insight for nanostructure design and controlled synthesis.

9:45 AM FF03.10.06
Toward Total Synthesis of Thiolate-Protected Metal Nanoclusters Jianping Xie; National University of Singapore, Singapore

Total synthesis, where desired organic- and/or bio-molecules could be produced from simple precursors at atomic precision and with known step-by-step reactions, has prompted centuries-lasting bloom of organic chemistry since its conceptualization in 1828 (Wöhler synthesis of urea). Such expressive science is also highly desirable in nanoscience, since it represents a decisive step towards atom-by-atom customization of nanomaterials for basic and
applied research. Although total synthesis chemistry is less established in nanoscience, recent years have witnessed seminal advances and increasing research efforts devoted into this field. In this talk, I will discuss our recent work on introducing and developing total synthesis routes and mechanisms for atomically precise metal nanoclusters (NCs). Due to their molecular like formula and properties (e.g., HOMO-LUMO transition, strong luminescence and stereochemical activity), atomically precise metal NCs could be regarded as “molecular metals” (or metallic molecules / molecular-like metals), holding potential applications in various practical sectors such as biomedicine, energy, catalysis and many others. More importantly, the molecular-like properties of metal NCs are sensitively dictated by their size and composition, suggesting total synthesis of them as an indispensable basis for reliably realizing their practical applications.

SESSION FF03.11: Aggregation-Induced Emission V
Session Chairs: Paul McGonigal and Xin Zhang
Thursday Morning, December 5, 2019
Hynes, Level 3, Room 313

10:30 AM *FF03.11.01
Time-Resolved Spectroscopy Studies to Better Understand Aggregation Induced Emission Properties and Phenomena Lili Du and David Lee Phillips; The University of Hong Kong, China

The aggregation-induced emission (AIE) phenomenon was first reported by Tang and coworkers in 2001 and this new phenomena has been utilized to revolutionize biological and optoelectronic materials for use in various scientific fields over the past two decades. Due to the importance of AIE, thousands of publications have been reported on developing new efficient AIE luminogens (AIEgens) and implementing them for practical applications. Although conical intersection, E/Z isomerization, proton transfer, charge transfer, intra- and inter molecular restrictions have been considered as the main reasons for the phenomenon of AIE to occur in a number of different systems, there have been few direct pieces of evidence reported to support these hypotheses. The time-resolved spectroscopy techniques are considered to be powerful tools for studying and characterizing the mechanisms of AIE materials. Here, we report the use of transient absorption and time-resolved resonance Raman to study a number of TPE-based derivatives with varying structural rigidity and AIE properties. This allowed an examination of the direct correlation between the state-dependent coupling motions and inhibited fluorescence. Our new results prove the existence of photocyclized intermediates in several systems. We demonstrate that the dominant non-radiative relaxation dynamics i.e. formation of an intermediate or rotation around the elongated C=C bond, is responsible for the AIE effect, which is strongly structure-dependent but not related to structural rigidity. In addition, femtosecond transient absorption spectroscopy was also employed to demonstrate that the excited state aromaticity inversion for the non-aromatic annulene derivative of cyclooctatetraene causes the typical AIE phenomenon for this system in spite of its rotor-free structure. Therefore, results from the study of the photophysical and photochemical mechanisms of AIEgens will be instructive to guide the tailoring and further development of more efficient luminogens in the future.

11:00 AM *FF03.11.02
Excited-State Aromatic Interactions in the Aggregation-Induced Emission of Molecular Rotors Paul R. McGonigal; Durham University, United Kingdom

Small, apolar aromatic groups, such as phenyl rings, are commonly included in the structures of fluorophores to impart hindered intramolecular rotations, leading to desirable solid-state luminescence properties. However, they are not normally considered to take part in through-space interactions that influence the fluorescent output. This presentation will detail (Figure 1) the photoluminescence properties of a series of phenyl-ring molecular rotors bearing three, five, six, and seven phenyl groups around carbacyclic cores. The fluorescent emissions from some of the rotors are found to originate, not from the localized excited state as one might expect, but from unanticipated through-space aromatic-dimer states. We demonstrate that these relaxed dimer states can form as a result of intra-
or intermolecular interactions across a range of environments in solution and solid samples, including conditions that promote aggregation-induced emission. Computational modeling also suggests that the formation of aromatic-dimer excited states may account for the photophysical properties of a previously reported luminogen. These results imply, therefore, that this is a general phenomenon that should be taken into account when designing and interpreting the fluorescent outputs of luminescent probes and optoelectronic devices based on fluorescent molecular rotors. In order to gain deeper insights, we have also taken a ‘minimum modification’ strategy to modify the conjugation and geometries present for one of the rotors, sym-heptaphenylcycloheptatriene.[2]

A General Way to Build Plasma-Membrane Specific Probes with Aggregation-Induced Emission Lei Shi, Yan-Hong Liu and Kun Li; Sichuan University, China

The abnormality of plasma membrane (PM) is an important biomarker for cell status and many diseases. Therefore, visualizing PM is crucially important in the fields of physiology, pathology and pharmacology1-2. Herein, we provide an effective way to generate dyes that suitable for PM imaging with easy operation (one step), rapid staining, good biocompatibility and high-fidelity imaging. Four compounds with aggregation-induced emission (AIE) characteristics were presented by changing the length of alkane chain and electrostatic interaction to investigate the relationship between amphipathy and positive charges as well as the imaging effect including specificity, staining period and dyeing continuity and retention. Besides, the 2D/3D imaging experiments indicated the high specificity of PM and ultrafast imaging without washing (2D at the second-level, 3D around 1 hour). More importantly, the probe Pent-TMP could light up the PM in complex systems (brain tissue and live zebrafish). For the first time, we have captured single erythrocyte in brain tissue by fluorescence. Besides, Pent-TMP could stain the PM of the zebrafish in vivo which typical probes can hardly do1. With these advantages, we hope that this method of constructing ultrafast and easy-operation PM Specific Probes will be helpful to molecular design, medicine and biology.

11:45 AM FF03.11.04
Unexpected Room Temperature Phosphorescence from a Non-Aromatic, Low Molecular Weight, Pure Organic Molecule through the Intermolecular Hydrogen Bond Manman Fang1,2 and Zhen Li2,1; 1Tianjin University, China; 2Wuhan University, China

Efficient pure organic room temperature phosphorescence (RTP) materials have drawn considerable attention. So far, most pure organic RTP molecules are aromatic compounds, and nonconjugated molecules are really scarce. The only few reported non-aromatic organic phosphorescence materials are polymers without confirmed subtle structures, and there are no reports concerning non-aromatic organic small molecules with persistent RTP. Here, we report an example of a pure non-aromatic organic small molecule, cyanoacetic acid, that shows unexpected persistent RTP behavior with RTP lifetime as long as 862 ms. According to the CAA crystal and theoretical calculations, the presence of strong intermolecular hydrogen bonds is the key factor for its persistent RTP effect. This discovery demonstrates a clear relationship between the molecular structure, packing mode and RTP effect in the non-aromatic system, which will largely extend the current pure organic RTP systems to deeply investigate the origin of light emission
Exploring How Bimetallic Nanoparticles Evolve—Growth, Etching and Catalysis

Bimetallic nanoparticles are commonly used as catalysts in a broad range of industrially relevant reactions. To enable the rational design of catalysts with better performance, it is necessary that we understand the relationship between a nanoparticle’s structure and its catalytic properties. However, such insights have to be obtained from catalysts under reaction conditions because the nanoparticles can exhibit dynamical structures that do not exist outside the reactive environment. TEM has always been a powerful technique for studying the detailed structure of nanoparticles. Recent developments in in situ environmental TEM, now allow us to study nanostructures within gas and liquid environments with TEM, and probe their formation pathways during the synthesis and reaction kinetics during the catalysis in real-time with nanometer resolution.

In the first part of my talk, using in situ liquid phase TEM, I will describe how bimetallic nanoparticles with different architectures form in solution. By directly visualizing the growth and electrochemical etching of such nanoparticles, I will show how bimetallic nanoparticles form under different physical and chemical environments. Next, using in situ gas phase TEM imaging, I will discuss the catalytic performance of these bimetallic nanoparticles and describe how these nanoparticles exhibit surprising structural changes during catalytic reactions. Using Pt-Ni bimetallic nanoparticles as a model system, I will show that these nanoparticles evolve differently in reactive gas conditions depending on the starting structure of the nanoparticle.

These insights into the evolution of nanoparticles both during their synthesis and application are important for the rational design of nanomaterials with tailored properties.

Observing the Early Stages of Protein-Metal-Organic Framework Formation by Cryotransmission Electron Microscopy

Materials that combine synthetic and biological nanotechnologies are inspired by Nature’s tight control over organic-inorganic interactions, such as in biomineralization, to assemble biological nanomaterial hybrids with optimized performance. Although engineering synthetic-biological hybrids would accelerate the development of next-generation materials, there are currently no design rules to effectively create these synthetic/biomimetic systems. This is largely due to a gap in knowledge of the interface between biological-synthetic materials and the fundamental interactions that govern their formation. Here, we establish an initial understanding of the interactions between bovine serum albumin (BSA) protein and metal-organic framework ZIF8 using electron microscopy and reveal complex growth mechanisms that govern the final BSA/ZIF8 single-crystal nanomaterial. By varying the amount of BSA incorporated into an in-situ ZIF8 synthesis, we observe significant control in the final crystal size, morphology, and porosity ranging from well-faceted dense crystals to porous crystals with rough surfaces. Using time-resolved cryotransmission electron microscopy, we found that these structural differences stem from the simultaneous formation of two amorphous metastable phases and their dynamic interactions in the early stages of BSA/ZIF8 formation. One phase is characterized by well-defined primary particles (~ 8 nm) and the second phase is characterized by BSA/ZIF8-precursor clusters that aggregate into branched networks (~ 1 µm). Lattice-resolution cryoTEM demonstrates an important interplay between these two phases during crystallization and growth through particle aggregation mechanisms. Real-time observation of the transition between these phases is further probed with in-situ liquid TEM. The presence of these amorphous phases and their dynamic interactions to form the final BSA/ZIF8 crystals provides an understanding of protein-MOF crystal formation that is analogous with established biomineralization mechanisms.

Conjugated Polymer Nanowires Based Thermoelectric Materials

One-dimensional polymer nanowires with highly ordered structure have fast carrier transport which is beneficial for improving polymer thermoelectric (TE) power factors. Tuning the nanowire structure and interfaces in conjugated polymer nanowires may lead to unique density of states and thus thermoelectric transports. In this talk, I will review our recent works that involve the structure and interface manipulation of conjugated polymer nanowires for higher
thermoelectric performance, the possible TE enhancement mechanisms will be discussed as well.

2:30 PM *FF03.12.04
Exploring the Surface Effects of Sub-10-nm Materials from Atomic Scale Litao Sun; Southeast University, China

With the development of semiconductor technology, the 10 nm feature size of fabrication is already achieved. It is thus quite essential to explore more precise nanofabrication and characterization method to evaluate the shape/structure stability and possible new properties of sub-10nm material components, especially under external stimuli such as strain, electric, or thermal fields. Along with the reduction of dimensions, the surface-to-volume ratio of the materials increases. For a 10 um particle, only about 0.036% of atoms occupy the surface positions, and the percentage rise to ~36% and ~62% for a 10 nm and a 6 nm particle respectively. Furthermore, surface atoms are preferably reconstructed for adapting their geometrical and electronic structure to the environment. Thus, the surface structure begins to dominate material properties ranging from electronic and structural aspects when the characteristic dimension is reduced to sub-10 nm. Here we review our recent progress in atomic resolution nanofabrication and dynamic characterization of sub-10nm individual nanostructures and nanodevices based on the idea of "setting up a nanolab inside a transmission electron microscope".

3:00 PM BREAK

SESSION FF03.13: Aggregation-Induced Emission VI
Session Chair: Xin Zhang
Thursday Afternoon, December 5, 2019

3:30 PM *FF03.13.01
Aggregation-Dependent Emissions and Cytotoxicity of AIEgens Deqing Zhang; ICCAS, China

AIEgens including silole and tetraphenylethylene show abnormal emissive behavior. They are almost non-emissive in the well-dispersed states, but their emissions are switched on upon aggregation. By taking advantage of this unusual emissive property, AIE gens have been successfully employed for chemo-/biosensing, fluorescence imaging and photodynamic therapy. In this presentation, I will show that the emission colors and efficiencies of AIEgens are affected the aggregation of AIEgens in terms of intermolecular interactions and orientations. Moreover, I will discuss the dependence of cytotoxicity on the size and surface zeta potential of aggregates of AIEgens.

4:00 PM *FF03.13.02
Understanding AIE with Theory and Computations Lluis Blancafort; Universitat de Girona, Spain

AIE has come a long way since its discovery almost 20 years ago. However, some questions about the basic mechanisms still remain open, and theory and computations can be very helpful in providing new fundamental insights. In this contribution we will center on how work from our group has contributed to a better understanding of the fundamental processes at the molecular level, both in solution and in the aggregate phase. We will center on two subjects: first, introduce our Restricted Access to a Conical Intersection (RACI) model to explain the photophysics/photochemistry in solution and in the crystal and discuss some examples (see for a review: Crespo-Otero et al, Chem. Asian J. 2019, 14, 700); and second, discuss some of the factors that affect morphochromism and, more in general, the emission color of AIEgens and their dependence on the aggregate form.
Mechanoluminescence (ML) is a light-emitting process induced by mechanical stimuli, such as grinding, rubbing, or shaking, which has attracted extensive attention because of its potential in displays, lighting, bioimaging, and stress-sensing applications. Regardless of its long history, which stems from the first report on sugar by Francis Bacon in 1605, reports on organic ML luminogens remain limited in number, partially because of a lack of reliable guidance and unclear inherent mechanisms. On the other hand, as the most investigated light-emitting process, photoluminescence (PL) is well-understood and has made great contributions to research involving other kinds of emitting processes, including electroluminescence (EL) and chemiluminescence (CL). Based on these success stories, and the previous reported ML luminogens, we decided to explore the unknown ML excitation process using well-understood PL as a template.

Nanoparticle Linker-Controlled Intermolecular Charge Transports in Double Molecular Monolayers
Sohyeon Seo1 and Hyoyoung Lee1,2; 1Sungkyunkwan University, Korea (the Republic of); 2IBS, Korea (the Republic of)

Highly conductive molecular wires are an important component for realizing molecular electronic devices and have to be explored in terms of interactions between molecules and electrodes in their molecular junctions. Here, we report new molecular wire junctions (e.g., Co(II)(tpyphS)2–AuNP–Co(II)(tpyphS)2) to enhance charge transport through gold nanoparticle (AuNP)-linked double self-assembled monolayers (SAMs) of cobalt (II) bis-terpyridine molecules (e.g., Co(II)(tpyphS)2). Electrical characteristics of the double-SAM devices are explored in terms of the existence of AuNP. The AuNP linker in the Co(II)(tpyphS)2–AuNP–Co(II)(tpyphS)2 junction acts as an electronic
contact that is transparent to electrons. The weak temperature dependency of the AuNP-linked molecular junctions strongly indicates sequential tunneling conduction through the highest occupied molecular orbitals (HOMOs) of Co(II)(tpyphS)₂ molecules. The electrochemical characteristics of the AuNP–Co(II)(tpyphS)₂ SAMs reveal the fast electron transfer through molecules linked by AuNP. Density functional theory (DFT) calculations reveal that the molecular HOMO levels are dominantly affected by the formation of junctions. The intermolecular charge transport, controlled by the AuNP linker, can provide a rational design for molecular connection that achieves a reliable electrical connectivity of molecular electronic components for construction of molecular electronic circuits.

3D Patterning of Nanoparticles by Molecular Stamping Yan Xiong¹, Shize Yang², Ye Tian¹ and Oleg Gang¹;²;¹Columbia University, United States; ²Brookhaven National Laboratory, United States; ³Nanjing University, China

Molecular patterning of nanoparticles can allow prescribing inter-particle binding sites, and that can permit creating tailored building blocks for assembly of targeted nanoparticle clusters and large-scale periodic nano-organizations. However, establishing a platform for rational patterning of nanoparticles has been challenging. We have developed a so-called Molecular Stamping approach for 3D nanoparticle patterning by templating target particles with designed molecular patches using DNA frame. In this method, molecular stamps, located at the prescribed locations of frame, can be engaged for transferring distinctive molecules onto different sites of nanoparticle surface. Our approach allows for creating molecular patches with a single molecule control and with same or different binding affinities. We applied the developed method to generate planar and 3D arrangements of molecular patches on nanoparticles, and investigated factors affecting pattern formation and its resolution. The developed approach was used to create nanocluster architectures containing nanoparticles of different sizes and from different materials. Electron microscopy and tomography were utilized to reveal spatial arrangements of molecular patches and the factors contributing to the patterning process.

8:45 AM FF03.14.04
Nonlinear Optics with Colloidal Superparticles Having Metamaterial Shell Joong Hwan Bahng¹, Saman Jahani², Douglas G. Montjoy³, Nicholas A. Kotov² and Alireza Marandi¹; ¹California Institute of Technology, United States; ²University of Michigan, United States

Colloidal nanoparticles have become essential components to a broad spectrum of scientific fields, accredited to their superior and tunable physicochemical properties exclusive to the nanoscale dimensions. For example, their exceptional surface to volume ratio, diffusion rate and dispersion stability markedly increase their reactivity and bioavailability. In addition, the colloidal nanoparticles exhibit diverse electromagnetic responses whose modes, intensities and spectral locations are readily adjusted according to the engineering needs. As such, colloidal nanoparticles have become integral optical-actuating platforms in catalytic reactions, targeted drug delivery, in vivo medical imaging and sensing. On the other hand, their ultraviolet and visible spectrum requirement for photo-stimulation poses intrinsic limitations due to poor light penetration into the reaction media and the biological tissues. Delivering optical energy through the ambient media within its specific transparency window that could trigger the target responses may immensely broaden the scope of the operation while enhancing its procedural compatibilities and efficiencies. Hence, robust in situ colloidal optical nonlinear transducer capable of all wavelength accessibility with practical conversion efficiencies could provide important solutions to these challenges. Here, we demonstrate a versatile pathway to obtain second harmonic generation (SHG) of light with practical conversion efficiencies from dielectric ψ(2) nanostructures by configuring them into a colloidal superparticle. Through one-pot chemical synthesis, we were able to blend multiple materials types of different constitutive properties, shapes and dimensions into a single colloidal superstructure in a hierarchical manner. An array ZnO nano-rods, a ψ(2) material, are vertically aligned to construct a corrugated shell around a dielectric SiO₂ sphere. Extensive control over the chemical synthesis of the ZnO nanostructures enabled us to transform the nanotopographic landscape into a shell of optical metamaterials having 2nd order nonlinearity (ψ(2) meta-shell). Our analysis show that the ψ(2) meta-shell exhibits radial graded index and anisotropy profile in its constitutive properties. The effective optical responses from the ψ(2) meta-shell is engineered in the linear regime to maximize the optical nonlinear effects in the ψ(2) meta-shell, the site of nonlinear conversion. We have experimentally observed strong enhancement of SHG in the meta-shell superparticle. The FDTD simulation revealed 10⁴ enhancement in the conversion efficiency between the meta-shell superparticle and a ZnO nano-rod. Furthermore, the SHG generated by the meta-shell particle is highly localized within the nanoscale confines, making it a desirable platform for photo-chemistry, photo-medicine, biotechnology and bio-photonics.
While the current demonstration focuses on the second harmonic generation, our colloidal meta-shell superstructure has the ingredients necessary for a cohort of optical nonlinear conversion processes.

9:00 AM FF03.14.05
Particle Assembly as Templates for Synthesis of 3D Interconnected Nanostructures Pratibha Mahale¹, Hiu Yan Cheng², Nabila N. Nova², Parivash Moradifar², Alex Grede², Byeongdu Lee³, Shi-Ying Yu², Nasim Alem², Noel C. Giebink², John V. Badding² and Thomas E. Mallouk¹; ¹University of Pennsylvania, United States; ²The Pennsylvania State University, United States; ³Argonne National Laboratory, United States

3D chemically bonded nanostructures combine the unique properties of nanomaterials with the periodicity of interconnected structures and the form of bulk materials, giving rise to new physical phenomena. We have combined the strength of particle assembly and High Pressure confined Chemical Vapor Deposition¹ (HPCVD) to create ordered and electrically continuous 3D nanostructures of both metals and semiconductors. These structures called “metalattices”(ML)² were made possible by void-free infiltration of silica colloidal crystals using HPCVD. We use a vertical deposition technique³ to assemble monodisperse silica nanoparticles in the range of 14nm-120nm, at controlled temperature and humidity, to form 3D colloidal crystals. The arrangement of silica nanoparticles in the template has a direct effect on metalattice (ML) properties. Structural characterization of the colloidal crystal templates which were grown as micron-thick films on silicon substrates and of MLs using Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) and Small Angle Xray Scattering (SAXS) shows a 3D-ordered and well connected structure. Extending this structural characterization of templates to metalattices, we are studying surface modification and spatial band gap modulation in Germanium metalattices. Germanium despite its high carrier mobility has suffered inefficiency in electronic applications due to formation of germanium oxide which is unstable and introduces defects at the interface. We use a core-shell approach to passivate Ge MLs and prevent oxide formation. A silicon shell is grown on the Ge core leading to the formation of a Si₆Ge₁ₓ alloy at the interface which acts as a passivating layer. TEM, Raman and X-ray Photoelectron Spectroscopy studies confirm the formation of the core-shell structure with polycrystalline Ge as core and amorphous Si as shell without any germanium oxide formation. Given the inherent structure of metalattices, there are different degrees of confinement at octahedral, tetrahedral and meta-bond site. We are currently studying this spatial band gap modulation using electron energy loss spectroscopy. This understanding and control of metalattice surface along with the spatial structural modulation will enhance their tunability for desired properties and will also enable their applications in opto-electronic devices.

Programmable Self-Assembly of 3D Printed Particles David Doan and Wendy Gu; Stanford University, United States

Particle-based crystallization relies on the synthesis and self-assembly of large numbers of monodisperse particles with nano to microscale dimensions. The fabrication of particles with diverse structures remains a challenge. Currently, inorganic nanoparticles with simple geometries (e.g. spheres, cubes, platelets) can be fabricated through bottom-up synthesis, while microscale Janus and patchy particles can formed through templating techniques. It is of interest to form lower symmetry shapes in which the direction of particle-particle interactions can be defined arbitrarily, and particle geometry can be used to precisely tune interparticle forces such as depletion forces. For instance, particles with one or more concavities (e.g. cube with concavities on 1 to 6 faces) can be combined with convex structures (e.g. spheres) to form complex self-assembled structures in 1D, 2D or 3D networks using lock and key mechanisms.

Here, we address the challenge of fabricating colloidal particles with complex geometries by using 2-photon
lithography to 3D print microscale particles of arbitrary shapes. This method has been used to print hollow cones, spheres, cubes, tetrahedra, and dumbbells with bounding box dimensions of 5 um x 5 um x 5 um out of a fluorescent photoresist, and can be extended to other structures. In this method, a focused 780 nm laser is used to directly write a freestanding 3D structure into liquid photoresist, or within photoresist at the interface with a solid substrate. The particles are then transferred to a microfluidic cell, and in-situ fluorescence imaging is used to observe the dynamics and final configurations of the assemblies that form from these 3D printed particles. These 3D printed particles (e.g. concave particles) will be combined with traditional particles (e.g. polymer or silica spheres) to form networks of multi-particle assemblies with controlled porosity, with the ultimate goal of forming periodic lattices with millimeter dimensions.

New Mechanistic Insights into the Formation of Epitaxially Connected Quantum Dot Superstructures
Jessica Akemi Cimada da Silva, Unmukt Gupta, Fernando Escobedo and Tobias Hanrath; Cornell University, United States

Epitaxially connected colloidal quantum dot superlattices with long-range atomic coherence have generated significant interest by virtue of their predicted emerging electronic properties. Whereas advances in controlled assembly and attachment at fluid-fluid interfaces have enabled the formation of high-fidelity superlattices in which constituent lead salt quantum dots are registered to within a single atomic bond length, significant gaps in our understanding of the fundamental mechanism underlying this transformation persist. The transformation involves a complex choreography of a number of sub-processes including: (i) the transport of a chemical trigger from the subphase to the quantum dot surface, (ii) the formation and removal of the ligand metal chelation complex, (iii) the rotation and translation of the quantum dots from their site in the initial assembly and (iv) the irreversible formation of an epitaxial bond between proximate dots through mutually exposed facets. What is astonishing and not yet understood is how the irreversible attachment of tens of thousands proximate dots are coordinated to enable the formation of micrometer-sized grains. Our recent experiments sought to capture intermediates of this intriguing transformation and revealed the existence of transient elongated structures along the <100> axis. New insights into the underlying processing-structure relationships coupled with computational simulations provide new understanding of the transformation mechanism. Beyond the specific model system of lead salt quantum dots discussed in this work, we expect that these new mechanistic insights will also provide valuable guidance to advance controlled assembly and attachment of related nanostructures.

Hierarchical Nanoscale Architectures for 3D Structuring of Functional Materials
Jason Kahn¹, Yan Xiong¹, Brian Minevich¹ and Oleg Gang¹,²; ¹Columbia University, United States; ²Brookhaven National Laboratory, United States

Until recently, the vast majority of functional materials organizations at the nanoscale have been based in studies of packed nanoparticle architectures. Rationally designed, periodic structures tailored towards enhancing the local environment for chemical or biological components are far less explored, but equally important in consideration of their optical, catalytic, and enzymatic applications. The ability to separate material function from binding parameters bridges the divide between nanoparticles and a vast materials space often exhibiting anisotropic structure. A universal platform enabling novel hierarchical assemblies can be achieved utilizing DNA constructs that carry a molecular or nanoscale material object, where different units can be encoded for location within a crystalline lattice as well as for material type. Three-dimensional, hierarchical architectures allow for precise control of locally-defined material stoichiometries at the nanoscale as well as their mesoscale arrangements, encoding the position of units over multiple coordination spheres. With this capability, novel research into 3D structure-function relationships can be explored, as demonstrated optically using quantum dot organizations and chemically utilizing catalytic enzyme systems.

Site-Selective Synthesis of Core-Shell Multi-Segment Nanowires for Nanoscale Soldering and Interconnection
Edward Fratto, Jirui Wang, Brendan Lucas, Hongwei Sun and Zhiyong Gu; University of Massachusetts Lowell, United States
One-dimensional nanowire-based structures enable sophisticated design and integration of functional electrical components for modern electronics and devices. Recent developments in nanowire miniaturization have the potential for the next level of advanced assembly and packaging, but thus far engineering of nanostructures has been limited by associated challenges of interconnection. This work presents a core/shell multi-segment nanowire which achieved macroscale interconnection via magnetically assisted assembly and soldering. Gold-nickel-gold (Au-Ni-Au) nanowires were synthesized via electrodeposition in anodic aluminum oxide (AAO) template, with nickel acting as a magnetic vehicle for assembly. Gold-selective deposition of tin was achieved via establishment of a chemisorbed nickel-protective monolayer, followed by immersing the nanowires in aqueous solution for selective chemical reduction. This resulted in seeded tin deposition along the gold tips, which were subsequently grown into a coherent shell on gold. Core-shell formation was confirmed by SEM, TEM, EDS and XRD. These “dumbbell” shaped core/shell nanowires were assembled tip-to-tip and subsequently soldered, establishing ohmic electrical and thermal interconnection. This work establishes an effective and scalable method for site-specific nanowire functionalization while simultaneously addressing miniaturization-associated assembly and packaging issues in its desired applications.

10:45 AM FF03.14.10
Patterns via Evaporative Self-Assembly and Dewetting Kibeom Nam, Dong Yun Lee, Jaebin Lee and Eonji Kim; Kyungpook National University, Korea (the Republic of)

We present applications of the flow coating methods to achieve unique and complex shapes of patterns or structures. Flow coating is one of the solution coating techniques that exploit the coffee-ring effect. The coffee-ring effect is referred to a circle of a non-volatile solute that is left by a droplet of the solvent after it evaporates from a flat surface. It can be fund after coffee drop dries on a table. This pattern originates from the capillary flow, which is induced by the different evaporation rates between the edge and center of the droplet. A flow coater is confined to the position of the droplet with the blade at a specific position, and the solute is deposited along the shore.

In this study, we combined such a simple phenomenon with different materials such as a polymer, silica particle, and organic semiconductors. Every material had proper conditions for flow coating from the solvent to the speed of the coating process. By control the factors, we could achieve various kinds of patterns without complicate process compare with other methods and determined the relationships between the control value and phenomenon. First, the relationship between stopping time of flow coater and deposition phenomenon of several times of patterning process was investigated. Stopping motion of blade of flow coater gave more deposition of solute, and it could make thick or wide patterns. The difference of pattern’s height impacted the additional patterning mechanism on the patterned surface. Height of patterns inhibited deposition of solute on its top inducing a dewetting phenomenon. We could observe a change of height with a dewetting phenomenon and the amount of deposition rate with the shape of patterns. Various kinds of non-linear dewetting induced patterns are reported in this study.

Second, the relationship between the speed of flow coater and deposition phenomenon such as height and structural morphology of the film was explained. Speed of flow coating process is one of the critical factors that can control the amount of evaporating solvent, flow coating could control the overall thickness, and it spontaneously changed along with the speed of the blade. In this study, nano-sized silica particles was deposited on the substrate, affording a closely packed, well-ordered structure. Photonic structures were achieved in the same manner. The thickness of photonic crystal was changed along with the speed and photonic property was examined.

Third, the relationship between the speed of flow coater and shear stress on the solution was determined with organic conducting materials. The flow coating system basically comes from solution shear coating method and the shearing gives shear stress on the solution. Shear stress deformed crystal structures and it made conducting property differently.

The patterns that came through flow coating had various shapes and its application and they were easy to obtain. Compared to other methods, flow coating is an important method due to the following reasons. First, lithography or nano-casting needs complex steps to achieve a photonic structure, while flow coating does not need a developed process. Second, deep coating takes a long time until the liquid evaporates to form a thick film. However, flow coating overcomes such problems and exhibits more advantages.

High Temperature Crystallization of Monodisperse and Optically Active Lanthanide Nanoparticulates for Noninvasive Optogenetics Eric Zhang1,2, Ashley Dickey1, Yura Bandera1,2, Isabell Foulger1, Jeffery Anker1, John Ballato1,2, Joseph Kolis1 and Stephen Foulger1,2; 1Clemson University, United States; 2Center of Optical Materials
Optogenetics is a field of study that combines optics and biology to control living tissues via light sensitive proteins (opsins) and radiative energy. Traditionally, optical fibers are used as a waveguide to introduce light pass the cranial; consequently, this has negative side effects such as localized heating and surgical scars. Here a noninvasive technique is proposed utilizing a high penetrating and low tissue attenuation x-ray excitation source and nanoparticulates that scintillates to deliver radiative energy to light sensitive proteins.

Scintillators are a class of materials that can experience a downconversion of electrons from a high energy excitation source, such as x-rays. The ideal scintillators utilized in radiation detection have a high atomic number, high density, inert, and have discrete emission behaviors suitable for its end use. Typical non-toxic and high light output scintillators that can be applied in the biomedical field are silicate materials which are synthesized at temperatures above 1000°C; as such the synthesis of sub 100 nm scintillators is a challenge not fully explored yet due to the difficulties from sintering.

Two polymorphs of the $\text{Re}_2\text{Si}_2\text{O}_7$ ($\text{Re} = \text{Y}^{3+}$ or $\text{Lu}^{3+}$) were crystallized at the nanoscale at above 1000°C while remaining monodisperse particulates. A core bishell architecture was used as a physical and chemical template composed of a $\text{SiO}_2$ core and a $\text{Re}_2\text{O}_3$ shell, followed by polymerization of a secondary pDVB shell, on the inorganic core-shell particulate. The organic coating carbonized to amorphous carbon at conventional sintering temperatures preventing particle-particle contact and was easily removed. Furthermore different lanthanide dopants ($\text{Ce}^{3+}$, $\text{Tb}^{3+}$, and $\text{Eu}^{3+}$) were incorporated into the particulates that can couple to different opsins. The sacrificial amorphous carbon process demonstrated control over structure-luminescent properties that can potentially be used for non-invasive optogenetics. The two atypical fields of organic and inorganic chemistry provided complementary abilities that were instrumental into the development of the high temperature nanoreactor and has the potential to be expanded upon to different crystals.
assembly mechanism were also discussed. The laser induced assembly not only demonstrates high positioning accuracy and wide material applicability, but also enables the alignment control of 1D nanomaterials in 3D assembly process. The laser-based strategy opens a route for advanced nano-device fabrication which will benefit numerous emerging fields including 3D electronics, integrated photonics, and MEMS/NEMS.

**From Diffusion Limited to Incorporation Limited Growth of Nanowires** [Jonas Johansson](mailto:Jonas.Johansson@lth.lth.se) and Martin H. Magnusson; Lund University, Sweden

Metal particle catalyzed semiconductor nanowire growth, or vapor-liquid-solid (VLS) growth, is a highly promising route to one-dimensional hierarchical materials. The most common catalyst particle material for III-V nanowires is gold and growth of such nanowires can be carried out in a variety of epitaxy set-ups, such as metal organic vapor phase epitaxy (MOVPE) and molecular beam epitaxy. Aerotaxy is a relatively new growth method that admits growth of nanowires without substrates, directly in the vapor phase at very high growth rates [1].

In this presentation, we propose a model for the length growth rate of nanowires grown by means of the VLS mechanism. Our model is based on deposition-diffusion-desorption-incorporation kinetics in steady state, and using this model we discuss nanowire growth in two experimentally relevant limits: mass transport limited growth and incorporation limited growth. We discuss our modelling results in view of experimental nanowire growth results with a special emphasis on the radius-independent, incorporation limited growth rate in the high pressure limit, observed under specific, extreme conditions of nanowire growth which are reached during aerotaxy growth. Based on diffusion calculations, we find it plausible that these growth rates are indeed the maximum growth rates under the given conditions.

Moreover, in the mass transport limit, our model explains nanowire growth in MOVPE. Specifically, we explain the experimental observations of the V/III ratio dependence of the nanowire growth rate, observed by Soci et al. [2]. According to our model, the higher the group V pressure, the more linearly does the growth rate depend on the group III pressure. In this well-known limit, the growth rate is proportional to the group III pressure and the surface diffusion length of group III material along the nanowire and inversely proportional to the nanowire radius. On the other hand, in the limit of low group V pressures the growth rate becomes independent on group III pressure.

If both the group III and the group V pressures are sufficiently high, the nanowire growth rate is at its maximum and is limited by the incorporation kinetics. In this regime the growth rate depends only on temperature but not on pressures. It might be that some processes operate at unnecessarily high pressures so that significantly decreasing the pressures would not lead to a decrease in the growth rate. Therefore the insights from our modeling not only provide valuable insights in mass transport limited growth, but could also be used to reduce the cost of some processes, where the aerotaxy process is one possible example.

**Hierarchical Pore Gradient Ceramic Foams for Thermal and Acoustic Superinsulation** [Ruizhe Yang](mailto:ruizhe.yang@buffalo.edu) and Shenqiang Ren; University at Buffalo, The State University of New York, United States
Light-weight aerogel materials hold great promise for thermal insulation. However, its low mechanical integrity and high-cost manufacturing hampered its progress for large-scale adoption in energy-efficient building insulations. In addition, it is indispensable for thermal management to achieve more soundproof and heat-resistant characteristics. In this study, we design and synthesize the scalable pore-gradient ceramic aerogel monoliths (PGAeros) through the biomimetic approach. The low-cost manufacturing of PGAeros is further facilitated by the in-situ gas bubble formation to support the pore gradient. The PGAeros exhibit a robust mechanical and thermal stability across a broad temperature range (0.040 W m\(^{-1}\) K\(^{-1}\), and a compressive strength of 100.56 MPa, respectively). The design of thermal regulation in such PGAeros is inherited from the human skin concept, where the pore gradient regulates the thermal management over the seasons. The integral ceramic monolith nature provides such PGAeros with robust soundproof and fire-retardant performance. The demonstration of scalable manufacturing of bio-mimetic inspired ceramic aerogel materials opens up thermal insulation applications with remarkable thermal management, high mechanical strength, low mass density, superior soundproof and fire-retardant performances.

Inverse Design of Colloidal Crystallization with Isotropic Pair Potentials Carl Simon Adorf, James Antonaglia, Julia Dshemuchadse and Sharon C. Glotzer; University of Michigan, United States

Colloidal and nanoparticle systems exhibit novel and unexpected phase behavior including the self-assembly of highly complex crystal structures. The inverse design of pair potential models provides a promising route for the \textit{a priori} approximation of required particle interactions for the targeted self-assembly of unique colloidal crystal structures. State-of-the-art techniques for the optimization of isotropic pair potentials tend toward overfitting, resulting in solutions with many features on different length scales that are challenging to map to mechanistic models. Here, we demonstrate how to effectively steer the optimization of pair interactions toward smooth, simple and possibly realizable solutions by amplifying relevant frequencies within the Fourier spectrum of the pair potential function. The resulting simpler functions should not only be more readily transferable to experiments, but simulated self-assembly pathways are generally also more robust and less prone to vitrification.

2:00 PM FF03.15.03
Ru,W\(_x\)O\(_y\)—A Novel Mixed Transition-Metal Oxide for Energy Storage Applications Sergio H. Domingues and Caroline B. Aquino; Mackenzie Presbyterian University, Brazil

Mixed transition-metal oxides (MTMO) are materials that its structural configuration consists in oxides with two different cations as AxBYOZ (where A and B are transition metals). This arrangement allows a several possibilities of structures and improve properties. The synergistic effect of multiple cations valences can to increase properties like, high conductivity and electrochemical activity, which contribute for uncounted applications, mainly in energy storage devices. Between metal oxides, ruthenium oxide (RuO\(_2\)) has been used, owing excellent electrochemical properties, such as wide electrical potential range, high conductivity and specific capacitance. However RuO\(_2\) shows many disadvantages, it is expensive and toxic, reducing severely its application. An interesting alternative is focused on the combination of RuO\(_2\) with other materials, like metals or oxides, decreasing amount of Ru in the oxide. In this way, we combined ruthenium with tungsten oxide (WO\(_3\)), in order to obtain a novel MTMO. WO\(_3\) is excellent candidate, due his unique properties. The development of novel MTMO structure (RuxWyOz) was based on bottom up strategy, using a modified polyol method, with a triblock polymer (Pluronic 123) as surfactant and different metal chlorides salts as precursors. Different precursors ratios were evaluated in order to obtain the better results. The nanomaterial obtained as characterized by different techniques such as: Raman and energy-dispersive X ray spectroscopy, scanning electron and atomic force microscopy. These analyses ensure the successful of material synthesized and shown the mainly properties of this new MTMO. RuxWyOz thin films were also characterized by electrochemical techniques, exhibiting superior capacitive performance when compared to control samples (RuO\(_2\) and WO\(_3\)). The results show promising application in energy storage field. Authors acknowledges Mackenzie Presbiterian University (UPM), FAPESP (2018/02142-0, 2017/21988-5 and SPEC2012/50259-8), CNPq (403544/2016-5), Materials Chemistry Group (GQM – UFPR), LNNano and INCT of Carbon Nanomaterials.

2:15 PM FF03.15.04
Shadow Boxing with Laser—Laser Damage Resistance of Three-Dimensional Photonic Crystals Lei Pan; Harbin Institute of Technology, China

The laser damage behavior of three-dimensional photonic crystals (3D-PCs) with an opal structure is investigated
using both experimental and simulation methods. Polystyrene (PS) colloidal crystals films with a reflection peak at 1064nm are used as the model material. Disordered films (DF) are fabricated with PS microspheres as contrast samples. The laser-induced damage threshold (LIDT) of 3D-PCs is tested, which is as 2.35 times high as the LIDT of DF. All laser damages are derived from defects in 3D-PCs, implying that the LIDT of ideal 3D-PCs will be significantly increased. The simulation results show that the electric field is contained in the pores of 3D-PCs while it is reduced in the PS microspheres, which may decrease the absorption of laser energy by 3D-PCs. In contrast, the electric field distribution is irregular in DF. Enhanced electric field areas are located in both the pores and microspheres of DF. Considering higher electric field intensity causes more energy absorption and higher temperature, the DF have a lower LIDT. The 3D-PCs structure uses ordered vacancy to contain and strike back laser energy and can increase the LIDT without changing the chemical composition of materials.

2:30 PM FF03.15.05
Robust Self-Assembled Nanofibers from Novel Small Molecule Amphiphiles for Heavy Metal Remediation Ty Christoff-Tempesta, Dae-Yoon Kim and Julia Ortony; Massachusetts Institute of Technology, United States

Traditional small molecule supramolecular assemblies (e.g. in natural systems like lipid membranes or those derived from peptides) generally exhibit high molecular exchange rates, molecular migration, and other dynamic instabilities. These dynamic processes may be beneficial for the application of supramolecular materials in biological environments, but the ability to increase nanostructure stability might provide a path forward for their application in non-biological applications. Here, we present the design of small molecule amphiphiles fabricated with robust intermolecular interactions which self-assemble into ultra-stable supramolecular nanofibers. These nanofibers notably maintain both the self-healing characteristics found in traditional amphiphilic systems and exhibit unique mechanical and thermal stabilities that arise from the tunable intermolecular interaction strengths within each assembly. Taking advantage of the high aspect ratio of these nanomaterials, heavy metal chelators are rationally chosen for expression in high densities on the nanofiber surfaces. We demonstrate the capacity for significant remediation of heavy metals from water using this novel class of materials with orders of magnitude improvement over macroscopic alternatives in use today.

Direct Detection of DNA Using 3D Surface Enhanced Raman Scattering Hotspot Matrix Yongkang Wang, Xiongyu Wu, Shuyu Huang, Chao Wu and Yunfei Chen; Southeast University, China

Direct detection of DNA by surface enhanced Raman spectroscopy has shown great advantages and potentials owing to its ability to provide intrinsic chemical information of DNA molecules themselves with a high sensitivity. However, much small Raman scattering cross section of DNA molecules causes the SERS spectra hard to be collected directly and the SERS spectra were found to be dominated by the vibration of adenine. Although various methods of direct DNA detection by surface enhanced Raman scattering (SERS) have been proposed, more reliable and more stable SERS platform with higher signal-to-noise ratio still requires.

In this study, we propose an evaporative self-assembly strategy for constructing long-life 3D SERS hotspot matrix with the assistance of glycerol to improve the spectral sensitivity and reproducibility in direct DNA detection. Silver nanoparticles (AgNPs) are dispersed in mixed solvents that contain a small amount of non-volatile solvent glycerol and volatile solvent water. Additionally, Mg^{2+} is introduced to the AgNPs colloids to construct the sandwich structure (AgNPs-DNA-AgNPs) between negative charge AgNPs and phosphate backbones through electrostatic interaction. When the droplet is dried on a hydrophobic silicon substrate, water evaporates rapidly and glycerol as a non-volatile solvent creates a liquid environment that can stop the AgNPs colloids turning into the drying state. Both AgNPs and DNA will be concentrated and assembled together to form a 3D AgNPs hotspot matrix at the silicon/glycerol solid-liquid interface. Brownian dynamics simulations reveal that more hotspots turn up in the glycerol-stabilized 3D AgNPs hotspot matrix and the distances between the AgNPs in the liquid environment are not fixed but balanced in a small range by the interplay of the van der Waals attraction and the electrostatic repulsion. Two orders of magnitude extra SERS enhancement, more stable peak frequencies and narrower peak full width at half maximum (FWHM) can therefore be obtained, which enable the direct detection of both single strand DNA (ssDNA) and double strand DNA (dsDNA) with stable, reproducible and reliable signal-to-noise ratio SERS signals. Using the symmetric stretching vibration peak of phosphodioxy (PO2−) at 1087 cm\(^{-1}\) as the intensity internal standard, we are able to quantitatively determine the base content in oligonucleotides with single base sensitivity.
This fascinating evaporative self-assembly strategy opens up a novel perspective in manipulating plasmonic nanoparticles to construct the SERS platforms at solid/liquid interface. Ultrahigh spectral sensitivity and reproducibility of the glycerol-stabilized 3D SERS hotspot matrix would promote the surface enhanced Raman spectroscopy to become a more practical and reliable tool in direct DNA detection and analysis.

3:30 PM FF03.15.07
Circular Polarized Light Sensors Using Cellulose Nanocrystals Self-Assembled Membranes  
Paul Grey, Susete Fernandes, Diana Gaspar, Elvira Fortunato, Rodrigo Martins, Maria Helena Godinho and Luis Pereira; Universidade NOVA de Lisboa, Portugal

Cellulose is ubiquitous in our everyday life from our homes to our offices. Cellulose nanocrystals (CNCs) that can be obtained from different cellulose sources are rod-like nanoparticles with dimensions on the order of a few hundredth nanometer in length and a few nanometers in width. When dispersed in water CNCs behave like a lyotropic liquid-crystal and give rise to either isotropic or anisotropic suspensions. Whereas drying an isotropic suspension (low CNC concentration) yields transparent films, interesting photonic properties (iridescence) can be obtained by drying an anisotropic suspension (CNC concentration > 2 wt%), owing to a twisted ordering on the nanoscale. This ordering is due to an evaporation induced self-assembly process and is referred to as a chiral nematic structure.

In this work we report on the integration of bio-inspired chiral CNC membranes into sensing devices with distinct sensing properties for left- and right-handed circular polarized light (LCPL and RCPL, respectively). The CNC films are employed as photonic dielectrics in oxide thin films transistors and light filters in amorphous silicon photodetectors with the capability of discrimination between LCPL and RCPL signals in the visible region.

3:45 PM FF03.15.08
Fabrication of Plasmonic Multilayer on Cellulose Fibrils Applicable to Versatile Label-Free Diagnostic Platform  
Hyeok Jung Kim, Jiwoo Hyung and Hyeran Noh; Seoul National University of Science and Technology, Korea (the Republic of)

Surface-enhanced Raman Spectrometry (SERS) based on localized surface plasmon resonance can recognize strong Raman signals highly specific to a chemical molecule by great analytical performances. SERS enhancement factor (EF) majorly relies on distribution and density of hotspots regarded as nanoscale gap distances among noble metal nanoparticles; increasing EF necessitates a sophisticated nanostructure, either two-dimensional arrangement or three-dimensional (3D) structuring. Cellulose fibril substrates demonstrate so highly porous network structure that researchers have investigated it for development of cellulose-based SERS platforms. However, the perpendicular distances between the fibrils exceed upon micrometers resulting in low reducibility and EF level. While numerous ensuing researches have attempted to fabricate nanopatterned structures, these methodologies required highly pricey equipment and intricate processes.

Herein, we demonstrate 3D plasmonic nanostructure built on cellulose fibril surfaces using Layer-by-Layer technique. The fabricating procedure consists of steps alternatively dipping a cellulose substrate into each solution respectively containing positively and negatively charged materials; silver nanoparticles were synthesized via in-situ reduction method with capping negatively charged molecules, and a positively charged chitosan derivate oligomer was employed for the fabrication. Structural parameters were deliberately adjusted by the stepwise methodology and changes in chemical reagents concentration. Optical and mechanical traits, and surface chemistry of the substrates were altered with accordance to increasing generations. Transverse routes of analytes were confirmed by morphological studies associated with energy dispersive X-ray spectroscopy mapping. In the analytical application, the SERS substrate demonstrated a gainful performance with bringing about respected EF, limit detection, and reproductivity.

This 3D plasmonic structure was sophisticatedly built on the cellulose microfibrils and revealed profitable functions when applied to SERS analysis. It achieved high reproducibility and sensitivity without engaging complex and costly fabricating procedure. Thus, this Multilayered SERS platform is potentially advantageous for numerous purposes, in particular for point-of-care diagnosis.

4:00 PM FF03.15.09
Synthesis of Bacteriochlorophyll Mimicking Molecule for Disk-Coil Motif Based Self-Assembly  
Eugene N. Cho1, Junwon Choi2 and YongJoo Kim1; 1Korea Advanced Institute of Science and Technology, Korea (the
Light-harvesting complexes in nature consist of disk-coil motifs, a chlorin- or porphyrin centered molecule with functionalized alkyl chain. Of the many light-harvesting complexes, bacteriochlorophyll (Bchl) is of special interest due to its role in particular bacteria living in a low light environment. Bchl is the building block of chlorosome, a large light-harvesting antennae complex that allows the bacteria to harvest energy efficiently from the low-light environment. It is believed that Bchl gives chlorosome such high light-harvesting abilities due to the molecule self-assembling based on bchl-bchl interaction, which differs from chloroplast, the light complex in green plants that self-assembles from chlorophyll-protein interaction. In Bchl, the dominating features that allow the bacteriochlorophyll to form the light harvesting complex are believed to be the metal core of the porphyrin, OH group, and the long alkyl chain. This allows a combination of hydrogen bonds, coordination bonds, and π-π interactions to occur between the disk coil motif which enables assembly into the light-harvesting complex. Hence, studying the self-assembly behavior of disk-coil motifs is essential to reproduce the self-assembled structure of chlorosome that may govern its photosynthetic performances. In this study, we synthesized a disk-coil motif that mimics the bacteriochlorophyll molecule. The disk-coil motif was designed with a porphyrin-based disk that accommodates the key features that are believed to allow bacteriochlorophyll to self-assemble in the confined environment. From this, the self-assembly properties of this structure were studied to understand the self-assembly of disk-coil structures.

Crystal Engineering of Copper Fine Particles Prepared by Solution-Based Strategies Tetsu Yonezawa, Mai T. Nguyen and Hiroki Tsukamoto; Hokkaido University, Japan

This research is devoted for making nanoparticles and fine particles of metallic copper by solution-based strategies.
Gelatin and other polymers can work as stabilizing polymers to keep the particle surface in metallic state. These particles can be used as the materials for the inner electrode of MLCC by using a high-temperature annealing process. But in the field of printed electronics as well as organic electronics, conductive materials for low-temperature sintering are highly demanded.

In this study, crystal engineering and surface engineering was applied for copper fine particles prepared by solution-based strategies. By using polymer-stabilized metallic copper fine particles, and transition metal oxides via solution syntheses that can be scalable for mass production. Our solution-based preparation of copper fine particles was carried out by chemical reduction of CuO micro particles by using hydrazine at alkaline conditions. Because this process is a low temperature process, the particles are consisted of small grains. According to the grain boundary in the copper fine particles, the diffusion of copper atoms becomes higher. Therefore, lower temperature sintering can be carried out with these copper fine particles even the particle sizes bigger than 100 nm. This situation indicates that low temperature sintering cannot be performed only by the melting temperature depression.

More detailed analyses of copper fine particles prepared by solution-based strategies found that the surface of the particles was slightly oxidized. But the structure is not Cu2O or CuO. These slightly oxidized states can be reduced readily in the presence using some reductive organic small molecules and metallic copper surface generates during sintering. Moreover, when oxygen atoms are eliminated from the surface, re-arrangement of copper atoms carries out. This situation also proceeds necking and sintering of the particles.

We discuss in this paper that the strategy of the crystal engineering of copper fine particles for the application of electroconductive materials and dyebonding materials.

9:00 AM FF04.01.02
Fabrication and Optical Properties of Globally Ordered Polymer-Grafted Gold Nanorod Assemblies Jason K. Streit1,2, Kyoungweon Park1,2, Yoon-Jae Yi1,2 and Richard A. Vaia1; 1Air Force Research Laboratory, United States; 2UES, Inc., United States; 3Wright State University, United States

Precise, large-scale assembly of polymer-grafted nanoparticles (PGNs) has shown great promise for the scalable manufacturing of sensors, energy storage devices, and photonic elements. Different than more traditional ligand-coated nanoparticles, PGNs are stabilized by high molecular weight polymers at relatively low grafting densities. In this regard, PGNs are considered soft colloids, possessing the favorable processing properties of polymers while also retaining the ability to pack into ordered nanoparticle assemblies. Using a simple flow-coating technique, we demonstrate that large scale, highly uniform monolayer films of gold-polystyrene nanorods can be fabricated from PGN inks within a few seconds. Applying a combination of atomic force microscopy, scanning electron microscopy, and grazing incidence X-ray scattering, we observe positional and orientational order dependent on coupling between surface energy, process methodology, and the architecture of the grafted polymer canopy. More specifically, we show that globally oriented films possessing two-dimensional orientation parameters greater than 0.7 can be achieved through evaporation induced-assembly when processing at slower deposition velocities on hydrophilic surfaces. Additionally, optical extinction measurements reveal strong plasmonic coupling between the gold nanorods which can systematically be tuned by varying film morphology. With fundamental understanding of structure-processing relationships, we demonstrate polarized optical notch filters using laser-induced reshaping of resonant nanoparticle subpoulations.

Plasmonic and Magnetic Nanoparticles for Biomedical Application Nguyen T. Thanh; University College London, United Kingdom

The development of new chemical methods for the next generation of nanoparticles with very high magnetic moment, fine tuning Au nanorods and novel hybrid and multifunctional nanostructure is presented. Detailed mechanistic studies of their formation by sophisticated and advanced analysis of the nanostructure allows tuning of the physical properties at the nanoscale; these can subsequently be exploited for diagnosis and treatment of various diseases. The studies are conducted to provide insight for future material design approaches. It will also help to identify the critical process parameters that can be manipulated in order to obtain the suitable physical properties for the intended applications.
In collaboration with chemical engineers in designing the reactors in microfluidic systems, this allowed for the first time to detailed study the physical properties such as X-ray diffraction (XRD), magnetic moment and morphology to unravel the particle formation mechanism during co-precipitation synthesis of iron oxide magnetic nanoparticles, which is very important for their robust, reproducible formation process for cancer treatment.

Quantitative Analysis of DNA-Mediated Solution and Surface Reductions on the Formation of Metal Nanocrystals Yiming Wang, Michael Counihan, Jeffrey Lin, Hong Yang, Joaquin Rodriguez-Lopez and Yi Lu; University of Illinois at Urbana-Champaign, United States

Predictive synthesis of metal nanocrystals with desired structures relies on precise control over the reduction pathways of metal ion precursors. Using capping ligand is an effective method to affect the reduction kinetic in nanocrystal formation. However, comprehensive understanding and predictive manipulation of reduction pathways is yet to be achieved by conventional capping ligand. DNA as one of the promising biomolecular capping ligand has been used to generate sequence specific morphologies in varies metal nanocrystals. Taking advantage of the well-defined binding mode between DNA and metal ions, we quantitatively analyzed the precise kinetic control of different DNA sequences over Ag+ reduction process and the relationship between reduction pathways and the structure of resulting nanocrystals. The complexation between DNA and Ag+ was shown to significantly affect the reduction potential of the precursor. The difference in binding equilibrium between DNA sequences and Ag+, as well as the interaction between DNA and the surface of the nanocrystals, synergistically determined the distinguishable Ag+ reduction path-ways with different DNA sequences. The DNA sequence specific control in reduction pathways also results in different mode of nanocrystal formation: layer growth, island growth, and the mixed of two. The discovery from this study demonstrates how rational design of metal-ligand interactions can be used to control precisely the growth kinetics of nanocrystals and the real potentials on using functional DNA sequences for the predictable synthesis of metal nanostructures.

The Solution Chemistry of CdS Pre-Nucleation Clusters Kevin Kittilstved, Fumitoshi Kato and Jillian Denhardt; University of Massachusetts Amherst, United States

The impact of defects on the photophysical and chemical properties of colloidal semiconductor quantum dots (QDs) is dominated by their large surface-to-volume ratios compared to bulk analogs. Understanding the formation mechanism of colloidal QDs is still largely unknown, however, the chemistry of well-defined molecular clusters has
revealed their ability to also serve as suitable pre-nucleation clusters in QD synthesis. This talk will highlight our recent studies in using high-resolution mass spectrometry and other spectroscopic techniques to study the solution chemistry and surface dynamics of a class of cadmium thiophenolate clusters with varying size and nuclearity (from 4 Cd ions to 17 Cd ions). The conversion of the tetrameric clusters to the heptadecameric clusters is complex involving numerous metastable intermediates including octameric and decameric clusters. We will also present synthetic design tools where we exploit this complex conversion chemistry to successfully dope Co(II) and Mn(II) ions into specific sites in the the decameric and heptadecameric clusters, including the core sites with metal sulfide bonds.

10:45 AM FF04.01.06
Silver Chlorobromide Nanocubes—A Class of Reactive Templates for Synthesis of Nanocages Sasitha C. Abeyweera and Yugang Sun; Temple University, United States

Transforming nanostructures into hollow ones represents a unique synthetic strategy for achieving new properties that do not exist in their solid counterparts, boosting applications in a broader range. The chemical nature of the reactive nanostructures (or sacrificial template nanostructures) determines the reaction kinetics of hollowing them along with the transformation of chemical compositions, which influences the controllability of synthesis. For example, uniform silver chlorobromide nanocubes can be used a class of sacrificial template nanostructures to regulate and maintain an extremely low concentration of available Ag⁺ that reacts with different thiol molecules to form silver thiolate with high controllability over the reaction kinetics. Such kinetic controllability enables the transformation of the silver chlorobromide nanocubes to hollow nanocages of silver thiolate. In contrast, the direct reaction of Ag⁺ ions with thiol molecules forms silver thiolate particles with irregular sizes and geometries. Moreover, the sacrificial silver chlorobromide nanocubes expose their surfaces to provide the heterogeneous nucleation sites for condensation of silver thiolate, further improving the controllability to benefit their transformation into hollow nanocages. Due to the improved controllability over reaction kinetics, the process of hollowing silver chlorobromide nanocubes can be terminated at any desired stage to form silver thiolate nanocages with the appropriate wall thickness. Time-dependent electron microscopic, X-ray diffraction, and UV-visible spectrometric studies reveal detailed insights into the structural evolution of crystals in terms of amount and dimensions during the hollowing transformation. This method represents scalable and versatile strategy to control the kinetics of fast reactions involved in the synthesis of colloidal nanoparticles, thus enabling the synthesis of uniform nanocages with desirable parameters. The availability of various silver-based hollow nanostructures provides the opportunity to explore potential interesting properties with real-world applications such as in electrocatalysis and photocatalysis.

Peptide Directed Enantioselective Morphology Evolution Pathways of Chiral Plasmonic Nanoparticles Sang Won Im, Hyo-Yong Ahn, Nam Heon Cho, Hyeohn Kim and Ki Tae Nam; Seoul National University, Korea (the Republic of)

Plasmonic chiral nanostructure has drawn significant attention due to its potential as a novel route for extraordinary optical properties such as negative refractive index and light polarization control. However, achieving chiral nanostructure remains as a challenge because of the complexity and resulting high cost of asymmetric morphology control at nanoscale. Inspired by natural process of chirality interaction between organic and inorganic materials, we reported a new pathway to control chiral morphology of gold nanoparticles. The resulted Helicoid nanoparticles were a new class of three-dimensional free-standing plasmonic chiral nanostructure, which exhibited strong chiroptical behavior such as anisotropic dissymmetry factor of 0.2. The chiral morphologies of Helicoid nanoparticles were further extended by establishing general model of chirality transfer from amino-acid or peptides to gold nanoparticles based on the concept of surface facet development pathway during nanoparticle growth. Asymmetric growth of chiral element is directed by enantioselective adsorption of amino-acids or peptides on high-Miller-index facet of nanoparticle which is formed in the course of particle growth. As the morphologies of nanoparticles are determined by exposed surface facets, we could establish nanoparticle growth pathway on stereographic projection of crystal plane by analyzing series of different surface facets Helicoid nanoparticles undergo. It was revealed that nanoparticle growth pathways not only depends on the types of seed particles and growth solution conditions, but also can be altered by interaction with amino-acids or peptides. The sequences of amino-acids or peptides determine on which step of growth pathway chiral morphologies are developed and which
high-Miller-index facets and final outline of nanoparticle are exposed. Understanding on peptide recognition and crystal growth enables design of diverse chiral morphologies and tailored optical response, and provides insight into further optical modification through coupling with molecular dipoles.

11:15 AM FF04.01.08
Room-Temperature Formation of Colloidal Alloy Semiconductor CdTeSe Magic-Size Clusters in a Single-Ensemble Form Kui Yu; Sichuan University, China

Alloy semiconductor magic-size clusters (MSCs) have been reported rarely, and little is known about their formation pathway. Here, we explored a room-temperature approach to alloy CdTeSe MSC-399, which is labelled according to the peak position of its sharp optical absorption at 399 nm. Also, we investigated its formation pathway. We mixed two binary CdTe and CdSe induction period samples at room temperature; after incubation, the evolution of MSC-399 was detected by optical absorption spectroscopy in toluene. The induction period is the prenucleation stage which occurs prior to nucleation and growth of quantum dots. We argue that substitution reactions take place after the two binary samples are mixed, which result in the formation of CdTeSe MSC-399 from its precursor compound (CdTeSe PC-399). The former is faster than the latter. Furthermore, we demonstrate that the formation of PC-399 is not via anion exchange nor addition reactions. The present study provides a room-temperature avenue to engineering alloy MSCs and an in-depth understanding of their probable formation pathway, making the synthesis less empirical. Given the complexity of the subject, it is impossible to extract complete mechanistic insight from one study. Even so, we believe that the present study is one solid piece, in a very large puzzle. Also, similar to the advance of organic chemistry, the field of colloidal nanocrystals is pressing forward and transforming from an empirical art to science.

Keywords: magic-size clusters, alloy, colloidal semiconductor nanocrystals, prenucleation stage, induction period

11:30 AM FF04.01.09
Impact of Template and Short Molecules on the Growth of Epitaxial Nanocrystal Superlattices Santanu Maiti1,2, Alexander André2, Sonam Maiti2, Martin Hodas2, Maciej Jankowski2, Marcus Scheele2, Stephan Förster1 and Frank Schreiber2; 1Forschungszentrum Jülich, Germany; 2Eberhard Karls Universität Tübingen, Germany; 3European Synchrotron Radiation Facility, France

We investigate the structure and growth of soft epitaxial nanocrystal (NC) superlattices, formed on the surface of designed templates. At first, we prepare template of ordered monolayer superlattice of PbS NCs, coupled with copper tetraaminophthalocyanines (CuTAPc) molecules [1-3]. Afterwards, we deposit as-prepared PbS NCs of different sizes on top of the templates and finally add short ligands on those adlayer assemblies. Here, we determine the structure of the templates and the adlayer NC assemblies by using grazing-incidence small angle x-ray scattering (GISAXS), grazing incidence x-ray diffraction (GIXD) and microscopy [4]. The deposited NCs self-assemble into ordered superstructures (sc, bcc) and show preferred atomic orientation with respect to the templates. After treating with short ligands, the bcc superlattices undergo a notable orientational change from [110]SL to [100]SL. This study provides new insight for designing epitaxial nanostructures of desired crystallographic orientation [5,6].

Growth Mechanism of Colloidal PbSe Nanorods Yiteng Tang1, Liangfeng Sun1, Zhoufeng Jiang2, Chandra P. Neupane1, Haowen Xi3, Randy Ellingson1, Paul J. Roland1, Wenhui Wan4 and Yugui Yao5; 1Bowling Green State University, United States; 2B207 Research Center, China; 3University of Toledo, United States; 4Yanshan University, China; 5Beijing Institute of Technology, China

Oriented attachment of nanoparticles in a colloidal solution is one of the important processes to form larger-scale anisotropic functional nanomaterials. However, the mechanism of oriented attachment is still poorly understood.
Our recent study on the growth of colloidal PbSe nanorods proves that the oriented attachment is driven by the dipole-dipole interaction among the seed quantum dots. The dipole-dipole interaction strength depends on their separation distance as well as their orientations. Hence the one-dimensional oriented attachment can be controlled by the quantum-dot surface capping ligands used as the cosolvent in the synthesis. In particular, changing the length of the surface ligands can significantly change the dipole-dipole interaction strength. We demonstrate that the oriented attachment can be reliably turned on or off during the growth of nanocrystals by choosing the proper length of the surface ligand.

This kinetic-controlled growth of the nanorods prefers low reaction temperatures. Colloidal PbSe nanorods with length > 100 nm and diameter < 4 nm can be synthesized at 110 °C. The as-synthesized PbSe nanorods exhibit a single exponential decay and an absolute photoluminescence quantum yield more than 30%.

Phase Modulation of Single Crystal MOFs through Growth on Self-Assembled Monolayers Marina Solomos, F. James Claire and Thomas J. Kempa; Johns Hopkins University, United States

Metal-organic frameworks (MOFs) are attractive crystalline molecular materials for enabling multifunctional properties in optoelectronic devices. Of particular interest are MOFs whose phases and properties can be dynamically and reversibly switched in response to external stimuli. We identify new MOF topologies prepared through tunable assembly of a modular cluster, Mo2(INA)4, and explore their electronic structures and redox capabilities. Several synthetic innovations allow us to prepare new MOFs from this Mo2(INA)4 cluster, including the use of self-assembled monolayers that template large-area thin film growth, and sacrificial pillaring molecules that control the ordering of two-dimensional (2D) layers within the MOF. This latter 2D phase exhibits anomalous gas adsorption characteristics, redox activity, and a significant photocurrent response. Reversible structural conversion between the multiple topologies is readily accomplished and associated with significant tuning of the MOF electronic properties. These efforts enable the development of sensors and actuators from stimuli-responsive molecular frameworks.

Making New Materials from Molecular and Superatomic Building Blocks Colin Nuckolls; Columbia University, United States

This presentation will describe our research in creating electronic materials from molecular and superatomic building blocks. We are designing crystalline and self-assembled systems from these building blocks. We have created clusters of atoms that behave like the functional equivalent of atoms, but are on the nanoscale. These materials form solid solutions that show drastically enhanced electrical conductivity. Thin films of these materials have low thermal conductivity and point to a new direction to optimize thermoelectric materials. In addition, using this building blocks, we have made new materials with unusual magneto-optical properties.

2:15 PM FF04.02.03
Predicting Material Properties of Superatomic Crystals Using Molecular Dynamics Simulations Matthew Bartnof1, Qi Liang1,2 and Alan J. McGaughey1; 1Carnegie Mellon University, United States; 2Xi'an Jiaotong University, China

The large unit cell compounds Co6E6(PEt3)6 (E = S, Se, Te) and [Co6E6(PEt3)6][C60]2, and C60 are modeled using molecular dynamics simulations to understand how intermolecular and intramolecular interactions affect their macroscopic properties. These compounds are examples of superatomic crystals (SACs), a diverse family of compounds that span the periodic table. To enable study across the spectrum of SACs, the Universal Force Field
(UFF) and the Extended Charge Equilibration (EQEq) scheme are employed. The resulting zero-pressure lattice constants are within 5% of the experimentally measured results and the predicted elastic moduli encompass the experimental value. Unique trends in thermal conductivity are explained by qualitative assessments and quantitative measures of the rotational diffusion coefficient of the C$_{60}$ molecules. Large rotational diffusion coefficients, indicative of freely spinning C$_{60}$ molecules, correspond to temperature-independent thermal conductivities, while librating C$_{60}$ molecules with proportionally small rotational diffusion coefficients correspond to crystal-like thermal conductivities. Finally, equivalent point mass models of the six compounds are generated and used to assess the impact of the C$_{60}$ rotation on thermal conductivity.

2:30 PM FF04.02.04
Towards a Deterministic Pathway for Chiral Shape Formation in Nanocrystals Assaf Ben-Moshe$^{1,2}$, Allesandra Da-Silva$^{3}$, Alexander Mueller$^{2}$, Anas Abu-Odeh$^{2}$, Andrew M. Minor$^{1,2}$, Mark Asta$^{1,2}$, Wolfgang Theis$^{3}$, Peter Ercius$^{3}$ and Paul Alivisatos$^{1,2}$; $^{1}$University of California, Berkeley, United States; $^{2}$Lawrence Berkeley National Laboratory, United States; $^{3}$University of Birmingham, United Kingdom

In a seminal experiment performed in 1848 Louis Pasteur separated the two mirror-images of chiral tartaric acid salt crystals. The chirality of the molecular building blocks manifested itself in the macroscopic shape of the crystals, that exhibited a chiral arrangement of facets. Following this work, many observations of macroscopic shape chirality in crystals followed, and yet relations between molecular scale and overall shape chirality are not well understood. Such understanding is highly desirable for the deterministic synthesis of crystals with chiral shapes. Nanocrystals represent an embryonic stage of crystal growth, and allow direct high spatial and temporal resolution studies of crystal growth mechanisms and the way defects, ligands, impurities and other reaction conditions affect growth. Working with tellurium nanocrystals that exhibit both a chiral crystal structure and a chiral shape, we shed light on a general mechanism that leads materials to exhibit chiral shapes in crystallization. This mechanism has to do with a unique topology of partial dislocations that we believe can be very general in crystal growth reactions. Alongside a fundamental understanding of how chiral shapes might emerge sometimes in crystals we offer design principles to achieve these shapes with control over their handedness, and therefore chiral properties.

2:45 PM FF04.02.05
Cluster Assembly Pathways to Gibbsite Nucleation and Growth Xin Zhang, Ying Chen, Suyun Wang, Jianzhi Hu, Nancy Washton, Sebastian Mergelsberg, Carolyn I. Pearce, Zheming Wang, James J. De Yoreo, Sue Clark and Kevin Rosso; Pacific Northwest National Laboratory, United States

Gibbsite ($\alpha$-Al(OH)$_3$) is an important archetype hydroxide of aluminum in nature that also plays diverse roles across a plethora of industrial applications. In addition, gibbsite is a prominent component of high-level nuclear waste stored in large quantities at the Hanford Site, Washington and at the Savannah River Site, South Carolina, with future processing plans dependent on developing a predictive understanding of its nucleation, growth and transformation in highly alkaline solution. However, mechanisms of gibbsite nucleation and growth remain poorly understood. In this work, magic angle spinning nuclear magnetic resonance (MAS-NMR), scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray absorption spectroscopy (XAS), high resolution powder X-ray diffraction (XRD), and X-ray Pair Distribution Function (PDF) techniques were used to investigate the crystallization of gibbsite from amorphous aluminum hydroxide gel precursors. By focusing on understanding the role of aluminum coordination change dynamics from tetrahedral in solution to octahedral in solids and vice versa, and by quantifying intermediate polyxoaluminate cluster formation, some unifying principles governing these transformations emerge. Furthermore, various advanced techniques reveal the transformation and aggregation of aluminum clusters during the hydrothermal process, which indicate cluster assembly pathways to gibbsite nucleation and growth. These findings are important for developing new methods to morphology and size controlled synthesis of gibbsite, and may aid in the design of chemical processes for managing the aluminum inventory in nuclear waste.

New Chemistry for Emerging Properties of Super Atomic Solids Jingjing Yang$^1$, Jake C. Russell$^1$, Songsheng Tao$^1$, Boyuan Zhang$^1$, Alexander D. Christodoulides$^2$, Qizhi Xu$^1$, Samuel Peurifoy$^1$, Amirali Zangiabadi$^1$, Evan A.
Superatomic solids are an emerging class of functional materials assembled from atomically precise clusters. Attributing to the unique properties of constituent clusters and their collective communications, superatomic solids show intriguing electronic, magnetic, and thermal properties. Previously, the assembly of atomically precise metal chalcogenide clusters combined with fullerenes resulted in electroactive superatomic crystals with high electrical conductivities up to 0.6 S/m. Here in this presentation, I would like to introduce two new chemistries for the superatomic solids that bring greatly enhanced or previously unattainable properties to this class of materials. Our first chemistry demonstrates solid solutions at the cluster level, namely superatomic solid solutions. We have mixed two metal chalcogenide clusters with similar sizes, Co₆Se₈(PEt₃)₆ and Cr₆Te₈(PEt₃)₆, with fullerene C₆₀ and demonstrate that the resultant superatomic solids maintain the structure of the original single component but with tunable cluster ratios [Co₆Se₈(PEt₃)₆]ₓ[Cr₆Te₈(PEt₃)₆]₁₋ₓ[C₆₀]ₓ (x = 0~1). We found that the superatomic solid solutions show up to 100 times enhanced electrical conductivities as well as tunable electrical and magnetic properties. Our second chemistry aims to explore the feasibility of integrating superatomic solids in devices. One key merit is the solution-processability of these materials, unfortunately, superatomic solids tend to be crystals due to the strong electrostatic interactions between the positive and negative charged clusters. Here, we show how to endow solution-processability to superatomic solids by frustrating the strong electrostatic interactions. By grafting flexible side chains to the clusters, we show that their crystallization tendency could be fully inhibited and they can be solution-processed into homogenous and amorphous thin films with arbitrary compositions that are not achievable in crystals ([Co₆Se₈(PPr₃)₆][PCBM]ₙ (x=2,3,4,5,7,9)). We then show these thin films possess high optical transparency of up to 92%, up to thousands of times higher electrical conductivities of up to 300 S m⁻¹ and several times lower thermal conductivities as low as 0.05 W m⁻¹ K⁻¹ compared to crystalline superatomic materials, as such, they are promising as solution-processable transparent conductors and thermoelectric materials (ZT=0.02 at RT).

3:45 PM FF04.02.07
Shaping Single Crystals at Low Reynolds Number
Semih Sevim, Carlos Franco, David Rodriguez San Migue, Alessandro Sorrenti and Josep Puigmarti-Luis; ETH Zurich, Switzerland

Self-assembly processes have a key role in the bottom-up fabrication of supramolecular structures and advanced functional materials. Traditionally, the control over non-covalent synthesis has relied on tailoring the building blocks for recognition and interaction, while targeting the global minimum of the free energy landscape (thermodynamic control). Recently, however, there is a growing interest in nonequilibrium approaches and methods that can potentially engender an improved spatio-temporal control over molecular self-assembly (kinetic control). Living systems, for example, master reaction-diffusion (RD) processes to finely tune the self-assembly of individual components in space and time leading to materials with structure and functions of remarkable complexity. In this communication, we will show how the unique physical conditions offered by microfluidic environments (e.g. laminar flow regime, mixing only through molecular diffusion, fine-tuning of the reactant gradients) facilitate an improved kinetic control over self-assembly, as well as they help to unveil the pathways underlying the formation of self-assembled materials. In particular, we will demonstrate how by using continuous flow microfluidic devices we have been able to isolate kinetically trapped crystal states of a coordination polymer (CP) (a result that leads to unprecedented materials’ properties), to enhance chiral induction in a supramolecular polymer, to uncover different crystallization pathways undertaken by a metal-organic framework (MOF) towards its thermodynamic product, as well as to shape MOF crystals at the millimeter length scale.

4:00 PM FF04.02.08
Reprogramming Granular Self-Assembly with the Control of Dynamic Boundaries
Utku Culha⁴, Zoey S. Davidson¹, Massimo Mastrangeli² and Metin Sitti¹; ¹Max-Planck Institute for Intelligent Systems, Germany; ²Delft University of Technology, Netherlands

Functional and complex structures can be generated during the self-assembly process via local interactions among a large set of simpler components. The ability to program the self-assembly of components enables novel bottom-up control strategies for multi-particle active systems, fabrication methods for functional materials, and exploration of fundamental physics. However, reprogramming requires multi-stability, and reversible selection of self-assembling
particle patterns which remains a challenge. We demonstrate the statistical reprogramming of two-dimensional, porous self-assembled structures by isothermal quenching of millimetric, orbitally-shaken, and magnetically repulsive particles. We select among a finite set of self-assembled patterns repeatably and reversibly by controlling the rate of change of the boundary volume. We report the transition from fluid- to solid-like states of driven granular particles during quenching to realize out-of-equilibrium self-assembly. With this method, we demonstrate the reprogrammable stiffness of granular self-assemblies. This work can extend to the tuning of mechanical, optical and electromagnetic properties of functional materials that depend on the spatial configuration of their components. The particles in the current work are morphologically and functionally symmetric; however the introduction of particle anisotropy may allow the programming of additional functionalities of the self-assembled structures.

4:15 PM FF04.02.09
An Inverse Pourbaix Approach to Predictive Hydrothermal Synthesis Wen Hao Sun1,2 and Gerbrand Ceder2; 1University of Michigan – Ann Arbor, United States; 2Lawrence Berkeley National Labs, United States

Pourbaix (E-pH) diagrams are often used to guide the hydrothermal synthesis of transition metal oxides. However, non-equilibrium oxide phases often precipitate from aqueous solution, which are difficult to anticipate from equilibrium Pourbaix diagrams. Here, we construct a theoretical framework to reveal the nanoscale and metastable energy landscapes of Pourbaix diagrams, providing quantitative insights into the size-dependent thermodynamics of metastable oxide nucleation and growth in water. We show that a thermodynamic analysis that takes into account these additional thermodynamic regimes can successfully capture which metastable MnO2 polymorphs appear during hydrothermal synthesis, and the order of their appearance. We further extend our theoretical framework to address the ‘inverse’ stability question for hydrothermal synthesis. That is, rather than plotting Pourbaix diagrams under varying solution conditions to search for a stable phase, can we instead solve for solution conditions where a target phase is stable? We demonstrate this ‘inverse’ formalism by computing the aqueous stability conditions for the relatively soluble compound LiFePO4, as a function of [Li], [Fe], [P], E, and pH.

4:30 PM FF04.02.10
Single Crystals from Solution at Room Temperature via Assembly and Epitaxy of Nanocubes Harshal Agrawal1, Biplab K. Patra1, Thomas Altantzis2, Annick De Backer2 and Erik Garnett1; 1AMOLF, Netherlands; 2University of Antwerp, Belgium

Additive manufacturing has enabled low cost, large area, and solution-based processing. Moreover, it is also possible to assemble full-scale working devices with quantum dots (QDs) as the active layer. Small fundamental building blocks (<100 nm) in the form of nanocrystals offer the unique flexibility to assemble crystals in complex shapes realizing novel functional properties via bottom-up assembly. In this work, we demonstrate the assembly of nanocubes capped with polyvinylpyrrolidone (PVP) into arbitrary patterns including curves of varying radii of curvature. We use polydimethylsiloxane (PDMS) as the flexible template to directly print and pattern the cubes at the same time on the substrate from a colloidal solution. Subsequently, we remove the ligands or use epitaxial overgrowth to convert them into single crystals. The effect of angular misalignment between adjacent cubes and the resulting crystallinity of the welded structure was investigated with high-resolution transmission electron microscopy (HRTEM). We demonstrate that single crystalline interfaces can form which are strain-free and without dislocations. The technique proposed enables room temperature fabrication of patterned single crystalline materials which makes it compatible with low heat resistant flexible polymeric substrates and roll to roll processing to enable next-generation optoelectronic devices.

4:45 PM FF04.02.11
Designed 3D Crystalline Organizations of Nano-Objects with Addressable Bonds Brian Minevich1, Jason Kahn1, Aaron Michelson1,2 and Oleg Gang1,2; 1Columbia University, United States; 2Brookhaven National Laboratory, United States

There have been significant advances in the field of self-assembly of functional, nanoscale materials into periodic
2D and 3D arrays. A number of strategies have been demonstrated for the crystallization of these materials using complementary DNA shells or other linking motifs. However, most notable methods are system-specific, dominated by particle shape, and remain challenging to obtain multiple lattices using a single set of particles. Instead, a more broadly accessible strategy for the assembly of crystalline organizations with programmable nanoscale features can be achieved using well defined DNA constructs integrated with nano-objects. Each of the integrated units can self-assemble in solution into periodic arrays, and can be probed in-situ by Small Angle X-ray Scattering (SAXS). The symmetry of the resulting crystalline assemblies is determined by the unit geometry and the pairwise DNA bonds. Due to the sequence specific nature of DNA, it is possible to encode unique bonds at these specified sites. The addressability of the inter-frame bonds provides the foundation for encoding multiple crystallographic organizations through specific sets of pair-wise bonds. We show that this strategy allows for the design and assembly of complex designed nanoscale architectures, including an analog of a perovskite’s structure, multiscale organizations, and chiral crystals.

Solution-Crystalized Large-Area Organic Semiconductor Films and High-Performance Organic Circuits Jun Takeya; The University of Tokyo, Japan

Electronic devices in the future sustainable societies require maximum function with minimum amount of constituent materials and energy cost for production. Electronic functions are often originated from two-dimensional material properties so that device components of large area and small thickness saves material consumption. The fundamental electronic functions such as switching “zero” and “one” in the digit of information are governed only by a nanometer-scale thin layer at the very surface of the semiconductor material due to the very short penetration length of electric field. Future ten-meter scale large-area display also needs to be more “two-dimensional” to save materials and save energies to carry and equip on billboards.

This presentation focuses on recently developed ultrathin organic semiconductor single crystalline films that is suitable for large-area production with low energy consumption; the films is easily formed to large area from solution at relatively low temperature at 80 degrees centigrade. Extremely thin crystal films are controllably grown to a-few molecular layers with the thickness of only 10 nm, so that material cost can be only 0.01 USD per cm2. The talk begins with material chemistry of designing the semiconductor molecules that causes very high carrier mobility more than 10 cm2/Vs. Furthermore, Recent development of key technologies for printed integrated circuits which can provide future low-cost platforms for RFID tags and sensing circuitries. Finally, a technology for large-area light-weight display sheets will be demonstrated.

Such prospect bears increasing reality because of recent research innovations in the field of material chemistry, charge transport physics, and solution processes of printable organic semiconductors. With excellent chemical and thermal stability in recently developed new materials, we are developing simple integrated devices based on CMOS using p-type and n-type printed organic FETs. Particularly important are new processing technologies for continuous growth of the organic single-crystalline semiconductor “wafers” from solution and for lithographical patterning of semiconductors and metal electrodes. Successful rectification and identification are demonstrated at 13.56 MHz with printed organic CMOS circuits.

8:30 AM *FF04.03.02
Motion-Programmed Bar-Coating Approach for Fabricating Highly Ordered and Oriented Organic Semiconductor Thin Films Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Solution-processed organic thin-film transistors (OTFTs) have received enormous interest due to their great potential for realizing low-cost, lightweight and flexible electronics applications, such as displays, wearable sensors and electronic skins. Although several novel solution-processing techniques for achieving highly-crystalline organic
Thin film transistors (TFTs) are essential building blocks in a variety of electronic devices, and play important roles in transmitting electronic information. Generally, the sequential deposition of each component such as a semiconductor layer, an insulator layer, and contact electrodes is required in TFT fabrication processes. In order to achieve high performance devices, it is necessary to control the interface between these layers, which makes the device fabrication process complicated. This difficulty is even more crucial in the case of organic TFTs (OTFTs), which are promising building blocks in printed electronic devices thanks to the soluble nature of organic semiconductors (OSCs). By utilizing the solution process, single-crystal thin films of OSCs composed of only a few molecular layers can be obtained with large areal coverage[1]. However, to obtain perfect single crystal, conditions of underlayers need to be precisely controlled. So far, there have been strict limitation on candidates for underlayers of OSCs. For example, they must satisfy the requirements such as heat tolerance, organic solvent durability and surface energy. In this study, we demonstrate water exfoliation to obtain self-standing thin films of solution-processed single-crystal OSC thin film. Furthermore, the developed transfer method allows the facile integration of OSC layer of OTFTs.

A single-crystal thin film of the analogs of our benchmarked material[2], 3,11-dinonyldinaphtho[2,3-d:2′,3′-d′]benzo[1,2-b:4,5-b′]dithiophene (C9–DNBDT–NW), was grown via continuous edge-casting method[3] on a freshly cleaved piece of natural mica. Then, the C9–DNBDT–NW/mica was carefully immersed in water. In only a few seconds, the C9–DNBDT–NW thin film was peeled off from mica substrate. The preservation of original single crystallinity during this step was confirmed by transmission electron microscope measurements. The successful exfoliation of an OSC thin film from a mica substrate can be attributed to the difference in the surface energy. C9–DNBDT–NW has a highly hydrophobic alkyl chain that stands perpendicular to the substrate, which gives a high contact angle of water of 108°, while a freshly cleaved mica has a super hydrophilic surface as indicated by a contact angle of 3°. The large difference in the surface energy allows water to infiltrate between the interface of OSC and mica.

In order to employ the exfoliated single-crystal OSC thin film as an active semiconductor layer in OTFTs, a transfer technique was developed. First, the super hydrophobic substrate on which the OSC thin film was fabricated was mounted on the destination substrate. Then, a few droplets of water were applied near the edge of the template substrate, which promotes an exfoliation of OSC thin film from the template substrate and results in perfect transfer to the destination substrate. The present transfer technique allows a wide usage for the underlayers of OSC layer. As representative examples, we demonstrated fabrication of OTFTs on (i) a highly hydrophobic surface (fluorinated polymer coated substrate), and (ii) a substrate with low thermal stability and solvent resistance (commercially available food wrap). The fabricated OTFT showed remarkably high electronic performance with a mobility up to 12 cm² V⁻¹ s⁻¹. We also demonstrated the deposition of large-area OSC thin films of 3 cm × 3 cm, which shows the scalability of the present technique. All of 100 OTFTs fabricated with photolithography process showed transistor operation with a high mobility of 10 cm² V⁻¹ s⁻¹. These results represent that the water exfoliation and the transfer method developed in this study enable an ideal production of OTFTs in printed electronic devices.

High Speed Real Time Single Droplet Analysis to Improve Spray Pyrolysis Deposition Process
Jonas Köhling, Kavish Tyagi and Veit Wagner; Jacobs University Bremen, Germany

Spray pyrolysis is a cheap, scalable process for deposition of thin functional layers that can be used in electronic or optic applications. Temperature is one of the crucial parameters that influence the properties of the thin layer. Deposition properties change around the Leidenfrost temperature where smoother films are obtained at higher temperatures. Leidenfrost temperature depends mainly on the solvent and the substrate. Other deposition parameters like the droplet lifetime, droplet movement and evaporation rate are usually neglected.

In this work we follow a new real time approach to determine the microscopic properties and the interaction of small droplets (smaller than 80 µm) on hot surfaces on a timescale below 1 ms. A uniform distribution of small droplets are produced by an ultrasonic atomizer and transported by an inert carrier gas onto the temperature controlled substrate. The behavior of the droplets at the surface is monitored by a high speed camera with up to 10,000 frames per second. Droplet properties are automatically extracted by a computer algorithm and statistically analyzed. For time-dependent properties the droplets are being automatically tracked on the surface. The findings enable to obtain physical parameters of the droplets during their lifetime. Furthermore, they help to optimize parameters of the spray pyrolysis deposition process, e.g. for thin film zinc oxide deposition used in thin film transistors.

Eliminating the Aging Effect in Organic Semiconductor Thin-Film Transistors
Jing Wan, Yang Li, Randall Headrick, Adam C. Whalley and Jonathan Hollin; University of Vermont, United States

The pen-writer solution deposition method is used to deposit 2,7-dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT) organic semiconductor thin films and also polymer dielectric layers. The performance of top-contact bottom-gate C8-BTBT transistor is found to improve with time in ambient air, which is consistent with passivation of shallow traps during exposure to air. In addition, severe non-ohmic injection and large contact resistance resulted from gold penetration during the evaporation process are observed with these top-contact transistors. This aging effect can be eliminated in the bottom-contact geometry when gold was deposited first without the penetration issue and contact resistance was reduced an order of magnitude by treating the gold electrode with pentafluorobenzethiol (PFBT). An optimized geometry is obtained by using pen-written Cytop™ dielectric in a top-gate bottom-contact structure, which exhibits a near-intrinsic average saturation mobility of 4.73 cm²/V-s with C8-BTBT thin films deposited at high writing speed (25mm/s) and contact resistance down to 5.52*10² W.cm. We will report temperature-dependent carrier transport results for the high mobility C8-BTBT top gate transistors.

9:45 AM FF04.03.06
Understanding of Structure-Property Relationship Enables Blade-Coated Amorphous In2O3 Thin-Film Transistors at Low Temperatures
Ahmad R. Kirmani, Emily F. Roe and Lee Richter; National Institute of Standards and Technology, United States

Metal oxide thin-film transistors (MOTFTs) are expected to play a vital role in enabling printed transparent and flexible electronics, given their excellent charge transport, wide bandgaps and solution processability. Compatibility with plastic electronics, however, strictly requires MOTFTs to be processed at low temperatures in a scalable fashion, a necessity that has so far been a challenge. Herein, we explore blade-coating of indium oxide (In2O3) TFTs via sol-gel and combustion chemistries using 2-methoxyethanol (MeOEt) as the processing solvent. Blade coating is an established prototyping technique for slot-die coating. We find that the sol-gel chemistry enables amorphous In2O3 TFTs annealed at 200°C with moderate electronic mobility (ca. 1 cm²V⁻¹s⁻¹). Subtle increase in annealing temperature to 212°C preserves the amorphous state whilst increasing the mobility (ca. 5 cm²V⁻¹s⁻¹). Films coated using combustion synthesis are found to bypass the electronically-active amorphous state leading to an early onset of crystallization. This behavior is expected given the lowered nucleation barrier thanks to the added fuel in the combustion ink. Paradoxically, blade-coated combustion TFTs are found to possess poor charge transport at low temperatures of 200-250°C. Small-angle X-ray scattering evidence suggests that early nucleation during combustion leads to formation of nanocrystalline domains that are deleterious to charge transport. Our results highlight that surprisingly it is not crystallization, rather the absence of it that is required to fabricate high-mobility, low-temperature In2O3 FETs using blade coating.

Solution-Processed High Temperature Organic Semiconductors and Devices Jianguo Mei; Purdue University, United States

High-temperature operation (i.e., beyond 150°C) is of great interest for many electronics applications. To achieve charge transport characteristics for organic semiconductors at elevated temperatures is fundamentally challenging. We report a general strategy to make thermally stable high-temperature semiconducting polymer blends, composed of interpenetrating semicrystalline conjugated polymers and high glass-transition temperature insulating matrices. When optimized, such polymer blends can display a temperature-insensitive charge transport behaviors. Further, We employ polyimide substrates, polyimide dielectrics, and a polyimide-based semiconducting blend to achieve flexible and thermally-robust transistors. An in situ temperature-dependent charge transport study was used to demonstrate that these devices can operate in extremely high temperatures and can sustain prolonged baking. Our devices maintained stable charge-transport characteristics with charge mobilities of 0.20 cm²/V s, ION/IOFF of 10⁴, threshold voltage of 3 V, and operational voltage of 10 V when baked at 195 °C for 2 h.

11:00 AM FF04.03.08
Femtoliter Meniscus-Guided Crystallization for 3D Printing Mojun Chen, Jihyuk Yang and Ji Tae Kim; The University of Hong Kong, Hong Kong

3D printing, one of the most disruptive technologies to emerge in recent years, has attracted increasing attention due to its potential impact on science, industry, and society. Winning high-quality materials is one of the most important challenges in modern 3D printing technology. To this end, beyond exterior shaping, 3D printing techniques that can also engineer crystallinity or molecular orientation are in a great demand. Here, we have developed a new method to incorporate solution-mediated crystallization into nanoscale 3D printing. The key idea is to exploit a femtoliter solution meniscus formed on a nanopipette to guide evaporation-induced crystallization in mid-air. Evaporative loss of solvent rapidly creates a supersaturated concentration field of solutes inside the femtoliter meniscus, leading to the nucleation and growth of nanocrystals. Furthermore, omnidirectional guiding of the meniscus with moving the nanopipette realizes freeform 3D nanostructures with excellent crystallinity. By employing this method, we have successfully demonstrated nanoscale 3D printing of two promising material systems: (1) organic-inorganic metal halide perovskites and (2) self-assembled peptides. In this talk, we will present the theoretical and experimental results including examples of 3D printed crystalline structures and discuss prospects of our work for potential applications in electronics and optoelectronics.

11:15 AM FF04.03.09
Controlled Synthesis and Transport of Micro- and Nanostructured Thin Films Using Microreactor-Assisted Nanomaterial Deposition Process Chih-Hung Chang, Zhongwei Gao and Yujing Zhang; Oregon State University, United States

Microreactor-Assisted Nanomaterial Deposition (MAND) process combines the merits of microreaction technology and solution phase synthesis of nanomaterials. This technique uses continuous flow microreactors for the synthesis, assembly and deposition of nanomaterials. MAND processes control the heat transfer, mass transfer and reaction kinetics using well-defined microstructures of the active unit reactor cell that can be replicated to produce higher chemical production volumes. This important feature opens a promising avenue in developing scalable nanomanufacturing. Furthermore, the continuous flow microreactor opens up the opportunity to conveniently assemble unique nanostructures and nanostructured thin films. In this presentation, we will report our recent progress in using continuous microreactors to achieve controlled synthesis and transport of reactive building blocks for the fabrication of micro- and nanostructured thin films of inorganic compound semiconductors such as metal oxides and metal chalcogenides and organic-inorganic hybrid materials like metal organic frameworks along with the applications of these functional materials.

Nickel-Rich Cathode Material Synthesized by Flame Spray Pyrolysis Yujia Liang, Jinhup Han, Kyojin Ku, Eungje Lee and Joseph Libera; Argonne National Laboratory, United States
Process scaling-up is an essential step to apply laboratory innovations into mass-manufacturing. Unfortunately, the small scale of laboratory synthetic routes makes them difficult to be scaled-up due to the significant difference of transport phenomena between the two scales and the resultant kinetics dilemma during scaling up. Development of the scalable process is a promising strategy to address that issue. Among those scalable processes, the ones based on aerosol science and technology are intrinsically easier to be scaled-up by simply increase the feed solution concentration or reduce the residence time. The product morphology, composition, and crystallinity can be designed a priori. Currently, three aerosol processes, spray pyrolysis, spray drying, and flame spray pyrolysis, are widely used to fabricate metals, composites, and oxides.

To meet the demands of the US Department of Energy (DOE) on the high energy density battery materials and large scale synthesizing, Argonne National Laboratory has built a state-of-art facility based on flame spray pyrolysis. Feed solutions containing salts are continuously atomized and fed into self-supported flame. Particle formation by gas-to-particle route is completed within milliseconds. A scalable process has been developed to manufacture nickel-rich cathode materials at a scale of 20 g/h. The synthesized materials displayed excellent battery performance in terms of cycling stability and rate performance. This solution-based synthetic strategy is a promising method to tackle the bottleneck of increasing production rate.

Flexible Thermochromic Smart Films by IPL Sintering of VO₂ Nanoparticle Ink Kwang-Seok Kim, Siwhan Lee, Ji Won Youn and Dae Up Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Large-area fabrication of vanadium dioxide (VO₂) on polymeric substrates has been a great challenge to manufacture the flexible thermochromic smart films which control the influx of radiant heat transfer by attaching to pre-installed windows. These smart window films are promising for applications in building windows and automotive glasses to improve the energy efficiency. However, the formation of VO₂ layer on flexible substrates has been rarely reported due to the high temperatures of VO₂ growth process. Herein, we demonstrate the fabrication of VO₂ layers from hydrothermal synthesized VO₂ nanoparticle ink using multi-step intense pulsed light (IPL) sintering. IPL irradiation rapidly triggers the evaporation of organic vehicles and the formation larger VO₂ clusters, and improves significantly the crystallinity and thermochromic performance of VO₂ granular films. These films exhibit visible light transmittance of 65.7%, excellent infrared modulation at 2000 nm of 43.8%, and salient solar modulation efficiency of over 12%. IPL sintering of VO₂ nanoparticles effectively enhances the crystallinity and stoichiometry of VO₂ layers on a polyethylen terephthalate substrate. It is believed that the proposed strategy provides new insight into the manufacturing of flexible thermochromatic smart films for energy saving.

SESSION FF04.04: Solution Processed Inorganic and Hybrid Semiconductors

Changing the Dimensions of Organic Metal Halide Semiconductors Michael L. Chabinyc; University of California, Santa Barbara, United States

Hybrid organic metal halides, such as CH₃NH₃PbI₃, have garnered significant attention because they are earth-abundant, solution-processable materials that can be used to form solar cells with high power conversion efficiency (>20%). Despite their high performance in lab-based devices, there are significant questions about the phase behavior of these materials and their resulting properties. For example, an interesting feature of these compounds is the ability to form layered Ruddlesden-Popper phases with quantum confinement by introduction of mixed organic cations. We will present our work on understanding the electronic properties of 3D and 2D Pb- and Bi-based systems. The microstructure of thin films of layered Ruddlesden-Popper compounds, (CH₃(CH₂)₃NH₃)n(CH₃NH₃)ₙ₋₁PbI₃n₋₁⁺ (n = 1, 2, 3, 4) suggests that they are not phase pure with varying composition depending on the growth conditions used. While these compounds are structurally disordered, apparent from quantitative analysis of grazing incidence X-ray scattering and electron microscopy, they surprisingly still have sharp band edges. Recent results on the optoelectronic properties of these materials will be discussed.
Lead halide-based perovskite nanocrystals are promising as optoelectronic materials for their easy tunable optical range, high absorption coefficient and photoluminescence quantum yield and solution processible preparation. However, ionic properties of the halide-based perovskite nanocrystals have a stability problem against humidity, heat, and long-term light irradiation. Especially the perovskite nanocrystals consisting of iodide as anion, which have larger ionic radius and lower electronegativity than chloride and bromide, show low crystalline phase stability and photoluminescence quantum yield without any surface post treatments. In order to enhance the stability of the materials and also tune the optical range up to near infrared region, it is necessary to introduce elements with low ionic radius and high electronegativity

Herein we report new perovskite nanocrystals substituted with the lead cation with iso-valent tin cations which have low ionic radius and high electronegativity for high stability issue. The tin cation can control the distortion of the metal halide octahedron and make the strong bond with iodide in nanocrystals. To control the activity of two different metal cations and enhance the stability of the nanocrystals, we use phosphine as a functional group of base ligands rather than alkyl amine ligands. Considering the pKa of the conjugate acid of the phosphine and amine as Brønsted bases, the phosphine is weaker Brønsted base than amine. And phosphine ligands are expected to have lower reaction constant for the acid-base reaction with oleic acid which is used for acid ligands for synthesis of perovskite nanocrystals. This results in the tuning the reaction between the oleate and metal cation to change the activity of the metal cation. Therefore, base ligands having phosphine as a head group are used to finely control the activity of the metal cation via acid-base reaction with acid ligands.

This results demonstrate that the acid-base reaction between ligands should be considered to control the activity of the precursor of the nanocrystals. Furthermore, the phosphine ligands as base ligands can control the activity of two different metal cations to mediate the growth of the alloyed perovskite nanocrystals via acid-base reaction. It is highly expected that the stable Pb-Sn alloyed iodide perovskite nanocrystals can be useful for various optoelectronic applications in the near future.

Reference:

Hybrid organic-inorganic perovskites have been of paramount interest for solution-processible solar cells, reaching photon conversion efficiencies larger than 23%. We will study in detail the effect of different processing routes, including use of different coating and annealing methods, antisolvent drip, as well as mixtures of organic cations, halogen anions, and metal cation additives. We have performed in-situ time-resolved x-ray scattering experiments during processing, that provide detailed information about the emergence and disappearance of different crystalline phases, and how these affect the final film morphology. Our method allows us to assess, how different material composition and processing conditions influence the crystallization process and we can correlate these findings with the resulting photon conversion efficiency of the films.

Mechanisms Study of Meniscus-Guided Perovskite Deposition for Photovoltaics Devices Xiaoyu Deng, Stephanie Guthrie, Luke Huelsenbeck, Gaurav Giri and Joshua Choi; University of Virginia, United States

In order to realize scalable fabrication of perovskite optoelectronic devices, large area deposition techniques such as solution shearing must be realized and perfected. However, the mechanisms of fabrication processes are still not well studied in different solution shearing regimes. By monitoring the precursor species during crystallization process using In-situ Grazing Incidence Wide-Angle X-ray Scattering, the crystallization process in low shearing speed meniscus regime is proven to happen under lower supersaturation. The low supersaturation contributes to the bigger crystal size of thin film while high speed shearing results in thin films with small size crystals. Photodetectors with perovskite thin films coated at low shearing speed meniscus regime show much higher internal quantum efficiency because of the larger crystal domain size and uniform orientation inside of domains. This shows continuing study and rational design of the crystallization process is needed to push perovskite technology toward useful applications.

Size-Dependent Phase Stability and Optical Properties of CsPbX₃ (X = Br, I) Nanocrystals Ruoxi Yang and Liang Z. Tan; Lawrence Berkeley National Laboratory, United States

Cesium lead halide perovskites are promising candidates for photovoltaic and light-emitting diode applications. Bulk CsPbX₃ however, are structurally unstable, transforming into an orthorhombic phase at room temperature. Improved thermal stability can be achieved in nanocrystal form with stability and optoelectronic properties dependent on the size of the nanocrystal.

Using first-principles calculations, we investigate phase stability and optoelectronic changes as a function of varying nanocrystal size. The stabilization of the CsPbI₃ cubic phase against the orthorhombic phase at nanocrystal dimensions of a few nanometers is explained by the competition between short-range bond formation and long-range electrostatic forces. We demonstrate lattice constants and band gap scaling behavior with nanocrystal size, explaining discrepancies between experiments and simple quantum confinement models previously proposed.

We also show that superlattices of CsPbBr₃ nanocrystals preserve the photoluminescence signature of the constituent nanocrystals, while undergoing structural changes that give rise to new photoluminescence peaks. With
multi-scale modeling, we predict the rate of these changes and simulate their optical properties.

Room Temperature Synthesis, Self-Assembly and Anion Exchange of Nano to Micron Scale Lead Chalcogenide Particles  
**Swapnil D. Deshmukh, Kyle Weideman and Rakesh Agrawal; Purdue University, United States**

Lead chalcogenides are one of the important class of semiconducting materials. PbS and PbSe have shown promising performance in the field of photovoltaic devices when synthesized in the form of quantum dots with power conversion efficiencies exceeding 11% while PbSe and PbTe in the pure and alloyed form are one of the best performing thermoelectric materials with the figure of merit (zT) greater than 2. These materials promise further scope in performance improvement by introducing controlled nano-structuring of material for device fabrication which is realized via solution chemistry.

In this work, we have synthesized lead chalcogenide materials via solution processing route at ambient reaction conditions using lead halide and pure chalcogen precursors. Unlike traditional syntheses routes, we have demonstrated phase pure, carbonaceous impurity free particle synthesis using a highly volatile organic mixture of amine and thiol. For these syntheses, we have observed instantaneous reactions with simultaneous self-assembly yielding nano to micron scale structures from PbS nanoparticles. These assembly sizes were further controlled such that the desired quantum confinement yielding specific optical bandgap of PbS nanoparticles is achieved in sub-micron structures. Similar controlled nano to micron scale structures for PbSe and PbTe materials were also synthesized and then studied using cross-sectional FIB milling and TEM/STEM analysis to understand the different interiors in the structures. Along with the size of the structures, the morphology and shape of the structures were also manipulated giving highly faceted cubic structures in addition to original spherical assemblies.

Similar to morphological evolution, compositional variation was also achieved at room temperature using this new solution route. Homogeneous alloys of PbSSe in the form of nanoparticles and self-assemblies were obtained via reaction and room temperature anion exchange strategy respectively. This alloy formation approach was further extended in the case of PbSeTe material where a homogeneity in alloy formation was realized by gradual diffusion of chalcogens in the structure as a function of heat treatment.

4:30 PM *FF04.04.09
Solution Processing of Metal-Halide Perovskite Films—Insight from In Situ X-Ray Diffraction  
**Michael F. Toney; SLAC National Accelerator Laboratory, United States**

Hybrid organic-inorganic metal-halide perovskites have excited the photovoltaic community due to their high light to power conversion efficiencies. One surprising aspect of HOIPs is that they are synthesized with solution processing and under mild conditions (e.g., 100°C annealing). Understanding the role of processing on crystallization pathways of HOIPs can provide insight into developing new processing strategies. In this talk I will show our recent results on the HOIP formation mechanisms during solution processing. We have investigated the film formation of Cs-FA-containing perovskites during in situ spin coating, blade coating, and the subsequent thermal annealing using X-ray scattering. Different processing approaches such as anti-solvent [chlorobenzene (CB)] and compressed-gas N2 treatments were applied during film casting. I will show how these different processing routes affect the competition between the formation of the non-perovskite δ-phase and perovskite α-phase during film formation and subsequent annealing. I will also discuss the formation of MAPbI3 films from the single-step deposition of lead chloride and three equivalents of methylammonium iodide (PbCl2 + 3(CH3NH3I)). We use X-ray scattering and absorption to determine the film formation mechanisms, revealing the importance of a self-regulating mechanism that slows the film growth. This work provides insight into optimizing processing conditions and realizing enhanced optoelectronic properties in HOIPs.
**FF04.05.01**

**Monitoring Solid State Reactions at the Nanoscale in Binary Nanocrystal Superlattices to Access Tunable Multinary Metal Oxides** Chethana Janardhana Gadiyar and Raffaella Buonsanti; Ecole polytechnique fédérale de Lausanne, Switzerland

Multinary metal oxides (MO) are the key active materials in a range of energy applications, from batteries to fuel cells, from water oxidation catalysts to light absorbing photoanodes for artificial photosynthesis. The synthesis of compositionally homogenous and morphologically-controlled films is crucial to understand how composition and structural parameters impact performance.

Here, we discuss our work on using colloidal nanocrystals (NCs) as nanoscale precursors to access tunable multinary MOs of interest as light absorbers for water splitting. We have already demonstrated that copper vanadates with variable grain size can be obtained when reacting copper NCs of different sizes with a molecular vanadium precursor.[1] By reacting two NC seeds (Cu +WO₃) with a molecular vanadium precursor, Cu₂V₂O₇/WO₃ heterostructures were also synthesized, thus increasing the level of complexity achievable by our NC-seeded growth.[2] To further advance the understanding of the solid state reactions occurring between NCs, we are now taking advantage of the formation of ordered binary NC superlattices.[3] The idea is to use in-situ electron microscopy to monitor the transformation of CuO NCs and Fe₂O₃ NCs towards copper ferrites.[4] We show that Fe₂O₃-Cu NC in AlB₂ and NaCl superlattices can be obtained by properly tuning the NC size, ligand shell and solvents. We use a combination of electron microscopy techniques together with elemental compositional mapping and X-ray techniques, like GIWAXS and GISAXS, to study the growth of compositionally homogenous copper ferrite from the reaction of the two components in the superlattice. We believe that this knowledge can guide the development of a general synthesis procedure for achieving ternary MO films with tunable composition and morphology.

**FF04.05.02**

**Tuning the Synthesis of Platinum–Copper Nanoparticles with a Hollow Core and Porous Shell for the Selective Hydrogenation of Furfural to Furfuryl Alcohol** Shuangshuang Huang; Wuhan University, China

In this work, we report the synthesis of Pt–Cu nanoparticles with hollow core and porous shell based on self-assembly of ultrasmall particles. At the initial stage, Pt–Cu cage frames with porous outermost shells were formed. These pores on the shells served as tunnels to afford getting across by residual Pt and Cu ions in the solution. These Pt and Cu ions then mostly deposited on the inside shells to thicken the width of the shells, leading to the smaller dimension of the hollow core. By carefully governing the reaction conditions, the thickness of the shell and the size of the hollow core could be precisely tuned. Furthermore, we compared the catalytic performance of Pt–Cu nanoparticles with hollow-core structures and Pt–Cu nanoparticles without a hollow-core structure for the selective hydrogenation of furfural to furfuryl alcohol. It is found that the Pt–Cu nanoparticles with a hollow-core structure exhibited an over 4-fold increase in catalytic activity, compared to Pt–Cu nanoparticles without a hollow-core structure. In particular, these Pt–Cu with hollow-core nanoparticles achieved almost 100% selectivity toward furfuryl alcohol, which cannot be obtained using bimetallic Pt–Cu nanoparticles without hollow-core structure.

**FF04.05.03**

**Decreasing Structural Disorder of ZrO₂ Nanocrystal by Ligand Exchange—A PDF and Theoretical Analysis** Edson R. Leite¹,², Içamira C. Nogueira³, Adalberto Fazzio¹, Gabriel Schleder³, Gustavo Azevedo⁴ and Querem Rebelo³; ¹Centro Nacional de Pesquisa em Energia e Materiais, Brazil; ²Federal University de Sao Carlos, Brazil; ³Federal University of Amazonas, Brazil; ⁴Centro Nacional de Pesquisa em Materiais e Energia, Brazil; ⁵Federal University of Western Para, Brazil

In this work, we report the synthesis of Pt–Cu nanoparticles with hollow core and porous shell based on self-assembly of ultrasmall particles. At the initial stage, Pt–Cu cage frames with porous outermost shells were formed. These pores on the shells served as tunnels to afford getting across by residual Pt and Cu ions in the solution. These Pt and Cu ions then mostly deposited on the inside shells to thicken the width of the shells, leading to the smaller dimension of the hollow core. By carefully governing the reaction conditions, the thickness of the shell and the size of the hollow core could be precisely tuned. Furthermore, we compared the catalytic performance of Pt–Cu nanoparticles with hollow-core structures and Pt–Cu nanoparticles without a hollow-core structure for the selective hydrogenation of furfural to furfuryl alcohol. It is found that the Pt–Cu nanoparticles with a hollow-core structure exhibited an over 4-fold increase in catalytic activity, compared to Pt–Cu nanoparticles without a hollow-core structure. In particular, these Pt–Cu with hollow-core nanoparticles achieved almost 100% selectivity toward furfuryl alcohol, which cannot be obtained using bimetallic Pt–Cu nanoparticles without hollow-core structure.
Nanocrystals (NCs) present unique physicochemical properties arising from their size and the presence of ligands. Comprehending and controlling the ligand–crystal interactions as well as the ligand exchange process is one of the central themes in NC science nowadays. However, the relationship between NC structural disorder and the ligand exchange effect in the NC atomic structure is not yet sufficiently understood. Here we combine pair distribution function analysis (PDF) from electron diffraction data (ED), extended X-ray absorption fine structure (EXAFS), and high-resolution transmission electron microscopy (HRTEM) as experimental techniques and first-principles density functional theory (DFT) calculations to elucidate the ligand exchange effects in the ZrO$_2$ NC structure. In our work, we have demonstrated that the combination of advanced characterization techniques (EXAFS and PDF from ED) with theoretical DFT calculations is a powerful tool to reveal the nature of NC structures. We presented the unprecedented result that the ligand exchange process causes a decrease in the static structural disorder of the ZrO$_2$ NCs, mainly due to strain rearrangement caused by solvothermal treatment at elevated temperatures and not due to the type of functional organic group (R) present in the X$_2$- type ligand. These results have a direct impact on NCs manipulation processes involving ligands, properties associated with their structural disorder degree, and the development of functional nanomaterials, especially for functionalities where the structural disorder located on the surface plays an important role in the physicochemical properties, such as in mechanical, photoluminescence, electronic transport, and catalytic properties.

FF04.05.04
Understanding the Electrochemically Mediated Growth of Crystalline III-V Semiconductors Using InAs as a Platform Yorick Bleijii, Marco Valenti, Mark Aarts, Loreta A. Muscarella and Esther Alarcon-Llado; AMOLF, Netherlands

III-V semiconductors have promising composition and size dependent optoelectronic properties for a variety of applications in nanophotonics and high speed electronic devices. Due to their increasing demand, large-scale production of the III-V semiconductors is required. New growth techniques have been proposed to tackle the resource- and energy-intensive techniques which are currently used. One of the proposed techniques is electrochemical mediated crystal growth, which has already been demonstrated for the III-V semiconductor growth at ambient conditions. One advantage of using electrochemical mediated growth is the possibility of controlling the crystal growth with the applied potential.

In this work, we assess via Raman spectroscopy the voltage effects on crystal quality in InAs grown at ambient conditions directly onto Indium foils. We find that the average crystal correlation size is not affected by using more cathodic potentials up to a critical potential. Beyond that critical value, the average correlation length decreases, following the phonon confinement model. This decrease can be explained by an increase in the nanostructured roughness and or porosity of the grown InAs crystals. Gas evolution of hydrogen and or arsenic and the overgrowth of As can induce this nanostructured roughness and or porosity. Therefore, we find that the crystal structure of the electrochemically grown InAs can be modified with applied potential, giving rise to the possibility to fine-tune optoelectronic properties at ambient conditions.

FF04.05.05
Excimer Laser Annealing of Sol-Gel Metal-Oxide Thin Films Christina Koutsiaki, Nikolaos Kalfagiannis and Demosthenes Koutsogeorgis; Nottingham Trent University, United Kingdom

Over the last decade, the transition from conventional vacuum based thin film deposition techniques to solution processes has remarkably empowered the evolution of a novel manufacturing scheme that involves state-of-the-art applications, such as flexible and high-performance electronics. Besides time and cost-efficiency included in their major advantages, solution processes additionally present an outstanding compatibility with a plethora of materials; small molecules, polymers and colloids, to name a few. Amongst them, metal oxides (MOs) constitute an attractive research field, as their significantly enhanced optoelectronic properties, concomitantly with high optical transparency and mechanical stability render them as highly promising, especially in delivering trend-of-the-future applications (e.g. IoT) into high throughput manufacturing.

“Sol-gel” is established as one of the currently favorable solution processes, as it uniquely links metal oxides to solution processing. This deposition of organometallic precursors via wet techniques, followed by a subsequent thermal treatment, prevails the formation of high quality, uniform and homogenous metal oxide thin films. Nevertheless, considering its demanding high processing temperatures (>250 °C), this post-deposition treatment remains challenging, as it constitutes a major obstacle that hinders the integration of temperature-sensitive materials.
(plastic) and thus large-scale manufacturing. Therefore, a breakthrough method of converting as-deposited organometallic precursors into uniform MO thin films with tunable morphological and chemical structure is essential.

A radically new idea for the processing of metal oxides is the implementation of a combination of solution-processing and laser annealing techniques. These methods marry two important attributes that are currently absent from the existing state-of-the-art commercial technologies, namely scalable manufacturing and high temperature annealing via ultra-fast laser post-processing. Because of the temporal nature of the laser-annealing step (typically nanoseconds), efficient conversion of the printed metal oxide precursor can be achieved even when the layer is deposited atop temperature-sensitive substrates such as plastic. There is currently no other method that combines these two highly attractive attributes while being compatible with existing manufacturing processes.

The applicability of this approach has already been demonstrated [S. Dellis et al. J. Mater. Chem. C] by the successful In(NO₃)₃ conversion into high quality In₂O₃ thin films, leading to the realization of high performance (μ>13 cm²/Vs) Thin Film Transistors (TFTs). We now expand the method to a pallet of metal-oxides of different opto-electronic nature (conductors, semiconductors and dielectrics) in an effort to develop a platform for a new era of metal-oxide based printable and flexible devices, on the route towards mass production of modern electronics. In particular, an extensive study regarding the optoelectronic response of three highly promising metal oxides such as ITO, In₂O₃ and Al₂O₃ after laser annealing is presented, shedding light onto the precise mechanism under which the photochemical conversion of their organometallic precursors occurs. Optical, structural and electrical behavior of the above-mentioned thin films will be reported, including their implementation in TFT manufacturing.

FF04.05.06
Residual Stress Reduction in the SiC Crystal Grown via Top Seeded Solution Growth Method Yunji Shin, Si-Young Bae, Myung-Hyun Lee and Seong-Min Jeong; Korea Institute of Ceramic Engineering and Technology (KICET), Korea (the Republic of)

During the last two decades, silicon carbide (SiC) has been widely studied for power electronics application because of its superior physical and chemical properties especially under high power and high frequency. For the reliable performance of SiC devices, control of the crystal quality related to polytype, defect density and residual stress, are very important. Thus, both thermodynamic and kinetic factors must be considered during SiC growth process. Despite the big advancement in SiC technologies, there still remain some open questions. For instance, the fabrication of high quality SiC wafers is still topical, because the commercialized crystal growing technique, physical vapor transport (PVT) method, could not easily grow high quality SiC crystal. As an alternative method growing SiC crystal, top seeded solution growth (TSSG) method has recently studied by many researchers. This method has a big advantage growing SiC crystal at low temperature and a big potential getting a high quality SiC crystal with low dislocation density. However, the thermal stress, which is the most important issue in TSSG, still exists without a key solution. During TSSG process over 1900°C, a seed crystal always experiences an abrupt temperature change when it reached the melt surface. Consequently, residual stress could remain after crystal growth, which brings about the deformation or the crack of the crystals in the subsequent processes. The melt droplet, which is often observed on the as-grown surface after process due to the surface tension, was benefited to reduce the residual stress locally but resulted in the generation of micropipes. Therefore, it is even more problematic in epitaxy growth and device performance.

Note that such stress is mostly caused by the differences in the thermal expansion coefficients between graphite and SiC material. Thus we consider that some kind of buffer layer would be helpful to reduce the thermoelastic stress. In the present study, we will discuss the recent progress on TSSG method for growing SiC crystal from the basic to the recent progress focused on the thermoelastic stress relaxation on the entire grown surface.

FF04.05.07
Intense Pulse Light Sintering Mechanism of Solution-Processed Indium-Tin-Oxide Thin Film Inyoung Kim; Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of)

Solution-processed metal oxide films have shown stunning properties of high charge carrier mobility, high electrical conductivity, large dielectric constants, or optical transparency in the application of flexible solar cells, thin film transistors, light emitting devices and various sensors. However, their high annealing temperatures are still incompatible with flexible polymeric substrates even though various chemical approaches have been studied to reduce the annealing temperature. In this study, we adopted intense pulse light sintering for solution-processed indium tin oxide films instead of thermal annealing. Multi-pulses of intense light consisting of 5 on/off pulses for 2
ms were repeatedly irradiated on the films. The electrical sheet resistance of indium tin oxide film decreased effectively as the pulse number increased. However, the decreased sheet resistance tended to return back before the microstructure of film was stabilized. After the full densification, the sheet resistance did not change again, and the solution-processed indium tin oxide film showed a sheet resistance of 95 Ω/sq and a high optical transparency of 98 %. The intense pulse changed the chemical organization of oxide bonding from M-OH to oxygen deficient M-O-M structure, which was a critical factor to complete the photonic sintering of metal oxide films.

**Self-Assembly of Quantum Dot Gold Heterostructural Nanocrystals into Orientational Ordered Superlattices**

Hua Zhu1, Zhaochuan Fan2, Yasutaka Nagaoka1, Dennis Eggert3,4, Yuzi Liu4, Ruipeng Li5, Zhongwu Wang5, Michael Gruenwald2 and Ou Chen1; 1Brown University, United States; 2University of Utah, United States; 3Heinrich Petter Institute-Leibniz Institute for Experimental Virology, Germany; 4Max Planck Institute for the Structure and Dynamics of Matter, Germany; 5Argonne National Laboratory, United States; 6National Synchrotron Light Source II, Brookhaven National Laboratory, United States; 7Cornell High Energy Synchrotron Source, United States

The self-assembly of nanocrystals into ordered superlattices is a powerful strategy for the production of functional nanomaterials. While much progress has been made assembling nanocrystals with homogeneous composition into superlattices with novel structures and properties, high-quality multicomponent nanocrystals and their ordered assemblies are rarely reported. Besides, controlling the orientations of nanocrystals in superlattices also remains a challenge. Here, we combine experiments with computer simulations to study the self-assembly of two unique quantum dot–gold (QD-Au) heterostructural nanocrystals (HNCs), namely heterodimers and satellites. Assembly of the heterodimers results in a superlattice with long-range orientational alignment of dimers while the assembly of satellites results in a close-packed superlattice with pronounced orientational orders. Molecular dynamics simulations of a coarse-grained model suggest that anisotropic interactions between the QD and Au is responsible for superlattice formation. We also demonstrate experimentally that the degree and type of orientational alignment can be controlled by changing ligand populations. This study provides guidance for the design and fabrication of nanocrystal superlattices with enhanced structural control and potential optoelectronic properties.

**Crystal Engineering of Chromium Molybdate Cluster Coordinated with Lanthanides as Potential Photoluminescence Materials**

Arunachalam Ramanan and Shilabh Tewari; Indian Institute of Technology Delhi, India

Lanthanide ion-based coordination solids are majorly sought after for their distinctive optical properties’ applications in OLEDs, lasers and sensors. Recent trends include incorporating suitable ligands to increase the quantum efficiency of parity forbidden f-f transitions through synergetic effects while simultaneously preventing the coordination of solvent molecules that can quench emissive processes. In our work, we employed the well-known Anderson-Evans cluster, \([\text{CrMo}_6\text{O}_{24}]^{n-}\), a molecular cluster, that exhibits ruby–like red emission and its optically inactive analogue, \([\text{AlMo}_6\text{O}_{24}]^{n+}\), as inorganic ligands to coordinate with optically active lanthanide ions (Ln=Sm, Eu, Tb, Dy). We have successfully synthesized the whole series of closely related structures with the general composition, \([\text{Ln(OH)}_2]_3\{X(\text{OH})_6\text{Mo}_6\text{O}_{24}\}\cdot n\text{H}_2\text{O}\) with varying dimensionality; the difference in supramolecular aggregation of the same set of molecular species appears to depend on the size of the lanthanide ions. Photophysical properties were dominated by Ruby-like emission in chromium analogues while characteristic emissions of lanthanide ions were observed in the aluminium counterparts. Our results strongly suggest a possible energy transfer between lanthanide ions to chromium levels resulting in the quenching of lanthanide emission in lanthanide coordinated chromium molybdates. We have also succeeded in preparing new analogues wherein more than one lanthanide ions are present in the same crystal as well as hybrid inorganic-organic solids based on these molecular building blocks. The structural features of the system change when a competing organic ligand is added to it leading to another series of photoluminescent materials. In this talk, we discuss the structural landscape, stability and photoluminescent behaviour of all the materials with an emphasis on structure-property correlation.

**Surface Conversion Growth of ZnO@ZIF-8 Core-Shell Nanowires and Their Application as Water Splitting Photoanode**

Alejandro G. Galan, Andrew Gallant, Del Atkinson and Dagou Zeze; Durham University, United Kingdom

Surface conversion growth of ZnO@ZIF-8 core-shell nanowires and their application as water splitting photoanode
The evolution of nanomaterials over the last few decades has prompted widespread research on their integration into a range of applications resulting from their outstanding physical, optical and electric properties. Nanowires (NWs) have been at forefront of these developments due to the variety of semiconductor materials, highly controllable growth coupled with the large surface to volume ratio and the high aspect ratio. ZnO in particular is highly researched due to its wide band gap (3.37 eV) and high exciton binding energy (60 meV) that confers interesting piezoelectric and optoelectronic properties. In recent years, research interest in metal-organic frameworks (MOFs) has developed rapidly. MOFs are a zeolite-like nanomaterial that have been extensively studied due to their remarkably high surface area, enabling catalytic and gas storage properties. MOFs are reticular nanomaterials formed by transition metal cations coordinated by multidentate organic linkers. This combination results in a crystalline material with a flexible structure. Among the many existent MOF families, the zeolitic imidazolate frameworks (ZIF) are one of the most researched because of their exceptional thermal and chemical stability. ZIF-8 is a standout MOF comprised of zinc as transition metal nuclei and imidazolate linkers as the coordinating agent.

Here, these different forms of nanoscale materials prompted the idea for synergetic combination to create novel nanocomposite materials that exploit the individual outstanding properties, in this case for ultimate application in hydrogen production. In this work, the idea is the realisation of the integration of ZnO NWs and ZIF-8 to form a core-shell structure in which ZnO is the core and ZIF-8 is the shell around it (ZnO@ZIF-8) via a low-cost and fast production processes. A two-step wet-chemistry process is used to grow the ZnO NWs: first, a thin ZnO seed layer is deposited using atomic layer deposition. Then, the sample is introduced in a solution containing the Zn precursor and a hydroxide source. The shell is grown by means of surface conversion of the ZnO NWs. For this, we introduce a novel method based on spin coating. A methanol solution containing the imidazole linker is spin coated on top of the NWs and, afterwards, the sample is heated above the melting point of the imidazole so the surface reaction with the ZnO NWs can take placing, thus using the ZnO NWs as sacrificial pattern to grow the ZIF-8 shell. The cheap and easy route to grow the core-shell structure through this process is remarkable, especially considering that the most commonly used alternative is a hydrothermal growth that requires the use of a pressure vessel, water/dimethylformamide mixtures and long reaction times. In our case, only few droplets of a methanol solution are required to obtain comparable results.

This work presents the structural analysis and the optoelectronic characterisation of these nanocomposite materials and aims to show the first results using ZnO@ZIF-8 structures as a photoanode for the photoelectrocatalytic (PEC) water splitting of water. Electron microscopy and x-ray analysis are used to study the structure of the NWs and the core-shell structure, while voltammetry and optical methods are sued to study the optoelectronic properties. Different NW and shell growth conditions are compared to demonstrate the control over the growth of the NWs and the MOF shell in relation the long-range homogeneity and shell thickness. It is shown that the shell thickness is a critical factor that can directly influence the performance of the photoanode by controlling the electrolyte diffusion time to the ZnO NW core. The effectiveness of the core-shell structure as photoanode is compared to as-grown ZnO NWs. The PEC tests also show that the presence of the shell in the core-shell structure passivates the surface states of the ZnO core, improving its stability over time, and protecting it from photocorrosion.

*Au-Pt-Pd Radially-Assembled Nanospheres as Multi-Functional SERS Sensors for Rapid Detection of Pesticides Residues* Yu-Cheng Chu, Fang-Ching Chang, Jing-Wen Huang and Chun-Hua Chen; National Chiao Tung University, Taiwan

In this work, a series of novel Au-Pt-Pd ternary self-assembled porous nanospheres with featured building segments and radially distributed composition have been successfully synthesized via a facial solution approach with tri-block copolymer F127 as soft templates and applied as surface enhanced Raman scattering (SERS) chemical sensors for identifying trace amount of pesticides. Based on our previously developed techniques used for synthesizing Pt-Pd binary self-assembled nanoparticles arrays[1], in this work, to further enhance the SERS performance, Au was mainly selected and has been successfully introduced as the third active component to form the Au-Pt-Pd ternary self-assembled porous nanospheres. By adjusting the amounts of the Au precursors and F127, two unique presentative Au-Pt-Pd nanospheres respectively with spherical-like and petal-like building segments were achieved. The decoration of tiny Au nanoparticles on the surface layer of the preformed Pt-Pd nanospheres could effectively enhance the SERS hot spots via increasing coupling modes for generating large local electromagnetic fields without crushing the specialized, transparent porous architectures. The liquid penetrable copolymer networks in the synthesized Au-Pt-Pd nanospheres could effectively enhance the ability to absorb target molecules and the
consequent SERS performance. Also, the extremely uniform dimension and morphology of the synthesized Au-Pt-Pd nanospheres are essential for having steady SRES signals. It was found that the petal-like Au-Pt-Pd nanospheres exhibit a lower limitation approaching 50 ppb in detecting malachite green oxalate (MGO) and show promising potential in sensing pesticides such as thiabendazole directly on apple skins. The unique architectures as well as the active chemical composition of the present ternary Au-Pt-Pd nanospheres improve the molecular detection limitation and also show high potential for practical applications in the fields of biochemistry, chemical analysis, food safety and environmental monitoring.

FF04.05.12
Rapid Synthesis of Copper Nanowires with High Aspect Ratios in Ascorbic Acid Aqueous Solution Hiroki Oikawa, Shun Yokoyama, Kenichi Motomiya and Hideyuki Takahashi; Tohoku University, Japan

Many efforts have been made to produce low cost, flexible and high performance transparent conductive materials, replacing high cost, brittle and high performance Indium tin oxide (ITO) films. Cu nanowires (NWs) with high aspect ratios are promising materials as an alternative to ITO because of their high performance, low cost and flexibility. To take the lower limitation, the process of Cu NWs synthesis is required to be low-cost and environmentally-friendly. Cu NWs are usually synthesized via chemical reduction as this method often requires high temperature, high pressure, organic solvent and toxic reagent\(^1\), resulting in high cost. Recently, we have developed a low-cost and environmentally-friendly synthesis method in which aqueous copper complexes are reduced to Cu NWs by using ascorbic acid in acidic region near room temperature under atmosphere. Cu atoms were produced by reduction of the Cu complexes using ascorbic acid, forming decahedral Cu seeds. Subsequently, PVP bound to the newly formed (100) planes of the seeds rather than the (111) planes, and Cu atoms were continuously deposited on the (111) facets along the [110] direction, leading to the Cu NW synthesis\(^2\). It is noted that the particle size depends strongly on the driving force for the reduction. As ascorbic acid is a mild reducing agent, the driving force is smaller than that of commonly employed reducing agents. As a result, Cu seeds become larger, leading to low aspect ratios. Besides, the small driving force caused long reaction time (48 hours or more), limiting practical use of Cu NWs. The rapid synthesis of Cu NWs with high aspect ratios requires large driving force. In this study, we reported the rapid synthesis of Cu NWs with high aspect ratios based on the environmentally-friendly method. The driving force is the difference between the half-cell reactions potential of ascorbic acid and Cu complex. The redox potential of ascorbic acid changed depending on pH, enhancing the driving force in alkali region. In addition, easily reducible Cu complexes also increase the driving force. Thus, we precisely controlled pH values in the synthesis and changed Cu complexes to increase the reduction potential, leading to Cu NWs with high aspect ratios in short reaction time (1h). Detailed results and discussion will be introduced in our presentation. Part of this work has been supported by the Grant-in-Aid for Scientific Research (B) (18H03416)

Synthesis of Ga-Doped ZnO Nanocrystals Using Esterification Reaction for High-Performance Transparent Conductive Films Takuya Endo, Shun Yokoyama, Kenichi Motomiya and Hideyuki Takahashi; Tohoku University, Japan

Transparent conductive films are currently used in various optical devices such as solar cells and smartphones. Indium tin oxide (ITO) is widely used as a high performance transparent conductive film, but it is toxic and expensive rare metal. Fabrications of ITO layer on substrates usually require a sputtering system with high material loss and high vacuum environment. Metal doped ZnO nanocrystals are promising materials as an alternative to ITO because of its low cost, high transparency and low resistivity. Besides, metal doped ZnO film can be fabricated on substrates by sintering metal doped ZnO nanocrystals without material loss and high vacuum environment. In order to make high-performance ZnO transparent conductive film, ligand on crystal surfaces and crystal size controls are needed to facilitate the sintering to become bulk ZnO at low temperatures. In addition, precise metal doping is required to optimize carrier concentration and mobility in ZnO for high conductivity. These control methods about
ZnO nanocrystal have been studied using thermal decomposition method as a typical synthesis method[1]. As the synthesis method often requires high reaction temperatures and toxic reagents, we developed the synthesis of ZnO nanocrystals via esterification reaction between zinc carboxylate and alcohols at low temperature. In this study, we changed surface ligands and crystal size of ZnO nanocrystal synthesized from the esterification method[2]. We precisely controlled the amount of Ga doping into ZnO. Finally, we fabricated Ga-doped ZnO films and discuss the effect of ligand, crystal size and Ga doping on performances of the film. In the esterification between zinc oleate and oleyl alcohol, oleic acid remained on ZnO nanocrystal. Low molecular zinc carboxylates and alcohols were used to change surface ligand from oleic acid to low molecular carboxylic acids. Although low molecular carboxylic acids also work as a surface ligand, the steric hindrance of the carboxylic acid modified ZnO nanocrystals decreased, leading to bigger nanocrystals. The size was decreased by decreasing the amount of zinc carboxylate to prevent nucleus growth. The sintering of low molecular carboxylic acid modified ZnO nanocrystals with small size were facilitated at low temperatures. Metal carboxylates react with alcohols to form M-OH species with the ester, and then H2O molecule is dehydrated by condensation to form a metal oxide. When a different element is doped, two different M-OH species formed with the ester react to form M-O-M1-OH species, and then H2O molecule is dehydrated, finally produces the doped metal oxide. The amount of Ga doping into ZnO were precisely controlled by changing the amount of Ga carboxylate. We will present details of these controls and performance of ZnO conductive films.

Overcoming the Charge Carrier Mobility Limitation of Inorganic p-Channel Thin-Film Transistors
Seonjeong Lee, Hanju Lee, Yena Ji and Kihyon Hong; Chungnam National University, Korea (the Republic of)

P-channel thin film transistors (TFTs) are essential components of complementary circuits, displays and flexible electronics. However, development of high performance p-channel TFTs has been delayed due to the charge carrier accumulation, large effective mass/low conductivity of semiconductor, and device optimization issues. Although tremendous efforts have been devoted to improve the device performance, the field effect mobility of p-channel TFTs still remained 0.01 ~ 5 cm²/Vs.

Recently, Electrolyte gated transistors (EGTs) have attracted attention for switching devices due to their low operating voltage and great device performance. We have employed EGT structure into p-channel TFTs to improve the electrical performance of devices. During the operation, EGT form high capacitance (> 1 uf/cm²) electrical double layer (EDL) and 3-dimensional hole transport channel. Thus, the huge amounts of charge carriers can be accumulated in the channel region and we can expect realization of the high performance p-channel TFTs. Using this EGT structure, we successfully demonstrated p-channel TFTs with ultra-high mobility exceeding 100 cm²/Vs and low operating voltage of ~ 0.5 V. As a semiconductor, copper iodide (CuI) was employed due to its small effective hole mass and high Hall mobility. For electrolyte gating, polymer electrolyte was used as a gate insulator. All the fabrication processes were conducted by low temperature (< 100 °C), solution process. We also examined the electrical and mechanical stability of CuI-TFTs. Finally, we demonstrated complementary inverters by the combination of CuI- and ZnO-TFTs and the circuits exhibited low operation voltage (0.7 V) and high voltage gain value of 18.

FF04.05.15
High-Performance, Solution Processed Vertical Thin-Film Transistors with p-Type CuSCN Semiconductor
Yena Ji, Hanju Lee, Seonjeong Lee and Kihyon Hong; Chungnam National University, Korea (the Republic of)

Copper(I) thiocyanate (CuSCN) has wide optical band gap (Eg = 3.5 ~ 3.9 eV), making it transparent in the optical spectrum, high charge carrier mobility, and solution processability. Due to these advantages, it has been used as a p-type semiconductor in thin film transistors (TFTs) and hole transport materials in organic/inorganic solar cells. Especially, high Hall mobility (10 ~ 70 cm²/Vs) of CuSCN allows for the possibility of realization of high performance p-channel TFTs. However, previously reported CuSCN-TFTs showed low field effect mobility in the range of 0.01 ~ 0.5 /Vs. This low mobility might be originated from the hole accumulation issue, non-stoichiometry of CuSCN and charge carrier scattering effect in the channel regions.
In this work, to realize high mobility CuSCN-TFTs, we introduced vertical structure and chlorine doping method. For vertical structured TFTs, the channel length (L) is defined as the thickness of CuSCN film. Comparing to the conventional planar structure, the L can be reduced from the several tens of micrometers to nanometer scale. Thus, employing vertical structure can minimize the charge carrier scattering effect in the channel region and our device exhibited high mobility about 3 /Vs with low operation voltage of 1V. This mobility value is 10 times higher than those of TFTs with conventional planar structure. To more improve the device performance, we doped SnCl into CuSCN. Our XPS and UPS analysis revealed that by the doping of SnCl, the Cl induces additional p-type doping effect with formation of acceptor states. The work function of material increased by 0.20 eV and the mobility of device also increased up to 4.13 cm²/Vs. Using this high performance CuSCN-TFTs, we could successfully demonstrate resistor-loaded inverters. The inverter was completely switched with in 1V of V_in variation. The dynamic response of the inverter was measured and it worked well at 500 Hz without a large rise-fall delay.

**Electrically Annealed and Densified Solution-Deposited Piezoelectric Thin Films** Rajinder S. Deol, Nitika Batra, Pranjal Rai, Henam Sylvia Devi, Bhaskar Mitra and Madhusudan Singh; Indian Institute of Technology Delhi, India

Sensors and actuators in various industrial, lab and environmental monitoring applications often require deposition of piezoelectric thin films like lead zirconium titanate (PZT). Such films require deposition temperatures (~600°C), are incompatible with traditional silicon-based foundries, and the high temperatures of deposition present unique process challenges. In recent years, several new classes of piezoelectric films such as sputtered lead-free potassium sodium niobate (KNN) and AlN have been developed. In the former case, owing to the differential response of potassium and sodium to needed annealing steps, and the result stoichiometric shifts near the (K:Na)=50:50 morphotropic phase boundary and the high temperature of annealing (~ 600-800°C) has created challenges to widespread adoption of KNN. In contrast, sol-gel based methods coupled with simple deposition methods such as spin-coating, dip-coating and printing offer process simplification at lower temperatures. However, the resulting amorphous films exhibit low values of d₃₃, resulting in inferior overall performance. In this work, we have examined the possibility of using high in-plane electric fields to modify the packing density of the material. A concentrated KNN sol (50:50) was synthesized using the sol gel method. Powder X-ray diffraction (XRD) measurements on the dried sol films reveal an amorphous product. Oxide substrates (University Wafers) were cleaned (RCA) and metal bottom contacts were deposited using successive DC sputtering (Cr/100Å) and RF sputtering (Au/500Å) at a base pressure of 2 x 10⁻⁶ Torr. The metal was patterned using maskless lithography (Intelligent SF100 Express) and etched (Sigma Aldrich CAS: 7681-11-0) with two electrode spacings of ~ 10μm. Films of KNN were deposited via drop casting of concentrated sol (~10 μL) onto the two electrode lateral structures and dried at 90°C prior to measurements. Energy dispersive X-ray fluorescence (EDX) reveals (K:Na)=50:50, which was confirmed using X-ray Photon Spectroscopy (XPS) surface survey measurements. The lateral devices were biased on a probe station (Cascade Microtech) with a Keithley 2450 source meter at 10V. Under the microscope, we observed sporadic possible reflow of the dried film on the positive pad, along with a 300% increase in the spot temperature estimated using a non-contact IR thermometer. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) measurements were used to gather information about the morphology of the film in the vicinity of the device, which shows cracks in shapes that closely resemble calculated electric field patterns (COMSOL), which predict a maximal electric field of ~330 kV/cm with the averaged field far away from the device subsiding to ~100 kV/cm. The resistance between the electrodes increased by ~44% as a result of the annealing, attesting to changes in local thickness due to crack formation. Post-annealing EDX measurements showed a ~16% reduction in the volatile potassium content suggesting a local migration of ions, resulting in a stoichiometric shift to (K:Na)=44:56. SEM and AFM measurements of the annealed film were combined to estimate a volume reduction of ~4.8% over an area of 100 μm². We are currently developing the above process in combination with successive spin-coating of sol on annealed films and reannealing to develop densified films of KNN suitable for measurements of relevant electromechanical coefficients.

**FF04.05.17**

**Sol-Gel Processed Mg Doped SnO₂ Thin-Film Transistors** Changmin Lee, Seunghyun Ha, Hyunjae Lee, Won-Yong Lee and Jaewon Jang; Kyungpook National University, Korea (the Republic of)

We demonstrate sol-gel processed Mg-doped SnO₂ thin film transistors (TFTs) with high performance and improved stability. To improve the performance of tin oxide, which is unstable at a high negative threshold voltage,
magnesium is used to suppress oxygen vacancy formation. As the Mg doping concentration increases, the oxygen deficiencies decrease, resulting in a negative shift in the threshold voltage and improved stability in negative bias stress environments. In this experiment, Mg-doped (0 to 1 wt%) tin oxide TFTs are fabricated. The tin oxide prepared from a synthesized solution of tin (II) chloride dehydrate precursor and ethanol has a mobility of 13.84 cm²/Vs and -32.13 V threshold voltage shift under negative bias stress. On the other hands, the SnO₂ TFTs doped with 0.5 wt% Mg also show a mobility of 4.23 cm²/Vs and a noticeable -6.98 V threshold voltage shift under negative bias stress. Our results suggest that sol-gel processed Mg-doped SnO₂ TFTs are a promising candidate for use in high stability and high-performance applications in transparent devices.

*Understanding the Effect of Capping Ligand Ratio in Colloidal Synthesis of Two-Dimensional TMDCs – Stoichiometric Differences Based on Surface and Defect States*

Meeree Kim¹² and Hyoyoung Lee¹²; ¹Institute for Basic Science (IBS), Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Colloidal synthesis and surface stabilization of nanocrystals (NCs) have been well-developed and established experimentally over the past 30 years. The role of surface increases as the size of materials shrinks, and this fact shines a spotlight on the surface ligands attached on the colloidal NCs. Ligands form a ‘capping’ layer on the surface which saturate dangling bonds and stabilize surface energy, and affect to the reaction mechanism in synthesis by kinetic and thermodynamic controls. However, detailed understandings on the ligand chemistry of NCs at the atomic level were largely focused on the ionic II-VI (CdSe, CdS) and IV-VI (PbS, PbSe) semiconducting NCs. Surface ligands are classified as L-, X- or Z-type depending on the number of electrons involved in ligand-NC bonds and the identity as electron donor or acceptor. Recent studies have shown that different types of ligands stabilize each facet of ionic NCs, resulting in mixed surface ligands during the synthesis (intentionally or not). In this study, we investigate the influence of molar ratio between X- and L-type ligands on the synthesis of colloidal transition metal dichalcogenides (TMDCs). Two-dimensional (2D) TMDCs have been considered to be attractive for numerous applications because of their broad range of properties from metals to insulators. However, wet chemical synthesis of 2D TMDCs is challenging because of their additional covalency requiring a high growth temperature, and even complicated by large anisotropy in layered structure. Ideally, layered TMDCs have no dangling bonds on the basal plane (001) and therefore their ligand chemistry is largely expected to rely on only edge sites (110), (100). Reflecting the ligand chemistry of ionic NCs, we control the molar ratio between different types of ligands (X-type and L-type; halides and amines), and monitor how the surface composition changes accordingly. Stoichiometric differences and oxidation states shift in overall TMD NCs show a correlated tendency, resulting in different surface states of colloidal TMDC NCs. Based on the observations, we conclusively demonstrate that the appropriate ligand ratio is required to synthesize the desired colloidal TMDC NCs, introducing an effectiveness of ligand control in colloidal synthesis of 2D TMDCs.

*Surface Coating of Cu Nanowires with ZnO Using Aqueous Ammine-Hydroxo Zinc Complexes for Stable and High-Performance Transparent Conductive Films*

Shun Yokoyama¹, Kenichi Motomiya¹, Balachandran Jeyadevan² and Hideyuki Takahashi²; ¹Tohoku University, Japan; ²The University of Shiga Prefecture, Japan

Many efforts have been made to produce low cost, flexible and high performance transparent conductive materials, replacing high cost, brittle and high performance Indium tin oxide films. Random networks of metal nanowires (NWs) possess optically transparent holes between nanowires and good electrical conductivity arose from metallic contacts between nanowires. Among metal nanowires, Cu has a disadvantage of low stability but is a top candidate due to its low cost. To take the cost advantage, synthesis and fabrication processes of Cu NW networks must be low cost and environmentally friendly. In addition, the surface must be modified with stable layers to avoid surface oxidation. Recently, we synthesized Cu NWs with different aspect ratios using an environmentally friendly synthetic method¹. However the surface easily oxidized, hindering NW performance.

In this study, we reported the surface coating of Cu NWs with ZnO layer based on aqueous solution processes for stable and high-performance transparent conductive films. To make transparent conductive films made of Cu NWs, a vacuum filtration and transfer method was used. The synthesized Cu NWs were deposited on a membrane filter and filtered under vacuum. Subsequently, the Cu NWs were transferred onto a glass substrate by pressing the filter against the glass substrate. After deposition of Cu NWs on the filter, aqueous ammine-hydroxo zinc complexes were employed to be absorbed on Cu NW surfaces. Although the complex easily converted to ZnO with heat treatment at low temperature, the complexes did not remain on Cu NW surfaces. As the complex condition and reactions
between Cu NW surfaces and the complexes dramatically changed depending on pH and zinc concentrations, we identified complexes using ESI-TOFMS and evaluated the surface reactions using surface analyses at different conditions. As a result, the ammine-hydroxo zinc complexes sufficiently remained on the Cu NW surfaces with appropriate conditions and then changed to thin ZnO layers. The thin ZnO layers on the Cu NWs improved the stability of Cu NWs under air without significant decreases in Cu NW performances such as transmittance and sheet resistance. In our presentation, detailed results and discussion will be introduced.

This work is partially supported by JSPS KAKENHI Grant-in-Aid for Young Scientists (A) 17H04721 and Scientific Research (B) 19H04324, and Mayekawa Foundation 2018 and The Iwatani Naoji Foundation.

Templated Growth of Two-Dimensional ZnO Nanoplates by the Hydrothermal Method toward Creating a Photocatalytic Surface Shota Sakurai1, Shinji Nozaki2 and Junghyun Cho1; 1Binghamton University, The State University of New York, United States; 2The University of Electro-Communications, Japan

Two-dimensional (2-D) nanomaterials have recently received a considerable attention because of their unique characteristics, which were not seen in their bulk or 1-D nanomaterials. Zinc oxide (ZnO) is one of the most industrially-promising materials because it is chemically stable, non-toxic and available at low cost. To synthesize the 2-D ZnO platelets, ZnO must grow in the a-axis direction, while suppressing its growth in the c-axis direction, which is often preferred in the ZnO growth. To control the growth direction, a seed layer plays an important role. In this study, we prepared a seed layer by spin-coating and high-temperature post annealing of the r-plane (1-102)-oriented aluminum oxide (Al2O3) thin films on Si (111) substrate. Then, ZnO nanoplates were hydrothermally grown on the seed layer in the a-axis direction with various growth parameters. Since a lattice mismatch between a-plane (11-20) of ZnO and r-plane of Al2O3 is only 1.53%, ZnO grows epitaxially along the a-axis. Such nanoplates contained a high concentration of the surface defects and were off-stoichiometric, thereby making them attractive as very effective photocatalytic surfaces for degradation of organic contaminants. In addition, these vertically-stacked ZnO nanoplate surfaces showed the electrical properties that strongly depend on the presence of oxygen and temperature. As a result, the templated growth of the 2-D ZnO nanoplates shows the great potential to form functional surfaces that can be very sensitive to external stimuli such as light and environment by controlling the concentration and type of defects. This presentation will highlight a current research progress made to the control of these defects to tailor the photocatalytic properties of the nanoplate-stacked surfaces.

FF04.05.22
Discovery and Liquid Exfoliation of 1D Materials Sudong Chae1, Seungbae Oh1, Kyung Hwan Choi2 and Jae-Young Choi1,2; 1Sungkyunkwan University, Korea (the Republic of); 2Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

For decades two-dimensional (2D) van der waals(vDw) materials, which have been isolated as one atomic sheet from their layered-bulk materials, are intensively studied due to their excellent and unique properties such as high mobility, flexibility, and two-dimensional quantum effects. In recent years, interest in 2D vDw materials has expanded to include a new type of nanomaterials, one-dimensional (1D) materials which are isolated as one molecular chain from their chained-bulk inorganic materials. The 1D bulk materials consist of chain-shaped inorganic molecule units which are assembled by weak physical interactions such as van der Waals or ionic bonding in their bulk materials. The inorganic molecular chain itself have a dimension of smaller than 1 nm in a diameter thus produce flexible characteristic even though they have inorganic compositions.

Here in, we synthesized new 1D materials [1,2](LiMo3Se3, V2Se9, Nb2Se9) and developed liquid-phase based exfoliation techniques for them which makes 1D bulk materials as an inorganic molecular chain. These include survey of solvents[3,4], design of dispersant[5] and ion exchange chromatography[6], and provides essential information on the material surface for additional stripping strategy design. The result of liquid exfoliation, colloidal nanomaterial, can be applied to various fabrication techniques for future applications.[7]

Crystallization Temperature Investigation of Cu₂ZnSnS₄ by Using Differential Scanning Calorimetry (DSC)
Jiayao Xu; The Hong Kong Polytechnic University, China

The Cu₂ZnSnS₄ (CZTS) powder was systematically investigated by energy dispersive X-Ray spectroscopy (EDX), X-ray diffraction (XRD), scanning electron microscopy (SEM) and Ramam spectrometer, and further studied by differential scanning calorimetry (DSC), thermogravimetric analysis (TGA). The Ramam and XRD results showed that the sample is a structure of Kesterite type under a condition of Cu-rich and Zn-poor with few impurity phases. The DSC results show that incubation time, peak time and end time of crystallization are all reduced with the increasing temperature; and the temperature of 550 °C will be more suitable for annealing treatment of CZTS. A CZTS film is also fabricated and annealed at 550 °C to confirm the result of the research. The systematic investigation of CZTS by using differential scanning calorimetry provided a fundamentally dynamic reference for the temperature selection of anneal during the fabrication of CZTS.

Photochemistry and the Role of Light in Submerged Photosynthesis of ZnO Nanorods
Lihua Zhang, Melbert Jeem and Seiichi Watanabe; Hokkaido University, Japan

Recently, metal oxide nanoparticles have gained much attention owing to their anticipated properties and application in different areas, such as photoelectron devices, sensors, catalysts, and photovoltaic devices. Among these metal oxides, zinc oxide is one of the most important natural n-type semiconductors with a direct wide band gap in the near-UV spectral region (3.36 eV at room temperature). The optical and electrical properties of ZnO are affected by many factors, such as the structure, size, shape, and defect concentration, which makes ZnO a very important and interesting subject to examine the controlled growth of novel materials. Recent work showed that metal oxide nanoparticles could be synthesized by a new pathway: submerged photosynthesis of crystallites (SPSC). In the SPSC method, the initial metal is surface treated by a submerged liquid plasma process, which creates a metal nano oxide semiconducting layer with surface protrusions. After that, the growth of metal oxide NCs is assisted by a ‘photosynthesis’ reaction, where the metal surface is irradiated with ultraviolet light in water. Thus, the SPSC process requires only light and water and does not require the incorporation of impurity precursors. Moreover, this method is applicable at low temperature and at atmospheric pressure, producing only hydrogen gas as the by-product. These characteristics give rise to the potential application of SPSC as a green technology for metal oxide nanocrystallites synthesis. Therefore, SPSC method is applied for ZnO nanorods synthesis in this work, and the photochemistry reactions and the role of light in the SPSC process are studied.

We carried out surface microstructural analysis and monitored the pH and temperature change of the water during the process. Based on this analysis, ZnO nanocrystallites formation mechanism was clarified. Furthermore, the effect of light irradiation during the process was elucidated by contrast experiments under dark conditions. The results show that both photoinduced reactions and hydrothermal reactions contribute to the SPSC process. The former generates OH radicals, which are one of the main sources of OH⁻ at the crystal tips, whereas the latter involve the ZnO growth reactions. Furthermore, ZnO nanocrystallites can be obtained under both light irradiation and heating in dark conditions, in which ZnO growth and corrosion reactions occur simultaneously. Light irradiation makes ZnO growth dominant and the water pH close to neutral, whereas thermal energy makes ZnO corrosion dominant and the water pH increases. The role of light in SPSC process is to enhance ZnO apical growth at relatively lower temperature by preventing the pH of water from increasing, revealing the environmentally benign characteristics of the present process.

Solutional Nanoparticle Syntheses of Layered Ternary Copper Selenides of Mo/W
Minyuan M. Li and Sergei A. Ivanov; Center for Integrated Nanotechnologies, Los Alamos National Lab, United States
Two-dimensional materials, especially transition metal chalcogenides MX₂, remain a dominant topic in novel material chemistry and physics. As we explore their layered ternary analogs with the formula Cu₂MX₄ (M = Mo/W, X = S/Se), we found few reports on the fabrication and characterization of those ternary selenides. Here we describe a solution processing method towards phase-pure nanoparticles and associated synthetic controls available in our method.

How do Surfaces Explain Growth Mechanisms and Growth Modes of KTa₁₋ₓNbxO₃ Nanoparticles? Tiffany Ly¹, Jianguo Wen² and Laurence D. Marks¹; ¹Northwestern University, United States; ²Argonne National Laboratory, United States

Predictable and consistent synthetic control of nanoparticle sizes, shapes, and properties through synthesis can be guided by comprehensive thermodynamic and kinetic models for nanoparticle growth. Establishing these models requires not only understanding how different growth mechanisms affect the size and morphology of nanoparticles, but also what factors determine the kinetic rates of these growth mechanisms and the resulting growth regimes. Here, electron microscopy characterization of hydrothermally grown solid solution KTa₁₋ₓNbxO₃ nanoparticles and density functional theory calculations revealed an intricate story, where complex relationships between several properties—including surface segregation, strain, and adsorption chemistry—affect and explain the surface behavior and growth regimes of the nanoparticles. Comprehensive study of these relationships informs mathematical models for predicting nanoparticle growth. In this case, these properties manifested in two surface composition dependent growth modes, where nanoparticles with tantalum-rich surfaces grew via step-flow growth to form smooth facets, while those with niobium-rich surfaces grew in a different growth mode to form rougher surfaces. Understanding how such properties affect growth mechanisms allows for further manipulation of nanoparticle growth, as demonstrated by the effects of adding potassium halide on KTa₁₋ₓNbxO₃ nanoparticle phase, composition, and morphology.

Characterization of Flash Lamp Cured, Sol-Gel Derived Tantalum Oxide Films Christopher Beale¹, Stefanie Hamacher¹, Oumaima Bensaid², Alexey Yakushenko², Dirk Mayer¹, Bernhard Wolfrum¹,³ and Andreas Offenhäusser¹; ¹Forschungszentrum Jülich GmbH, Germany; ²is it fresh GmbH, Germany; ³Technische Universität München, Germany

Prior attempts at reducing the crystallization temperature of metal oxide films have succeeded via chemical solution deposition and photochemical solution deposition [1]. These methods include seeding solutions with crystalline nanoparticles in order to reduce the activation barrier for nucleation and crystal growth, or incorporating photosensitive compounds into the solution and thereby reducing the crystallization temperature during exposure to continuous UV irradiation. In one study, a xenon flash lamp was utilized to obtain nanocrystalline thin films by the use of a metal β-diketonate solution [2]. Thus, the aim of this study is to determine whether such solutions can be used to obtain tantalum oxide films with a xenon flash lamp, and how future studies could allow for crystallization from the amorphous state via pulsed laser irradiation, or from the solution state via seeding or the incorporation of photosensitive tantalum complexes [1].

In this investigation, the characteristics of a photosensitive, tantalum β-diketonate sol-gel ink were studied as a function of flashes from a xenon flash lamp at room temperature. The ink was printed on quartz substrates for UV-Vis spectrophotometry in order to follow the absorption versus flash lamp exposure, and on interdigitated electrodes in order to follow the capacitance versus flash lamp exposure. The results indicate that the UV-Vis absorption spectrum is similar to those found for tantalum oxide films obtained by photo-irradiation [3], [4], and the interdigitated electrode capacitance increases with the number of xenon flash lamp flashes. An increase in capacitance hints at oxide densification and formation [5], thus allowing for a photopatternable material. The amorphous film could be subsequently heat treated to achieve polycrystalline films [6], or exposed to pulsed laser irradiation to similarly achieve high temperatures [1]. The photosensitivity of the ink also allows for future investigations involving low temperature crystallization via photochemical solution deposition, as has been performed for lead-titane based precursors, among others [1]. Moreover, the air stable solution would further increase the ease of manufacturing and allow for it to be implemented into a roll-to-roll manufacturing line [7].

*Nanoscale V₂O₃ Films Prepared by Magnetron Dc Sputtering Technique—Metal-Insulator Phase Transition and Magnetic Ordering*  
*Ivan Castillo, Karuna K. Mishra and Ram S. Katiyar; University of Puerto Rico, Rio Piedras Campus, San Juan, United States*

Vanadium sesquioxide, a transition metal oxide, is an important metal transition insulator (MTI) material for its potential applications in novel electronic and memory devices. thin films of ~230 nm thick were grown on Si/Pt substrate using a D.C magnetron sputtering system deposited at substrate temperature 450°C in a controlled atmosphere of 35:2.5 sccm of Ar:O₂. X-ray diffraction studies confirm the formation of corundum rhombohedral phase. EDAX analysis and X-ray photoelectron spectroscopy were carried out to identify the elemental compositions and their chemical states. Magnetization studies down to 5 K were measured to predict the paramagnetic to ferromagnetic transition around 53 K. Out of 7 expected Raman active modes, Raman active modes located at 242 and 500 cm⁻¹ were observed at ambient phase. Temperature dependent Raman spectroscopic studies carried out in the temperature range of 80-300 K to identify the low temperature metal-insulator transition at 153 K. A possible coexistence and hysteresis of metal and insulator phases are evident from the intensity analysis. These results will be presented in detail at the meeting.

*Fundamental Understanding of Polymorph Formation via Structural Evolution and H₂ Storage Properties in Nanohybride of Magnesium Borohydride Supported by Reduced Graphene Oxide*  
*Sohee Jeong and Jeffrey Urban; Lawrence Berkeley National Laboratory, United States*

Magnesium borohydride (Mg(BH₄)₂, abbreviated MBH) have received tremendous attention as a promising onboard hydrogen storage media due to its excellent hydrogen storage capacity and high volumetric density. While each polymorph of MBH — alpha (α), beta (β), and gamma (γ) — is interesting, their synthetic homogeneity is not well developed owing to complex structures and similar thermodynamic properties of the polymorphs. Here, we demonstrate effective synthetic strategies to obtain pure polymorphic phases of MBH nanomaterials supported by reduced graphene oxide (MBHG) under mild conditions (60 – 190 °C under low vacuum, 2 Torr). Different polymorphs of MBH are obtained from the different starting materials dried in two different ways (under Ar or vacuum) via the phase evolution, which mechanism elucidated by computational analysis. Specifically, we selectively synthesize thermodynamically stable phase (α-MBH) and metastable phase (β-MBH) from γ-MBH within the explored temperature ranges (150 °C to 180 °C). The relevant underlying phase evolution mechanism is analyzed by theoretical thermodynamics and kinetic nucleation modeling. Furthermore, the resulting MBHG composites were found to have an oxidational resistivity, structure stability, and expression of partially reversible [BH₄]⁻ species during de(re)hydrogenation processes, offering a potential for realizing hydrogen storage cyclability.

*Liquid Phase Deposition and Properties of Ni Doped ZnO for Magnetic Application*  
*Vitaly Bondarenko, Konstantin Yanushkevich and Eugene Chubenko; BSUIR, Belarus*
The ZnO films were deposited on n+-type antimony doped silicon (111) substrate (0.01 Ω×cm) using an electrochemical deposition from aqueous solution containing zinc nitride, nickel nitride and isopropyl (IP). Deposition was carried out in galvanostatic mode at current densities of 15 – 30 mA/cm² and at temperature of 80 °C. The structure and optical properties was correspondingly studied by Raman and photoluminescence spectroscopy.

According to Raman spectra the obtained films consist of ZnO doped with Ni atoms. Existence of ZnO was verified by a typical number of Raman modes for ZnO, such as E1, A1 and et. al. Nickel doping was indicated by an increase in the intensity of the 1050 cm⁻¹ Raman spectra band and smoothing of the band at 1150 cm⁻¹. The observed intense photoluminescence band in visible range on all spectra corresponds to radiative transitions through three main group of deep levels in the band gap of semiconductor ZnO: a oxygen atoms in zinc interstitial (2.28 eV or 523 nm); a complex of an oxygen vacancy and zinc interstitial (2.16 eV or 576 nm) and oxygen vacancy (2.00-1.62 eV or 640-765 nm).

ZnO films were created by standard solution (without IP). Films with arrays of crystals on them were obtained for the solution with IP. The surface density of ZnO crystals on the ZnO film surface depends on the current density and increase with increasing current density. The size of crystal also increases by increasing deposition time. For example, at current density of 15 mA/cm² and deposition time 30 min continuous ZnO film with thickness of 7 um with an array of crystals of approximately 30 x 30 um in size and thickness of 7 um on it was obtained.

Based on the data extracted from the photoluminescence spectra of annealed samples, the number of such defects as oxygen atoms in zinc vacancies are significantly reduced and the emission peak redshifts. At the same time, annealing of samples prepared with the addition of 5 vol.% IP leads to a blueshift due to the annihilation of oxygen vacancies.

After annealing, the mode at 280 cm⁻¹ appeared on all Raman spectra. This mode stand for the mute B1low mode, the display of which in an optical spectra is related to the disorder of the crystal lattice. But, this Raman mode doesn’t presented for samples that was preparing from solutions with isopropyl.

This work was supported by the Belarus Government Research Programs “Photonics, opto- and microelectronics”, Grant 2.1.02, “Physical materials science, novel materials and technologies”, Grant 1.15.

FF04.05.31
Formation of Layered Structures in Biogenic Magnesium Calcite Single Crystals via Spinodal Decomposition of Mg-ACC Precursor Alex Katsman and Boaz Pokroy; Technion–Israel Institute of Technology, Israel

Some calcitic biominerals have been shown to be formed through the crystallization of a Mg-rich amorphous calcium carbonate (Mg-ACC) precursor. That non-classical crystallization pathway allows the formation of out-of-equilibrium supersaturated solid solutions (such as high-Mg calcite) as well as the formation of intricate rounded crystal shapes. Formation mechanisms of multiscale biogenic single crystal structures at ambient temperatures, in conditions of limited solid phase diffusion, remain largely incomprehensible. Based on experimental results, we develop a model describing the formation of the brittle star Mg-calcite nanostructure from an amorphous Mg-ACC precursor to a Mg-calcite nanostructure containing periodic layers with varying concentrations of coherent Mg-rich nano-inclusions. The amorphous ACC precursor can exist as a gel or as a liquid depending on amount of Mg and acidic proteins present in the system. The formation route is rationalized in a two-step model: the first step involves spinodal decomposition of a liquid or gel-like Mg-ACC precursor into Mg-rich nanoparticles and a Mg-depleted amorphous matrix. The second step is the crystallization of the decomposed Mg-ACC precursor. The crystallization probably starts in the Mg-depleted matrix. We consider two possible crystallization routes leading to the layered structure formation. In the first route, crystallization front faces Mg-rich nano-domains and alternatively repels them to amorphous phase or embeds epitaxially to the crystalline matrix, depending on the local effective viscosity varying with the density of nano-domains. In the second route, the crystallization of Mg-depleted ACC matrix is accompanied by the exclusion of Mg ions into a diffusion zone adjacent to the crystallization front; after crystallization of a certain layer, the Mg concentration ahead of the layer exceeds the critical value above which the Mg-ACC matrix becomes unstable against spinodal decomposition. A secondary spinodal decomposition will then start and result in the formation of additional Mg-rich nano-domains. As a result, the density of Mg-rich nano-domains changes periodically and forms periodic layered structure inside magnesium calcite single crystals. The model was supported by our experimental results in synthetic Mg-calcite, which suggest a spinodal decomposition in the amorphous precursor. These new insights have significant implications for fundamental understanding of the role of Mg-ACC material transformation during crystallization and its subsequent stability.
SESSION FF04.06: Solution Processed Organic Semiconductors

Twisted Crystals of Chiral and Achiral Functional Materials David B. Amabilino and C. Elizabeth Killalea;
University of Nottingham, United Kingdom

The formation of twisted crystals of a family of low molecular weight organic dye molecules from solutions of the
compounds has been discovered. This phenomenon is fascinating because the chirality arises over the lengthscale of
microns, which is not accessible by simply relying on chiral materials (where helical pitch is short) or by twisting
fragile macroscopic organic crystals. The properties of this new kind of material are potentially unique for a range of
optoelectronic applications.

The twisting occurs across a broad range of compounds based on the diketopyrrolopyrrole family, substituted at the
core of the molecule or at the terminus. Chiral side chains induce single handed crystals with very regular pitch
related with the thickness of the objects. Achiral sidechains result in the formation of twisted crystals of more varied
morphology, and a variety of twisted crystal types depending on the constitution of the side chain.

Electron and atomic force microscopy have been used to understand the morphology of the materials, and single
crystal diffraction and scanning tunnelling microscopy reveal the nature of interactions between the molecules and
their long range packing. Circular dichroism has been used to demonstrate the huge optical activity of the twisted
crystals compared with the solution phase systems, thereby demonstrating the interest for chiroptical phenomena.

8:30 AM *FF04.06.02
Crystal Engineering for Oligoacenes John Anthony; University of Kentucky, United States

The precise nature of intermolecular interactions, both in solution aggregates and in the solid state, plays a key role
in the electronic and photonic properties of any material. We developed a reliable functionalization strategy that
allowed the tuning of the solid-state order of a variety of aromatic chromophores, and established a rough set of
guidelines to predict how functional group size impacts crystal packing. For this talk, I will discuss several
refinements of our models, including (1) the use of computational screening to reduce the time and effort required to
engineer the crystal packing of new semiconductors for electronic and photonic applications, (2) the impact of
disorder on electronic properties, and how functionalization can diminish or enhance several types of disorder, and
(3) efforts to minimize dynamic disorder, and minimize phonon modes that are disruptive to charge transport.

9:00 AM FF04.06.03
Controlling Solid-State Packing and Spectroscopy of Conjugated Molecules Using Discrete Non-Covalent
Interactions of Pendants Samuel W. Thomas; Tufts University, United States

Despite the importance of conjugated materials in organic optoelectronic devices, the rational design of their
properties as solid state ensembles is currently not possible. The current design paradigm of conjugated materials
uses long, often branched alkyl side chains to impart solubility to otherwise insoluble conjugated backbones that are
responsible for the key optoelectronic properties of these materials. This talk will summarize work in which discrete
non-covalent interactions between pendants and conjugated backbones can dictate the conformations, and resulting
spectroscopic characteristics, of conjugated molecules in the solid state. In particular, intra- and intermolecular
arene-fluoroarene stacking interactions twist phenylene-ethyne linkages as revealed by X-ray crystallography.

The weak nature of this interaction results in surprising sensitivity to seemingly insignificant changes in chemical
structure that impact interaction strengths and the resultant conformations of these solids. This non-covalent control
over solid state conformation and spectroscopy extends to a wide variety of conjugated materials, including
organometallic phosphors. Mechanofluorochromism—the reversible change in photoluminescence upon application
of force—is a shared feature of many of these solids. The temperatures at which the force-induced phases revert to
the thermodynamically favored crystalline states is tunable over a wide range by changing the lengths of alkyl
substituents. Overall, this collection of materials opens a new path forward to controlling the properties of solid conjugated materials, for which rational design is most difficult, yet critically important for future technological development.

9:15 AM FF04.06.04
Crystal Engineering of Solution-Processable Organic Semiconductors to Enhance Optoelectronic Properties
Kai o. Zong¹, Yichen Ma¹, Kamran Shayan¹, Jack Ly², Emily Renjilian¹, Chunhua Hu³, Stefan Strauf¹, Alejandro Briseño² and Stephanie Lee¹; ¹Stevens Institute of Technology, United States; ²University of Massachusetts Amherst, United States; ³New York University, United States

Control over the out-of-plane molecular orientation of solution-processed organic semiconductors is a long-standing challenge in the organic electronics field. We present a generalizable strategy to orient the nucleation of small-molecule organic semiconductors during solution-phase deposition using nanoconfining scaffolds. Employing a simple dip coating process, triisopropylsilylethynyl-derivatized acene molecules were deposited onto nanoporous anodized aluminum oxide (AAO) and Si scaffolds exhibiting cylindrical pores with average diameters ranging from 60 – 500 nm. Preferentially oriented nuclei were found to form within the pores such that the fast growth direction (i.e. the π-stack direction) aligned with the long axes of the pores. Well oriented vertical crystal arrays with the π-stack direction of organic semiconductor crystals perpendicular to the substrate surface were found to form on both scaffolds. By varying the dip coating speed, the diameters and heights of these crystals on scaffolds were tunable over ranges of 100 – 600 nm and 0.8 to 6.7 m respectively. Photoluminescence (PL) experiments further revealed an eight-fold enhancement of the PL signal from vertical crystal arrays compared to horizontal crystals deposited on flat SiO₂ substrates due to waveguiding along the crystal length. This strategy is suitable for continuous deposition methods that will enable the large-area manufacturing of flexible and inexpensive optoelectronic devices.

9:30 AM FF04.06.05
2D Organic Semiconductor Monolayer for the Ohmic Contact Field-Effect Transistor Applications
Paddy K. L. Chan; University of Hong Kong, Hong Kong

In the organic field-effect transistors (OFETs), the charge accumulation region is usually within several nanometers from the dielectric surface. For small-molecule organic semiconductor material with monolayer thickness, all the molecules in the monolayer organic crystals are in principle contributed in forming the conductive channel. A meniscus-guided solution-processing method is employed to grow monolayer crystals of C₁₀-DNTT with single-crystalline domain size as large as millimeters. The intrinsic field-effect mobility of >12 cm²V⁻¹s⁻¹ is achieved. More importantly, the ultrathin thickness minimizes the charge injection barrier for the top-contact electrodes, allowing an ohmic hole injection and a low contact resistance (Rc×W) of 75 ohm-cm. Such low contact resistance not only allows short channel devices but also ensures low voltage drops at the metal/semiconductor interface, allowing the device to operate even at VDS = -1 mV. It opens a new direction of low-power OFET that operates at pico-watts, which can only be achieved by high-mobility short-channel OFETs with very low contact resistance. The physics origin of forming such low contact resistance OFETs will also be discussed.

10:15 AM FF04.06.06
A Framework for Screening the Kinetic Stability of Packing Polymorphs
Lynn Loo; Princeton University, United States

The weak intermolecular forces inherent to organic semiconductors give rise to polymorphism, or the ability for these materials to adopt multiple solid-state packing arrangements. And since the details of intermolecular packing can substantively influence charge transport, the ability to predict which of the available polymorphs is preferentially accessible and stable should shed light on charge transport characteristics. In this talk, I will discuss a simple framework that directly correlates the presence of short intermolecular contacts with polymorphic stability. Quantification starts with assessing whether intermolecular contacts within a crystal structure are smaller than the
sum of the van der Waals radii of the same atoms. Polymorphs with such short intermolecular contacts are substantially more resistant to polymorphic transformation while those without exhibit an added degree of freedom for molecular rearrangement; the said polymorph can thus be easily destabilized with post-deposition processing. Starting with a series of core-chlorinated naphthalene diimide derivatives, we show this framework to be widely applicable to a wide range of molecular semiconductors, and even extending to pharmaceutics and biological building blocks. In this era of machine learning and materials by design, this framework can help refine computational predictions by identifying the polymorphs that are practically stable [1].

10:45 AM FF04.06.07
Enhancement of Charge Transfer in Thermally-Expanded and Strain-Stabilized TIPS-Pentacene Thin Films
Yang Li1, Jing Wan1, Detlef M. Smilgies2 and Randall Headrick1; 1The University of Vermont, United States; 2Cornell University, United States

We present an extensive study of the optical and electronic properties and the phase transition in 6,13-Bis(triisopropylsilylethynyl)pentacene (TIPS-pentacene) thin films utilizing in situ x-ray diffraction, polarized optical spectroscopy, terahertz spectroscopy and ab initio density functional theory. The influence of molecular packing on the properties are reported for thin films deposited in the temperature range from 25°C to 140°C, and for films that are strain-stabilized at their as-deposited lattice spacings after cooling to room temperature. Anisotropic thermal expansion causes relative displacement of neighboring molecules while maintaining a nearly constant stacking distance. This leads to a large blueshift in the absorption spectrum as the temperature increases. The blueshift is a signature of charge transfer excitations, which depend sensitively on the alignment of the nodes of the frontier molecular orbitals with those on neighboring molecules. This effect is correlated with an enhancement of the field-effect transistor mobility in strain-stabilized thin films. These results suggest approaches to improve carrier mobility in strained thin films and for optical monitoring of electronic changes.

11:00 AM FF04.06.08
Molecular-Bilayer Organic Semiconductors—High Layered Crystallinity for Innovative Solution Processing
Tatsuo Hasegawa; University of Tokyo, Japan

High performance organic thin-film transistors (OTFTs) are attainable with molecular materials that show high degree of layered crystallinity, because the feature is best suitable to obtain two-dimensional channel layers interfaced with gate-dielectric layers. Here we present and discuss that some asymmetric rod-like organic molecules, composed of p-conjugated backbones linked with relatively long alkyl chains, provide molecular-bilayer-type organic semiconductors that involve intralayer herringbone-type molecular packing [1-5]. The materials exhibit considerably high layered crystallinity, allowing to realize innovative solution processing for obtaining extremely uniform channel semiconductor layers [6,7]. Based on ab initio quantum chemical calculations, we discuss that the high layered crystallinity are strongly enhanced by the intermolecular attractive forces between alkyl chains [3]. Based on molecular dynamics study, we show that the molecules are self-organized at around air-liquid interface via intermediate liquid-crystal phases, which eventually leads to the large-area single-crystal film growth [8]. We also demonstrate that the formation of single molecular bilayers becomes possible by using frustration effects for the alkyl chains [7].

11:15 AM FF04.06.09
Solvent-Free Coating of Organic Semiconductor Thin Films with Large-Area Single-Crystalline Domains
Yu
Organic semiconductors (OSCs) have been the cornerstone of organic electronics in a variety of applications, including photovoltaics, thin-film transistors (OTFTs) and electrochromics. Although OSCs promise to be lower in cost, more flexible and compatible with roll-to-roll processing compared to inorganic semiconductors, they suffer from a lack of long-range order, especially when deposited from solution over large areas. Defects, such as grain boundaries and dislocations, in as-cast OSC films, have been widely recognized to impede charge transport. While the introduction of an external field during solution processing, such as that during blade coating, has resulted in high quality millimetric single-crystalline domains and ribbons, these techniques still face formidable drawbacks because they employ chlorinated organic solvents that pose significant health and environmental hazards, and are often trapped in the resulting OSC films.

Herein, we introduce a scalable, solvent-free technique to prepare single crystalline OSC films with low defect densities over several centimeters. This approach leverages the liquid crystallinity of OSCs; depositing the OSCs at temperatures within their smectic window over a metal frame forms a freely suspended membrane. Given the elasticity of the smectic phase and that the OSCs are individually mobile at the surface, the resulting membrane – comprising of OSC molecules preferentially aligned with their long axis normal to the surface – is defect-free and uniform across its entire area. Transferring this membrane onto desired substrates and cooling it slowly from its smectic phase into its crystal phase preserves this high quality assembly. In the particular example of an equimolar blend of dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT) and didodecyl[1]-benzothieno[3,2-b][1]benzothiophene (C12-BTBT), we have produced BTBT cocrystalline films with single-crystalline domains that span ca. 30 mm laterally. Varying the deposition temperature and coating speed produces membranes that are 20 nm to a few hundreds of nanometers thick.

To assess the electrical properties of these single crystalline films, we fabricated OTFTs by transferring the OSC membranes to heavily n-doped silicon wafers with a 100 nm thick SiO2 as the gate dielectric and cooling them slowly into their crystalline phase. Evaporation of gold contacts defined individual transistors with a channel width of 200 mm and a channel length of 500 mm. We chose a particularly large channel length of 500 mm to demonstrate the uniformity and quality of our films over large areas. Such devices exhibit an average hole mobility of 8.5 ± 2.3 cm²/V.s⁻¹ and an average on/off ratio that exceeds 10⁶, independent of device location across the entire film. This solvent-free scalable approach of producing single crystalline OSC films at wafer dimensions (ca. 50 mm) should be amenable for broad applications in organic electronics.

Molecular and Supramolecular Engineering of Thienoacenes for Improved Charge Transport

Yves H. Geerts; Univ Libre de Bruxelles, Belgium

A large diversity of π-systems exist, nearly all transport electrical charges but only a few molecular structures qualify as best-performing organic semiconductors with μ ≥ 10 cm²/V.s. But charge carrier mobility is more a material than a molecular property. One has, thus, to consider supramolecular order at all length scales. The best organic semiconductors self-organize into large plate-like monocrystals as evidenced in recent papers. Due to their electronic properties but also to their favorable crystalline morphology, thienoacenes derivatives exhibit record charge carrier mobility above 10 cm²/V.s. We will report our latest results on the molecular and supramolecular engineering of BTBT semiconductors, including: design by theory, synthesis, crystal engineering, calculation and observation of crystal morphology, and processing into single crystal thin films for transistor fabrication.
**Desalination** Ryan Andris, Phillip Ridley and Ekaterina Pomerantseva; Drexel University, United States

Nanowire morphology combined with one-dimensional (1D) diffusion pathways is advantageous for the enhanced electrochemical performance of materials in a wide range of applications. In this work, we for the first time report the performance of highly ordered Na-2x3 and Na-2x4 tunnel manganese oxide (TuMO) nanowires with 1D crystallographic channels for the hybrid capacitive deionization (HCDI) of water. TuMOs are a family of relatively low cost, sustainable, and highly electrochemically active materials. In addition, the size of the tunnel opening can be modified by altering the nature of the stabilizing ion and hydrothermal treatment parameters of the precursor materials. The Na-2x3 and Na-2x4 tunnel dimensions refer to the number of MnO₆ octahedra on perpendicular sides of the tunnel walls, and the ordered nature of these structures is revealed via scanning transmission electron microscopy (STEM). Thus, TuMOs provide a unique platform to investigate the relationship between the size of the 1D diffusion channels and their electrochemical performance, including potential selectivity for removing various ions from aqueous solutions.

The homogeneity of tunnel sizes was achieved through improving crystallinity of the layered Na-birnessite precursor material via extended aging and control over the pH of the solution during hydrothermal treatment. The Na⁺ ions that stabilize the tunnels have increased radii in basic solutions that result in increased tunnel dimensions [1]. In addition, a study that investigated ion transport properties demonstrated that sodium preferentially diffuses into the larger tunnel sizes [2]. Therefore, the ion removal performance of Na-2x3 and Na-2x4 TuMO nanowires is investigated in a variety of solutions to gain insight into relationships between cation hydrated radii, charge, and electrode ion removal capacities.

NaCl, KCl, MgCl₂ solutions, and mixtures of all three were analyzed. In sodium chloride solutions, the Na-2x3 and Na-2x4 electrodes demonstrated ion removal capacities as high as 20 mg g⁻¹. Previous research conducted on TuMOs with an irregular distribution of tunnel sizes and incomplete formation of tunnel walls demonstrated higher ion removal capacities up to 45 mg g⁻¹. This data indicates that structural defects can be a vital factor in determining performance [3]. In addition, the highly ordered nanowires showed capacity retention as high as 90% after 20 cycles compared to 100% in the disordered material. To further understand the relationship between tunnel size and HCDI performance, both Na-2x3 and Na-2x4 tunnel structures were tested with a mixed ion solution containing all three chloride salts: NaCl, KCl and MgCl₂. Our results indicate that Na-stabilized TuMO electrodes may preferentially remove ions with larger hydrated radii from solution as demonstrated by a 40% drop in concentration of potassium ions compared with a 50% drop in concentration of magnesium ions. Interestingly, we observed that the concentration of sodium ions in mixed solution increased after cycling, indicating that stabilizing Na⁺ ions can be released from the structural tunnels of TuMO electrodes. This result suggests that there is interesting ion dynamics between stabilizing sodium ions and ions electrochemically removed from the mixed solution. In summary, this work contributes to the overall scientific understanding between ion transport and tunnel structure within manganese oxide materials used as electrodes in HCDI for water desalination.

**Understanding Electrical Conduction Mechanisms in Polycrystalline Indium Antimonide Nanowires Grown in Flexible Polycarbonate Membrane Pores** Abhay P. Singh and Usha Philipose; University of North Texas, United States

A dense array of vertically aligned indium antimonide (InSb) nanowires with high aspect ratio (diameter ~150-200 nm, length 20 µm) were grown in the pores of a track-etched polycarbonate membrane via a one-step electrochemical method. There are several reports on InSb nanowire growth in the pores of mechanically rigid, nano-channel alumina template (NCA), where nanowire growth occurs in the pores of the NCA. However, non-uniform pore size across the thickness of the template and the roughness within the pore tubules translate to the nanowires, resulting in them having non-uniform diameters and rough surfaces. In contrast, InSb nanowires grown in polycarbonate (PC) membranes appear to have uniform diameters and smooth surfaces. However, transmission electron microscopy images show that despite their smooth surfaces, InSb nanowires grown in PC membranes are
polycrystalline and in some cases even amorphous. A possible nanowire growth mechanism explaining the variation in crystallinity based on the template type will be presented in this work. The electronic quality of the nanowires was assessed by fabricating a back-gated InSb nanowire field effect transistor (NWFET), with a channel length of 1 µm. Analysis of the transport measurements show the nanowires have high resistivity (4 Ω cm), and a majority hole carrier concentration of the order of $10^{16}$ cm$^{-3}$.

**Electrochemical Nanofabrication with Pulsed Electrical and Mechanical Techniques Using Scanning Probes**
Mark Aarts$^1$, Alain S. Reiser$^2$, Ralph Spolenak$^2$ and Esther Alarcon-Llado$^1$; $^1$AMOLF, Netherlands; $^2$ETH Zürich, Switzerland

Bottom-up fabrication holds great commercial potential due to the cost-effectiveness of saving material. Solution-based fabrication methods are particularly attractive due to their scalability, low cost, and mild operating conditions. In this respect, electrodeposition using scanning probe microscopy provides a unique platform. Scanning probes allow for additive nanoscale manufacturing under ambient conditions, and additionally provide 3-dimensional spatial freedom which enables the fabrication of structures that are hard to realize in conventional cleanroom environments.

We report on the direct writing of Copper and Cobalt nanostructures using pulsed mechanical and electrical techniques in both an Atomic Force Microscope (AFM) and a Scanning Tunneling Microscope (STM). We demonstrate the writing of arbitrary structures beyond the sizes characteristic of single clusters and with lateral dimensions down to tens of nanometers, which can be read in-situ using the scanning probe. The extent of the deposition is interpreted based on the charging dynamics of ions in the liquid, determined by fundamental constants of the electrolyte such as the concentration, dielectric constant, and diffusion coefficient.

Due to the wide variety of electrochemical deposition and conversion processes, the technique of controlled electrochemical deposition with a scanning probe can be extended to different materials and morphologies. As such, we envision this technique to enable the manufacturing and rapid prototyping of novel devices at the nanoscale such as optical resonators, magnetic elements, and semiconductor devices.

**Solution-Grown Organic Single-Crystalline Heterojunctions**
Hanying Li; Zhejiang University, China

Organic heterojunctions are widely used in electronics and well ordering in the molecular packing inside the heterojunctions is highly desired. However, it is still challenging to interface organic single crystals to form single-crystalline heterojunctions. In this work, two novel methods will be introduced to describe how to prepare, from solutions, single-crystalline heterojunctions. On one hand, organic single-crystalline planar heterojunctions are grown in a single step from a mixed solution of p-type and n-type molecules. Based on crystallization of six organic semiconductors from a droplet on a substrate, two distinct crystallization mechanisms have been recognized in the sense that crystals form at either the top interface between the air and solution or the bottom interface between the substrate and solution. The preference for one interface rather than the other depends on the semiconductor-substrate pair and, for a given semiconductor, it can be switched by changing the substrate, suggesting that the preference is associated with the semiconductor-substrate molecular interaction. Furthermore, simultaneous crystallization of two semiconductors at two different interfaces to reduce their mutual disturbance results in the formation of bilayer single crystals interfaced together for organic heterojunctions. On the other hand, single crystals are prepared in organogels of a typical conjugated polymer. Instead of pure crystals, crystals containing the gel nanofibers are obtained. Essentially, nanofiber networks are incorporated into growing crystals and penetrate through the crystals, resulting in a crystal/gel-network interpenetrating composites. Based the two types of single-crystalline heterojunctions, charge transport and charge transfer process are studied. Hence, by demonstrating these two solution methods for the preparation of single-crystalline heterojunctions, this work should greatly harvest the highly ordered organic crystalline materials for high performance electronics.

Solution-Based Growth of Co- and Cu-Doped ZnO NWs with Controllable Optoelectronic Properties

Aswathi K. Sivan1, Alejandro G. Galan2,3, Lorenzo di Mario1, Andrew Gallant2, Del Atkinson2, Dagou Zeze2 and Faustino Martelli1; 1Istituto per la Microelettronica e i Microsistemi (IMM), Italy; 2Durham University, United Kingdom; 3Istituto di Struttura della Materia-CNR, Italy

The application of nanoscale oxide semiconductors for optical applications is growing, which drives research that seeks to modify and tune the electronic behaviour for technological applications. ZnO is a wide bandgap (3.37 eV) semiconductor with a large exciton binding energy (60 meV) at room temperature, making it a good candidate as a transparent conductive oxide and as part of optoelectronic-based or piezoelectric devices. For ZnO nanowires (NWs), the options for growth are vast, including pulsed laser deposition (PLD), chemical vapour deposition (CVD), molecular beam epitaxy (MBE) or chemical synthesis. Among them, the latter represents a cheap and simple route towards the production-scale synthesis of high quality single crystal ZnO NWs. Typically, the chemical route is a two-step process: first, a seed layer is deposited followed by the NW growth using chemical bath deposition (CBD). The CBD process allows tuning of the electronic properties via the introduction of doping agents to the growth solution that can be incorporated within the ZnO NW lattice during growth.

In this work, the optical properties of Co and Cu-doped ZnO NWs were studied by photoluminescence (PL) and fast-transient absorption spectroscopy (FTAS) with temporal resolution of 50 fs using a pump-probe method. The doping levels used were 1%, 5%, 10% and 20% in order to study how the doping levels affected the optoelectronic properties of ZnO NWs. The NWs were around 4 µm long and 120 nm in diameter.

For undoped NWs, the FTAS measurements show a sharp absorption bleaching at 3.3 eV with bandgap value comparable to those largely reported in the literature. As the cobalt doping was increased, a red-shift in the bandgap bleaching appeared (resulting in bandgap reductions from 3.3 eV to 2.95 eV), we also see that the bandgap bleaching has become broader. Co-doping modifies both spectral and dynamic properties of the ZnO NWs. The defect band became more prominent with increasing doping levels. This may be attributed to the modification of surface states in the presence of Co. Thy dynamics of bandgap bleaching also becomes faster with increasing Co doping. In the case of Cu-doped samples, a similar red-shift was obtained for the bandgap bleaching. The crystallinity and crystalline structure of the NWs was also demonstrated by x-ray diffraction and transmission electron microscopy to show that the original wurtzite phase of the ZnO NWs was maintained after doping. These experiments prove that by including a certain amount of dopant species, the optoelectronic properties of the ZnO NWs can be tuned, opening up a host of new and improved applications in which bandgap engineering and defect states control are key, such as selective gas sensing or photoelectrochemical water splitting.

Mechanistic Understanding of Ultrathin Single Crystalline Pt Nanowire

Debadarshini Samantaray and Ravishanakar Narayanan; Indian Institute of Science, India

Wet chemical synthesis provides a simple yet scalable route to synthesize nanomaterials with controlled size and shape. Tuning size and shape of nano crystal often leads to enhancement of various properties which could be very different from their bulk counterpart. Many exciting properties of the nanocrystals arise due to their higher surface area, hence shows excellent catalytic property. Noble metal nanowires are extremely important from fundamental and application point of view. However, anisotropic growth (1D here) in case of high symmetry material (specifically FCC crystal like Au, Ag, Pt) is not trivial to achieve. But, in these systems the inherent symmetry can be broken by using suitable capping agent or template. Though ultrathin Au nanowire of 2nm diameter has been synthesized and studied extensively, achieving Pt nanowire of such dimension remains challenging due to its intrinsic isotropic nature. Herein, we report synthesis and mechanism of formation of ultrathin Pt nanowire which has been achieved via a simple solvothermal method without making use of any special atmosphere.

As synthesized Pt nanowires have a diameter of 2-3 nm and lengths in microns. HRTEM images of these wires confirm that these are single crystalline in nature and interestingly the growth direction is <110> which is different from that of Au nanowire, where the growth direction is <111>. Theoretical calculation suggests the nature of binding of capping agent could be responsible for such type of growth direction. To understand the formation and growth mechanism of these nanowires, several control experiments have been performed. TEM analysis of the quenched samples at an earlier stage reveals that initially bigger particles (7-8 nm) form which eventually break down to smaller monodispersed particles of size 2-3 nm. The breaking of larger particles to smaller ones (in
presence of excessive capping agent) can possibly be attributed to digestive ripening. Further these monodisperse particles could undergo oriented attachment to form the 1D structure. It has been observed that the presence of capping agent plays a critical role in the kinetics of the reaction.

Since these nanowires are only few atoms thick, they show very interesting electrical transport property. Thermal stability of these wires has been studied by in situ TEM heating as well as ex situ heating. Moreover, these wires show superior thermal stability as compared to Au nanowire of similar dimension and hence can be used as a promising candidate for interconnects. These wires have been further converted to bimetallic nanowires like PtPd and PtCu by using Pt nanowire as template. Electrocatalytic studies on these single crystalline bimetallic nanowire shows better performance.

Pt-Based Nano-Dendrites as Highly Active and Stable Oxygen Reduction and Methanol Oxidation Bifunctional Catalysts Wenjuan Lei, Menggang Li, Yongsheng Yu, Weiwei Yang and Frances M. Ross; 1Harbin Institute of Technology, China; 2Massachusetts Institute of Technology, United States

Platinum (Pt) has been proven to be the most efficient candidate for the cathode catalyst of proton exchange membrane fuel cells (PEMFCs). However, the intrinsically sluggish kinetics and ultrahigh price of Pt severely limit the widespread application of PEMFC technology. Incorporating Pt with less expensive transition metals to form stable bimetallic PtM alloys, where M = Fe, Co, Ni, Cu, etc., has been considered as an effective approach to address these issues. This not only largely reduces Pt consumption but also enhances the activity of Pt-based electrocatalysts due to possible synergistic effects and electronic and lattice shrinking/strain effects. In addition, a nanodendrite (ND) structure with open skeletons can endow Pt-based electrocatalysts with higher atomic utilization and higher active surface area. Therefore, the design and synthesis of PtM alloys with highly open structure is crucial for fuel cells reaction applications.

Here, we report a highly universal approach for preparing PtM bimetallic NDs with M = Fe, Co and Ni by solution phase synthesis. By reacting Pt(acac)2 and M(acac)x at elevated temperature, we achieve NDs with a fcc crystal lattice. The as-prepared PtM NDs have a polycrystalline structure and are rich in steps and kinks on the surface, which ensure the PtM alloy has excellent bifunctional catalytic properties in acidic electrolytes for both the oxygen reduction reaction (ORR) and the methanol oxidation reaction (MOR). The ORR and MOR activities of the PtM NDs both show a sequence of PtCo/C > PtFe/C > PtNi/C > Pt/C. We conclude that the development of a novel strategy to prepare various types of bimetallic or ternary and Pt- or Pd-based alloy NDs can advance fuel cell applications by improving electrocatalytic performance.

Block Copolymer-Directed Hierarchically Structured Materials from Transient Laser Heating Kwan W. Tan; Nanyang Technological University, Singapore

Hierarchically porous structured materials with multifunctional properties and higher order complexities are highly desirable for many applications such as separation and energy storage. Here we describe the generation of hierarchically porous organic and inorganic structures coupling block copolymer self-assembly with spatially- and temporally-controlled laser irradiation. A simple and rapid laser irradiation of block copolymer-directed hybrid films with a continuous wave laser in the sub-millisecond timescales enabled synthesis of 3D mesoporous polymer structures and shapes. Backfilling the polymer template with amorphous silicon followed by pulsed laser annealing enabled transient melt transformation of amorphous precursors into 3D mesoporous crystalline silicon nanostructures. Mechanistic studies on laser-induced crystalline silicon nanostructure formation during the nanosecond silicon melt-crystallization process and polymer template stability at temperatures above 1200 degrees Celsius are highlighted.

Extended Carrier Lifetime of Faceted PbS Quantum Dots in Superlattice Film Formed by Sedimentation Method  
Kohki Mukai, Ryota Kimura, Shunta Sugisaki, Takuya Sugimoto and Masanobu Fujishima; Yokohama National University, Japan

In this paper, we report the successful fabrication of a superlattice film composed of PbS colloidal quantum dots (QDs) with three-dimensionally-coincident crystal orientations. Semiconductor solar cells using QD superlattice has been expected to realize energy conversion efficiency of 70% or more owing to the intermediate energy bands. The chemically synthesized colloidal QDs self-form densely-packed structures when they are deposited on a substrate in solvent. However, since the QDs can move freely on the substrate, grain size of the packed structures is on the order of micrometers. Long carrier transportation is effective to improve energy conversion efficiency of solar cells. We have proposed a method to realize a large area superlattice structure by restricting the free motion of QD using pyramidal microhole array as a template produced by anisotropic wet etching. In this study, faceted QDs of truncated octahedral shape were prepared and deposited on the template of Si(100) substrate. During the deposition, facets of neighboring QDs came into contact with each other. The three-dimensional crystal orientation alignment was confirmed by X-ray pole figure mapping. QD superlattice film with aligned crystal orientation are expected to further improve carrier transportation. We found that emission lifetime of QDs became longer after the formation of superlattice film, and that the usage of template extended the lifetime of the film especially at the excited states. The emission decay curves were double exponential at the excited state, one of which was a few nanoseconds and the other was several tens of nanoseconds or more. The results suggested that two type regions, where the intermediate bands were formed or not, were mixed in the film.

**FF04.08.03**  
Programmed Twisting of Phenylene–Ethynylene Linkages from Aromatic Stacking Interactions  
William Mullin; Tufts University, United States

Control over the conformation and packing of conjugated materials is an unsolved problem that prevents the rational design of organic optoelectronics, such as preventing self-quenching of luminescent molecules. Exacerbating this challenge is a general lack of widely applicable strategies for controlling packing with discrete, directional non-covalent interactions. Here, we present a series of conjugated molecules with diverse backbones of three or four arenes that feature pentafluorobenzyl ester substituents. Nearly all the compounds reveal intramolecular stacking interactions between the fluoroarene (ArF) side-chains and nonfluorinated arenes (ArH) in the middle of the chromophores; a twisted PE linkage accompanies each example of this intramolecular ArF–ArH stacking. Furthermore, these molecules can resist dramatic changes to emission upon transition from organic solution to thin film when ArF rings prevent interchromophore interactions. Not only does this design paradigm apply to fluorophores, but we also demonstrate its utility in inducing solid state phosphorescence in platinum acetylide small molecules. By broadening the structural space of conjugated backbones over which ArF–ArH stacking can twist PE linkages reliably and prevent self-quenching of solids with simple synthetic approaches, this work suggests fluorinated benzyl ester substituents adjacent to phenylene ethynylene linkages as supramolecular synthons for the crystal engineering of organic optoelectronic materials.

High-Stability Photocatalyst Based on Methylammonium Lead Tribromide Perovskite Single Crystals  
Xingmo Zhang, Feng Li and Rongkun Zheng; The University of Sydney, Australia

Hydrogen (H₂) production using the suitable semiconductors through photocatalytic water splitting process is a much sought-after technology to reduce the greenhouse gases and to further contribute to clean solar hydrogen energy production [1][2]. To date, it is still a big challenge to search for a stable semiconductor photocatalyst responding to wide-ranged light illumination. Recently, methylammonium lead halide perovskites have emerged as promise candidates for varieties optoelectronic devices, because of their low-cost, large carrier mobilities, long carrier life time and tuneable bandgap [3]. Moreover, recent advancements have demonstrated that their extraordinary optical and electrical properties make this class of perovskites a promising mediums for the high-performance photocatalysts beyond the optoelectronic device technologies. However, Most of the present works regarding the perovskite photocatalysts usually employed the hybrid perovskites in the form of thin polycrystalline...
films [4][5], and little effort is paid to apply the perovskite single crystals on photocatalysis, which is aiming at splitting water and generating H₂. Here we synthesized MAPbBr₃ single crystals by Inversed Temperature Crystalization (ITC) method and used them to fabricate the photocatalyst for water splitting with simple device structure, which exhibits high photocurrent, high H₂ evolution activity, and good stability.

Fluorescent One-Dimensional Molecular Crystals for a Novel Emissive Chemosensor Yuri Banno, Kanae Kitao and Norifumi Fujita; Meijo University, Japan

Contamination of the drinking water by heavy metal ions is a frightful problem for present and future generations. These contaminants are difficult and expensive to detect and remove and their lethal effect on the human health is of a long term and it’s impossible to trace it immediately. The permissive concentrations for the water in the environment are specified in 10⁻⁶ mol/L to 10⁻⁹ mol/L by WHO, whereas the detection limits of general chemosensors were around 10⁻⁷ mol/L. Thus, the detection properties leave something to be desired. To aim at development of molecular crystal-based chemosensor for highly ion-sensitive materials for optode, curcumin was chosen as molecular core structure because of its high absorbance and emission properties and fine coordination properties with heavy metal ions. We synthesized curcumin-based mesogenic molecules with hydrophobic tethers (1) and hydrophilic tethers (1′). Upon addition of heavy metal ions to the oligomeric assembly of 1 in the solution, UV/vis absorption spectra were more obviously changed than those of monodispersed state. The fluorescent quenching of the assembly was also detected efficiently upon metal ion addition, suggesting that the oligomeric 1D molecular crystals contribute to high detection properties for optode. For metal ion sensing properties of oligomeric 1′ will also be discussed.

FF04.08.06
Formation of Multiple Cocrystal Stoichiometries in Solution Edward Van Keuren, Andrew Fitzgerald and Scott Melis; Georgetown University, United States

The study of cocrystal formation has seen a great deal of attention in the past decade. Cocrystals have important applications as pharmaceutical compounds and in the development of organic electronics. However, for a given set of coformers, different cocrystal stoichiometries may exist, and multiple polymorphs are also more likely than in single component crystals. We have recently developed a model to describe the equilibrium formation of multiple stoichiometries under various crystallization conditions such as evaporation. By tracing the path through the phase diagram, we can identify the conditions under which individual stoichiometries will form. We present work on applying this model to explain the spatial distribution of different cocrystal stoichiometries in a drying film due to the changes in concentration along the contact line.

FF04.08.07
In Situ Studies on the Kinetic Controlled Morphology Development of Conjugated Polymer Films Processed by Blade Coating Yeon-Ju Kim¹, Jong-Jin Park¹, Kyoungtae Hwang¹, Detlef M. Smilgies², Aram Amassian² and Dong-Yu Kim¹; ¹Gwangju Institute of Science and Technology, Korea (the Republic of); ²Cornell University, United States; ³King Abdullah University of Science and Technology, Saudi Arabia
The thin-film morphology of conjugated polymers regulated by coating conditions can significant impact on electrical properties in organic field-effect transistors. Here, we analyze thin-film morphology of blade-coated poly [N,N’-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl]-alt-5,5’-(2,2’-bithiophene)] (P(NDI2OD-T2)) thin-films varying with the solvent and coating temperature. In order to achieve P(NDI2OD-T2) thin-films revealing large polymer domain, elongated packing structure and predominant face-on orientations, the consideration of pre-aggregation of P(NDI2OD-T2) in solution and the amount of thermal energy from coating temperature is crucial during film formation. The direct investigation of evolution of film formation is highly desirable with in situ measurements. By combining in situ UV-Vis spectroscopy and in situ grazing incidence wide angle X-ray scattering, we observed five stages which appear during blade coating. The insight will offer fundamental understanding of the relationship between film morphologies and charge transport properties as well as a potentially powerful method to control film microstructure of various organic electronics.

FF04.08.08
Dynamic Crystallization Behavior of Metal-Organic Framework Particles in a Polymeric Capsule
Liihan Chen, Sanfeng He and Tao Li; ShanghaiTech University, China

As a new class of crystalline porous materials, metal-organic frameworks (MOFs) have attracted broad attention for their fascinating chemistry as well as potential industrial applications as sorbent materials. However, the stability of MOFs towards water vapor and acid containing environments has been continuously criticized over the past decade and may well be one of the major bottlenecks for its many industrial deployments. Understanding the mechanism of the MOF degradation process may help us find the key towards increasing MOF stability in aggressive environments. In this talk, I will present our recent finding on the dynamic crystallization behavior of MOF particles confined in a polymeric capsule. By compartmentalizing MOF components within a polymeric boundary, the dissolution and crystallization processes are occurring simultaneously which led to a significantly extended MOF’s longevity under aggressive conditions. Such strategy may be extended as a universal method to improve the stability of MOF materials for industrial applications.

FF04.08.09
Green Sensitive Phototransistor Based on Solution Processed Two-Dimensional n-Type Organic Single Crystal
Jin Hong Kim and Soo Young Park; Seoul National University, Korea (the Republic of)

Two-dimensional (2D) organic crystals are receiving tremendous attention in next generation phototransistors for high-performing image sensor due to their potential color selective absorption and favorable electrical properties. However, organic crystals showing selective absorption in visible region have not been reported yet. Recently, we developed green color absorbing 2D single crystalline n-type material, 2F-4-TFPTA, which exhibited field effect electron mobility of up to 0.9 cm² V⁻¹ s⁻¹. 2F-4-TFPTA could form bilayer thick self-assembled 2D morphology due to the brickwork molecular packing structure with balanced intermolecular interactions along the two principal in-plane directions in the crystal. Based on the excellent optical and electrical properties, 2F-4-TFPTA single crystal exhibited decent photoresponsivity of 3.6 × 10³ A W⁻¹ under green LED irradiation and fast response time of less than 85 ms.

FF04.08.10
Lead Free Perovskite Single Crystal—Crystal Growth and Insight into Structural and Optoelectronic Properties
Naveen K. Tailor and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

Lead halide semiconductors with perovskite crystal structure and APbX₃ stoichiometry [A = MA+, FA+, Cs+; X = I⁻, Br⁻, Cl⁻ or mixtures there of] have recently become perhaps the most intensely studied class of inorganic optoelectronic materials. These materials are now widely used in light-emitting diodes, lasers, photo-detectors as well as in X-ray and gamma-ray (γ-ray) detectors. In these applications large single crystals (SCs) grown by precursors solutions of perovskites are mostly utilized because of low trap density and less grain boundary. Therefore, the rapid emergence of halide perovskites based single crystalline materials for wide variety of as mentioned applications has drawn much research attention in recent years. Though lead-based perovskites single crystals have made a significant contribution in the various applications in the photodetector and imaging application, many challenges are yet to be overcome. Limitations of lead perovskites such as toxicity of lead, easy decomposition in the presence of moisture, heat, and photo instability make them non eco-friendly and are eventually restricting their further development and commercialization potential. Moreover, Pb can accumulative in
the human body causing several physiological disorders such as abdominal pain, constipation, and headaches. It is more important now to develop lead free and stable perovskite materials.

In our present study, we have reported the lead free perovskite single crystals grown by the slow cooling method. The synthesis, crystal growth, and detailed structural and optoelectronic characterization have been carried out by Optical microscopy, EDXA, single crystal XRD, UV-Vis, PL, Raman and TCSPC. The synthesized single crystals have orthorhombic structure and Pnma space group and the corresponding lattice parameters and reciprocal lattice parameters are calculated. The I-V characteristics and impedance spectroscopy of this lead free single crystal are also discussed. With all the measured characteristics, we can conclude that our synthesized lead free inorganic halide perovskite based single crystalline material is very interesting and potential candidate for the optoelectronics and photodetector applications.

FF04.08.11
Electrochromic Naphthalene Diimide-Based One-Dimensional Molecular Crystals in Organogels Yoko Maeda and Norifumi Fujita; Meijo University, Japan

Electrochromism (EC) in which the color tone changes reversibly by voltage application is well studied in various fields ranging from inorganic to organic, and polymer chemistries. Among them, organic EC materials possess a lot of advantages such as low environmental impact, easy to design, and rich properties in multicolor. In this research, we have focused on EC supramolecular gel materials which can gelate solvents and prevent from leakage of electrolytes solution. An amphiphilic naphthalene diimide derivative (1) having long alkyl chains and a pyridinium ion was synthesized for one-dimensional (1D) crystal. 1 has fine self-assembling and gelation properties through noncovalent interactions such as π–π interaction and van der Waals interaction. When a voltage was applied to 1 gel on an ITO electrode, the gel showed EC properties in which the color tone reversibly changed from pale yellow to deep brown for at least 3 times. EC properties of polymer blend film prepare from 1D molecular crystals of 1 and conventional polymers will also be discussed.

FF04.08.12
Physical Solution Blending of Diketopyrrolopyrrole- and Thiophene-Based Semiconducting Polymers for Highly Stretchable Organic Thin-Film Transistors Chun Yan Gao1, Hyoung Jin Choi1, Yun Hi Kim2 and Hoichang Yang1; 1Inha University, Korea (the Republic of); 2Gyeongsang National University, Korea (the Republic of)

There are many efforts to achieve flexible or stretchable electronics based on organic semiconductors. A certain decrease in the π-conjugated structure of semiconducting polymer chains can drastically degrade the π-overlap driven chain rigidity and conductivity, which are important factors to enhance the intra- and inter-molecular charge-carrier transport in organic electronics. Diketopyrrolopyrrole (DPP)-based semiconducting copolymers can yield excellent charge-carrier mobilities in solution-based organic thin film transistors (OTFTs) ranged from 0.01 to 6.2 cm²V⁻¹s⁻¹, due to well-defined conjugated structures. However, the poor ductile conjugated structures of these DPP-based copolymers are hard to be used as semiconducting materials for flexible or stretchable devices. Here, we simply prepare solutions including a minor portion of high electric performance P29-diketopyrrolopyrrole-selenophene-vinylene-selenophene (P29-DPP-SVS) copolymers and a major portion of flexible regiorandom poly(3-hexyl thiophene)s (rr PHT) dissolved in chloroform respectively, and develop self-assembled structures of the P29-DPP-SVS in the semiconductor/semiconductor polymer blends to improve the ductility of film. On polymer-treated gate dielectrics, these blend films are spun-cast from the solutions optionally pretreated to induce better self-assembled structures of the semiconducting polymer in spun-cast films. The semiconducting polymer blend films show greatly improvement in stretchability of the resulting OTFTs, and they can show enhanced charge-carrier mobility and on/off current ratio values in OTFTs including a hole transport layer between Au electrodes and the blend films. These phenomena indicate that the simple blending of the semiconductor polymers can achieve unexpected high π–π stacking and stretchable structures in the spun-cast films, which improving the electrical properties and flexibility in the OTFTs.

FF04.08.13
Local Temperature Reduction Induced Crystallization of MASnI3 and Achieving a Direct Wafer Production Zhun Yao and Shengzhong (Frank) Liu; School of Materials Science & Engineering, China
Despite the rapid advancement of perovskite solar cells, the fundamental drawback of toxicity in lead based materials has largely limited their large-scale development and application. Hence, we developed a local temperature reduction induced crystallization (LTRIC) method to directly obtain a lead-free perovskite wafer (CH3NH3SnI3), which is 110 mm-thick, in an oil bath. The XRD diffraction peaks of the MASnI3 wafer are indexed to (001) and its parallel crystal planes, demonstrating its high orientation. The UV-vis-NIR discloses that the absorption onset of the MASnI3 wafer is red-shifted to 1015 nm, corresponding to a narrow bandgap of 1.21 eV.

Characterizing a Novel Series of Coordinated Polymers Using Low-Frequency Raman Spectroscopy
Tal Ben Uliel¹, Eliyahu Farber², Yaakov R. Tischler¹ and David Eisenberg²; ¹Bar Ilan University, Israel; ²Technion–Israel Institute of Technology, Israel

Coordinated polymers are an important class of designer materials for broad set of applications including energy research and nano-patterning, where single atom substitution can have a dramatic impact on both structure and function. For our research, we have synthesized a novel series of coordinated polymers, which consisted of alkaline earth metals and nitrilotriacetic acid, in particular Ba-NTA, Sr-NTA, Ca-NTA, and Mg-NTA, and we used Raman spectroscopy, in particular low frequency (LF) Raman spectroscopy, as a sensitive and a nondestructive method for characterizing the materials based on their vibrational resonances. Since vibrational modes can originate both from the atomic vibrations of molecular bonds and from more distributed phonon modes of nanoscale structures and crystals, atomic mass changes can have a strong influence the observed vibrational spectra, as described by the harmonic oscillator model. Our goal was to study the effect of one atom replacement on the shift of the related Raman band. According to single crystal x-ray diffraction (XRD) measurements, Ba-NTA and Sr-NTA have the same crystalline structure despite their different central metals, while Mg-NTA and Ca-NTA have different crystalline structures. Raman measurements of the chemical fingerprints region (i.e. above 200 cm⁻¹) exhibited high similarity, however for the Raman band associated with vibration of the Metal-Oxygen bond, the lightest metals exhibited the highest frequency Raman shifts. This is expected since the lighter metals form the shortest bonds and consequently their vibrational energies are higher according to the harmonic oscillator model. We found the LF-Raman spectral range, which captures the inter-molecular interactions, to be more sensitive to differences between the compounds. Despite the Ba-NTA and Sr-NTA being highly similar and presenting almost identical regular chemical fingerprint Raman spectra, expanding the measurements to the LF-Raman region enabled us to distinguish between them. In addition, we conducted polarized LF-Raman measurements of Ba-NTA single crystals, which provided additional information on the assignment of specific LF-Raman bands to specific vibrational modes and crystallographic planes as determined by XRD.

Using PRISM Theory and Molecular Simulations to Understand the Complex Interplay of Solvent and Polymer Architecture on Structure and Thermodynamics in Polymer Solutions
Arthi Jayaraman; University of Delaware, United States

My research group has focused recent efforts into using molecular simulations and liquid state theory in an integrated fashion to better understand and predict effects of polymer design on the resulting macromolecular material structure and thermodynamics. In this talk I will present these efforts in the context of polymer solutions. I will describe how we have used coarse-grained models, Polymer Reference Interaction Site Model (PRISM) theory and molecular dynamics (MD) simulations to study structure and effective interactions in polymer solutions with linear, cyclic and bottle-brush polymer architectures.

A Density Functional Theory Study on Why Pristine PEDOT is Oxidized to 33.3%
Donghyun Kim and Igor
Poly(3,4-ethylenedioxythiophene) (best known as PEDOT) is one of the most important and most studied conducting polymers due to its superior features such as high electronic and ionic conductivities, versatile optical properties, as well as stability against oxidants and air-humidity. Owing to these properties, PEDOT has been utilized for various applications such as photovoltaic cells, supercapacitors, organic electronic ion pumps, light-emitting diodes and electrochromic displays, field effect transistor and many others. While a number of papers that address various aspects of structural, optical, electronic and transport properties of PEDOT have been published, a few studies have so far focused on its polymerization mechanisms. Moreover, a theoretical understanding of thermodynamics and kinetics of the polymerization of PEDOT is completely missing. For example, it is generally accepted that PEDOT polymerizes into relatively short oligomers consisting of 10-20 monomer units. Factors that limit the chain length are not understood, and, to our knowledge, have never been discussed in the literature. Another important property of PEDOT is its oxidation level. In contrast to most other conjugated polymers, a pristine (i.e. as polymerized) PEDOT is heavily oxidized (p-doped). In most studies the oxidation level of pristine PEDOT is typically found to be 33%, i.e. one charge per three monomer unit. Currently, the understanding of this “magic number” of 33% is not available. Apparently, understanding of the factors that determine and limit the oxidation level during polymerization is instrumental for design and improvement of charge storage material and devices such as supercapacitors and batteries with the enhanced performance.

Motivated by the need for theoretical understanding of the thermodynamics and kinetics of the oxidative polymerization, we performed step-by-step density functional theory calculations of the oxidative polymerization of PEDOT:TOS. Using the density functional theory, we calculated the Gibbs free energy for the conventional mechanism that consists of polymerization of a neutral PEDOT oligomers first, followed by their oxidation (doping). We also corroborated the feasibility of alternative mechanism of polymerization in which already oxidized oligomers are used as reactants, leading to doped(oxidized) oligomers as products during polymerization. Our study, for the first time, provides a theoretical insight into PEDOT polymerization, which has been completely missing so far. Our focus of our study is understanding of the maximum oxidation level that can be achieved during polymerization. Our calculations provide a theoretical explanation of “the magic number” of 33% for the oxidation level typically reported for the pristine (i.e. as polymerized). Another result of our study is that the proposed alternative mechanism is likely to be more feasible for longer PEDOT oligomers (chain length N>6).

Conjugated Carbon Cyclic Nanoring as Additives for Intrinsically Stretchable Semiconducting Polymers
Jaewan Mun and Zhenan Bao; Stanford University, United States

Molecular additives are often used to enhance dynamic motion and tune microstructures of polymeric chains, which subsequently alter the functional and physical properties of polymers. However, controlling chain dynamics and microstructures of semiconducting polymer thin films, and understanding the fundamental mechanisms of such changes is a new area of research. Here, cycloparaphenylenes (CPPs) are used as conjugated molecular additives to tune the dynamic behaviors of diketopyrrolopyrrole-based (DPP-based) semiconducting polymers. It is observed that the addition of CPPs results in significant improvement in the stretchability of the DPP-based polymers without adversely affecting their mobility. Specifically, the DPP-based polymer thin films originally form cracks at 15% strain, while the addition of 5 wt% CPP improves the stretchability to 105% strain, which arises from enhanced polymer dynamic motion and reduced long-range crystalline order. The polymer films retained their fiber-like morphology and short-range ordered aggregates, which lead to high mobility. Fully stretchable transistors are subsequently fabricated using CPP/semiconductor composites as active layers. These composites are observed to maintain high mobilities when strained and after repeated applied strains. Interestingly, CPPs are also observed to improve contact resistance and charge transport of the fully stretchable transistors. In summary, the above results collectively indicated that controlling the dynamic motion and crystalline structures of polymer semiconductors proved to be an effective way to improve their stretchability.

Dynamic-Template-Directed Crystallization of 2D Conjugated Polymer Thin Films and Their Distinct Electronic Properties
Prapti Kafle, Fengjiao Zhang, Noah B. Schorr, Kai-Yu Huang, Joaquín Rodríguez-López and Ying Diao; University of Illinois at Urbana-Champaign, United States
Solution-processable polymeric semiconductors have received an increasing attention in the past two decades due to their wide range of potential applications in large-area, low-cost, flexible devices. In recent years, studies pertaining to 2D films of these semiconductors are gradually emerging owing to the development and wide recognition of 2D inorganic materials which exhibit incredible properties compared to their bulk counterparts. Analogous to the phenomenon observed in inorganic materials, reducing the dimension of polymer semiconductors films to 2D could potentially give rise to unique optoelectronic and mechanical properties. Moreover, the molecular level ultrathin body of the 2D conjugated polymer films can be incorporated in field effect transistors (FETs) to develop highly sensitive sensors for biologically relevant molecules. Despite their growing interest and utilization of a wide variety of solution processable methods, crystallization of these polymers into 2D films over large area still remain challenging. This is partially due to one dimensional nature of their intermolecular interactions as well as high conformational degrees of freedom of the polymer chains. Because 2D charge transport demands highly ordered 2D films, novel methods that enhance 2D polymer crystallization are needed. So far, fundamental questions of how electronic structure and charge transport properties depend on the number of molecular layers are still unclear. Methods for fabricating 2D layers with controlled morphology will lay the foundation for understanding these questions.

In this talk, we present dynamic-template integrated meniscus-guided coating as a new technique to fabricate 2D films of conjugated polymers over centimeter length scale using a wide processing window. Using two different polymeric systems, DPP2T-TT and PII2T, we demonstrate enhanced 2D crystallization on dynamic template leading to highly ordered and aligned 2D layer with edge-on pi-pi stacking. This is in contrast to 1D fiber network morphology obtained on static substrates. Our results show that while static substrates favor ordering of alkyl side chains in 2D films, dynamic template enhances ordering of the conjugated backbone with favorable interaction between the polymer backbone. As a result, charge transport was observed only in 2D films printed on dynamic template but not in monolayer films coated on solid substrates. In addition, we also observed a change in molecular packing from edge-on to bimodal when the film reaches a critical thickness of ~25 nm as well as an abrupt increase in J-aggregation, absorption coefficient and decrease in band gap and HOMO level until the critical thickness. This phenomenon was independent of the substrate and possibly arisen from straightened polymer backbone. Furthermore, we also observed an abrupt increase in hole mobility with film thickness reaching a maximum of 0.7 cm²V⁻¹s⁻¹ near the critical thickness which further corroborates with the drastic increase backbone planarity as film thickness increases. Finally we also fabricated chemical sensors using bilayer polymer films which demonstrated ultrahigh sensitivity < 1 ppb to breath biomarkers.

In this talk, we present dynamic-template integrated meniscus-guided coating as a new technique to fabricate 2D films of conjugated polymers over centimeter length scale using a wide processing window. Using two different polymeric systems, DPP2T-TT and PII2T, we demonstrate enhanced 2D crystallization on dynamic template leading to highly ordered and aligned 2D layer with edge-on pi-pi stacking. In the past two decades, significant progress has been made in the fabrication of polymer-based devices, such as organic light-emitting diodes (OLEDs), organic field-effect transistors (OFETs) or organic photovoltaics (OPVs), predominantly due to important improvements of existing materials and the creation of a wealth of novel compounds. Many challenges, however, still exist: from achieving reliable device fabrication, increasing the device stability and, more fundamentally, gaining a complete understanding how structural features over all length scales affect important optoelectronic and photophysical processes in such polymers, including charge transport, charge generation, and general photovoltaic processes. Here we demonstrate how classical polymer science tools can be used to elucidate the structure development of semiconducting polymers from the liquid phase, how such knowledge can be exploited to manipulate their phase transformations and solid-state order and, in turn, their electronic features and device performances. To exemplify our approach, we discuss bulk heterojunction solar cells, which are comprised of active layers that are generally comprised of a complex phase morphology where intermixed and neat phases of the donor and acceptor material co-exist. We show that the fate of photogenerated electron/hole pairs – whether they will dissociate to free charges or geminately recombine– is determined at ultrafast times, despite the fact that their actual spatial separation can be much slower. The local arrangement of the donor and acceptor plays a critical role in this phenomena as we demonstrate on a series of donor polymer:fullerenes binaries by combining 2D-NMR data with time-resolved ultra-fast spectroscopy results as well as detailed structural data. We discuss that similar considerations apply also to other functional blends, such as semiconducting polymer:dopant systems that can lead to highly conductive systems. The spatial arrangement of the polymer with the dopant, which is dictated by
the blends phase behavior, strongly affects charge transport in analogy to the photovoltaic donor:acceptor systems. We will conclude with providing a tentative picture of the complex correlation of structure and electronic landscape for the understanding of organic photovoltaic cells as well as doped, conducting “plastics” of metallic-type transport – and beyond.

Organic Semiconductor/Dielectric Composites for Flexible Field-Effect Transistors Tomasz Marszalek1,2, Ke Zhang1, Paul Blom1 and Wojciech Pisula1,2; 1Max Planck Institute for Polymer Research, Germany; 2Lodz University of Technology, Poland

Plastic transistors do not only create an interesting field of science but also belong to a highly promising technology for future electronic devices, especially for field-effect transistors. Thereby, conjugated small molecules or polymers are used as organic semiconductors for solution deposition onto flexible substrates. The deposition methods are based on roll-to-roll printing such as inkjet or gravure, while the substrate consists of thermoplastic polymers such as PEN, PET or PMMA. The benefits of such printed organic transistors in comparison to their traditional silicon counterparts are mechanical flexibility and low cost fabrication. To reduce the production costs, new processing concepts are required. One approach is focused on the deposition of the substrate polymer together with the organic semiconductor from the same solution or melt. During solvent evaporation or after post-treatment a vertical phase separation between the isolating polymer and the semiconductor occurs1,2. In the final bilayer structure, the semiconductor crystallizes on top of the polymer layer ensuring a charge carrier transport in the transistor. As further key factors, the molecular order, organization and film microstructure of the organic semiconductor are crucial for the charge carrier transport3.

Leveraging Molecularly Doped Semiconducting Polymers as Functionally Graded Organic Thermoelectric Materials Tengzhou Ma, Ban Dong and Shrayesh Patel; University of Chicago, United States

With the ability to modulate electronic properties through molecular doping coupled with ease in processability, semiconducting polymers are at the forefront in enabling organic thermoelectric (OTE) devices for thermal energy management. The challenge lies in the judicious control of thermoelectric transport properties: electronic conductivity (σ), Seebeck coefficient (α), and thermal conductivity (κ). One approach considers functionally graded materials (FGMs) where one locally tunes the material properties across an operational temperature gradient. While FGMs has shown to improve the performance of inorganic thermoelectric materials, similar concepts have not been considered in the field of molecularly doped organic semiconductors. Here, we present the fabrication, structure and transport characteristics of poly[2,5-bis(3-tetradecylthiophen-2-yl) thiieno [3,2-b]thiophene] (PBTTT) thin film (ca. 30nm) with compositional functional grading control of the molecular dopant, 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ). By using an in-house designed vapor doping process, we specifically fabricate a double – segmented PBTTT thin film consisting of two segments with different doping levels of F4TCNQ. Electrical conductivity and structural characterizations (X-ray scattering and Raman spectroscopy) indicate the existence of an interface region of ca. 1000 mm between the two segments within which the F4TCNQ concentration, polymer morphology, and conductivity gradually vary. The measured effective Seebeck coefficients at two sides of the two segments and across the interface match with known models describing transport in graded thermoelectric systems. Our results demonstrate the first successful fabrication and characterization of functionally graded organic thermoelectric materials, and thus providing guidelines to further develop more complex FGMs leveraging high mobility organic semiconductors and molecular doping.

A Stretchable Semiconducting Polymer Blend Film Including Regioregularity-Driven Phase-Separated
Domains of Poly(3-hexylthiophene)s Chun Yan Gao, Mingyuan Pei, Hyoung Jin Choi and Hoichang Yang; Inha University, Korea (the Republic of)

It has been known that poly(3-hexylthiophene) (PHT), constituted of asymmetric 3-hexyl thiophene repeat units, is a benchmark semiconducting polymer for solution-processed organic electronics. High regioregular (RR) PHTs with a backbone rigidity due to the strict head-to-tail manners approach tends to grow into an ordered domain of π–π overlapping chains in spun-cast films, facilitating the charge-carries to move along the intra- and inter-chains to yield high hole mobilities. Generally, conjugated semiconductors can't have both high electrical performance and flexibility. In order to obtain a flexible device with high optoelectrical properties, researchers have proposed many approaches. For example, semiconducting RR PHTs were chemically modified with thiophene segments generated better π-conjugated and deformable film structures and some semiconducting polymers were physically blended with elastomers or amorphous polymers to achieve stretchable semiconducting films, etc. However, most of these strategies to realize stretchable organic semiconducting films suffer from limitations of available materials and tedious fabrication processes.

Here, via simple blending a high-RR PHT (with a regioregularity of 97%) with the chemically identical but regiorandom (rr) PHT (55%) without any assistance, the RR PHT chains from the rr PHT media and develop highly conjugated nanodomains in both solution and film. In the spun-cast blend film, the rr PHT matrix imparts enough deformability of the channel layer required for stretchable organic thin film transistors (OTFTs), compared to neat RR PHTs and blends with a deformable polymer. OTFTs including RR PHT/rr PHT blend film showed excellent hole mobility (μ) values up to 0.13 cm2 V-1 s-1, surpassing that of the best RR PHT films (0.026 cm2 V-1 s-1) fabricated by ultrasound solution pretreatment. Furthermore, a 50% stretched RR PHT/rr PHT film maintains ~55% of its μ value at no strain, while RR PHT film shows a sudden decrease in μ even at 10% stretch. The simple blending approach imparts deformability to π-conjugated polymer films for application in stretchable OTFTs.

11:30 AM *FF04.09.10
A Molecular Route to Control Morphology in Solution-Processed Polymer Solar Cells Ellen Moons; Karlstad University, Sweden

The fabrication of polymer solar cells involves coating processes from a solution of electrically conducting donor and acceptor molecules, resulting in the photoactive layer. During the solvent evaporation, structures with a variety of length scales can be formed, the control of which is key to the high performance recently achieved for polymer solar cells. These structures are initiated through molecular self-assembly in which molecular interactions between donor, acceptor, and solvent have an important role. The choice of coating technique and post-fabrication annealing steps also have a significant effect on the final film morphology.

We will present one route towards estimating the molecular interactions between donor and acceptor molecules. With the help of a large set of solvents, the Hansen Solubility Parameters (HSP) of donor and acceptor are determined separately. Their distance in Hansen space presents an estimate for the mutual miscibility of donor and acceptor. From the HSPs, the Flory-Huggins interaction parameters can be determined, leading to a general strategy to control the donor/acceptor system's tendency to phase separate.

Soft X-ray based spectro-microscopy techniques provide excellent nanoscale resolution and chemical contrast to resolve the nanostructure of the donor/acceptor bulk heterojunction, as well as the composition of the domains, for systems where the acceptor is a fullerene derivative. However, the transition to non-fullerene acceptors brings along new challenges for morphology studies, because orthogonal photon energies that correspond to X-ray absorption resonances for donor and non-fullerene acceptor molecules are more difficult to find. Taking advantage of distinct functional groups on the non-fullerene acceptor molecules, new strategies for the imaging of the nanoscale morphology are being developed, such as AFM-IR spectro-microscopy.

We will present results from our multi-disciplinary effort to generate fundamental understanding about how molecular interactions drive the structure formation at different length scales in solution-borne polymer blend systems and how these processes can be manipulated by external stimuli. We aim to use this knowledge to formulate general design principles for polymer-polymer structures, as well as to apply these to guide the development of novel materials with structures that are tailor-made to improve properties and functionality of optoelectronic devices.
Emerging Approaches to Measure Orientational Order in Organic Semiconductors
Dean M. DeLongchamp; National Institute of Standards and Technology, United States

Organic semiconductors typically exhibit a rich variety of ordered phases. Orientation occurs during processing, often by passing through lyotropic liquid crystalline phases, and dried films exhibit orientation at many length scales. Liquid crystallinity appears almost ubiquitous in organic semiconductors we have studied, including behaviors similar to nematics, smectics, or sanidics. Uniaxial orientation where the conjugated plane exhibits a preferential “face on” or “edge on” orientation is the most commonly characterized aspect of orientational order, and mature techniques such as near edge X-ray absorption fine structure (NEXAFS) spectroscopy and grazing incidence X-ray diffraction (GIXD) are frequently employed to measure it. Significant challenges remain, even for this seemingly simple aspect of orientational order. For example, these approaches are often found to be insufficient when films exhibit a complex depth profile of orientation, composition, or both.

As the materials diversity of organic semiconductors increases thanks to achievements in synthetic chemistry, and as the complexity of formulation, blending, and coating increases as process design knowledge matures, there is a commensurate need for more advanced approaches to characterizing orientational order. Biaxial orientation is increasingly observed, where “face on” or “edge on” preferences are combined with an in-plane preference imparted by a substrate or processing vector. Domain-relative orientations are also been observed, with correlations in domain-to-domain orientation thought to influence charge transport.

I will describe some emerging approaches to measure orientational order in organic semiconductors. Resonant soft X-ray reflectivity (RSoXR), a method capable of measuring thin film depth profiles using the spectroscopic principles of NEXAFS, will be discussed. I will also summarize progress on in-situ spectroscopic and scattering-based structure measurement techniques that are combined with ex-situ probes including imaging and image analysis to determine how orientation originates during the processing of organic semiconductors. These new measurements will support science-based approaches for orientation control and optimization, helping to maintain the rapid pace of organic semiconductor technology development in an era where increasing complexity renders matrix-style empirical approaches too inefficient to contemplate.

Key Roles of Structural Order and In-Plane Alignment of (Semi)-Conducting Polymers on their Optical and Charge Transport Properties
Laure Biniek; CRNS, University of Strasbourg, France

This presentation focuses on recent advances in growth control and oriented crystallization of (semi)-conducting polymers for organic electronic applications. The performance and lifetime of organic electronic devices are critically dependent on the morphology of the active layers and structural order of the materials. For instance both molecular and crystalline orientations of the polymers determine optical and charge transport properties in thin films since these properties are by essence highly anisotropic.

Particular emphasis will be given to the progress made in high-temperature rubbing of conjugated polymers films. This effective large scale alignment method can orient a large palette of semiconductors with α- or ρ-type character without the use of alignment substrate. High degrees of crystallinity and in-plane alignment can be obtained which provide well-defined electron diffraction patterns essential for structure refinement. The concurrent roles of polymer molecular weight distribution and rubbing temperature (T_R) on the in-plane orientation are rationalized for P3HT and PBTTT. Correlations are drawn between nanomorphology/crystallinity on one side and charge transport and optical properties on the other side. It is shown that the exciton bandwidth in P3HT crystals is determined by the length of the average planarized chain segments in the crystals. The high alignment and crystallinity observed for T_R > 200 °C cannot translate to high hole mobilities parallel to the rubbing because of the adverse effect of amorphous interlamellar zones interrupting charge transport between crystalline lamellae of semi-crystalline P3HT.
opposite, hole mobilities along the polymer chains of rubbed PTB7 films are observed to be 6 times higher than the non-rubbed films.\textsuperscript{3} This is due to the smectic-like character of this alternated donor-acceptor copolymer. Interestingly high-Tr rubbing and post annealing process of PTB7 provide well-defined electron diffraction pattern. Combined with DFT calculation, this helps refining the structure and the chain conformation of this benchmark electron donor polymer for OPV application.

In a second part of this presentation, we show that soft doping of aligned P3HT yields highly oriented conducting polymer films with anisotropic charges and thermal conductivities. The thermoelectric properties are enhanced along the rubbing direction. The unique in-plane orientation in such conducting polymer films helps rationalizing the mechanism of redox doping.\textsuperscript{4}

Real-Time Structural Evaluation of Naphthyl End-Capped Oligothiophenes in Organic Thin-Film Transistors During Deposition
Mathias Huss-Hansen\textsuperscript{1}, Peter Siffalovic\textsuperscript{2}, Nad’a Mkyvková\textsuperscript{2}, Jakub Hagara\textsuperscript{2}, Martin Hodas\textsuperscript{3}, Frank Schreiber\textsuperscript{3}, Eva Majková\textsuperscript{2}, Jakob Kjelstrup-Hansen\textsuperscript{4} and Matti Knaapila\textsuperscript{1}; \textsuperscript{1}Technical University of Denmark, Denmark; \textsuperscript{2}Slovak Academy of Sciences, Slovakia; \textsuperscript{3}University of Tuebingen, Germany; \textsuperscript{4}University of Southern Denmark, Denmark

The electrical properties of organic thin film transistors (OTFTs) are strongly influenced by the structural characteristics and thin film morphology. Understanding the growth dynamics that lead to preferential molecular orientation and changes in crystal structure remain an important factor in the design of new high-performance OTFTs as well as in their fundamental studies. In this contribution, we have investigated the thin film growth behavior of 5,5′-Bis(naphth-2-yl)-2,2′-bithiophene (NaT2) and 5,5″-bis(naphth-2-yl)-2,2′:5′,2″-terthiophene (NaT3) during the deposition process using real-time grazing incidence X-ray diffraction (GIXRD) \textit{in situ}. The thin films were prepared by vacuum sublimation atop various substrates, including monolayer graphene on 90 nm SiO\textsubscript{2}, in a custom-built ultra-high vacuum (UHV) chamber with a 360° cylindrical beryllium window that allows for \textit{in situ} X-ray measurements within realistic deposition time scales. The crystal structure analysis revealed that the preferred orientation of the molecules were dictated by the substrate and that the unit cell underwent significant changes when transitioning from monolayer to multilayer structure. The changes of the unit cell were not readily observed when measuring thin films of corresponding thicknesses \textit{ex situ}, suggesting that the molecules undergo further re-organization/relaxation upon terminating the deposition. From the evolution of the crystal structure, a connection to the film growth mode and kinetics is made. These findings are rationalized based on the surface energies of the studied substrates and supplemented with AFM and helium ion microscopy. Finally, the crystal structure and morphology are correlated with charge transport properties of the final thin films.

3:30 PM *FF04.10.04/EN12.14.04
Semiconducting Polymers for High Performance Organic Transistor Applications Iain McCulloch; King Abdullah University of Science and Technology, Saudi Arabia

The evolution of organic electronics has now reached the commercial phase, with the recent market introduction of the first prototypes based on organic transistors and organic solar cell modules fabricated from solution. Understanding the impact of both the organic semiconductor design and processing conditions, on both molecular conformation and thin film microstructure has been demonstrated to be essential in achieving the required optical and electrical properties to enable these devices. Polymeric semiconductors offer an attractive combination in terms of appropriate solution rheology for printing processes, mechanical flexibility for rollable processing and applications, but their optical and electrical performance requires further improvement in order to fulfil their
potential. Synthesis of conjugated aromatic polymers typically involves carbon coupling polymerisations utilising transition metal catalysts and metal containing monomers. This polymerisation chemistry creates polymers where the aromatic repeat units are linked by single carbon-carbon bonds along the backbone. In order to reduce potential conformational, and subsequently energetic, disorder due to rotation around these single bonds, an aldol condensation reaction was explored, in which a bisisatin monomer reacts with a bisoxindole monomer to create an isoindigo repeat unit that is fully fused along the polymer backbone. This aldol polymerization requires neither metal containing monomers or transition-metal catalysts, opening up new synthetic possibilities for conjugated aromatic polymer design, particularly where both monomers are electron deficient. Polymers with very large electron affinities can be synthesised by this method, resulting in air stable electron transport, demonstrated in solution processed organic thin film transistors. We present an electrical, optical and morphology characterisation of polymer thin films, illustrating structure-property relationships for this new class of polymers.

**Charge Transport in Conjugated Polymers and the Importance of Order—From Atomic to Mesoscale**  
*Alberto Salleo; Stanford University, United States*

Carrier mobility in conjugated polymers continues to increase with recent reports of field-effect mobilities exceeding 10 cm²/Vs. Charge transport is intrinsically dependent on processes occurring across multiple length scales. In order to access order parameters at the molecular scale we use charge modulation spectroscopy combined with theory. Furthermore, we study the mesoscale organization of polymers using a new technique in the transmission electron microscope. These techniques are used on homopolymers and donor-acceptor copolymers. Such multiscale studies of microstructure are instrumental in guiding our understanding of charge transport in conjugated polymers.

**Charge Transfer State Lifetimes in P3HT:F4TCNQ Co-Processed Films**  
*Bharati Neelamraju, Kristen Watts, Jeanne Pemberton and Erin L. Ratcliff; University of Arizona, United States*

Doping is a fundamental strategy to increase the carrier density and conductivity of organic electronic layers for opto-electronic devices. The model system for p-doping is poly(3-hexylthiophene (P3HT) with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F₄TCNQ), whereby increases in conductivity occur through integer charge transfer (ICT) to form mobile carriers in the P3HT. Extensive work in the organic electronics field has revealed the interplay between film microstructure, the opto-electronic properties, and conductivity.

This talk asks the simple question: How stable are ICT states in doped films? An alternate undesired reaction pathway is formation of a partial charge transfer complex (CPX), which results in a localized, trap-like state for the hole on P3HT. Starting first with our recent observation that both ICT and CPX states exist simultaneously in a single film, this talk will focus on thermodynamic and kinetic pathways that lead to conductivity loss in F₄TCNQ-doped P3HT films. Both reaction chemistries and microstructural effects will be discussed.

DFT Study on Atomic Layer Deposition of Cobalt and Ruthenium on NHx-Terminated Nitrogen Plasma Treated Metal Surfaces Ji Liu and Michael Nolan; Tyndall National Institute, Ireland

Cobalt (Co) and Ruthenium (Ru) are used as a seed layer for metallization of interconnects, where atomic layer deposition (ALD) is applied to achieve conformality and precise thickness control at the atomic scale. Plasma-enhanced ALD (PE-ALD) is used for low-temperature thin film growth by alternating exposures of metal precursors and plasma reactants. During the PE-ALD growth of metals, N-plasma, for example, NH3 or a mixture of N2 and H2, has been developed to avoid surface metal oxidation. In this presentation, we study the PE-ALD growth of Co and Ru by first principle calculations. Experimentally known surfaces were constructed including (001), (101), and (100). The (001) surface with a hexagonal structure is the most stable surface and the (100) surface with a zigzag structure is least stable but with high reactivity. The two surfaces were chosen to study the surface saturation coverage by considering individual adsorption and co-adsorption of NH and NH2. On the (001) surface, the saturation coverage for NH is 1ML on Ru and 5/9ML on Co. For NH2, the saturation coverages are 5/9ML on both Co and Ru surfaces. Additionally, NH2 is unstable under high coverage by either desorbing from the metal surface or dissociating into NH. The calculated dissociation barrier for NH2 dissociation on both Co and Ru surfaces is 0.71eV. On the (100) surface, the saturation coverages are 2ML for NH and 1 ML for NH2 on both Ru and Co surfaces. The larger saturation coverage on (100) surfaces is attributed to the unique trench structure, which provides more available surface sites than that of (001) surfaces. We also consider co-adsorption of NH and NH2 on (001) and (100) surfaces. The results are analyzed with ab initio thermodynamics by calculating the Gibbs energy. Both the ultra-high vacuum (UHV) condition and standard ALD operating condition are used to elucidate the effect of pressure and temperature on the termination of metal surfaces.

The adsorption and reaction of metal precursors (CoCp2 and RuCp2) on NHx-terminated metal surfaces was investigated with inclusion of van der Waals corrections. Two possible adsorption structures, namely the precursor parallel and perpendicular to the NHx-terminated surfaces, were considered. The adsorption and reaction of metal precursors are classified into four steps: adsorption, pre-reaction, proton transfer, and ligand desorption. The barrier for proton transfer is calculated using climbing image nudged elastic band (CI-NEB) method. After desorption of Cp ligand, the Co or Ru metal binds to the N atom that transferred the H atom to the Cp ligand. The remaining Cp ligand will be consumed in the second half cycle with the help of the N-plasma. After a full cycle, the surface is an NHx-terminated metal surface and ready for the next cycle. In addition, the NHx-covered SiO2 surfaces are examined to investigate the initial nucleation process. This work will be important to reveal the mechanism and feasibility of atomic layer deposition of metals using N-plasma.

Multi-Scale Modelling and Experimental Analysis of ALD Alumina—Interplay of Process Dynamics, Chemistry and Interfacial Phenomena Giorgos Gakis¹, Emmanuel Scheid², Hugues Vergnes³, Andreas Boudouvis¹, Brigitte Caussat¹ and Constantin Vahlas⁴; ¹National Technical University of Athens, Greece; ²LAAS, France; ³Institut National Polytechnique de Toulouse, France; ⁴CNRS, France

Under optimized conditions, atomic layer deposition (ALD) allows processing of films with high uniformity and conformity on 3D surfaces. These characteristics make ALD an appropriate tool to produce ultra-thin films for a variety of applications in microelectronics, optoelectronics, catalysis, renewable energy and more. Nonetheless, ALD processes still suffer from some non-uniformity of the deposited films on large area wafers, from initial substrate inhibited island growth and from the formation of an interfacial layer with uncontrollable characteristics. In order to overcome such drawbacks, the thorough understanding of the phenomena and mechanisms involved during the ALD process is essential. In this work, we present a framework for the integrated study of the ALD of Al₂O₃ from TMA and H₂O on Si, using a commercial ALD reactor.

The framework consists of a combined computational and experimental approach. A three-dimensional Computational Fluid Dynamics (CFD) model is built for the ALD reactor, designed to treat large area 20 cm substrates. The model aims to investigate the effect of the reactor geometry and process parameters on the gas flow and temperature fields, and on the species distribution on the heated substrate surface. We couple this model to a surface chemistry one, which considers adsorption, desorption and reactions on the substrate surface. We combine it with ellipsometry measurements to access the limiting mechanisms, the competition between surface phenomena and their effect on ALD growth. This integrated (surface chemistry/kinetics and CFD) approach reveals a direct link between film uniformity and deleterious transport phenomena due to gas flow recirculation and low temperature zones in the reactor.

We also develop a computational model based on geometric principles to study the initial nucleation and growth steps of the Al₂O₃ film. Using XRR measurements, we evidence a substrate inhibited growth regime, attributed to the low reactivity of the HF-cleaned Si surface, together with an island growth mode for Al₂O₃. Due to these phenomena, 25 ALD cycles are needed to produce a continuous film. Our computational model, numerically reproduces these findings and allows deriving the film nucleation mechanisms and the phenomena leading to island growth.

We call for a complete range of techniques, including TEM, XPS, EDX and ToF-SIMS to get insight to the morphology and chemical nature of the deposited film. We also precisely analyze the chemical composition of the (Al, O, Si) interfacial layer to get insight in the mechanisms of its formation. We show that Si oxidation occurs during the island growth, catalyzed by the presence of Al, while it is also fed by species interdiffusion through the film.

In order to enhance the initial surface reactivity, we implement an in situ plasma N₂-NH₃ pretreatment of the HF-cleaned Si substrate prior to ALD. We use STEM coupled to EDX to show that the initial deposition is clearly increased on the pretreated surfaces, resulting in a linear ALD regime even after 5 ALD cycles. Furthermore, a Si₃N₄H layer is formed by the N₂-NH₃ plasma pretreatment, which acts as a barrier layer, reducing the oxidation of the Si substrate beneath it.

This integrated analysis provides a general framework for the study of the mechanisms and phenomena involved during the ALD process as well as the non-ideal aspects leading to the drawbacks of ALD. This can lead to the determination of adequate surface pretreatments, able to combat the witnessed drawbacks during metal-oxide ALD on Si, thus paving the way for the effective production of nanometric thin films with sharp interfaces for microelectronic and other applications of the future.

CVD and ALD Processes from an Ab Initio Perspective Ralf Tonner; University of Marburg, Germany

Progress in thin-film deposition methods often depends on our understanding of the underlying elementary steps at the level of atomic and electronic structure. For key questions, theoretical investigations can help by complementing the experimental investigations. Nevertheless, the goal for theoretical approaches is to move beyond interpretation of already available data and provide predictions and guidance for future investigations. Predictive computations
require high accuracy which directly leads to \textit{ab initio} methods like density functional theory (DFT) or wave function-based methods combined with methods for larger length and time scales.

For CVD, the low-temperature growth of GaP on H/Si(001) by metal-organic vapor phase epitaxy (MOVPE) is taken as an example to highlight the strengths (and limitations) of these \textit{ab initio} approaches. For the first step - the gas phase decomposition of precursors - we find very high barriers for several reactions proposed earlier for tert-butylphosphine (TBP) and triethylgallane (TEGa) and unusual $\beta$-H elimination reactions relevant for ligand design.\cite{1} DFT approaches including methods for treating dispersion interactions (DFT-D) are in good agreement with gold-standard quantum chemical coupled-cluster methods. This lends confidence for using these methods to reveal characteristics of surface adsorption for TBP – accurate enough to predict the outcome of growth experiments and ex-situ scanning tunneling microscopy measurements. Unusual electronic vacancy stabilization effects are revealed by theory to lead to non-statistical growth in the nucleation phase.\cite{2}

In a joint endeavor of experiment and theory, we could further reveal the thermodynamic and kinetic reasons for the unexpected structure of GaP/Si interfaces. Intermixing models established previously are not sufficient to explain the pyramidal structure observed experimentally. Instead, relative facet stabilities and ad-atom mobility in the interface region needs to be quantified to find a rationale for the atomically-resolved measurements.\cite{3} Further fruitful experiment-theory collaborations resulted in transfer of these ideas and approaches towards modelling of CVD of boron carbides.\cite{4}

Recently, the insight gained from \textit{ab initio} CVD modelling are transferred to ALD research. We will present initial results focusing on surface chemistry in ALD and AS-ALD of prototype systems. The specific angle taken is based on electronic structure analysis conducted with our recently proposed energy decomposition analysis for extended systems (pEDA) giving quantitative insight in surface-adsorbate bonding crucial for the growth mechanism.\cite{5}

\textbf{Development of Selenium Containing Single Source Precursors for the AACVD of SnSe and ZnSe Thin Films}

\textbf{Emily Taylor}1,2, Ibrahim Ahmet3 and Andrew Johnson1; 1University of Bath, United Kingdom; 2Centre for Sustainable Chemical Technologies, United Kingdom; 3Helmholtz-Zentrum Berlin, Germany

Whilst heavy chalcogenide containing materials play an important role in a number of opto and thermo electric materials, the development of single source precursors containing elements such as Se and Te has been hindered by the inherent weakness of the elemental bonds. Without the use of expensive techniques or phosphorus containing precursors, metal selenide deposition commonly results in poorly orientated, polyphasic thin films.\cite{1} Aerosol Assisted Chemical Vapour Deposition (AACVD) circumvents the need for volatile materials and uniquely allows access to kinetically stable phases which are typically inaccessible through high temperature deposition techniques.\cite{2}

Based on our work on the development of thioureide complexes for the AACVD of metal sulphide thin films, such as SnS and ZnS, we describe here our initial studies into the synthesis, characterisation and utilisation of the seleno analogues (selenoureides) for the deposition of SnSe and ZnSe thin films.\cite{3, 4}

We have successfully deposited uniform, thin films of phase- pure SnSe which display temperature dependent orientation at temperatures as low as 200 °C. Highly orientated ZnSe polycrystalline thin films at low temperatures have also been produced utilizing the same ligand system.

Vanadium dioxide ($\text{VO}_2$) is a strongly correlated oxide widely studied for applications in electronics due to its metal-insulator transition at approximately 68°C. While thin films and nanostructures of VO$_2$ have been grown on common rigid substrates like sapphire, TiO$_2$, Si and Ge, further expansion of the scope of their application lies in their growth on transferable or flexible substrates making it easier to integrate them into devices. In this work, we report the epitaxial growth of VO$_2$ nanowires on h-BN substrates by chemical vapor transport. We observe that nucleation and growth of VO$_2$ on h-BN proceeds very differently than that on c-plane sapphire: higher nucleation unexpectedly occurs on the h-BN surface and growth tends to proceed outward i.e. toward and beyond the edges of the h-BN substrate. We study the resulting epitaxial strain in h-BN by mapping a shift in a characteristic h-BN Raman peak. We further reveal that the temperature-driven phase transition of VO$_2$ on h-BN proceeds via a single phase boundary which is drastically different from that on substrates such as SiO$_2$ and sapphire, suggesting the presence of weak bonding at the VO$_2$/h-BN interface. Such growth of single crystal VO$_2$ nanostructures not only provides an ideal system to study properties of VO$_2$ based heterostructures but may also be extended to other flexible, transferable substrates.

*Design Rules for Atomic Layer Deposition Precursors and Why You Should Break Them*  
Sean T. Barry; Carleton University, Canada

Atomic layer deposition processes are fundamentally controlled by surface-gas phase reactions, and so depend to a great degree on the nature of the precursor. There are many general rules for the design of precursors: they should have strong metal-ligand bonds to prevent thermolysis, but these bonds should react to allow chemisorption of the precursor to the surface. The precursor should be low molecular weight, since (to ideal assumptions) vapour pressure is related to the inverse of molecular weight, and should be designed to minimise intermolecular interactions. The precursor needs steric protection to assist with self-limiting monolayer formation, but the metal centre must be accessible to reaction with both the surface and the second reactant. Many of these design rules are in opposition to each other, and so a balance must be struck.

When comparing families of precursors, a simple Figure of Merit has allowed us, in a straightforward manner, to compare and diagnose precursor performance. Using examples from across the periodic table, this presentation will demonstrate how a Figure of Merit can highlight when these design rules succeed and when they fail. For example, a molybdenum diimide dimer shows similar volatility to a variety of its base-stabilized monomers but has superior thermal stability. This ultimately makes the dimer a better precursor candidate. In this case, the coordination base in the monomers can be thermally reactive, leading to a low-temperature decomposition route. Similarly, a gold(I) precursor candidate shows its best performance with a ligand with an intermediate steric bulk, mainly due to stabilization of the precursor thermally.

*Influence of Precursor Chemistry on Phase, Morphology and Composition of CVD Grown Metal Oxide and Noble Metal Nanostructured Films*  
David Graf, Michael Frank, Lasse Jurgensen, Aida Jami, Isabel Gessner and Sanjay Mathur; University of Cologne, Germany

The proper selection of tailored precursors plays a crucial role in chemical vapor deposition techniques for the fabrication of high-performance functional nanostructured films. Metal alkoxides are most suitable precursor class for depositing well-defined metal oxide thin films on various substrates with different surface chemistry and complexity, due to their high volatility and defined decomposition mechanism. We demonstrated the strong
influence of the alkyl function in vanadium(IV) alkoxides on phase and morphology. Phase selective chemical vapor deposition of thermochromic vanadium dioxide was achieved by deploying homogeneous and monomeric [V(OBu)t] as a precursor. The produced thin films of monoclinic VO₂ (M1) exhibited a small hysteresis at lower temperatures (63°) in the reversible thermochromic metal-to-semiconductor transition (MST), due to the anisotropic one-dimensional growth. In contrast, use of trimeric [V(OEt)] generated conductive thin films of crystalline vanadium sesquioxide with a flower-like morphology. The in-situ reduction mechanism of the V(IV) precursor to V₂O₃ was elucidated by in-operando mass spectrometry. Moreover, novel volatile and stable heteroleptic bimetallic alkoxides ([LaFe(OBu)₄(L)] and [LaSn(OBu)₄(L))] with L = trifluoro-butenone-tert-butyl amine) as well organometallic noble metal complexes ([M(COD)(L))] COD = Cyclooctadiene; M = Rh, Ir) were synthesized by using tailored multidentate enamino ligand (L) systems. The interdependence of the organic backbone, choice of donor atoms and denticity in the ligand systems on the reactivity, stability and volatility of the resulting precursors were investigated by single crystal structure analysis, NMR-spectroscopy and thermogravimetric measurements (TGA-DTA). Chemical vapor deposition of LaFe(OBu)₄(L) and LaSn(OBu)₄(L) revealed the selective conversion into perovskite LaFeO₃ and pyrochlore Sn₃La₃O₇ thin films, respectively, which shows superior gas sensing characteristics in terms of sensitivity towards sulfur-containing gases (LaFeO₃) and selectivity towards hydrogen (Sn₃La₃O₇). The decoration of noble metals on nanostructured metal oxides was performed in a second CVD step by using our developed heteroleptic janus-type precursors [M(COD)(L)] enhanced their (photo-)catalytic as well gas sensing performance.

11:15 AM FF05.01.08
Reactivity of Atomic Layer Deposition Precursors with OH/H₂O-Containing Metal Organic Framework Materials Kui Tan¹, Stephanie Jensen², Liang Feng³, Jing Li⁴, Hongcai J. Zhou⁴, Timo Thonhauser³ and Yves Chabal¹; ¹The University of Texas at Dallas, United States; ²Wake Forest University, United States; ³Texas A&M University, United States; ⁴Rutgers, The State University of New Jersey, United States

The ability to incorporate metal atoms into nanoporous materials such as metal organic frameworks (MOFs) in a well-controlled fashion provides new opportunities to prepare functionalized and modified materials for potential applications such as catalysis and gas separation. There are however new challenges that need to be overcome such as understanding the reaction mechanisms in order to develop structural and process optimization. MOFs possess three-dimensional structures, with complex pore architecture, leading to a number of possible processes (gas transport, adsorption and reaction) that are much more complex than on flat surfaces. To address these issues, we have combined in-situ infrared spectroscopy, X-ray-photoelectron spectroscopy and ab initio calculation to study the reaction of a number of common ALD precursors --trimethylaluminium (TMA), diethylzinc (DEZ), titanium tetrachloride (TiCl₄)-- with several Zr-MOFs containing hydroxyl (OH) and water (H₂O) groups. Differentiating reaction with OH and H₂O groups is particularly interesting since their reactivity highly depends on both the chemical and structural (i.e. steric) environments. We find that the OH groups in the Zr₆(μ₃-OH)₄(μ₃-O)(OH)₄(OH)₂, cluster node do not all react at similar rates (i.e., the reaction pathway and energetics are highly dependent on their location, accessibility and chemical environment). For different OH-containing MOFs without H₂O groups, the activation temperatures for the TMA reaction with bridge OH of Zr₆ clusters decrease with their node connectivity, and are 250 °C, 150 °C and 24 °C for UiO-66-NH₂, Zr-abc and MOF-808, respectively. Interestingly, the amine group in UiO-66-NH₂ is found to act as a catalytic active site by anchoring TMA molecules and facilitating their reaction with nearby hydroxyl groups, which is not observed in un-functionalized UiO-66. This synergistic effect between -NH₂ and -OH is fully elucidated by first-principles calculations. In addition, we find that TMA easily reacts with water adsorbed on the external surfaces of wet MOFs crystals at room temperature, forming a thick Al₂O₃ blocking layer on the periphery of MOFs crystals. These findings provide a basis for the design and synthesis of new MOFs structures requiring ALD for new applications.

11:30 AM FF05.01.09
Enumeration as a Computational Strategy for Automating the Design of CVD and ALD Precursors Simon D. Elliott, David J. Giesen, H. S. Kwak and Mathew D. Halls; Schrödinger Inc, United States

Chemical vapor deposition (CVD) and surface-limited variant atomic layer deposition (ALD) are strongly dependent on the chemistry of the precursors that are used, affecting yield/througput, stoichiometry, impurities and process temperature. In metalorganic precursors, the central question is therefore the choice of ligands that surround the metal center. Heteroleptic precursors (containing more than one type of ligand) are one way to compromise between conflicting chemical requirements, such as surface reactivity versus thermal stability in the gas-phase. A well-known
example is the Zr precursor that combines cyclopentadienyl and amido ligands (ZyALD(TM), Air Liquide), used commercially in fabrication of DRAM memory for electronics.

However to date we have barely 'scratched the surface' of the vast chemical space of possible heteroleptic precursors. As an example to illustrate the magnitude of the design problem, 715 chemically-distinct heteroleptic complexes can be formed by combining four of 10 ligands around a tetravalent metal center, and 8,855 complexes can be formed from a library of 20 ligands. Clearly, an exhaustive experimental analysis is not possible. Instead we look to computational screening to narrow down the search to the most promising options. Here we present a computational approach for screening metal precursors with respect to a property that is crucial for CVD and ALD: thermal stability. The computational strategy is illustrated on the example of Zr precursors for zirconium nitride, a material that is deposited as a hard coating to protect industrial parts in corrosive environments.

CVD precursors should decompose unimolecularly at elevated temperature in the reactor and we therefore seek complexes with moderately low energies for homolytic bond dissociation (i.e. into a pair of radical fragments). ALD on the other hand requires the gas-phase stability of precursors to be as high as possible, as this dictates the upper temperature limit for ALD. Such stability should be balanced against the requirement of high reactivity of ligands towards the growing surface in ALD.

We first enumerate over ligands. Even a small ligand library of just six O-free, N-bearing ligands (amines, amidinates, cyano and guanidinate, with various alkyl groups) gives $6^4=1296$ possible complexes. However, 94% of these can be neglected as symmetrically equivalent or over-coordinated, leaving 81 for optimization with density functional theory (DFT). To study thermal stability requires a second phase of enumeration, over the 1280 different bonds that can be broken in these complexes (612 C-C and C-N bonds, 446 C-H bonds and 222 metal-ligand connections), yielding a set of radical fragments that are also computed at the DFT level. It is clear that every step in this computational workflow requires robust and efficient automation.

DFT reveals that the lowest bond dissociation energies are obtained for cleaving intact ligands from the metal, ranging 133-471 kJ/mol (compared to higher energies for ligand decomposition by abstracting radicals: 198-371 kJ/mol for the ethyl radical, 233-401 kJ/mol for methyl and 310-463 kJ/mol for the hydrogen atom). The least thermally stable complexes are found to be zirconium amides with bidentate amidinates/guanidinates, and so we predict that these would be the best CVD precursors. We observe very little steric effect when replacing methyl groups with ethyl groups. By contrast, cyano groups have a stabilizing influence, suggesting that they would be useful as spectator ligands in heteroleptic precursors for ALD. On the basis of this sample system, we discuss the general requirements for chemical enumeration software and the limits faced by automation.

**Atomic Layer Deposition of Zinc-Doped Alumina at Room-Temperature for Organic Opto-Electronics**  
Sabrina M. Wack, Shiv Bhudia, Noureddine Adjeroud, Jérôme Guillot and Renaud Leturcq; Luxembourg Institute of Science and Technology, Luxembourg

We investigate a new process for the low-temperature atomic layer deposition (ALD) of high-quality insulating layers based on alumina. In organic opto-electronics, alumina thin films play a major role as insulating material (gate dielectric), passivation layer or encapsulation layer (gas permeation barrier). Atomic layer deposition (ALD) is known for growing amorphous alumina with high density and high electrical quality, but the deposition conditions usually require either a temperature above 100°C or highly oxidative condition (oxygen plasma or ozone) to obtain a reasonable deposition rate and high material quality. A method for producing high quality alumina below 60°C using low oxidative conditions would be highly welcome for the highly sensitive materials used in organic electronics.
By incorporating zinc as dopant during the deposition of alumina, we demonstrate the ALD of high-quality alumina films at room-temperature, while keeping a single ALD cycle below 1 minute. The resulting material shows physical properties very close to alumina grown above 80°C. The films with 5% Zn content are amorphous, with a density above 3 g/cm³, and a dielectric constant of 7.7 ± 0.4. The gas permeation rate though the zinc-doped alumina thin films has also been investigated, showing gas barrier performances comparable to alumina deposited above 80°C. In order to understand the role of zinc doping in the deposition mechanism, we have performed in-situ mass measurements using a quartz crystal microbalance, and have analysed high resolution X-ray photoemission spectra. They reveal that zinc might help the growth of alumina at low temperature by avoiding trapping of water molecules on the surface.

1:45 PM FF05.02.02
Hydrogen-Free CVD of WSe2 Monolayers from Inorganic-Se Precursors Mauro Och¹, Pawel Palczynski¹, Giulia Z. Zemignani¹,², Evgeny Alexeev³, Alexander Tartakovskii³ and Cecilia Mattevi¹; ¹Imperial College London, United Kingdom; ²Politecnico di Milano, Italy; ³The University of Sheffield, United Kingdom

Chemical Vapour Deposition (CVD) of Transition Metal Dichalcogenides (TMDs) is a promising fabrication technique that can enable both scalable synthesis and high crystal quality, both required for applications of TMDs in monolayer form. The state-of-the-art of CVD of WSe2 often relies on the use of large quantities of H2 gas as reducing agent for Se0, which represents a hazard in research laboratories and for the future industrial upscaling. Furthermore, metal-organic CVD (MOCVD) syntheses employ H2Se along with hydrogen gas, increasing the potential hazard of the process. Here, we present a H2-free low pressure CVD of WSe2 based on the chalcogen precursor chemistry. We discovered that ZnSe, containing already reduced Se (Se-2), allows the fabrication of large WSe2 monolayer flakes as well as thin films with grain size up to 100 µm. The uniqueness of this inorganic Se-precursor have been demonstrated by performing synthesis from Se powder and other inorganic Se compounds (Cu2Se, CdSe and Na2Se), which did not lead to evidence of WSe2. The chemical reaction steps have been identified and will be discussed. In addition, since our W- and Se-precursors possess similar volatilities we have simplified our CVD setup from a two-zone furnace, usually used for TMDs growth, to a single-zone furnace. The growth temperature has been selected according to vacuum TGA data, whereas the other growth parameters, i.e. pressure, growth time and quantities have been optimised to yield mono- and few-layered WSe2 crystals. The synthesized material possesses optical properties comparable to exfoliated crystals, assessed by room temperature (RT) and low temperature PL measurements on WSe2 deposited onto SiO2. The RT-PL peaks exhibit FWHM of ~50 meV, while low T PL shows a defect-bound exciton signal similar to mechanical exfoliated crystals. XPS analysis demonstrate high chemical purity of the synthesized material, and absence of Zn in the flakes.

2:00 PM *FF05.02.03
Engineering of Molecular Architectures of Metal Precursors for Vapor Phase Routes to Energy Harvesting and Energy Conversion Systems Nishant Peddagopu¹,², Anna Pellegrino¹,² and Graziella Malandrino¹,²; ¹Universita' degli Studi di Catania, Italy; ²INSTM, Italy

Nanostructured advanced materials require challenging synthetic methods ultimately suited for large scale fabrication of materials with specifically designed properties. Vapor phase routes are appealing synthetic approaches following a bottom-up building strategy, but for the synthesis of multicomponent nanostructures and films, the availability of suitable precursors is of crucial importance.

The various vapor routes require precursors with different properties, thus in conventional Metalorganic Chemical Vapor Deposition (MOCVD), the metal sources must be thermally stable and volatile, liquid assisted MOCVD processes require soluble complexes and atomic or molecular layer deposition (ALD, MLD) routes need volatile and reactive sources.

With this perspective, the presentation will focus on metal adducts bearing linked β-diketonate (β-dik) and ancillary Lewis ligands L of general formula “M(β-dik)nL”. The relationships involving the molecular architectures and mass transport properties of the adducts in function of the metal nature (M= alkaline, alkaline-earth and rare-earth metal) will be discussed. The effects due to the nature of the β-diketonate (1,1,1,5,5,5-hexafluoroacetylacetone or 2-thienoyl trifluoroacetonate) moiety as well as of the ancillary ligand L [L= monoglyme (dimethoxyethane), diglyme (bis(2-methoxyethyl)ether), triglyme (2,5,8,11-tetraoxadodecane), tetraglyme (2,5,8,11,14-pentaoxapentadecane), tmeda (N,N,N',N'-tetramethylethylenediamine], on mentioned properties will be addressed as well.

The perspectives of applications of these precursors to MOCVD and MLD of advanced materials for energy harvesting and energy conversion are presented.
In regard to energy harvesting applications, novel lithium precursors will be described for the MOCVD of LiNbO₃ thin films. As energy conversion systems, alkaline earth fluorides such as MF₂ (M: Ca, Sr) and the multicomponent MREF₄ (M: Na,K; RE: Y,Gd) are studied as materials for the production of new and more efficient photovoltaic (PV) devices due to their efficient hosts behavior for upconversion (UC) or downconversion (DC) processes. Finally, a case study of application of MLD to the fabrication of inorganic/metalorganic hybrid system will be commented.

Part of this work is supported by the European Community under the Horizon 2020 Programme in the form of the MSCA-ITN-2016 ENHANCE project, Grant Agreement N.722496.

2:30 PM FF05.02.04
Chemical Vapor Deposition of Cuprous Halide Thin Films Christina M. Chang¹, Luke M. Davis¹,² and Roy Gordon¹,¹; ¹Harvard University, United States; ²Tufts University, United States

Metal halide compounds tend to possess large bandgaps, optical transparency, ion conductivity, and semiconducting or dielectric properties. Thin films of metal halides are thus promising for use in a wide range of applications, from optical coatings and imaging devices to optoelectronic devices like photovoltaics. To be useful in many of these applications, the metal halide thin films must meet several requirements, including continuity, purity, and smoothness. Chemical vapor deposition (CVD) is one of the main techniques used in industry to fabricate device-quality films of other materials, because of its molecular-level control of the fabrication process. However, research efforts in the development of a CVD process to deposit continuous metal halide thin films have met several reactivity challenges. The few known metal halide CVD and ALD processes have been confined almost entirely to metal fluorides, and have typically required ancillary metal halides as the halide source. A more general route to metal halide vapor deposition, such as one using the hydrogen halides (HX) as the halide source, would be of considerable interest. Some researchers have succeeded in producing discontinuous “islands” of metal halides (e.g., CuCl, CuI) using HX as a precursor, but continuous thin films of metal chlorides, bromides, and iodides have remained elusive.

In response to this challenge, we have developed a pulsed chemical vapor deposition method that produces continuous CuBr thin films by reaction between HBr gas and vinyltrimethylsilane(hexafluoroacetylacetonato)copper(I). CuBr films were grown in a custom-built, hot-walled ALD reactor, at a range of substrate temperatures, between 65 and 135 °C. Rutherford backscattering (RBS) was used to quantify and confirm the 1:1 Cu:Br stoichiometry, and the RBS peak shapes indicate compositional uniformity throughout the film. γ-phase CuBr was confirmed by X-ray diffraction. Scanning electron microscopy was used to characterize the morphology of the films resulting from a variety of temperature and substrate conditions. We have found that the substrate surface can strongly influence film morphology, and that appropriate substrate choice can enable device-quality film continuity. Whereas CuBr islands were produced when grown on oxide surfaces such as SiO₂, we found that continuous CuBr films could be produced on other surfaces, such as glassy carbon, silicon nitride, or platinum.

To the best of our knowledge, these results constitute the first continuous, non-fluoride metal halide thin films deposited by CVD using the hydrogen halide as the vapor source. Our method provides a reaction pathway that may offer a more general route to CVD of metal halide thin films.

2:45 PM FF05.02.05
Facile Synthesis of Nickel Sulfide Millimeter Long Nano-Arrows (NiS₂) Using Chemical Vapor Deposition Pola Shriber¹, Rimon Tamari², Maria Tkachev¹, Sharon Bretler², Louisa Meshi² and Gilbert D. Nessim¹; ¹Bar Ilan University, Israel; ²Ben-Gurion University of the Negev, Israel

Transition metal sulfides, and in particular nickel sulfides with various compositions and phases, are gaining attention due to their potential application in practical devices.¹⁻³ We have previously demonstrated the bottom-up synthesis of bulk metal sulfides using atmospheric pressure chemical vapor deposition (AP-CVD), with elemental sulfur as a precursor.⁴ The method we developed allows us to synthesize a wide range of materials; by tuning precursors and process parameters, we can somehow control the morphology, stoichiometry, and structure of the synthesized materials. Here, we present the synthesis of arrow-like structures of nickel sulfide using chemical vapor deposition. To the best of our knowledge, these arrow-like morphologies (with pyramidal termination) were not reported before. A carpet of
long nickel sulfide arrows grew on a nickel foil. The arrows are up to 2 mm long with a high aspect ratio and a diameter of a few microns. XRD examination of the samples indicates Ni$_3$S$_2$ stoichiometry although detailed EDAX along the arrow indicates slight changes in stoichiometry as a function of the position in the arrow (closer or farther from the tip).

We will discuss the synthesis and the growth mechanism of these original structures based on extensive characterizations such as HRSEM, EDS, FIB, and HRTEM.

Prospects for Nanostructuring Ultrathin Organic and Hybrid Films via Molecular Layer Deposition
David S. Bergsman$^{1,2}$, Richard G. Closser$^3$, Christopher J. Tassone$^1$, Bruce M. Clemens$^2$, Dennis Nordlund$^3$ and Stacey F. Bent$^2$; $^1$Massachusetts Institute of Technology, United States; $^2$Stanford University, United States; $^3$SLAC National Accelerator Laboratory, United States

Molecular layer deposition (MLD) is an increasingly popular process for the growth of organic and coordination polymer ultrathin films. This vapor-phase, layer-by-layer technique, which relies on the same principle of self-limiting surface reactions as atomic layer deposition, has shown promise for the development of many applications that require conformal organic-containing coatings. However, in many technologies, such as membranes, catalysts, and semiconductor devices, there is a growing need for ultrathin films with precisely controlled pore structure and crystallinity. Despite recent developments in MLD, there is still a significant gap in our understanding of the fundamental mechanisms that affect film structure, such as the origin of the film growth rate or their molecular-level properties. In this presentation, we present results of our recent studies to understand such mechanisms and discuss prospects for better controlling film structure moving forward.

First, we discuss our exploration of the growth behavior of MLD films by examining trends in film properties as a function of backbone flexibility [1]. Our results suggest that changes in growth rate between the most rigid and most flexible backbones (4 Å/cycle vs 1 Å/cycle) are not caused by differences in length of molecular precursors, chain orientation, or film density, but are instead caused by an increased frequency of terminations in the more flexible chemistries. These terminations likely result from monomers reacting with more than one functional group on the underlying surface, which reduces the total number of available reactive sites. We further elaborate on the relationship between the number of reactive sites and the film growth rate by modeling growth behavior after an intentional reduction in the number of reactive sites [2]. We show that terminations caused by dual-reacting monomers reduce the film growth rate; however, the adsorption of monomers likely reintroduces reactive sites, preventing the complete cessation of film growth. We also present diffraction and infrared absorption data, which suggest that films consist of a mixture of upward growing chains and horizontally aligned layers of paracrystalline polymer segments [1]. Combined, these results provide a clearer picture of the disordered nature of MLD and provide insight for the design of future ultrathin film synthesis chemistries. We conclude by highlighting recent work to create structured ultrathin films and propose several avenues of research to create films with precise morphological control.

Gallium oxide (Ga$_2$O$_3$) possesses an extremely wide bandgap around 5 eV and has attracted more attention for applications to power devices and optoelectronic devices. Ga$_2$O$_3$ exhibits five polymorphs of α, β, γ, δ, and ε phases. Among these polymorphs, only metastable-phase orthorhombic ε-Ga$_2$O$_3$ exhibits large spontaneous polarization and ferroelectricity. [2, 3]

The polarization of ε-Ga$_2$O$_3$ is expected to lead to two-dimensional electron gas (2DEG) induced at ε-(Al$_x$Ga$_{1-x}$)$_2$O$_3$/ε-Ga$_2$O$_3$ hetero-structure interface, like conventional AlGaN/GaN-type high electric mobility transistor (HEMT). Furthermore, the ferroelectricity of ε-Ga$_2$O$_3$ expected to be ferroelectric devices, such as ferroelectric field effect transistor (FeFET). It has been reported an epitaxial growth of ε-Ga$_2$O$_3$ thin films by physical vapor deposition (PVD) and chemical vapor deposition (CVD) techniques. Among various growth techniques, we have focused on mist CVD for the epitaxial growth of ε-Ga$_2$O$_3$ thin films. Also, we previously reported that orthorhombic ε-(Al$_x$Ga$_{1-x}$)$_2$O$_3$ and ε-(In$_x$Ga$_{1-x}$)$_2$O$_3$ alloy films were epitaxially grown via mist CVD. [4, 5]

To achieve ε-Ga$_2$O$_3$ based device applications, such as HEMT and FeFET, high crystal quality ε-Ga$_2$O$_3$ thin films with smooth film surface are essential issues of the crystal growth. In this study, we report on investigations to improve crystal quality and to obtain a smooth surface using mist CVD. In the mist CVD, gallium (III) acetylacetonate is generally utilized as Ga precursor dissolved in a water solution. We have previously demonstrated that controlling the Ga/O ratio by varying the Ga precursor concentration in the solution enables smooth film surface under stoichiometric conditions [6], indicating that chemical reactions under the growth of ε-Ga$_2$O$_3$ film can be controlled in the mist CVD process like other CVD techniques.

Besides, we performed two approaches to improve the crystal quality of ε-Ga$_2$O$_3$ thin films using mist CVD; use of carbon-free gallium (III) chloride as CVD precursors and a surfactant effect of heavy atom addition in a precursor solution.

We obtained ε-Ga$_2$O$_3$ thin films grown on epitaxial substrates using gallium (III) chloride with higher crystal quality than that using gallium (III) acetylacetonate, considering incorporation of impurities, such as carbon was reduced.

The surfactant effect can be expected to enhance the migration of atoms on the film surface in the growth process. We utilized bismuth atom as a surfactant and the precursor was bismuth basic nitrate dissolved in the starting solution with gallium precursors. FWHMs of XRC for (004) ε-Ga$_2$O$_3$ with and without Bi precursors were estimated as 0.13 and 0.43, respectively, indicating that the crystal quality was drastically improved by only containing Bi precursors in the starting solution. Furthermore, the RMS roughness calculated from AFM was also improved 1.0 nm to 0.4 nm by using Bi precursors. Thus, we assumed that the Bi-assisted growth of ε-Ga$_2$O$_3$ thin films in the mist CVD method to improve the crystal quality and the surface morphology. We believe that our results in the mist CVD will be useful in the development of device applications.

Atomic layer deposition (ALD), self-limiting version of CVD, is a very attractive method due to superior characteristics of conformal deposition, precise thickness and composition control, and pinhole-free thin films. The advantages make ALD used widely in various applications such as microelectronics, photovoltaics, and energy storage systems. One of the most widely used and studied ALD materials is alumina which has great mechanical, optical, and electrical properties and functions as high-k dielectrics, chemical protection layers, and encapsulation layers for flexible devices. However, because of the brittle nature of the ALD alumina, cracks in the ALD alumina layer in flexible devices occur commonly by bending. Considering the mechanical problem, it is most important to measure precisely mechanical properties of the ALD alumina. Despite the importance, studies on intrinsic mechanical properties of the ALD alumina have been very insufficient. Previous works measured mechanical properties of the ALD alumina by using indirect methods such as nanoindentation, nanobeam bending, and bulge test, which are difficult to obtain accurate mechanical properties due to substrate effect or complicated calculation. In this study, we conducted tensile tests on ALD alumina thin films on the water surface without substrate and obtained stress-strain curves and intrinsic tensile properties of the ALD alumina itself directly and easily. Deposition temperatures of the ALD alumina for tensile tests were 80, 100, 150, 200, and 250 °C, and deposition temperature effect on the tensile properties were investigated. The tensile properties such as Young’s modulus and strength were increased with the increase of deposition temperature up to 200 °C, and then the tensile properties were reduced again. We proposed the defect generation mechanism related to impurities and hydroxyl groups, where the major defects in the ALD alumina thin film are changed, depending on deposition temperature. The defect generation mechanism was verified by the composition, roughness, and density of the ALD alumina measured by XPS, AFM, and XRR, respectively. The deposition temperature effect on tensile properties of ALD alumina was explained successfully by using the mechanism.

Characterizing Ultra-Thin Layers Using High Resolution Low Energy Ion Scattering (LEIS) Thomas Grehl1, Philipp Brüner1 and Nathan Havercroft2; 1IONTOF GmbH, Germany; 2ION-TOF USA, Inc., United States

Layers of only a few atomic layers are often deposited by ALD, intending high control over the properties of the film. In these cases, the characterization of the early stages of film growth is crucial to optimize the process and quality of the film. For example, the initial thickness distribution before layer closure, created by the nucleation process, will often remain after the film is complete. To analyze these early stages of growth requires very surface sensitive analytical techniques with excellent detection limits. Specifically for area selective deposition, the demand for characterization increases even further. The deposition process becomes more complex, involving etching steps to remove nucleation on blocked areas. In this case, means of characterization are required which determine the effects of etching steps on the growing film, possible contamination and the level of success of the blocking.

A technique specifically suited for these application is Low Energy Ion Scattering (LEIS). By scattering noble gas ions from the surface of the sample, the mass of the atoms in the outer atomic layer is determined non-destructively. Due to specific charge exchange processes, the peaks in the scattering spectrum correspond only to the outer atomic layer, making LEIS the most surface sensitive technique to determine the elemental composition of a surface. In addition, information from deeper layers is available in two ways: First of all, features in the spectrum contain information about the first few nm of the sample – especially for heavier elements, the in-depth distribution can be determined non-destructively. For more complex systems or light elements, sputter depth profiling can be applied as well.

We will highlight the very special analytical possibilities of LEIS in the context of thin film analysis. Examples from industrial as well as academic collaborations will demonstrate typical analytical tasks. These include compositional analysis of the outer layer to determine residues of the precursor (e.g. fluorine), layer thickness evolution with varying process parameters, and core-shell nanoparticle analysis with respect to shell closure.

SESSION FF05.03: Theoretical and Experimental Advances in ALD/CVD Chemistry III
Session Chairs: Kevin Musselman and Greg Randall
Tuesday Morning, December 3, 2019
Hynes, Level 3, Room 310
Off-stoichiometric copper chromium delafossites demonstrate the highest values of electric conductivity among the non-doped p-type transparent conducting oxides. Values of electrical conductivity beyond $100 \text{ S/cm}$ are measured, this is only one order of magnitude lower than the actual n-type standard semiconductors. Values for carrier concentration beyond $10^{21}/\text{cm}^3$ are determined for the as deposited films. However, a good understanding of the doping source and conduction mechanism is required in order to tailor the optoelectronic properties towards values required in industrial applications. Controlled annealing was performed on the as deposited samples. A dramatic five order of magnitude decrease for the conductivity was measured, without observing any significant phase changes or alteration of average chemical environment. The thermal treatment proves itself as a useful tool for: first, tailoring the electric properties (such as electrical conductivity or Fermi level) ; second, investigating the source of the high level of doping on this material. High resolution Helium Ion Microscopy, Secondary Ion Mass Spectroscopy and Transmission Electron Microscopy and Positron Annihilation Spectroscopy were used to investigate the fine morphological and structural changes in $\text{Cu}_{0.66}\text{Cr}_{1.33}\text{O}_2$ upon annealing processes. The results indicate the chained copper vacancies as source of p-type doping and suggest furthermore that the changes in electrical conductivities within the off-stoichiometric copper-based delafossites are triggered by atomic rearrangements. This process, similar with an Oswald ripening mechanism, is based on the dissolution of the chains of vacancies into single Copper vacancies migrating to grain boundaries. A significant rearrangement of copper and chromium atoms after thermal treatments is revealed. The inhomogeneous distribution observed in the as-deposited high conductive thin films evolves to a uniform atomic dispersion within the annealed low conductive samples.

Vapor deposition (VD) techniques have been highly successful in a wide variety of nanotechnological applications. However, films prepared by current VD methods are easily either highly continuous or have difficulties in functionalizing surfaces far out-of-sight, and therefore scaling them down to complex nanostructures can be challenging. It has been shown that with capillary condensation (CC) it is possible to coat and fill nanostructures selectively and controllably from the vapor phase.[1]

CC is a phenomenon of gas-to-liquid condensation inside nanocavities below the saturation point of the condensate. Because CC scales negatively with the surface feature size, it is possible to coat or fill selectively those surfaces and spaces which have been considered to be the hardest to reach, for example complex nanopores, ledges, and particle interstices.[1] First a reagent is allowed to reach a gas-liquid equilibrium at a predefined partial pressure. Then it is fixed into solid phase by a chemical reaction.

CC based methods are capable of bypassing and reversing many traditional problems related to VD, such as limited scalability in nanostructures, low control over spatial selectivity, sensitivity to gaseous inhibitors, and sometimes high process complexity and harsh conditions.[1] Due to the simplicity of CC, the process is easy to apply with no prior expertise in simple reactors which vary from a closed container with overpressure venting[2], to self-built reactor line for high process control with manual[1] or computer-assisted controls[3], or likely even established iCVD reactors[4] if the parameters were optimized below supersaturation. CC has been utilized for processes with polyacrylates and polystyrene on various substrates with UV initiation[1], silicon on carbon with thermal initiation[2] and silica on titania with chemical initiation[3].

In the presentation we explore principles and applications for CC based coating methods. We also show early results on how the fillings could be used as nanotemplates for inorganic material deposition during Vapor Phase Infiltration.[5] Studying the fundamentals of CC based methods could create a foundation for a novel VD paradigm for toposelective vapor deposition in nano- and micron-scaled structures. Additionally, CC based processes could be attractive also for industry due to their simplicity.

Advanced technologies in electronics, energy production, and energy storage require increasingly robust protection against destructive environmental conditions, such as high humidity, condensation, reactive gases and organic contaminants. At the same time, conventional encapsulants can interfere with performance, due to modified surface roughness or changes in optical, mechanical or thermal properties of the substrate.

Chemical vapor deposition of conformal films addresses many of the challenges with changes in substrate properties. The relatively low thickness and high conformality of vapor-deposited coatings allows for minimal alteration in substrate properties while ensuring a high level of protection.

GVD Corporation is developing a vapor-deposited, multilayer gas barrier coating for environmental protection specifically for flexible substrates. GVD’s approach combines its proprietary method for vapor deposition of polymers, called iCVD, and plasma enhanced chemical vapor deposition into a single, streamlined process. The coating takes advantage of fine thickness control to achieve the barrier properties of brittle materials in flexible films. To maximize the commercial potential of this technology in advanced applications, like elastomeric seal protection and solar cell encapsulation, GVD has optimized the process for barrier performance and film deposition rate. The impact of coating uniformity, chemical structure and multilayer stack design will be discussed.

*In Situ Characterization of Metal Oxide Films Produced Using Atmospheric Pressure Spatial ALD*  
Alexander Jones, Kissan Mistry, Manfred Kao, Mustafa Yavuz and Kevin Musselman; University of Waterloo, Canada

Metal oxide films are a common component in modern electronic devices, from cell phones to photovoltaics. Atmospheric Pressure Spatial Atomic Layer Deposition (AP-SALD) is a novel technique for producing these films, retaining the high conformity and precise thickness control of conventional ALD, but without expensive vacuum chambers or time-consuming purge cycles. Where conventional ALD may take hours to produce a 100 nm Al2O3 film, our AP-SALD system can produce the same film in under twenty minutes. It is beneficial to couple AP-SALD with characterization tools that can quantitatively determine the properties of a film as it is being deposited in real time. Thus, the properties of the film can be optimized immediately via the deposition parameters such as precursor concentrations, deposition speed, reactor head height, or temperature. Using a combination of reflectance spectrometry and a novel flexible printed circuit board (PCB) our group was able to characterize how doped and undoped ZnO films change during depositions under various conditions. This allows for observation of film nucleation mechanisms, and determining the thickness, optical band gap, resistivity, refractive index, and uniformity of the films while they are forming. Notably, analytical models (Cauchy, Tauc-Lorentz, Drude-Lorentz) are used to determine the optical properties, with a feed-forward neural network providing initial guesses for those models.

*Nanometal Interconnection Layers Deposited via Site-Specific Chemical Vapor Deposition for High Conductivity Copper-Carbon Nanotube Hybrids*  
Anthony P. Leggiero1, Dylan J. McIntyre1, Erin D. Loughran1, Shannon Driess1, Cory D. Cress2, Ivan Puchades1 and Brian Landi1; 1Rochester Institute of Technology, United States; 2U.S. Naval Research Laboratory, United States

Carbon nanotubes (CNTs) hold great theoretical promise as electrical conductors due to a combination of high conductivity, flexure tolerance, tensile strength, and a low thermal coefficient of resistivity (TCR). However, the resistive junctions between individual carbon nanotubes and bundles of CNTs, along with misalignment within bulk structures presents a unique challenge in the translation of the individual electrical conductivity to bulk applications. One strategy currently under investigation to alleviate these issues is to integrate CNTs with traditional metallic conductors yielding a hybrid material which combines the metal’s high conductivity with the low density and TCR of CNTs. Copper has traditionally been chosen to produce such composites, although the metal has limited interaction with the underlying carbon nanotubes.

In this study, site-selective chemical vapor deposition (CVD) is used to deposit nanometal interconnection seeds onto a porous, low-density (0.12 g/cm3, ~9 mg/m) CNT template. This site-specific method utilizes localized changes in the resistance within the bulk CNT template to preferentially deposit an organometallic precursor at thermally active sites. The deposited seeds act as interconnections sites with an electrodeposited copper metal overcoating. Group 10 elements like nickel, palladium and platinum exhibit more favorable wetting characteristics with the CNTs, allowing for more efficient interaction between the copper overcoat and the underlying CNTs. The deposited mass and distribution of seeds may be tuned through process parameters including precursor temperature, current density, time, etc., allowing for sparse depositions of seeds localized to hot spots (<20% w/w metal) as well as high densities of seeds leading to interconnection of the deposited nanometal network (>80% w/w metal). These nanometal seeds can be deposited throughout the carbon template in relatively short periods of time (~1 hour) compared to previous techniques such as electroplating (>10 hours). The morphology of depositions from various seeding metals have been investigated using scanning electron microscopy. In an example study with a low mass (~20% w/w) of deposited platinum seeds, alteration of electroplating rate allowed for the tuning of properties such as electrical conductivity, specific conductivity, density and TCR. Conductivity as high as 31.3 MS/m and TCR as low as 0.97 x 10^-3 K^-1 were achieved at 94.4% w/w total metal mass through modification of deposition and plating parameters. These values are increasingly competitive with traditional copper, which has an electrical conductivity of 58 MS/m and TCR of 3.83 x 10^-3 K^-1 at room temperature. Overall, the present results demonstrate the potential of site-specific CVD towards the enhanced nanometal interconnection of carbon conductors (NICCs).

Atomic Level Selective Surface Treatment by Down-Stream Plasma Generated Organic Radicals in Semiconductor Device Fabrication Xinliang Lu1, Haochen Li1, Hua Chung1, Michael Yang1, Ting Xie1, Qi Zhang1, Shawming Ma1, Il-Kwon Oh2 and Stacey F. Bent2; 1Mattson Technology Inc, United States; 2Stanford University, United States

With continuous CD scaling of semiconductor devices, surface and interface engineering plays an increasingly important role in semiconductor device fabrication, and atomic level surface treatment has been incorporated in thin film deposition, lithography and etch processes. Radicals are highly reactive yet do not damage materials surfaces, thus have become popular precursors in emerging atomic surface engineering applications.

In the present study, a high flux of methyl radicals is generated in a down-stream plasma setup in combination with optimized gas flow, pressure and plasma source power. Methyl radicals from the down-stream plasma source can be applied for treatment of semiconductor, dielectric and various metal surfaces. Surface methyl group coverage can be controlled by methyl radical exposure time and substrate temperature, as evident in surface infrared (IR) characterization and surface contact angle measurement.

Methyl groups on semiconductor and dielectric materials surfaces are stable upon air exposure. Sub-monolayer methyl group coverage can passivate silicon and silicon germanium surfaces, effectively eliminate native oxide growth, and thus alleviate issues with tedious queue-time control in semiconductor fabrication flows. In addition, surface methylation offers unique materials protection against chemical corrosion, including a complete stop of silicon loss in aqueous tetramethylammonium hydroxide (TMAH), a significant reduction of silicon oxide loss in aqueous HF and KOH, and a significant reduction of silicon nitride loss in aqueous H3PO4 solutions.

Low-k, silicon oxide and silicon nitride films are subject to carbon loss upon exposure to oxygen-based dry etch chemicals, etc. The surface methylation process can be adopted to restore carbon content in the surface region of low-k materials, as indicated by a recovery in X-ray photoelectron spectroscopy (XPS) carbon intensity and surface wetting angle.

Various metal materials are incorporated in semiconductor devices as work function, interconnect liner and conductor materials, respectively. Surface chemistry of hydrocarbons on different metal surfaces has been well studied [1]. Methyl radicals break down to carbon residues on reactive metal surfaces (e.g. Co). In comparison, surface methyl groups can be converted to volatile hydrocarbon products on clean metal surfaces with moderate reactivity (e.g. Cu), and thus contamination of the metal surfaces can be negligible in this methyl radical process. Overall, a selective surface methylation process is feasible on patterned wafers with exposed dielectric and copper surfaces. The selective surface methylation process can be inserted into standard back-end-of-line (BEOI) dual damascene interconnect fabrication process flow, leading to a reduction in effective capacitance with no increase of Cu line and via resistance.

The selective surface methylation pretreatment process can be further extended to area-selective chemical vapor deposition (CVD) and ALD, particularly for selective dielectric materials deposition on metallic surfaces. In our exploratory studies, ZnO ALD is carried out on silicon oxide surfaces with and without surface methylation pretreatment, and film growth is characterized by surface IR, transmission electron microscopy (TEM), XPS, X-ray fluorescence (XRF) and atomic force microscopy (AFM). In absence of surface methylation treatment, dielectric films can be deposited readily on silicon oxide surfaces. After a methylation pretreatment, however, silicon oxide surface exhibits an incubation period in ZnO ALD cycles. We propose that the dielectric film deposition on silicon oxide surface can be further suppressed with a periodic surface methylation treatment. Subsequently, a novel selective ALD process can be developed to deposit dielectric thin film on top of Cu interconnect structures vs dielectric materials in BEOI integration scheme.

Area-Selective Atomic Layer Deposition of 2D WS₂ Nanolayers
Shashank Balasubramanyam, Mark Merkx, Erwin Kessels, Adrie Mackus and Ageeth A. Bol; Eindhoven University of Technology, Netherlands

With continued downscaling of device dimensions, ultra-thin two dimensional (2D) semiconductors like WS₂ are considered as promising materials for future applications in nanoelectronics. At these nanoscale regimes, device fabrication with precise patterning of critical features is challenging using current top-down processing techniques. In this regard, area-selective atomic layer deposition (AS-ALD) has emerged as a promising candidate for bottom-up processing to address the complexities of nanopatterning. Till date, AS-ALD of metals¹ and dielectrics² have been successfully demonstrated. However, AS-ALD of 2D materials has remained elusive. In this contribution, we demonstrate area-selective deposition of 2D WS₂ nanolayers by using a three-step (ABC-type) plasma-enhanced ALD process.

AS-ALD of WS₂ was achieved by using acetylacetone (Hacac) inhibitor (A), bis(tertbutyllimido)-bis(dimethylamido)-tungsten precursor (B), and H₂S plasma (C) pulses. This process resulted in immediate growth on SiO₂ while a significant nucleation delay was observed on Al₂O₃, as determined from in-situ spectroscopic ellipsometry and ex-situ X-ray photoelectron spectroscopy measurements. The surface chemistry of this selective process was analysed by in-situ Fourier transform infrared spectroscopy. The analyses revealed that the inhibitor adsorbed on the Al₂O₃ surface, blocking precursor adsorption, while little or no inhibitor adsorption was detected on the SiO₂ surface where WS₂ was readily deposited. Furthermore, the area-selective growth was demonstrated on SiO₂ samples with patterned Al₂O₃ on top.

To improve the crystallinity, the AS-ALD WS₂ films were annealed at temperatures within the thermal budget of industrial semiconductor processing (≤ 450°C). The annealed films exhibited sharp Raman peaks, which is a fingerprint of highly crystalline WS₂. Furthermore, Raman line scans over the patterns showed very sharp peak intensity transitions at the SiO₂-Al₂O₃ interface which confirmed that annealing had no impact on selectivity. To summarize, this work pioneered the combination of two key avenues in atomic-scale processing: area-selective growth and ALD of 2D materials. It is expected that the results of this work will lay the foundation for area-selective ALD of other 2D materials.

Area-Selective Deposition Using Atomic-Layer-Deposited Carbon, Fluorine-Free SiOₓ as an Inhibitor
Taewook Nam, Inkyu Sohn, Seunggi Seo, Tatsuya Nakazawa and Hyungjun Kim; Yonsei University, Korea (the Republic of)

In area-selective atomic layer deposition (AS-ALD), the chemisorption of a precursor and reactant can be promoted or suppressed depending on the terminal groups of the substrate. For instance, nucleation and growth of an ALD film will be suppressed when the surface reaction sites are fully terminated with -CH₃ or -CF₃ groups, which have low reactivity with precursors or reactants. These chemical species that hinder the reaction on the substrate surface are called inhibitors, among which self-assembled monolayers (SAMs) have been widely studied because of their excellent inhibitor characteristics. However, the formation of a SAM on the surface of a substrate with excellent packing density requires extremely long times, which renders it not applicable to large-scale fabrication processes. Furthermore, chemisorption of a SAM requires the use of a specific substrate depending on the SAM head group, and carbon- or fluorine-containing byproducts with deleterious effects on devices can be produced during post-processing. Thus, the development of a simple approach for the fabrication of inhibitors without carbon and fluorine is required.

Hydrogen-terminated species are alternative candidates as inhibitors. The adsorption of a precursor or reactant can be inhibited when the substrate surface contains H-terminated reaction sites, which are formed by H₂ plasma treatment or hydrofluoric acid dipping. However, these processes may induce damage on the substrate or device, and complete passivation of the surface reaction sites is not ensured. Moreover, H-terminated species has poor stability and can be easily oxidized in ambient condition after only a few hours of exposure, loosing its inhibitor characteristic.

In this study, we firstly report the use of atomic layer-deposited SiOₓ as an inhibitor for AS-ALD. Unlike the traditional hydrophilic SiO₂, the SiOₓ formed by ALD using an aminodisilane precursor i.e., 1,2-bis(diisopropylamino)disilane, showed excellent hydrophobicity, even though the film was only one nanometer thick. From a thorough analysis of the film, including X-ray photoelectron spectroscopy (XPS) and Fourier-transform infrared spectroscopy (FT-IR), we confirmed that this peculiar hydrophobicity is caused by the presence of SiH₃ species, not by surface carbon from incomplete ALD reaction or by hydrocarbon from the air. The excellent stability of the SiOₓ film was also demonstrated. Thus, it retained its hydrophobicity over a month and after
exposure up to 350 °C in dry gas or at 250 °C in the ambient atmosphere. The ALD growth inhibition was confirmed by comparing the deposition of ALD Pt on the bare substrate and on the SiO$_x$-deposited substrate; the nucleation of Pt starts on the bare Si substrate after the 100th cycle of ALD, whereas no Pt growth was observed on the SiO$_x$-deposited substrate. On the SiH$_x$-terminated surface, the suppression of chemisorption was confirmed by using first-principle calculation. Although the ALD-based inhibitor covers all the substrate regardless of the material present on its surface, the reaction sites can be generated by the combination with a functional metal oxide, TiO$_2$. Using the photocatalytic effect of TiO$_2$, the inhibited sites can be easily changed to reactive sites, enabling the subsequent chemisorption of a precursor/reactant. From these results, we are certain that an ALD-based inhibitor deposition technique can be a promising method for the next generation of AS-ALD.

11:30 AM *FF05.04.05
CVD Polymers on Heterogeneous Substrates for Energy Storage and Area-Selective Applications Kenneth K. Lau; Drexel University, United States

To form uniform and conformal polymer thin films, particularly with nanometer resolution, chemical vapor deposition (CVD) is an attractive approach. Specifically, initiated and oxidative chemical vapor deposition (iCVD, oCVD) are widely used to cleanly deposit a variety of polymers. Polymers – such as acrylates, methacrylates, vinyls, ethers, silicones, and fluorocarbons – are cleanly deposited by iCVD through an array of heated filaments that thermally activates an initiator for polymerization. Conjugated (conducting) polymers – like thiophenes, pyrroles, and anilines – are easily deposited by oCVD using an oxidizing agent that oxidizes the monomer to create polymerizable species.

This talk will focus on our recent efforts in using iCVD and oCVD to apply thin polymer films on heterogeneous/textured (physical or chemical) substrates. Physically heterogeneous substrates, e.g. nanoporous particles, networks and membranes, are commonly found in gas separation, biomolecular sieving, sensors, water/oil repellency, catalysis, energy capture, and energy storage. Likewise, chemically heterogeneous substrates, i.e. surface chemical patterns or chemically disparate surfaces, are common in many areas, including integrated circuits, sensors, biology, and 3D batteries. Our work aims to fundamentally understand the chemistry and physics of iCVD and oCVD that would allow us to precisely control polymer growth on physically and chemically heterogeneous substrates. Such working knowledge enables us to apply these CVD techniques in energy storage and area-selective applications, which will be highlighted.

iCVD and oCVD Thin-Film Multilayer Coatings for Board-Level and Wafer-Level Protection Scott Morrison and William S. O'Shaughnessy; GVD Corporation, United States

Circuit boards and integrated circuits require protection from both RF interference as well as against the physical probing used in reverse engineering. Typical conformal coatings such as urethane or parylene have been used for environmental protection of circuit boards, but are too thick to be applied at the wafer level. In addition, the standard coatings are purely dielectric in nature and do not have any conductive aspect which could be used for either anti-tamper or RF shielding applications.

This paper describes a multi-layer coating which combines both dielectric and conductive characteristics. The dielectric material is a highly cross-linked polysiloxane polymer fabricated using a hot-filament CVD process referred to as iCVD, or “initiated chemical vapor deposition”. The iCVD process was invented at MIT by Prof. Karen Gleason and accommodates a wide range of off-the-shelf monomers and precursors. In iCVD, a gas or mixture of gases is introduced into a reactor under mild vacuum in the vicinity of an array of heated filament wires. The gas decomposes into reactive species – radicals – that serve as monomer units. These units then migrate to a cold surface (e.g., the surface of an electronic device) on which they combine and grow into a conformal polymer
thin film. That is, the monomer units successively add to one another, forming the dielectric polymer. The conductive film within the multilayer coating is pure poly(ethylene-3,4-dioxythiophene) polymer [PEDOT] deposited using a coating process referred to as oxidative chemical vapor deposition (oCVD). The oCVD method combines the clean, solventless character of chemical vapor deposition (CVD) with the versatility of radical-based chemistry techniques used in bulk polymer processing. This deposition process produces pure, mechanically-flexible coatings of intrinsically-conductive PEDOT; these PEDOT coatings are conformal to the topology of the substrate and renders surfaces electrically conductive. The novelty of the oCVD process is in the highly-conformal deposition of the polymers, which show conductivities up to $10^3$ S/cm. oCVD coatings are suitable for conformal coverage of even the most complicated surface topologies, including foams, fibers, and fabrics.

The ‘as-deposited’ multilayer coating can provide protection against RF interference. However, if the dielectric and PEDOT layers are selectively patterned then the coating can be used as an active anti-tamper coating. In this paper, the deposition processes are described in detail. The properties of the individual films are presented, along with the results of multilayer and patterning tests.

Direct Transfer of Graphene on Paper Surface Using Hydrophobic Primer Layer Deposited by iCVD
Emre Citak1, Mehmet Gursoy1, Huseyin Sakalak2, Bilal Istanbullu2 and Mustafa Karaman1; 1Konya Technical University, Turkey; 2Selcuk University, Turkey

With its superior physical properties and band structure, the graphene has become one of the most attractive materials of recent years. Among many graphene synthesis techniques, CVD is considered as the most important and efficient method to synthesis high quality and large area graphene for high-tech applications. In CVD-grown graphene is typically produced by decomposing a hydrocarbon gas on the surface of a transition metal catalyst. However, synthesized graphene must be transferred from the catalyst surface to desired surfaces for final product application. In the typical CVD-grown graphene transfer process, firstly, graphene on the catalyst surface is coated with a support layer to prevent disintegration of as-deposited graphene layers. After that, graphene is separated by selective etching of the catalyst using solvents. Usually, rigid materials such as silicon and glass are used as substrate. Recently, paper has an important place as a substrate in high-tech applications as compared with rigid substrates due to its lightweight, flexible, biocompatible and foldable structure. However, in the transfer of graphene on the paper, the presence of solvents can lead to damages on paper surface. In this study, paper surface was functionalized with hydrophobic thin films using initiated chemical vapor deposition (iCVD) to make an graphene transfer feasible. For this purpose, two different fluoropolymers, namely poly(hexafluorobutyl acrylate) (PHFBA) and poly(perfluorodecyl acrylate) (PFDA) were deposited on the paper surface by iCVD. Graphene layers were transferred on the encapsulated papers and their electrical conductivity performances were tested. When PHFBA film was used as a prime layer, the better conductivity performance was obtained from graphene-on-paper. Our results showed that, PHFBA thin film is more suitable for graphene transfer due to its very smooth surface structure. As-transferred graphene layer on PHFBA coated paper surface showed high conductivity, even after repeated folding and flattening cycles.

Benchtop Evaporative iCVD Coater for Nanoglue Bonding
Greg Randall; General Atomics, United States

Initiated chemical vapor deposition (iCVD) enables high-purity polymer coatings at room temperature through a reactor design that segregates the high temperature initiation (e.g. $T>200^\circ$C) and surface polymerization reactions. A complex interplay between mass transport, thermal management, and surface adsorption under vacuum drives continuous flow iCVD reactor design. This talk reviews a simplified evaporative iCVD reactor that can be assembled with off-the-shelf parts in a chemical fume hood. Aspects of steady transport and reaction rates are compromised for ease-of-use and low cost. However, the simple evaporative iCVD coater is capable of providing coatings suitable for testing and for some applications, e.g. gluing small parts together with submicron glue thicknesses. Along with the evaporative iCVD reactor process design, I detail a case study where it is used to achieve sub-micron thick glue coatings on laser compression target materials (Cu, Si, CH, Al, Mo, LiF, quartz). These glued foil stacks are compressed or shocked by a laser impact in order to probe materials science at extreme pressure and/or strain rate. Sub-micron glue thicknesses are particularly important in the design and interpretation of these modern high energy density materials science experiments because the experimental foils are thin ($O[10 \mu m]$) and thick glue layers can seed instabilities and shock reflections.
Thermo-Responsiveness Linked to Deposition Conditions in Initiated Chemical Vapor Deposition of Smart Hydrogel Thin Films for Sensor Applications

Fabian Muralter¹, Alberto Perrotta¹, Oliver Werzer² and Anna Maria Coclite¹; ¹Graz University of Technology, Austria; ²University of Graz, Austria

With initiated Chemical Vapor Deposition (iCVD), it is possible to deposit smart hydrogel thin films conformally into 3D-nanostructures for sensor applications. In this contribution, we report on the thin film synthesis of such a thermo-responsive co-polymer by iCVD for the first time: namely, poly(N-vinylcaprolactam) cross-linked with di(ethylene glycol) divinyl ether; short p(NVCL-co-DEGDVE). In water, the transition of the polymeric system between a swollen state below to a shrunken state above the corresponding lower critical solution temperature (LCST) is investigated by spectroscopic ellipsometry (SE). By water contact angle (WCA) measurements and nano-indentation experiments, we show that the transition is accompanied by a change in wettability and elastic modulus. As previously shown for other polymers, the amount of cross-linking is successfully used to tune the temperature-responsive behavior of the deposited pNVCL-based systems. Higher swelling and LCST, higher surface rearrangement and lower stiffness are achieved in less cross-linked polymers. Interestingly, pNVCL is also reported to show decreased transition temperatures for higher molecular weight systems. Thus, by changing the filament temperature during iCVD, it is possible to lower the LCST by almost 20°C, without changing the (nominal) composition and, thus, the maximum swelling. Overall, maximum swelling degrees of the polymer below the transition temperature of up to 250% of the dry thickness are achieved and the LCST can be tuned in the range of 16-40°C. For probing the applicability in sensor setups, these polymers are also investigated in terms of swelling in humid environment (relative humidity, RH). There, three regions could be identified: First, in rather dry environment (up to ~40% RH), the material responds by mainly filling open porosity, but not showing a temperature-responsive behavior. Second, up to ~80% RH, the response in swelling is close to linear to the measured RH. Third, in very humid environment, the swelling is highly non-linear and temperature-dependent. Moreover, the film thickness approaches the value that can be observed when the polymer is immersed in water at the respective temperature. Furthermore, the response of the polymer in water as well as in humid environment is observed to be very fast; e.g., it responds faster than the commercial sensor used for monitoring the RH in the measurement cell (8 s response time). Together with the biocompatibility reported for pNVCL, the knobs of filament-temperature and cross-linking to tune the described features of the temperature-responsive swelling behavior of these systems make them highly promising for biomedical and/or environmental (sensor) applications.

The Wrinkling Concept Applied to Plasma Polymers—An Innovative Approach for the Fabrication of Flexible Electrodes

Damien Thiry¹, Nathan Vinx¹, Pascal Damman¹, Pierre-Yves Tessier² and Rony Snyders¹; ¹University of Mons, Belgium; ²IMN, France

Following the current development of strategies for the fabrication of structured surfaces, we present in this work an innovative approach for the synthesis of thin films with tunable morphology. Our method is based on the controlled generation of surfaces instabilities in bilayer systems formed by a mechanically responsive plasma polymer films (PPF) synthesized by the Plasma Enhanced Chemical Vapor Deposition (PECVD) method in combination with stiffer coatings.

As a case study, PPF were grown from propanethiol on silicon or flexible polyethylene terephthalate (PET) substrates. AFM data (i.e. peak force quantitative nanomechanical property mapping, scratching experiment) reveals that the nature of the PPF is dramatically affected by the substrate temperature (T_s): from a high viscous liquid (η ~ 10⁶ Pa.s.) to a viscoelastic (E ~ 0.1 GPa) and finally to a stiffer elastic solid (E ~ 0.9 GPa) material when increasing T_s from 10°C to 45°C. This evolution in the mechanical properties is correlated with a pronounced increase in the cross-linking degree of PPF evaluated by ToF-SIMS measurements, combined with a statistical treatment of the data. This trend is ascribed to an increase with T_s in the flux of energy brought to the growing film by positive ions and normalised with respect to the total amount of matter deposited.

In order to inducing a morphological reorganization of the material, we have deposited an Al thin film (50 nm) by the magnetron sputtering technique on the top of a mechanically responsive PPF. The mismatch between the mechanical properties of both layers results in the spontaneous formation of a wrinkled surface. By tuning the thickness as well as the mechanical properties of the PPF layers, the height (i.e. from 0.4 to 5.2 µm) and the width (i.e. from 0.6 µm to 6.5 µm) of the nano/micro wrinkles can be easily tailored in a wide range offering a great
flexibility in terms of surface engineering.

The same methodology was applied on flexible PET substrates. To evaluate the potential of the Al-based wrinkled/PET material as a flexible thin-film electrode, the mechanical stability of the electrode is explored under severe and repeated deformations. For this purpose, applying a strain of 1%, the electrodes are bent up for 10,000 times. The electrical resistance, measured after each bending cycle, shows a relatively stable behavior (the resistance increase only by 15%). In contrast, for a flat Al thin film directly deposited on flexible PET, the electrical resistance dramatically increases by 12,000% after 500 cycles indicating failure of the electrode.

Our results reveal the attractiveness of our method for the fabrication of micro/nano pattern with tuneable dimensions with potential applications in flexible electronics.

Controlling the Composition, Hardness and Function of Vapor-Phase Deposited Polymer Films Sung Gap Im; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

iCVD (initiated chemical vapor deposition) is a powerful tool to deposit various kinds of functional polymer films. Especially, the process is capable of exquisite control of its surface composition, elastic modulus, and functions through the introduction of various combinations of functionalities onto target substrates. Compared to conventional liquid phase-based methods, the solvent-free process can generate polymer coatings of extremely high purity, which is essential for various field applications, because such residual impurities produce harmful side effects. In addition, the thin iCVD polymer films remained durable and robust via proper crosslinking, rendering them suitable for the applications in hard environments. Such advantageous characteristics of the iCVD process have been exploited for tissue regeneration, flexible/wearable electronics, biosensors, and functional surface modification for various devices. In this presentation, the controlling of surface properties of functional polymer films and their application to various fields will be reviewed.

Scalable, Single-Source, One-Step Synthesis of an Electrocatalyst Sebastian Tigges, Axel Lorke and Nicolas Wöhrl; University Duisburg-Essen and CENIDE, Germany

A novel manufacturing method for the scalable, one-step synthesis of a Pt/C electrocatalyst by inductively coupled plasma-enhanced chemical vapor deposition is presented. The metal-organic precursor platinum acetylacetonate is used to deposit platinum nanoparticles (NPs) and support, carbon nanowalls (CNWs), simultaneously in a single, uncatalyzed process at remarkably low temperatures of 350°C. In general, CNWs exhibit exceptional thermal as well as electrical conductivity and widely adjustable surface area, making them an ideal support for use in energy conversion applications. By adjusting specific process parameters, such as pressure, gas flow rate and temperature, the density, thickness and height of the CNWs, as well as the platinum loading and oxidation state of the resulting catalyst can be tuned according to requirements. Scanning electron microscopy and Raman spectroscopy are used to determine the CNWs’ structural and electronic properties, respectively. Additionally, X-ray photoelectron spectroscopy and Auger electron spectroscopy are used to determine the overall and spatially resolved chemical composition and oxidation state of the catalyst. High-resolution transmission electron microscopy (TEM) reveals the presence of homogeneously distributed platinum particles with a mean particle diameter below 3 nm, resulting in an exceptionally narrow particle distribution with a polydispersity index below 0.1. Furthermore, due to the simultaneous synthesis of both NPs and support, the nanoparticles are expected to be incorporated into the carbon matrix, which is supported by TEM tomography. Such incorporation would greatly improve the immobilization of NPs on the support and thus the long-term stability of the catalyst. Finally, due to the use of a metal-organic precursor, the process can be adjusted to deposit almost any transition metal/CNW-hybrid material, making it a versatile method for a variety of different applications.

Chemical Insolubility of Vapor Phase Infiltrated Poly(methyl methacrylate) / AlOx Hybrid Materials Emily K. McGuinness, Collen Z. Leng and Mark D. Losego; Georgia Institute of Technology, United States
Vapor phase infiltration (VPI) is a relatively new processing technique used for transforming polymers into organic-inorganic hybrid materials. VPI has been used to improve polymer mechanical properties, protect fabrics from UV and thermal degradation, dope conducting polymers, and act as a contrasting agent in electron microscopy for imaging phases of polymer blends. Recently, our group has explored a new application for VPI, the protection of thermoplastic polymers from solvent dissolution. In this study, poly(methyl methacrylate) (PMMA) thin films were infiltrated with trimethylaluminum (TMA) and water at different temperatures and to different depths of infiltration. The resultant AlOx / PMMA hybrid films were then exposed to a variety of solvents to explore their stability. Chemical stability was found to vary non-linearly, with infiltration temperature. Films infiltrated at lower temperatures (70°C and 100°C) swelled or partially dissolved in good solvents for neat PMMA, such as toluene or chloroform, and partially dissolved in isopropanol and water, which are not good solvents for PMMA. In comparison, films infiltrated at higher temperatures (130°C) showed enhanced solvent stability in most solvents, even those that dissolved neat PMMA. The increased solvent resistance is likely due to crosslinking between PMMA functional groups and TMA molecules, a reaction that has been reported to vary with temperature. Due to this variability, PMMA films infiltrated at low temperatures are only partially crosslinked while those infiltrated at high temperatures are fully crosslinked, making them more solvent resistant. The increased dissolution of hybrid films in certain alcohols and polar solvents is hypothesized to result from an interaction between the inorganic crosslinker and the solvent. We also found that complete transformation of the polymer into hybrid material was unnecessary for dissolution resistance at higher temperatures. An infiltration depth of 0.5 mm was sufficient for complete resistance to toluene dissolution at room temperature. For proof-of-concept, we applied this treatment to a quarter inch thick laser-etched PMMA sheet and then exposed it to toluene at 60°C for 30 minutes. While the design on the neat PMMA version rapidly dissolved, the sheet with a 0.5 mm AlOx / PMMA subsurface layer showed nearly complete retention of its design. In this talk, we will explore these findings and discuss the differences in solvent stability of AlOx / PMMA hybrid materials as a function of temperature as well as investigate the underlying chemical and structural variations that yielded these results.

Novel Metal-Organic Structures and Engineered Inorganic-Organic Interfaces through ALD/MLD Maarit Karppinen; Aalto University, Finland

The combined ALD/MLD (atomic/molecular layer deposition) technique is strongly emerging as a viable technology for the fabrication of new types of functional metal-organic materials and inorganic-organic interfaces not readily accessible through any other fabrication route. Most excitingly, it is capable of yielding in-situ crystalline thin films of structures similar to those known for so-called coordination polymer or metal-organic framework (MOF) materials synthesized from solutions,[1] or even entirely new compositions/structures.[2] An attractive example is the in-situ lithiated and crystalline thin films of lithium quinone, a promising cathode material for a Li-ion microbattery;[3] the lithium quinone structure contains the Li⁺ cations in a coordinatively unsaturated three-fold coordination, which explains why it can not be synthesized through conventional solution synthesis. Equally exciting are the new metal-organic structures based on photoactive azobenzene,[4] or upconverting lanthanide-ions.[5] Another interesting approach enabled by ALD/MLD is to build artificial superlattices or gradient materials with precisely tailored inorganic-organic interface frequencies,[6] in such layer-engineered hybrid materials the periodically introduced monomolecular organic layers between nm-scale metal oxide layers may efficiently block phonon conduction, enhance mechanical flexibility, control band-gap or magnetic properties, etc.

Processing and Characterization of Hexagonal Boron Nitride Films of Wide-Area by Chemical Vapor Deposition on Silicon Substrates Ranjan Singhal and Raj N. Singh; Oklahoma State University, United States

Two-dimensional hexagonal boron nitride (2D h-BN) is a single - atom thick layer (monolayer) of alternating boron and nitrogen atoms, which is of great interest and potential due to its excellent electrical, optical, and mechanical properties and isostructural to graphene. To fully utilize the potential of 2D h-BN, wide area processing of high-quality 2D h-BN is of utmost importance. As of now, chemical vapor deposition (CVD) is the most promising method to synthesize 2D h-BN because it provides great control on the thickness of the deposited films (number of layers) and is the best candidate for the industrial scale-up process. In this study, a CVD system was designed for synthesis of two-dimensional hexagonal boron nitride with low and atmospheric pressure capabilities as well as a solid and liquid precursor delivery system. The customized CVD system is also capable of synthesizing other 2D materials like graphene and molybdenum disulfide since it can incorporate different types of precursors and reaction gases. This presentation explores the CVD aspects of h-BN synthesis with a specific focus on the designed CVD reactor system and associated components. h-BN was synthesized directly on non-catalytic silicon substrates via LPCVD, which eliminated the need for a transfer process that can introduce impurities and surface defects (wrinkles, folding). Subsequently, the effect of the precursor flow behavior on the growth of hBN was studied. Scanning electron microscopy (SEM), Raman spectroscopy, X-ray Photoelectron Spectroscopy (XPS), and UV-vis spectroscopy were then used to characterize the deposited h-BN and study the effect of precursor flow kinetics. XPS analysis confirmed the presence of h-BN. Raman spectroscopy further corroborated the formation of h-BN. The approximate crystallite size of the deposited h-BN was also determined by Raman spectroscopy analysis. SEM confirmed the crystallite size estimated from Raman spectroscopy analysis of between 60 – 100 nm.

Microplasma-Driven, Area-Selective Atomic Layer Deposition of Aluminum Oxide at 300K Jinhong Kim, Andrey Mironov, Sung-Jin Park and J G. Eden; University of Illinois Urbana Champaign, United States

Area-Selective Atomic Layer Deposition (AS-ALD) of aluminum oxide (Al2O3), driven by arrays of microcavity plasmas (MALD), has been demonstrated. Al2O3 films were grown at 300 K by dissociating oxygen in an array of microcavity plasmas. Metal-oxide-semiconductor capacitors (MOSCAP), fabricated from Al2O3 films deposited on p-Si by MALD with Al top ohmic contacts and Au bottom electrodes, exhibited a breakdown electric field strength of E_{BR} = 6.1 ± 0.2 MV/cm and a hysteresis width of < 1 mV, indicating the presence of negligible traps in the film. The dielectric constant of Al2O3 films, ε_{ox}, was measured from MOSCAP C-V curves to be ε_{ox} = 9.7 ± 0.3. The measured values for E_{BR} and ε_{ox} are higher than conventional values, exhibiting that MALD-grown films are suitable for MOS devices operating under demanding ambient conditions which require extraordinary radiation resistance, thermal conductivity, and chemical stability. The ability to grow Al2O3 films of high quality at 300 K prompted experiments to fabricate Al2O3 arrays of small feature size. AS-MALD of Al2O3 films was accomplished by lift-off lithography. With this process, Al2O3 films having a lateral dimension of 1 - 10 µm and a thickness of ~ 68 nm were deposited. Due to the complete reaction between precursors, the oxygen and aluminum stoichiometric ratio for amorphous Al2O3 films has been measured by EDX and RBS to be ~ 1.5 ± 0.1, demonstrating that negligible levels of impurities and oxygen vacancies exist in the films. All experimental results show that MALD process can be compatible with semiconductor area-selective patterning with narrow lateral dimensions through simple lithography and lift-off.

Growth and Characterization of Corundum Structure Oxide Semiconductor on α-Fe2O3 Buffer Layers by The Mist CVD Method Kazuki Shimazoe, Hiroyuki Nishinaka, Daisuke Tahara, Yuta Arata and Masahiro Yoshimoto; Kyoto Institute of Technology, Japan
Corundum structured III-IV oxide materials have been attracted considerable interest from oxide based wide bandgap semiconductor researchers. Typical corundum structured α-Al₂O₃ are widely used as substrates for wide band gap semiconductors, such as GaN, ZnO, and α-Ga₂O₃. The α-Ga₂O₃ in the series of corundum structure exhibits bandgap energy of 5.3 eV and controlling carrier concentration by n-type doping. Further, the α-Ga2O3 produces the possibility to tune a wide range of bandgap by alloying with α-Al₂O₃ (8.8eV) and rh-In₂O₃ (3.7eV) exhibiting the same corundum structure. The epitaxial growth techniques are usually used for the synthesis of these materials. For example, the epitaxial growth supported by α-Fe₂O₃ buffer layers showing the same corundum allowed growing single phase rh-In₂O₃ thin films which have been difficult to synthesis [1].

In this study, the mist CVD method was utilized for the epitaxial corundum oxide thin films and solution mist dissolving precursors was used as CVD precursors. Any precursor can be used as mist CVD precursors that only dissolves the precursor in any solvent. Taking advantages of its feature, we have demonstrated that the phase controlling of corundum oxide thin films were successfully obtained by using various corundum substrates and α-Fe₂O₃ corundum buffer layers.

For the α-Ga₂O₃ epitaxial growth, most researchers have utilized only α-Al₂O₃ substrates with large lattice mismatch for α-Ga₂O₃. However, we featured the LiTaO₃ and LiNbO₃ substrates showing nearly corundum structures with smaller lattice mismatches for α-Ga₂O₃. XRD results revealed α-Ga₂O₃ epitaxial thin films were successfully grown on LiTaO₃ and LiNbO₃ substrates with α-Fe₂O₃ buffer layers. The epitaxial ε-Ga₂O₃ thin films were grown on LiTaO₃ and LiNbO₃ without buffer layer. This is because ε-Ga₂O₃ also has a similar oxygen atom arrangement of the corundum structure and the phase is more stable thermodynamically than that of α-Ga₂O₃. Furthermore, to compare the crystal quality of α-Ga₂O₃ layers on LiNbO₃, LiTaO₃ and α-Al₂O₃, we investigated XRC of asymmetric plane (10-14) α-Ga₂O₃. The FWHMs of XRC for α-Ga₂O₃ on LiTaO₃ and LiNbO₃ were evaluated to be 0.51 degree and that for α-Ga₂O₃ on α-Al₂O₃ is evaluated to be 0.85 degree, indicating that the LiTaO₃ and LiNbO₃ with α-Fe₂O₃ buffer layers are promising materials for α-Ga₂O₃ epitaxial growth.

ITO, which is a typical transparent conductive oxide, possesses two polymorphs; bcc-ITO (bixbyite) and rh-ITO (rhombohedral, corundum). Since the synthesis of rh-ITO requires high-pressure and high-temperature, few reports exist on rh-ITO thin films. Our group previously reported the epitaxial growth of rh-ITO using α-Fe₂O₃ buffer layers on various plane α-Al₂O₃ substrates [2]. However, detailed characterizations, such as dependence on the impurity concentration of rh-ITO thin film is not still investigated. Hence, we report on the characterization of the epitaxial rh-ITO thin films grown on various plane α-Al₂O₃ by mist CVD with α-Fe₂O₃ buffer layers. The rh-ITO thin film prepared on the r-plane α-Al₂O₃ substrate with 5 at.% of Sn ratio in the starting solution possessed the resistivity of 1.73×10⁻⁴ Ωcm, the mobility of 25.8 cm²/Vs, and carrier density of 1.40×10²¹ cm⁻³. Furthermore, the carrier concentration dependence of the mobility of rh-ITO epitaxial thin films was almost similar to that of single crystal bcc-ITO. In this symposium, we will discuss the detailed electrical and optical properties of rh-ITO on various α-Al₂O₃ substrates.

FF05.06.04 Fabrication of Flexible and Epitaxial Oxide Thin Films on Cleaved Synthetic Mica Using Mist Chemical Vapor Deposition
Yuta Arata, Hiroyuki Nishinaka, Daisuke Tahara, Kazuki Shimazoe, Yusuke Ito and Masahiro Yoshimoto; Kyoto Institution of Technology, Japan

Flexible electronic devices leading various wearable applications are expected to revolutionize modern society [1]. For the use of flexible functional materials, it has been mainly reported that the organic materials were formed on flexible substrates by low-temperature processes, such as inkjet printing [2]. However, organic materials generally exhibit low heat resistance and poor stability in a high-temperature environment. Conversely, flexible inorganic materials possess a high heat resistance and high stability in a harsh environment. However, it has been difficult to prepare single crystal thin films allowing to maximize the properties. In this study, we demonstrated the epitaxial growth of oxide thin films on two-dimensional (2D) layered materials by atmospheric chemical vapor deposition (CVD) technique without requiring a vacuum process. The 2D layered materials can be simply peeled off and utilizes as flexible substrates. It has already been reported that oxide thin films were epitaxially grown on 2D layered materials by pulsed laser deposition (PLD) [3]. Moreover, the oxide epitaxially grown on the 2D layered materials maintained its characteristics even in a bent state or after repeated bending. We utilized the mist CVD methods for the epitaxial growth of oxide thin films on 2D layered materials.
The mist CVD can be operated under atmospheric pressure for thin film growth because the stable mist including the CVD precursors is utilized instead of precursors vaporized by bubbling or heating. The mist is ultrasonically atomized from the solution made by dissolving the precursors. Furthermore, any solution precursor can be utilized as CVD precursors if it can be dissolved in solvents. Thus, one apparatus of mist CVD allows growing the various materials, as long as the solution precursors can be prepared. We have demonstrated that the growth of metastable phases gallium oxide (Ga$_2$O$_3$) is controlled by mist CVD using other material buffer layer on 2D layered materials. Ga$_2$O$_3$ has recently attracted attention as an ultra-wide bandgap semiconductor in power devices and deep ultraviolet device applications. Ga$_2$O$_3$ possesses five polymorphs of α-, β-, γ-, δ- and ε-phase [4]. Ga$_2$O$_3$ thin films were grown on cleaved synthetic mica wafers as a 2D layered material substrate. A solution of gallium chloride (GaCl$_3$) in de-ionized water was used as the Ga precursor of mist CVD. X-ray diffraction (XRD) results revealed that ε-Ga$_2$O$_3$ thin films were grown on synthetic mica wafers at the growth temperature of 450-600°C without buffer layers. To obtain α-Ga$_2$O$_3$ thin films, we inserted α-Fe$_2$O$_3$ buffer layers grown by using iron acetylacetonate (Fe(C$_5$H$_7$O$_2$)$_3$) dissolved in de-ionized water as the Fe precursor [5]. As a result, the insertion of the buffer layers allowed growing epitaxially another metastable phase α-Ga$_2$O$_3$ thin films on synthetic mica wafers at the growth temperature of 350-600°C. We succeeded in epitaxial growth of the metastable ε phase and α phase Ga$_2$O$_3$ which are promising as power devices and deep ultraviolet devices on flexible substrates using mist CVD.

In the symposium, we will introduce and discuss the results of epitaxial growth on synthetic mica by mist CVD for not only several Ga$_2$O$_3$ phases but also various oxide thin films.

**FF05.06.05**

**Gaining Insight into Self-Limiting Surface Reactions During Plasma-Assisted Atomic Layer Deposition of III-Nitrides via In Situ Ellipsometry**

Deepa R. Shukla$^1$, Adnan Mohammad$^1$, Saidjafarzoda Ilhom$^1$, Ali Okyay$^2$, Blaine Johns$^3$, Brian Willis$^3$ and Necmi Biyikli$^4$; $^1$University of Connecticut, United States; $^2$Stanford University, United States; $^3$Film Sense LLC, United States

Atomic layer deposition (ALD) is an emerging field in nanoscale materials research featuring atomic-level precision due to its self-limiting growth character. Besides fine thickness control, ALD also provides unmatched three-dimensional conformal and uniform film deposition. Owing to these advantages, ALD already has created a significant impact in aggressively scaled logic and memory device technology based on 3D CMOS transistors, as well as energy storage, solar cells, surface passivation, catalysis, and flexible/wearable devices.

ALD-grown films are vastly characterized via ex-situ measurements to quantify various material properties. However, gaining insight into the saturating surface reactions and growth mechanisms is only possible with real-time in-situ process monitoring of individual ALD cycles. While several in-situ measurement techniques have been employed in ALD research, in-situ ellipsometry stands out as one of the best options for real-time monitoring surface reactions. The promising potential of in-situ spectroscopic ellipsometry has already been demonstrated for a number of materials grown by remote plasma-ALD. Here, we verify that cost-effective multi-wavelength ellipsometer (MWE) can also be used effectively for real-time in-situ analysis of plasma-ALD growth cycles. We demonstrate for the first time that real-time dynamic in-situ MWE measurements convey not only accurate film deposition rate, but as well resolve single chemisorption and ligand exchange reactions with remarkable clarity. Moreover, forcing the limits for fitting the acquired in-situ MWE data, we were able to track the evolution of the optical constants of III-nitride films along the ALD cycles which showed thickness-dependent behavior.

Our main motivation behind this study is to analyze and compare the self-limiting growth characteristics of binary III-nitride (AlN, GaN, and InN) thin films via real-time in-situ ellipsometry and to gain insight into the ALD surface reaction mechanisms including chemical adsorption, ligand removal, and nitrogen incorporation steps.

Despite using the conventional alkyl metal precursors (trimethylaluminum, trimethylgallium, triethylgallium, and trimethylindium) utilized also widely in MOCVD epitaxial growth, their solid-gas surface interactions with nitrogen plasma species shows notable differences, particularly with respect to substrate temperature, plasma power, plasma
exposure time, and plasma gas composition. In terms of substrate temperature, AlN exhibited crystallinity at lower temperatures when compared to GaN and InN. Even at 100 °C, AlN showed crystalline behavior whereas GaN displayed amorphous character up to 200 °C. While Ar/N₂/H₂ composition is optimal for AlN, N₂/H₂ and Ar/N₂ mixtures proved to be optimal for GaN and InN film quality, respectively. Furthermore, we have observed that the inclusion of H₂ gas into the plasma cycles led to substantial deformation of the hexagonal crystal structure and resulted in mixed phase growth with notable c-In₂O₃ and metallic tetragonal In. The possible surface reaction mechanisms that lead to these different growth behaviors will be discussed in detail.

The real-time in-situ data is correlated with film structural, optical, and chemical properties obtained by ex-situ spectroscopic ellipsometer, x-ray diffraction (XRD), x-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM), and transmission electron microscopy (TEM) measurements. Our results demonstrate that dynamic in-situ MWE measurements can provide significant insight about the surface reactions taking place during low-temperature plasma-ALD of III-nitride compounds.

FF05.06.06
Fabrication of Ferroelectric Hf₀.₅Zr₀.₅O₂ Thin Film by Atomic Layer Deposition (ALD) Using H₂O₂ Precursor
Hyoungkyu Kim¹, Seokjung Yun¹, Hoon Kim¹, Changdeuck Bae² and Seungbum Hong¹; ¹Korea Advanced Institute of Science and Technology, Korea (the Republic of); ²Sungkyunkwan University, Korea (the Republic of)

Zr doped-hafnium oxides (HZO)-based FeFET/FRAM has recently emerged as the next-generation memory device due to its low power operation, scalability, and Si compatibility. However, it suffers from the limited processing window to secure their ferroelectric properties in terms of thickness, thermal processing effect and high dependence on ozone (O₃) as the oxygen precursor of atomic layer deposition (ALD). Herein, we report on the use of hydrogen peroxide (H₂O₂) precursor as the O₂ source to fabricate HZO thin films via ALD. We optimized the deposition parameters such as purging time, deposition time, and temperature to obtain high and stable ferroelectric properties. Furthermore, we evaluated the thermodynamic reaction energy of hydrogen peroxide and compared the two classes of samples in terms of deposition state, thickness, and chemical composition using X-ray photoelectron spectroscopy (XPS). To analyze the ferroelectric properties of HZO thin films, we characterized the crystalline structure using X-ray diffraction (XRD), and the electrical properties using C-V and P-V measurements. Finally, we investigated the grain size distributions using atomic force microscopy (AFM) and correlated them with their respective crystalline phase. Through this study, we provide a new ALD technique for high-quality HZO thin films for FeFET/FRAM device applications.

FF05.06.07
Use of Refractory-Metal Diffusion Inhibitors in Catalytic Metal Particles for Catalytic CVD Growth of Ultra-Long Carbon Nanotubes (CNTs)
Michael J. Bronikowski and Melissa King; University of Tampa, United States

Recent results are presented from studies of the growth by Chemical Vapor Deposition of Carbon Nanotubes (CNTs), using a novel technique which it is hoped will ultimately lead to the availability of ultra-long CNTs. The method used involves incorporation of refractory, high-melting-point metals into the nano-particles of catalyst metal from which the CNTs nucleate and grow. The refractory metal acts as a diffusion inhibitor, and inclusion of these diffusion inhibitors slows the erosion of the catalyst particles, and thus extends the lifetime of the catalyst particles and hence the length to which CNTs can be grown. This effect has previously been demonstrated for several catalyst/diffusion-inhibitor systems including Mo/Re and Fe/Mo. Here we present new results on the Fe/Re catalyst system: it is shown that inclusion of Re diffusion inhibitor can enhance the lifetime of the iron catalyst particles and give CNT growth to lengths greater than would otherwise result.

FF05.06.08
A Study of Initiated Chemical Vapor Deposition (iCVD) Siloxane Thin-Film Conformality at Different Length Scales
William Livernois, Scott Morrison and William S. O'Shaughnessy; GVD Corporation, United States

Conformal polymer thin films have a wide variety of uses ranging from protective coating applications to surface functionalization and modification. There are a variety of traditional wet methods for depositing polymer films, such as spin coating or drop casting, but substrates with complex features will have issues caused by varying wettability and capillary forces. Initiated chemical vapor deposition (iCVD) is a low-temperature, dry process that deposits conformal polymer thin films from the gas phase. The process uses an initiator compound that is activated by a hot
filament array and polymerizes adsorbed organosilicon precursor on the substrate surface. For this study the reactor parameters have been optimized to maximize conformality of the coating at multiple length scales.

Coating features with irregularities at multiple length scales is a challenge that is commercially relevant both for scaling the process and improving reliability of the coating across a diverse range of substrates. To test conformality and study the effect of geometry on the deposition process high-aspect ratio (>10:1) millimeter and micron scale testing devices were fabricated on silicon. In both length scales, lowering the sticking probability improved conformality of the coating, which could be achieved by varying the temperature of the substrate and reactor pressure. On the millimeter scale, it was clear that the conformality was reaction limited by depletion of the initiator, whereas film growth in the micron-scale features was limited by monomer diffusion and adsorption. Conditions for optimal conformality at both length scales was demonstrated with different sets of reactor conditions which can be combined into a multi-step conformal coating process.

FF05.06.09
Atomic Level Surface Functionalization of a Graphene Oxide Membrane to Break the Permeability-Selectivity Trade-Off in Salt Water Desalination Jihoon Ahn and Kyu-Jung Chae; Korea Maritime & Ocean University, Korea (the Republic of)

Graphene oxide (GO) membranes have shown promising ionic and molecular sieving due to their unique interconnected nanochannels; however, their low salt rejection efficiency caused by an enlarged interlayer spacing between GO flakes limits their wide application in water desalination. For the purpose of enhancing GO membrane performance, this research applies a novel approach to atomic level surface functionalization with precise control, which allowed for the formation of an ultra-thin Al2O3 layer by sequential atomic layer deposition (ALD) to the GO membrane. Due to the strong chemisorption of trimethylaluminum (TMA) to GO, an ultra-thin (1.44 nm) and uniform hydrophilic Al2O3 layer was successfully deposited on the GO membrane under low numbers of ALD cycles. The GO membrane coated with an atomically thin and uniform Al2O3 layer achieved enhanced water permeability (from 40 LMH/bar to 70 LMH/bar) and NaCl rejection up to 67.4 %, successfully overcoming the trade-off between permeability and rejection efficiency. This enhanced water permeability is mainly attributed to the increase in surface hydrophilicity without narrowing the GO membrane pore structure. Dspacing via X-ray diffraction (XRD), surface chemistry via Fouriertransform infrared spectroscopy (FTIR), and water contact angle (WCA) measurements confirmed the effect of ALD on the physico-chemical properties of the GO membrane. The distinctive features of ALD to the GO membrane may contribute towards enhancing its wider application in water desalination.

Controlling the Optical and Electronic Properties of Polyaniline (Pani) Using Vapor Phase Infiltration of Titanium Tetrachloride Shawn A. Gregory, Yi Li, Shannon Yee and Mark D. Losego; Georgia Institute of Technology, United States

This talk will discuss our use of vapor phase infiltration (VPI) to alter the optoelectronic properties of poly(aniline) (Pani). VPI is similar to atomic layer deposition (ALD), but instead of cycling viscous flows of co-reactants, VPI doses a single reactant vapor in a static atmosphere followed by a purge-pump cycle. ALD typically provides conformal surface coatings while VPI enables extensive sub-surface diffusion and reactions within organic substrates. In our study, Pani was infiltrated with a single cycle of TiCl4-H2O to yield a hybrid film. This chemistry has not been explored before and was specifically selected because of its reaction products; TiOx has useful optical properties for photovoltaic and photochemical applications while HCl is known to dope Pani and create polaronic charge carriers. We found that Pani films optimally infiltrated with TiCl4 have an electrical conductivity of ca. 0.2 S/cm. To the best of our knowledge, this is the highest electrically conducting Pani film achieved with a single-cycle exposure to a metal-halide vapor. Additionally, as VPI hold time increases, Pani films turn from blue to nearly transparent to green. This color transition is believed to be evidence of the generation of polaronic charge carriers and the concomitant formation of TiOx. The polaronic carriers absorb the red-NIR-MIR spectra (700-5000 nm) while TiOx contributes to unusually high absorbance in the blue-UV region (450 - 350 nm). This combination of optical absorbances in Pani has not been documented before and could be valuable for electrochromic or photovoltaic applications. To better understand processing parameters, we varied the TiCl4 exposure time and measured ex-situ optical signatures. We calculated an effective TiCl4 diffusion coefficient of ca. 10^-15 cm²/s at 80°
C. Additionally, we demonstrated that the relative ratio of UV and IR absorbent species can be controlled by varying reaction temperature. Increasing the reaction temperature likely decreases HCl sorption, ergo decreasing the extent of doping, polaron formation, and IR absorbance. Lastly, we performed XPS measurements to elucidate a reaction mechanism. We found that titanium effectively only binds with oxygen and that nitrogen radical cations (polarons) are present; this further corroborates our hypothesis that TiOx is responsible for the unique blue-UV absorbance and that the electrical conductivity is dominated by polaronic carriers. By better understanding this reaction mechanism and kinetics, VPI precursor chemistry and processing conditions can be optimized for future organic semiconductor doping.

**Improving the Wet Strength of Nanopaper with Atomic Layer Deposited (ALD) Subnanometer Metal Oxide Coatings**

Yi Li, Mark D. Losego, Rampi Ramprasad and Lihua Chen; Georgia Institute of Technology, United States

Nanocellulosic films (nanopapers) are of interest for packaging, printing, chemical diagnostics, flexible electronics and separation membranes. These nanopaper products often require chemical modification to enhance functionality. Most chemical modification is achieved via wet chemistry methods that can be tedious and energy intensive due to post-processing drying. Here, we discuss the use of atomic layer deposition (ALD), a vapor phase modification technique, to quickly and simply enhance the wet strength and durability of nanopaper. Here, we specifically consider ALD processes that use only a “few” cycles (< 10) to maintain the potential for process scalability and commodity manufacturing. While these “few cycle” ALD treatments do not appear to alter the mechanical properties of the nanopaper in the dry state, wet strength shows a significant enhancement. Here we will report that up to 10 cycles of either aluminum oxide or titanium oxide ALD is sufficient to significantly increase the durability of nanopaper under aggressive aqueous sonication or burst testing (9x increase). In this presentation, we will discuss our investigation into whether this increase in wet strength is the result of enhanced hydrophobic attractions or increase hydrogen bonding attraction. Through a combination of experimental investigations and *ab initio* calculations, we currently believe the M-OH terminations enhance hydrogen bond strength between the neighboring cellulosic nanofibrils.

**Understanding the Initial Growth During Atomic Layer Deposition of Nickel Sulfide via *In Situ* X-Ray Photoelectron Spectroscopy and Low Energy Ion Scattering**

Ran Zhao, Xinwei Wang and Yuanhong Gao; Peking University, China

Atomic layer deposition (ALD) is a highly useful synthesis method to grow highly-controllable thin-film materials. In a typical ALD process, the initial nucleation and growth is of particular importance, because it not only is crucial for preparing high-quality film–substrate interfaces but also can be engineered to synthesize well-controlled nanoparticles. Therefore, understanding the initial surface chemistry as well as the growth mechanism is of crucial importance for rationally designing functional materials and interfaces by ALD. Over the past several years, ALD of metal sulfides has aroused great attention, especially for their numerous applications in the emerging energy technologies. Many new ALD processes of metal sulfides have been recently developed, and the metal sulfides of which the ALD processes were only recently available include GaS (2014), GeS (2014), MoS2 (2014), LiS (2014), CoOxSx (2015), NiS (2016), MnS (2016), FeS (2017), VSx (2017), Bi2S3 (2017), AlSx (2017), and ReS2 (2018). The investigation of the initial growth on these new metal sulfide ALD processes is certainly valuable and in need.

Our group recently developed a new ALD process of nickel sulfide (NiS) using bis(N,N’-di-tert-butylacetamidinato)nickel(II) (Ni(amd)2) as the nickel precursor and H2S gas as the sulfur source. Herein, we study the initial ALD growth of NiS on SiOx by using the in situ techniques of X-ray photoelectron spectroscopy (XPS) and low-energy ion scattering (LEIS). The reaction scheme during the initial ALD stage is found to be rather different from that in the later steady film growth stage, and therefore a reaction-agglomeration mechanistic scheme is proposed to describe the initial ALD growth. In the scheme, the conversion from Ni–O to NiS in the H2S half-cycles is suggested to be accompanied by the spontaneous agglomeration of the ligand-stripped Ni-containing species to afford NiS clusters, and the agglomeration can re-expose the surface of SiOx and therefore allow the surface to further react with Ni(amd)2 in the subsequent ALD cycles. Using LEIS, the transition from the initial reaction-agglomeration growth to the continuous steady film growth is found to be between 100 and 300 ALD cycles. Ex situ atomic force microscopy (AFM) and transmission electron microscopy (TEM) are further employed to further understand the growth mechanism.
to corroborate the presence of the agglomeration during the initial growth. The results reported herein and the implied growth mechanism should be of great representativeness for the ALD of metal sulfides, and therefore, the findings should be highly valuable for future engineering of functional metal sulfide nanomaterials and interfaces by ALD.

Epitaxial Growth and Band-Gap Control of Ni$_{1-x}$Mg$_x$O Thin Film by Using Mist CVD Method
Takumi Ikenoue, Masao Miyake and Tetsuji Hirato; Kyoto University, Japan

Development of wide band-gap p-type oxide semiconductors with good properties is essential for various applications that realize resource saving and low power loss. Although oxide semiconductors that show p-type conductivity with wide band-gap are rare, nickel oxide (3.7 eV) has attracted attention. In recent years, p-type oxide semiconductor materials having a larger band gap are required. Therefore, we focused on Ni$_{1-x}$Mg$_x$O, which is a mixed crystal with MgO, which has the same rock salt structure as NiO and has a band gap of 7.8 eV. In addition, in order to improve the properties of these materials, growth was performed using a mist CVD method that enables high-quality film growth even under atmospheric pressure.

In this presentation, Ni$_{1-x}$Mg$_x$O thin films grown by using the mist CVD method will be described in detail. Ni$_{1-x}$Mg$_x$O epitaxial growth was performed on α-Al$_2$O$_3$ or MgO substrates, and carrier concentration control by Li doping was studied. The bandgap of Ni$_{1-x}$Mg$_x$O monotonously increased according to the Mg composition and was controlled in the range of 3.4–4.0 [eV]. It was revealed that the carrier concentration in the Li-doped NiO thin film can be controlled in a wide range only by controlling the Li concentration in the precursor solution.

A wide band-gap p-type oxide semiconductor Ni$_{1-x}$Mg$_x$O was grown by the mist CVD method. These are very high quality despite being grown in a non-vacuum process and are expected to be applied to various devices.

Chemical Vapor Deposition Synthesis of a High-Quality MoS$_2$ Layer by H$_2$S/H$_2$ Mixture—A Reactive Molecular Dynamics Study
Sungwook Hong$^{1,2}$, Ken-ichi Nomura$^1$, Rajiv Kalia$^1$, Aiichiro Nakano$^1$ and Priya Vashishta$^1$; $^1$University of Southern California, United States; $^2$California State University, Bakersfield, United States

Layered transition metal dichalcogenides (TMDCs) such as a layered MoS$_2$ are attracting great attentions owing to their outstanding physical, chemical, and mechanical properties, compared with their bulk counterparts. Chemical vapor deposition (CVD) is known to be the most effective way to synthesize the layered MoS$_2$ on the target substrate. While previous studies suggested to use different types of reactants/precursors like sulfur powders, and gaseous H$_2$S and H$_2$ precursors for a higher-quality MoS$_2$ layer, their reaction kinetics and mechanisms have yet to be fully understood. Here, we perform reactive molecular dynamics (RMD) simulations for CVD synthesis of MoS$_2$ layer using three different systems: 1. MoO$_3$ and S$_2$; 2. MoO$_3$ and H$_2$S; 3. MoO$_3$ and H$_2$S/H$_2$ mixture. Our goal is to clarify atomic-level reaction pathways for reduction/sulfidation of the MoO$_3$ slab using different gaseous environments. RMD results reveal that MoO$_3$ slab could be effectively sulfurized by the H$_2$S/H$_2$ mixture. As such, our computational work provides a valuable input for experimental synthesis of TMDCs using the CVD technique.

The simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE and Aurora Early Science programs, and at the Center for High Performance Computing of the University of Southern California

Finally, this work was supported by a grant from the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607. The simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE and Aurora Early Science programs, and at the Center for High Performance Computing of the University of Southern California.
Oxidative Chemical Vapor Deposition (oCVD) and Atomic Layer Deposition (ALD) accomplish polymers and oxides synthesis, thickness-defined patterned deposition, and doping in a single process at near-room temperatures (40 - 80 °C) for a broad range of technological applications. Also, both function independent of material solubility and substrate properties to enable insoluble polymers and oxides to be coated in a conformal or uniform manner without any solvent damage to the substrate. This key differentiator from solution-based approaches makes them substrate-independent scalable platform technologies for surface modification and device fabrication.

Based on the commercialization-critical benefits, semiconducting and conducting polymer thin films with suitable properties, patterns, and size can be directly integrated into flexible electronics such as organic photovoltaics on unmodified papers, thereby enhancing the efficiency and lifetime significantly. Meanwhile, H⁺-conducting and O₂ impermeable ultrathin (2 nm) SiO₂ membrane leads to runaway H⁺ flux (3000 nm² s⁻¹) faster than maximum solar photon flux (1500 nm² s⁻¹). As a result, the SiO₂ membrane can act as an enhanced charge-carrier platform, where pushing artificial photosynthesis beyond mass (H⁺) transfer limits, and thus making it scalable to the unprecedented level of several terawatts.

**Fabrication and Characterization of Two-Phase Nanocomposites by Atomic Layer Deposition of Metal Oxides into Mesoporous Thi-Film Oxide Ceramics**

Dominic Boll¹², Erdogan Celik³³, Matthias T. Elm³³ and Torsten Brezesinski¹¹;¹ Karlsruhe Institute of Technology, Germany; ²Technische Universität Darmstadt, Germany; ³Justus-Liebig-Universität Giessen, Germany

Solid electrolytes are one of the key parts in the field of modern energy technology. While zirconia based oxides are used as electrolytes for e.g. solid oxide fuel cells (SOFC) or oxygen sensors, ceria-based solid solutions are promising for applications for electrode materials in SOFCs and heterogeneous catalysts. Great efforts are made to enhance the electrical and / or the ionic conductivity of these solid electrolytes. The transport properties of these oxides can be altered by varying the composition or by nano- and microstructuring the materials. For the later, the primary reason is the increased density of interfaces and/or surfaces. In recent years, enhanced conductivity in nanostructured oxides compared to their bulk counterparts has been observed, but the underlying mechanisms are still not fully understood. This work aims at evaluating the surface effects on the transport properties of nanostructured thin film oxide ceramics. Therefore, a suitable route to produce single-phase mesoporous thin films and two-phase-nanocomposites thereof has to be established.

In this work, we present a method to prepare two-phase nanocomposites made of different types of oxides. The method of Atomic Layer Deposition (ALD) was used to deposit a thin layer of different oxides, e.g. Al₂O₃ or TiO₂, into a mesoporous thin film of yttria-stabilized zirconium oxide (YSZ). Thin porous films were synthesized by an evaporation-induced self-assembly (EISA) process using the dip coating method. Following this route, a mesoporous film of 8mol% YSZ was produced with a pore size diameter of 18 nm and a well-ordered pore structure. This porous film was used as the host material for the Atomic Layer Deposition. The process of ALD is so far the best technique to coat a three-dimensional structure having a high-aspect ratio with a thin, homogeneous and conformal layer along with highly precise thickness control. Up to date, there are only few studies about an ALD process into ordered mesoporous structures. In this context, a new ALD process is established to coat the three-dimensional surface structure of a highly ordered mesoporous thin film. Processing parameters were optimized to enhance the diffusion of the precursor molecules through the entire mesoporous network. The characterization of the coated mesoporous film was done by both scanning electron microscopy (SEM) and transmission electron microscopy (TEM). X-ray reflectometry (XRR) was used to measure the growth rates of this specific ALD process. To ensure a complete coating on the surface throughout the entire mesoporous film, a cross-section of the film was measured by atom-probe tomography (ATP). Finally, the effect of the surface coating on the transport properties were investigated by impedance spectroscopy. The modification of the pore surface structure was found to affect the conductivity of the mesoporous thin film.

**Zinc Oxide Nanostructure Synthesis on Si(100) by Vapor Phase Transport and the Effect of Antimony Doping on pHotoelectric Properties, Morphology and Structure**

Tarek M. Trad, Parker Blount and Zuleyma Romero; Sam Houston State University, United States

Zinc Oxide (ZnO) has been shown to exhibit semiconducting and piezoelectric dual properties. This has led to a
large commercial demand of ZnO for optoelectronics that operate at the blue-ultraviolet regions. Consequently, varying techniques have been devised to create different nanostructures of ZnO. Here, the single step synthesis of ZnO nanostructures was performed on Si(100) substrates with a thin ZnO seed-layer. A modified chemical vapor deposition (CVD) method was developed to accomplish the structure formation. Sb doping of the structures in the gas phase was performed to study its effects on structure and optoelectronic properties. Different structures were realized including nanofilaments, nanoparticles, microflowers, nanorods, and nanocolumns. Only nanorods/columns are shown in this work. Morphology was examined using scanning electron microscopy (SEM). Energy-dispersive X-ray spectroscopy (EDS) and X-ray powder diffraction (XRD) were used for structural studies. Optoelectronic properties were explored using room-temperature photoluminescence (PL) spectroscopy. PL data show the relative increase in the number of defects and decline in crystal quality upon dopant introduction. Some structural defects might be attributed to the diffusion of Sb ions into the lattices of ZnO, replacement of Zn by Sb, and ionic radii difference. These stacking faults are most likely the reason behind the dominance and broadening of DLE peak.

**Good Step Coverage of Iridium Metal Films by Spray CVD**

Yoshiyuki Seki¹, Yutaka Sawada¹, Hiroshi Funakubo², Kazuhisa Kawano³ and Noriaki Oshima³; ¹Tokyo Polytechnic University, Japan; ²Tokyo Institute of Technology, Japan; ³TOSOH Corporation, Japan

Metal Ir films have been widely used as electrodes, especially for oxide capacitor including ferroelectric random access memory. For these applications, chemical vapor deposition (CVD) is a most promising process because three dimensional structure capacitor structures are essential to increase the capacitor area on the limited foot print of the substrate. We developed spray chemical vapor deposition, in which CVD source was spray on the heated substrate in air [1-4]. By using this process, three dimensional films of indium tin oxide and Ru with good step coverage were successfully obtained on the trenched substrates. In the present study, we apply this spray CVD to Ir metal films deposition using novel of Ir precursor, (1,3-cyclohexadiene)(ethylcyclopentadienyl)iridium, Ir(EtCp)(CHD). Ir(EtCp)(CHD) is a liquid source at room temperature and exhibited enough vapor pressure (0.1 Torr/75°C), excellent volatility and adequate decomposition temperature. It is already ascertained that Ir metal films grown using Ir(EtCp)(CHD) showed shorter incubation time and higher nucleation density than those of films using Ir(EtCp)(CHD)[5]. Ir(EtCp)(CHD) was dissolved in ethanol and the concentration was fixed at approximately 0.05-0.1 mol/l. The solution was sprayed manually on the substrates in air with an inexpensive atomizer used for cosmetic purposes. The substrates were heated on a hot plate at 200–430 °C. We used non-flat Si substrates (patterning SiO₂/Si, opening depth: 1 μm, opening sizes: less than 1 μm) and plane SiO₂/Si substrates. Film deposition was ascertained on SiO₂/Si substrate at 240–430 °C and deposition rate increased with the deposition temperature, but was saturated above 330 °C. Obtained films consist of Ir metal without any oxide impurity irrespective of the deposition temperature. Films tend to orient to (111) with increasing deposition temperature. Resistivity of these Ir metal films was on the order of 10⁻⁶ Ωcm, which was on the same order with that of bulk Ir metal. Good step coverage was observed for Ir metal films deposited at 270 and 330 °C. This shows that simple spray CVD process deposited in air is a good way to deposit Ir metal films with good conductivity and step coverage.

**FF05.06.20**

**Direct Growth of Single-Layer Terminated Vertical Graphene Nanosheets on Germanium Using Plasma Enhanced Chemical Vapor Deposition**

Abdulrahman S. Al Hagri and ChunYu Lu; Khalifa University, United States

Vertically aligned graphene nanosheet arrays (VAGNAs) exhibit large surface area, excellent electron transport properties, outstanding mechanical strength, high chemical and thermal stability, and enhanced electrochemical activity, which makes them highly promising for application in supercapacitors, batteries, fuel cell catalysts. It is shown that VAGNAs terminated with a high-quality single-layer graphene sheet, can be directly grown on germanium by plasma enhanced chemical vapor deposition without an additional catalyst and at low temperature, which is confirmed by high-resolution transmission electron microscopy and large-scale Raman mapping. The
uniform, centimeter-scale VAGNAs can be used as a surface-enhanced Raman spectroscopy substrate providing evidence of enhanced sensitivity for rhodamine detection down to $1 \times 10^{-6}$ mol L$^{-1}$ due to the existed abundant edges.

**Growth Yield Variation of Single-Walled Carbon Nanotubes Inside a Horizontal Chemical Vapor Deposition System** Sung-II Jo and Goo-Hwan Jeong; Kangwon National University, Korea (the Republic of)

Single-walled carbon nanotubes (SWNTs) have been expected to be applied to various fields such as nanoelectronic devices, transparent conducting films, energy devices and sensors due to their outstanding physical and chemical properties. A chemical vapor deposition (CVD) is the most popular method for SWNTs synthesis because of its simplicity on SWNTs synthesis process and easy control of process parameters. In general, most of the synthesis experiments have been performed in the central region of the reactor so far where temperature uniformity is guaranteed.

In this study, we report the result of detail investigation of the SWNTs synthesis yield depending on sample position in a horizontal CVD system. Methane and Fe thin films were used as feedstock and catalyst for SWNTs synthesis, respectively. Ultra high resolution scanning electron microscope (UHR-SEM) was used to confirm the synthesis yield variation of SWNTs along the axial distance of the reactor. The morphology and crystallinity of the synthesized SWNTs were evaluated by atomic force microscope and Raman spectroscopy, respectively. Main result of this study shows that the highest synthesis yield of SWNTs was observed at the rare region of the reactor not the central region. The results of this study are expected to be applicable to the synthesis of various nanomaterials using CVD process.

**FF05.06.22**

**Effect of Plasma Ignition on Growth Temperature Decrease of Single-Walled Carbon Nanotubes Using Plasma-Coupled CVD System** Sung-II Jo and Goo-Hwan Jeong; Kangwon National University, Korea (the Republic of)

Single-walled carbon nanotubes (SWNTs) have attracted much attention due to both their outstanding physical properties and their nanoscale dimensions. Although SWNTs can be obtained by several processes, the most prevailing method to control tube structure, growth direction, diameter, and chirality, would be a thermal chemical vapor deposition (TCVD). However, the high temperature operation of this method limits the industrial accessibility. Plasma-enhanced chemical vapor deposition (PECVD) is a well-known for growth temperature reduction although the SWNTs grown by PECVD are generally perpendicular to the substrate in conventional vertical chamber along the electric field line, which limits the further manipulation of SWNTs.

We here demonstrate the low temperature growth of SWNTs using a plasma-assisted TCVD system. The system is made of 1 inch horizontal quartz tube and composed of inductively coupled plasma (ICP) production region for efficient decomposition of feedstock and TCVD region for SWNTs growth region. The growth substrate installed at the center of the TCVD region and varied the distance from the plasma generation region to find avoid probable ion damages. We used iron thin film and ethylene gas as growth catalyst and feedstock, respectively. Optical emission spectroscopy was used to analyze ion and active species in the plasma with respect to the process parameters, such as plasma power, pressure, gas composition, and distance from the plasma formation region. The detail of the results will be discussed at the meeting.

**FF05.06.23**

**Synthesis of Bulk 2D Layered Silver Selenide (Ag$_2$Se) Using Chemical Vapor Deposition as a Potential Candidate for Oxygen Reduction Reaction** Konar Rajashree$^1$, Suparna Das$^1$, Eti Teblum$^1$, Gilbert D. Nessim$^1$ and Alex Schechter$^2$; $^1$Bar Ilan University, Israel; $^2$Ariel University, Israel

Bulk 2D layered materials are promising material platforms to study their properties, surfaces, chemical reactivity, as well as potential applicability in diverse applicative areas. Some of the most commonly researched 2D layered materials under this category are: graphene, boron nitride, black phosphorous, and transition metal chalcogenides (TMCs).

Among the TMCs, silver selenide is of particular interest because this promising Al$_3$B$_2$VI$_2$semiconductor can be used to make solid-state electrochemical sensors, solar cells, magnetic field sensors, optical filters, etc. [1]. Some of the established synthesis methods include the use of micro-emulsion mixing, microwave radiation, sonochemistry, and
Electrochemical potential to drive the decomposition of selenium and/or silver compounds to form Ag₂Se [2]. Although all these synthetic approaches are significant in their respective fields, in our case, we have synthesized Ag₂Se using an atmospheric pressure chemical vapor deposition (AP-CVD). We grew the material on a silver foil in an inert atmosphere, using elemental selenium as the precursor. We characterized the final product using XRD, HR-SEM, TEM, and Elemental Mapping (EDX) to ascertain its stoichiometry and we concluded that we obtained β-Ag₂Se (low-temperature phase). To our knowledge, this is the first report of β-Ag₂Se grown using AP-CVD with this specific morphology to be tested as a prospective candidate for oxygen reduction reaction (ORR). Since any non-platinum catalyst is always considered a viable and cheaper alternative, our idea behind the preparation of this material was to test it for ORR and to find out its applicability towards fuel cells. From the linear sweep voltammograms (LSV), we observed that β-Ag₂Se exhibited -0.2 mA current in 1 M KOH solution at 400 RPM, which is quite higher than that observed for 20 wt.% Pt/C, i.e., -0.2 mA. Again with increasing rotating speed of the rotating disc electrode (RDE), we saw that the current density for both the studied catalysts increased due to the effect of higher mass transfer to the working electrode. Furthermore, our studied catalyst, i.e., β-Ag₂Se exhibited -0.55 mA current in 1 M KOH solution at 2400 rotations per minute (RPM), whereas commercial Pt/C shows -0.2 mA current under the same conditions. These encouraging results point to the unique structural 2D layered morphology of β-Ag₂Se to be responsible for the improved electrocatalytic activity towards ORR in the alkaline medium compared to that of the state-of-the-art cathode catalyst Pt/C.

Carbon Nanotubes Growth on TiSiN Barriers via Plasma Enhanced CVD—Analysis of the Physical and Chemical Processes and Modeling Ahmed H. Andalouci1, Ivaylo Hinkov2, Salim Mourad Cherif1 and Samir Farhat1; 1Université Paris 13, France; 2Département de Génie Chimique Université de Technologie Chimique et de Métallurgique, Bulgaria

Aligned multiwall carbon nanotube (CNT) arrays on conductive substrates have been envisaged as interconnects in microelectronics and ultra-high density magnetic information storage material in spintronics. Such applications require the CNTs to be grown vertically aligned, and in direct contact, to conductive substrates [1]. This could be achieved by controlling the physical aspects related to the dewetting of the metal catalyst leading to the formation of a stable assembly of self-organized nanoparticles suitable to catalyse CNT growth. In addition, the use of plasma enhanced chemical vapour deposition (PECVD) allows controlling the gas phase chemistry. In these directions, we propose a simple and reliable fabrication approach to produce controlled cobalt (Co) magnetic nanoparticles by solid state dewetting of ultra-thin Co films deposited on a conductive titanium silicon nitride (TiSiN). TiSiN layers act as barriers to limit diffusion into the bulk of the substrate. Moreover, the low surface energy of TiSiN favours catalyst dewetting, thereby improving CNT forest density and verticality. To control gas phase chemistry, (CH₄/H₂/O₂) mixture gases were decomposed over the catalyst nanoparticles after their dewetting. The addition of oxygen leads to the formation of water H₂O and OH radicals that improves CNT quality.

Experimentally, we achieved the dewetting of cobalt films with thicknesses h=1, 2 and 3 nm by thermal heating at 750°C followed by hydrogen plasma treatment. This resulted in assembly of nanoparticles with quasi spherical shapes and well-controlled size distribution. The mean particle size (D) have been measured from scanning electron microscopy and correlated with the initial film thickness, namely D [endif]--> 6h. Moreover, using the TiSiN barrier allowed obtaining homogeneous nanoparticle distribution with density as high as ~ (4.2 ± 0.1) ×10¹ⁱ cobalt nanoparticles/cm². This value is smaller than the one reported for iron ~ (5.1 ± 0.1) ×10¹² [1]. However, cobalt is more stable regarding oxidation and thus presents a higher magnetization at saturation. After addition of (H₂/CH₄/O₂) (90:10:x) sccm at 10 mbar, PECVD allowed to obtain vertically aligned multi-walled nanotubes. Oxygen flow rate x was varied from 0 to 4 sccm and correlated to the CNT growth rate and surface density. At 2 sccm of oxygen, ultra-dense (10¹¹ nanotubes/cm²) vertically aligned CNTs with well graphitized walls as characterized by high resolution transmission electron microscopy (HRTEM) were obtained. Tow numerical models were proposed to understand the experimental results. As a first approximation, the plasma is described by spatially averaged bulk properties in (0D). This model extends the classical chemistry formulation to nonequilibrium plasma reactors for CNT growth from 134 species in (C,H,O,e-) system involved in 471 gas-phase reactions [2]. The small computational demands of (0D) model, allows kinetics sensitivity analysis and permit the identification of dominant
reactions and key species depicting CNT growth. The reduced chemical scheme was then used within (2D) model including 22 gas species and 100 homogeneous reactions. Both gas and surface chemistries were taken in consideration to calculate CNT growth rate using Surface-Chemkin and Ansys-Fluent softwares. Surface-reaction mechanism specific to cobalt under (H2/CH4/O2) CVD plasma is proposed and considers 16 surface species and 81 surface reactions involving both gaseous species impinging on the surface, adsorbed molecules, atoms and free sites. The bulk material considered is CNT, with mass density of 2.2 g/cm3 and site density ~3.6 ×10^10 moles/cm^2 as estimated from measured nucleation surface density, CNT diameter and number of walls. Optimal CNT rate was found for 2 sccm O2 in good agreement with experimental measurement.

**FF05.06.25**

**Layer Control in Asymmetric CVD Graphene Growth** Haozhe Wang¹, Wei Sun Leong¹, Zhenpeng Yao², GangSeob Jung¹, Qichen Song¹, Marek Hempel¹, Tomas Palacios¹, Gang Chen¹, Markus J. Buehler¹, Alan Aspuru-Guzik²,³ and Jing Kong¹; ¹Massachusetts Institute of Technology, United States; ²Harvard University, United States; ³University of Toronto, Canada

Chemical vapor deposition (CVD) is the most promising approach to obtain high-quality, large-area graphene. Recently, bilayer graphene has attracted massive interests owing to its promising applications as twistronics, superconductors, etc. To obtain graphene layers beyond monolayer, counter-intuitive asymmetric CVD growth is developed to break the original self-limiting nature of growth on copper substrate (Nat Nano 11, 426 (2016)). However, the layer control in graphene remains challenging and lack of study. Researchers fail to obtain pure, high-quality large-scale bilayer graphene and have thus perceived that thicker graphene impurities are inevitable, after more than one decade of research efforts.

Here, we report a technique to control the graphene layer number in asymmetric CVD growth. Owing to counter-intuitive growth principle, we proposed a new physical quantity, named “interface adhesive energy”, that can be used to predict the CVD growth behavior. We show that, through first-principle calculations, this new physical quantity can used to control the resulting graphene layer number. Based on these theoretical understandings, we have devised a new CVD strategy, which results in layer control in asymmetric CVD bilayer graphene growth. Through systematic materials characterization studies (SEM, XPS, Raman, STEM, and AFM), we found that the growth of CVD bilayer graphene on copper catalyst consists of several major steps: (i) dehydrogenation of carbon precursor (i.e. CH₄) at the Cu interior resulting in free carbon atoms, (ii) bulk diffusion of carbon atoms from inner to outer surface of the Cu pocket, (iii) interface diffusion of carbon atoms between the 1stLG and Cu exterior, and (iv) nucleation of graphene adlayers (i.e. 2ndLG, 3rdLG, 4thLG etc.) or growth continuation of the existing graphene layer (i.e. 2ndLG). Through Raman studies, we confirmed that our bilayer graphene is of AB stacking with small twisting angles (θ = 0 - 5°), namely quasi AB-stacked bilayer graphene. Specifically, our samples exhibit 4 Raman characteristic signatures: the positions of G bands ~1580/cm, the positions of 2D bands ~2680/cm, 2D/G intensity ratio ~1, and 2D bands’ full-width-half-maximum ~58/cm. We also proposed an unsupervised learning approach to manage large-volume Raman data. Our artificial-intelligence-assisted Raman analysis approach is very useful for graphene samples in identifying regions of different stacking orders and layer numbers.

In summary, by introducing the concept of interface adhesive energy, we managed to prevent the growths of thicker graphene islands of impurities and realized the long-sought layer control in graphene CVD growth. Confirmed by artificial-intelligence-assisted Raman analysis, the obtained graphene layers were in AB stacking with small twisting angles. Our discoveries on well-controlled growth and coherent characterization of large-area graphene are essential for unlimited innovations based on two-dimensional materials, owing to their electrical, optical, mechanical and chemical properties.

**Comparative Study of the Effect of Thermal Processes and Rapid Thermal Annealing on the Photoluminescent Emission of Amorphous Silicon Carbide (a-SiC:H)** Maricela Meneses, Mario Moreno, Alfredo Morales, Alfonso Torres, Pedro Rosales and Javier de la Hidalga; National Institute of Astrophysics, Optics and Electronics, Mexico

Nowadays device applications of amorphous silicon carbide (a-SiC:H) include light emitting diodes,
phototransistors, photodetectors, MEMS and solar collectors. The a-SiC:H films have different optical, electrical and structural characteristics depending on the gases mixtures and the deposition technique used. The plasma enhanced chemical vapor deposition (PECVD) technique has several advantages, as its low temperature of deposition (< 200°C), which implies the use of different substrates, as plastics and metal foils, as well this technique produce uniform films.

However also it has been reported that as deposited a-SiC:H films have instability and this could affect the photoluminescent (PL) emission of a-SiC:H films. One way to reduce the instability and defects is by thermal treatments. In conventional thermal treatments the films are exposed to high temperatures for long periods of time in an inert environment, while in the rapid thermal annealing (RTA) the substrates are subjected to very short periods of time (seconds).

In this work we present the effect of thermal processes and rapid thermal annealing on the PL emission of amorphous silicon carbide (a-SiC:H). The a-SiC:H thin films were deposited at a substrate temperature of 150 °C by PECVD, silane (SiH4) and methane (CH4) gases were used. The rapid thermal annealing (RTA) was carried out with a ramp up of 50°C/s at 500 °C for 40 seconds and with a ramp down 120 seconds. The conventional thermal treatment was done with a temperature of 1100 °C for 5400 seconds in forming gas environment.

Our results shows that the a-SiC:H films as deposited, present emission in orange region of the visible spectrum, while the films treated with RTP have an increase in the PL emission intensity, with an emission in the visible region (in the blue color), that increment is attributed to radiative centers related to oxygen. On the other hand with conventional thermal processes the emission is decreased with respect to the deposited films. The above is related to the structural change suffered by the films when are exposed to thermal treatment process. Finally, our results show that RTA is more efficient than conventional thermal treatments in order to increase the PL emission of a-SiC:H films, which is of interest for light emission applications.

The Effect of Different Ti Doping Ratios for ZnO Active Layer Thin-Film Transistors Kelsea Yarbrough, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Flexible and transparent electronics have presented a groundbreaking era for the world of display technologies. Zinc oxide (ZnO) amongst the popular transparent conducting oxides are the most commonly used semiconductor for transparent devices, such as liquid crystal displays, solar cells, transparent heaters, and etc. Liquid crystal displays most significant component are thin film transistors (TFT). Modern day TFTs are produced with an active layer of either hydrogenated amorphous silicon(a-Si:H) or indium gallium doped zinc oxide (IGZO). A-Si:H will soon be out shadowed by doped ZnO counterparts due to its minimal channel mobility. IGZO contains indium, which is a toxic, expensive, and whose supply will not be enough for demand by 2020. The indium free oxide-based channel material such as titanium doped zinc oxide (TiZnO) has been immensely studied due to its good electrical and optical properties. High quality TiZnO thins films were grown by atomic layer deposition on n-type silicon, glass, and sapphire substrates. The films were varied with different dopant ratios to properly evaluate and analyze the effect of Ti substitutional atoms in the crystal lattice. The effect of Ti content on microstructures, surface morphology, electrical properties, and optical properties of the films were investigated by Atomic Force Microscopy (AFM), X-Ray Diffraction, Ultra-violet Visible Spectroscopy (UV-VIS), and Hall Effect Measurement System (HMS). AFM provided thin films roughness, grain size, and surface morphology for glass, silicon, and sapphire thin films. XRD provided the effect of how different Ti substitutional atoms doping ratios invaded the crystal lattice. UV-VIS was performed to investigate the high optical transparency for the glass substrates. HMS provided the electrical mobility, conductivity, and resistivity for the active layer of TFT TiZnO thin films. The present work will provide valuable scientific input for TiZnO thin films for the advancement of TFT devices.

This work was supported by the NSF-CREST Grant number HRD 1547771 NSF-CREST Grant number HRD 1036494

FF05.06.28
Thickness Gradient Film Formation by Spatial Atomic Layer Deposition for High-Throughput Screening of MIM Diodes Abdullah Alshehri1,2, Khaled Ibrahim1, Kissan Mistry1, Jhi Y. Loke1, Mustafa Yavuz1 and Kevin Musselman1; 1University of Waterloo, Canada; 2Prince Sattam Bin Abdulaziz University, Saudi Arabia

Atmospheric pressure spatial atomic layer deposition (AP-SALD) is a fast and scalable thin film deposition
technique that operates in atmospheric pressure. It has the ability to control the film thickness in the atomic scale range and produce uniform and pinhole-free films at modest temperatures (e.g. 80-200°C). AP-SALD is implemented to deposit an insulator film with a thickness gradient as opposed to a film with uniform thickness. To obtain a thickness gradient of metal oxide layers such as Al2O3 or ZnO on Si or glass substrates, we adjusted the distance between the deposition reactor head and the substrate to be 100µm on one side and 150, 190, or 230 µm on the other side. The head-substrate separations used here are sufficiently large that some mixing of the precursors occurs in the gas-phase, resulting in some chemical vapour deposition (CVD). By varying the head-substrate separation across the substrate, the amount of CVD was varied, resulting in different deposition rates across the substrate. To demonstrate the applicability of this technique, combinatorial MIM diodes are fabricated, i.e. diodes with many different thicknesses can be fabricated on a single substrate. The diode performance showed variation with aluminum oxide thickness and the optimal thickness is identified.

FF05.06.30
Vapor-Based Synthesis of Poly(ethylhexyl acrylate-co-acrylic acid) Thin Films as Pressure Sensitive Adhesives Huseyin Sakalak1, Kurtuluş Yılmaz2 and Mustafa Karaman2; 1Selcuk University, Turkey; 2Konya Technical University, Turkey

Pressure sensitive adhesives (PSA) are materials that can bind different surfaces together. They can easily adhere to various surfaces at a light pressure at room temperature. Common acrylate monomers which are used to produce PSA materials are ethylhexyl acrylate (EHA), methyl methacrylate (MMA), and acrylic acid (AA). PSAs based on acrylate polymers are widely used because of their useful properties such as high bonding strength, easiness of application to various surfaces, and low manufacturing cost. Commercially, PSAs are deposited using wet techniques. In this study, P(EHA-co-AA) copolymer thin films were deposited on different surfaces using initiated chemical vapor deposition (iCVD) technique. iCVD is an all-dry, solvent-free vapor deposition strategy for coating of polymers from their corresponding monomers. Use of initiator di-tert butyl peroxide (TBPO) together with the monomer precursors improved the deposition rates substantially while decreasing the activation energy required to carry out the surface polymerization reactions. Acrylic acid was chosen for its suitable polarity and ethyl acrylate was chosen for its hydrophobicity and fluidity. Furthermore, because of its low glass-transition temperature (Tg) EHA acts as a plasticizer in the copolymer film. P(EHA-co-AA) copolymers were synthesized using different ratio of EHA to AA flowrates in the reactor feed to achieve tunable adhesive properties. The adhesive properties of the obtained films were characterized by mechanical tensile tester. XPS, FTIR and SEM analyzies were performed to characterize the chemical structure, composition and surface morphology of the as-deposited nano-adhesive copolymer films. DSC analysis was used to reveal the Tg of the as-deposited copolymer films. It was found that highly homogeneous thin films of P(EHA-co-AA) can be obtained by iCVD with high retention of EHA and AA monomer functionalities. Very high deposition rates up to 400 nm/min were observed. As-deposited materials possessed high adhesive properties, which could be tuned by changing the comonomer ratios in the reactor feed.

FF05.06.31
VACNT/Al2O3 Nanocomposite Fabrication via Novel Water-Assisted Chemical Vapor Deposition Followed by Atomic Layer Deposition Lev Rovinsky1, Barun K. Barick2, Tamar Segal2 and Noa Lachman1; 1Tel Aviv University, Israel; 2Technion–Israel Institute of Technology, Israel

Nanocomposite materials exhibit properties unreachable by conventional materials, as the nanoscale of the fillers allows for size-dependent effects including enhance mechanical and transport properties. However, these exact scales also complicate fabrication making traditional fabrication methods incompatible with ultra-high surface area and the van der Waals forces it creates. By combining chemical vapor deposition (CVD) with atomic layer deposition (ALD), bottom-up approaches, one can circumvent the difficulties plaguing the field of nanocomposites. Alumina (Al2O3) exhibits excellent chemical and thermal stability and very good resistance to wear. However, low thermal and electrical conductance could be both an asset and a liability, sometimes in the same application. These properties can be tailored by incorporating highly thermally and electrically conductive carbon nanotubes (CNT). With that said, in order to conserve the anisotropic properties of CNT in the final form of the material, they must be aligned.

In this work, a vertically aligned carbon nanotubes (VACNT)/alumina nanocomposite material was fabricated. VACNT arrays were grown via water-assisted CVD and then coated with alumina via ALD. Before the ALD step, functionalization in the form of controlled oxidation was done in order to enhance the adhesion between the phases without destroying the anisotropicity. The synergistic effect of alumina and carbon nanotubes allows for improved
thermal stability of the nanocomposite. Properties in the axial and transverse directions of the nanocomposite will be explained.

**A CsVO3/Quasi-2D Oxide Heterostructure by Chemical Vapor Deposition**  
Saloni Pendse and Jian Shi;  
Rensselaer Polytechnic Institute, United States

As strongly correlated oxides continue to be studied for next generation electronic devices, van der Waals epitaxy is gaining popularity as an effective technique to grow such oxides while ensuring a low-density of misfit and threading dislocations as well as minimum interdiffusion at the interface. In this work, we report an exception to this trend. While attempting to grow VO2 via chemical vapor deposition on CsBiNb2O7, a layered Dion-Jacobson perovskite, we observe the epitaxial growth of CsVO3 instead. This points to an aspect of van der Waals epitaxy not encountered so far - the possibility of an interaction between surface ions of van der Waals epitaxy substrates and the growing material. We confirm the growth of CsVO3 by Raman mapping and reveal the epitaxial relation between CsVO3 and CsBiNb2O7 via electron microscopy diffraction. Since CsVO3 is an excellent broad-band emitting phosphor currently being explored for use in rare-earth free white light-emitting diodes, we also probe photoluminescence properties of the epilayer and model the probable electronic structure. Based on our study, we suggest that the substrate – oxide chemistry may need to be considerably taken into account while designing and implementing van der Waals epitaxy in correlated oxide systems.

**Role of Gold and Dielectric Spacer in the Manufacture of Electroluminescent Devices Based in Silicon Quantum Dots**  
Arturo Rodríguez-Gómez; Instituto de Física - Universidad Nacional Autónoma de México, Mexico

With the purpose of increasing the efficiency and control of light emission from silicon quantum dots (SiQDs), several research groups have used different configurations of nanoparticles and nanostructures made by using noble metals (Au, Ag) near the silicon quantum dots [1,2]. A shared feature in the coupled structures reported in those previous works is that all of them have a spacer between the metal and the SiQDs. In turn, the spacer must be a dielectric and must have a well-defined thickness ranging from 10 to 20 nm.

In this work, we use nanolayered structures like those mentioned previously, to manufacture a light emitting device (LED) with a metal-insulator-semiconductor (MIS) configuration. SiQDs embedded in silicon nitride acted as luminescent films and pure silicon nitride serve as a dielectric spacer. Both films were deposited by Remote Plasma Enhanced Chemical Vapor Deposition (RPECVD). Meanwhile, gold nanoparticles (AuNPs) were deposited by sputtering on a p-type silicon substrate.

We evaluate the electroluminescent (EL) spectral enhancement factor which is defined as the ratio of EL intensities of samples with AuNPs and their references without AuNPs. In one of our samples, this ratio at 27.7 mA shows a maximum EL enhancement factor of 7 at about 510 nm and 5.4 at about the maximum EL intensity peak (~600 nm). It is worth to notice that the higher EL enhancement factor in these structures is close to the absorption peak of gold nanoparticles at 538 nm. Therefore, our devices allowed us to prove that there is indeed an electroluminescent enhancement when the appropriate AuNPsSpacer-SiQDs configuration is used.

We have found that EL enhancement may indeed be due to a plasmonic coupling. Nevertheless, we also identify that the presence of gold nanoparticles in the EL device allow a more efficient distribution of charge carriers towards the luminescent centers (SiQDs). Consequently, we conclude that more than one mechanism should be involved in the optimized electroluminescence.

**Influence of Active Nitrogen Species on InN Growth and Structural Properties in Migration-Enhanced Remote Plasma MOCVD**  
Zaheer Ahmad, Mark Vernon, Garnett B. Cross and Alexander Kozhanov; Georgia State University, United States

We report on the influence of various nitrogen plasma species on the growth and structural properties of indium nitride in migration-enhanced remote-plasma metalorganic chemical vapor deposition. The ion energy and flux have been determined via the atomic emission spectroscopy by the analysis of emission spectra recorded at the growth
surface. The atomic nitrogen ions’ flux has been found to have a significant effect on the growth rate as well as the crystalline quality of indium nitride films. Results of Raman spectroscopy, infrared reflectometry, atomic force microscopy, and charge transport Hall measurement are discussed.

**Plasma-Enhanced Atomic Layer Deposition of Vanadium Dioxide (VO2) Using TEMA V and Oxygen Plasma**

Adnan Mohammad, Saidjafarzoda Ilhom, Deepa R. Shukla and Necmi Biyikli; University of Connecticut, United States

Vanadium dioxide (VO2) exhibits a unique low-temperature (~70 °C) phase-transition behavior due to a structural change from monoclinic phase (low temperature) to a tetragonal rutile phase structure (high-temperature). Moreover, this phase-transition is ultrafast (< ps) and reversible, which makes VO2 attractive for a wide variety of applications. Also known as metal-insulator transition (MIT), this property can be effectively used in optical and electrical switches, RF-microwave switches, tuneable plasmonic and metamaterial systems, and smart windows. Among the synthesis methods used to deposit VO2 films, chemical vapor deposition, reactive electron-beam evaporation, reactive magnetron sputtering, pulsed-laser deposition, sol-gel methods, and hydrothermal processes have been reported. Atomic layer deposition (ALD) of VO2 films have relatively recently been of interest, mainly due to it’s precision thickness control, large-area uniformity, and low-temperature compatibility. Majority of VO2 ALD research focused on thermal-ALD based growth recipes with either ozone or water vapor are used as the oxygen co-reactant and reported film properties as a function of post-deposition annealing.

In this work, we report on the low-temperature self-limiting growth of VO2 thin films using tetrakis(ethylmethylamino)vanadium(IV) (TEMAV) as metal precursor and oxygen plasma as co-reactant in a plasma enhanced atomic layer deposition system. To the best of our knowledge, this is the first study on the plasma-ALD of VO2 via oxygen plasma. Our main motivation behind using O2 plasma is to reduce the necessary substrate temperature via energetic oxygen radicals and gaining additional degree of freedom in adjusting the film growth conditions through plasma variables such as plasma power, exposure time, O2 partial pressure and plasma gas composition.

VO2 films are deposited on Si(100) samples, which went through a conventional solvent cleaning process just before loading into the reactor chamber for the growth process. Ultratech Fiji G2.0 Plasma-ALD system has been used to carry out the deposition experiments. The substrate temperature has been set to a fixed temperature of 150 °C, mainly due to the narrow temperature window where TEMA V precursor has reasonable vapor pressure and is below the thermal decomposition temperature. The unit ALD cycle used for the VO2 deposition consists of 30-100 ms TEMA V dose which is carried into the reactor via 20 sccm Ar-carrier flow, Ar-purge for 10 s, O2 plasma (50 sccm) at 300W for 10 s, and finally another 10 s of Ar purge. In addition, the TMA V precursor is heated at 115 °C in order to provide sufficient amount of precursor vapor into reactor chamber. The total number of ALD cycles used for film deposition is 300. VO2 film thickness is checked by ex-situ ellipsometry after deposition. The film thicknesses measured for TEMA V pulsing times of 30 and 100 ms are 15.5 and 20.5 nm, respectively. The extracted refractive index ranges within 2.25 - 2.35, while the growth per cycle (GPC) values varied from ~0.5 Å to 0.7 Å. The obtained results agree fairly well with previously published reports in the literature. X-ray diffraction measurements as a function of annealing temperature and ambient will be presented along with the detailed temperature-dependent electrical characteristics of the synthesized VO2 films.

**FF05.06.36**

**Real-Time In Situ Monitoring Atomic Layer Doping Processes for Group-III Doped ZnO Layers—Super-Cycle Versus Co-Dosing Approach**

Adnan Mohammad, Saidjafarzoda Ilhom, Deepa R. Shukla, Md Tashfiq Bin Kashem, ABM Hasan Talukder, Helena Silva, Ali Gokirmak, Brian Willis and Necmi Biyikli; University of Connecticut, United States

We report a comparative study investigating different atomic layer doping (ALDp) strategies to achieve effectively doped ZnO layers. The main motivation of our study is to gain insight into how the surface reactions are affected during the relatively conventional super-cycle approach and less-used co-dosing method. To achieve real-time information, we have carried out in-situ ellipsometric measurements which reveal sub-angstrom film thickness changes as a result of individual chemisorption, ligand exchange, and incorporation reactions. Aluminum-doped ZnO (AZO) has been studied as the material of interest, which finds a wide range of use in solar cells and
transparent/flexible electronics as transparent conducting oxide layers.

Thermal atomic layer deposition (ALD) with diethylzinc (DEZ) and trimethylaluminum (TMA) were used as the metal precursors for ZnO film growth and Al-doping, respectively, while H2O was used as the common co-reactant. We experimented conventional sequential or super-cycle approach and simultaneous or co-dosing methods to form AZO layers with the target of reaching the highest possible conductivity. To the best of our knowledge, the co-dosing approach has not been studied or reported for AZO layers which motivated us for this systematic study. The deposition recipe used for AZO film growth is as the following: DEZ pulse or TMA pulsing for 15 ms; nitrogen purging at a flow of 20 sccm for 10 s; de-ionized water pulse of 15 ms as a co-reactant; nitrogen purging at a flow of 20 sccm for 10 s. The substrate temperature was varied as 100, 150, and 200 °C to understand its impact on doping efficiency. Total number of ALD cycles used is 300 cycles for each film, where the super-cycle ratios were tuned from 1:10 to 1:50 and the priority pulsing of DEZ and TMA is changed for co-dosing experiments.

We have observed that the refractive index of the AZO films changed between 1.95 - 1.87, depending on the Al-doping ratio for super-cycle doped AZO films. However, AZO films doped with the co-dosing approach resulted in films with a refractive index of around 1.6, which very much resembles Al2O3 films. To double-check this result, DEZ is first pulsed shortly before the TMA pulse, however the result did not change, resulting in an Al2O3-like refractive index. This observation indicates that chemisorbed DEZ groups are being replaced by incoming TMA molecules and as a result, ZnO is converted into Al2O3. We have carried out detailed in-situ analysis of the surface reactions for both doping approaches and particularly the co-dosing method where ZnO-to-Al2O3 conversion is observed. The ellipsometric data is supported by x-ray photoelectron spectroscopy (XPS) which reveals the chemical composition and level of atomic doping concentrations. The co-dosing approach is further tested for other group-III element precursors such as triethylgallium (TEG), trimethylindium (TMIn), and triethylboron (TEB), and these experimental results will be presented as well.

**FF05.06.37**
Large-Area, Uniform Growth of Nanoporous Biocompatible Polymer by Pressure- and Flux-Controlled Vapor Deposition
Katelyn Ramsey, H M Azazul Karim and Joonhee Lee; West Virginia University, United States

Nanoporous polymers are emerged as important elements due to their potential applications utilizing controllable optical, mechanical, and microfluidic properties, such as biosensor, which bulk polymer cannot offer. Parylene-C has been used for various micro-electromechanical systems (MEMS) and optoelectrical devices due to its electrical insulation and optical transparency. Moreover, it is commonly used as an encapsulation layer in biomedical devices to take advantages of biocompatibility, low water absorption rate, and pinhole free conformal coating. Several methods were suggested to grow nanostructured parylene-C but still limited to a small area or difficult to control the porosity [1-2]. In this work, to overcome current limitations, we report the novel combinatorial approach of nanoporous parylene growth method by controlling process pressure and vapor flux. Commercial PDS2010 (Specialty Coating System) was modified with custom-designed 3D printed nozzles to provide the directional and localized vapor flux to the substrate, while other parameters are the same. With the elongated tip of nozzle geometry (rectangular) and in increased process pressure, the porous layers were formed due to the enhanced deposition rate. The uniform layers over the 4-inch diameter were successfully grown in the optimized nozzle design. Together with scanning electron microscopy observation, we also characterize the optical properties of the films with the spectroscopic ellipsometry tool for precise porosity measurement. Along with pressure- and flux controlled nanoporous polymer growth, potential applications and an outlook to the future will be discussed.

**FF05.06.38**
Control of Micro-Ring Generation of Fullerene Thin Films Using Mixed Solvent in Mist Vapor Deposition Method
Shigetaka Katori and Risako Taguchi; National Institute of Technology, Tsuyama College, Japan

The mist vapor deposition is one of the film formation technique of organic semiconductor materials that enables printed electronics. The liquid is ultrasonicated into particles of about 20 m in diameter, and sprayed onto the heated...
substrate. The evaporation rate of the solvent is controlled by the substrate temperature. At this time, innumerable micro droplet traces, that is, coffee rings are formed. In the solution process, this undesired structure are affecting the physical and electric properties of formed films. Similarly, in the spray method and the ink jet method, the formation of this coffee ring is one of the causes of deterioration in film quality as compared with vacuum deposition. We examined controlling the generation of micro-coffee ring in the mist deposition method by changing the evaporation rate of the solvent.

A bare fullerene was used as the organic semiconductor material. Two solvents having different boiling points were mixed and used as a solvent. A solvent with a high boiling point is A, a solvent with a low boiling point is B, and the mixing ratio is 20%, 25%, 30%. The difference between the boiling points of these solvents was about 80 degree. The substrate temperature during film formation was changed in the range of 120 to 300 degree. The surface morphology was observed by AFM, and ultraviolet spectroscopy (UPS) and XRD measurements were performed. When the substrate temperature was high a uniform coffee ring with a diameter of about 15-20 microns was formed at 300 degree regardless of the mixing ratio of the solvents. The surface roughness Rq was about 35 nm to 45 nm. On the other hand, when the film formation temperature was changed in the range of 180 to 210 degree, Rq was 7nm to 20 nm. Significant improvement of surface roughness, and no formation of coffee ring was observed in the solvent ratio of 30%

A variation was found in the HOMO level determined by the UPS measurement results due to the difference between the solvent mixing ratio and the film formation temperature. The HOMO level changed in the range of 5.7 eV to 6.26eV. The value of vacuum evaporated fullerene thin film is known to be 6.25 eV. When the mixing ratio of the high boiling point solvent was 25% and 30%, it showed a lower value than the HOM level of vacuum evaporation. On the other hand, when the mixture ratio of the solvent was 20%, the HOMO level equivalent to vacuum evaporation was shown. In particular, the surface roughness was low and the value was at the same level.

We controlled the generation of coffee ring and realized a thin film with the same roughness as vacuum deposition by changing the mixing ratio using high boiling point solvent and low boiling point solvent. Furthermore, by controlling the surface roughness, a thin film with a HOMO level equivalent to that of vacuum deposition was achieved.

Atomic Layer Deposition of Titanium Sulfide Thin Films and Its Oxidation in Ambient

Hochul Nam, Changdeuck Bae and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

We describe the atomic layer deposition (ALD) of titanium oxysulfide films. A new ALD chemistry of tetrakis(dimethylamido) titanium (IV) and hydrogen sulfide (H2S) is suggested for the synthesis of amorphous titanium sulfide layers. We found that the resulting films subsequently underwent oxidation upon reactions under ambient condition, resulting in titanium oxysulfide (TiO2-xSx). The resultant structures were analyzed by using X-ray diffraction, transmission electron microscopy, and X-ray photoelectron spectroscopy, indicative of the formation of TiO2-xSx. A combined study of Hall-effect measurements and Mott-Schottky analysis showed n-type semiconductor behaviors possessing a good conductivity. Optical properties testify that the present system has a moderate band gap in between the related binary end compounds such as TiS2 and TiO2

Conformal Coating of Freestanding Particles by Vapor-Phase Infiltration

Andreas C. Liapis¹, Ashwanth Subramanian², Kim Kisslinger³, Chang-Yong Nam³⁴² and Seok-Hyun Yun¹; ¹Harvard Medical School & Massachusetts General Hospital, United States; ²Stony Brook University, The State University of New York, United States; ³Brookhaven National Laboratory, United States

Three dimensional (3D) encapsulation of free-standing particles and powders by atomic layer deposition (ALD) remains a technical challenge. Current solutions, such as fluidized bed reactors, rotary tumblers etc, employ physical agitation to vary the orientation of the particle during the deposition process, thereby exposing all surfaces to the flowing precursors. As a result, these methods require large amounts of the material to be coated, with minimum working quantities typically on the order of 10s to 100s of mg. A technique for encapsulating static particles on substrates would enable the processing of small volumes of material (c.f. bulk powders), down to individual micro- and nano-particles.

Here, we demonstrate the coating on all sides of individual particles resting on an inert polystyrene film. Vapor-phase infiltration [1] is performed on a commercial ALD tool. During this process, organometallic precursors diffuse
through the inert polymer and lead to the growth of a target inorganic film on the particle’s surface, even on the bottom side that is in contact with the polystyrene. We examine the uniformity of the coating by cross-sectional transmission electron microscopy and measure its thickness for different numbers of infiltration cycles.

To demonstrate the usefulness of our technique, we coat III-V semiconductor microdisk particles with a thin layer of aluminum oxide. These microdisks support whispering gallery mode resonances and under optical pumping exhibit single-mode lasing. As free-standing particles, microdisk lasers have applications in biomedical imaging as intracellular probes [2]. We show that a thin (sub-10-nm) coating of aluminum oxide applied by our technique can improve the stability of lasing emission under continuous illumination in an aqueous environment compared with uncoated semiconductor disks.

Our technique is applicable to a range of particles, and generalizable to the growth of different inorganic films. Moreover, sequential vapor infiltration can be performed on a regular ALD tool without needing a special chamber or cleaning procedure.

**FF05.06.41**

Saidjafarzoda Ilhom1, Adnan Mohammad1, Deepa R. Shukla1,2, Brian Willis3 and Necmi Biyikli1; 1The University of Connecticut, United States; 2University of Connecticut, United States; 3University of Connecticut, United States

In this work, we have investigated the influence of critical growth parameters on the electrical and optical properties of indium nitride (InN) thin films grown at relatively low-temperatures via hollow-cathode plasma-assisted atomic layer deposition (HCPA-ALD). InN films were deposited on Si(100) substrates using trimethyl-indium (TMI) and variants of Ar/N2/H2 plasma (N2-only, Ar/N2, and Ar/N2/H2) as the metal precursor and nitrogen co-reactant, respectively. ALD growth experiments have been performed within 50 - 150 W plasma power range and 160 - 240 °C substrate temperature. Dynamic in-situ ellipsometry was employed to observe individual ligand exchange events in real-time during the growth process. Additionally, ex-situ characterizations were done to identify the optical, structural, and chemical properties of the grown InN films. X-ray diffraction (XRD) results showed that only the samples grown at 200 and 240 °C with 100 W rf-power displayed single-phase hexagonal crystalline structure with peak intensity values increasing as a function of substrate temperature. Moreover, varying the plasma chemistry such as addition of H2 to Ar/N2 led to significant microstructural changes resulting in crystal quality degradation and porous films with high carbon content. As such, x-ray photoelectron spectroscopy (XPS) measurements are carried out to further understand the possible reactions taking place in the presence of H2 plasma. The electrical properties (resistivity, carrier density, and Hall mobility) of the polycrystalline InN films are analyzed using I-V and Hall measurements and will be presented in detail. Spectroscopic ellipsometer is utilized to study the spectral absorption characteristics of the optimal InN films to extract the corresponding optical band edge. Finally, with the highest quality InN films, a proof-of-concept visible/near-IR photodetector will be fabricated and tested for performance.

**FF05.06.42**
Growth Behavior and Electrical Properties of Atomic Layer Deposited SrTiO3 on Ge Substrate

Dong Gun Kim; Seoul National University, Korea (the Republic of)

Germanium (Ge) is an impending p-channel substrate to overcome the drain-current saturation problem of MOSFET due to its higher carrier mobility. However, the most critical challenge for adopting Ge as the substrate for the next generation p-MOSFET is the instability at high-k/Ge interfacial region. Strontium titanate, SrTiO3(STO) film was selected as the dielectric because its bulk dielectric constant is as high as 300. In this study, therefore, the growth behaviors and electrical properties of the atomic layer deposited (ALD) SrTiO3 films were studied with the various deposition temperature and annealing temperature. SrTiO3 films were deposited by using Sr(iPr3Cp)2 and Ti(CpMe3)(OMe)2 (Pr, Cp, and Me are propyl, cyclopentadienyl, and methyl groups, respectively) precursor on Ge substrates at 230°C and 370°C. 370°C deposition showed more initial excess deposition of Sr element than 230°C
deposition. Also, a higher growth rate was confirmed at the higher deposition temperature. For ex-situ crystallization, the STO films were annealed at the various annealing temperature ranging from 550-650°C for 5min by rapid thermal annealing. For the electrical analysis, Metal-Insulator-Semiconductor (MIS) capacitors were prepared by depositing TiN/Pt as the metal gate. An extremely high dielectric constant (~285) was confirmed from the slope of the equivalent oxide thickness (EOT) vs. physical oxide thickness (POT) plots. However, the quite high interfacial oxide thickness increased the total EOT values, requiring further interfacial engineering.

**Characteristics of 2D SnS2 as a Channel Layer in TFT Device**
Hyeongsu Choi, Hyunwoo Park, Namgue Lee and Hyeongtag Jeon; Hanyang University, Korea (the Republic of)

Recently, there were many researches on two-dimensional (2D) materials having semiconducting characteristics like transition metal dichalcogenides (TMDCs). These researches have mainly focused on the realization of original 2D materials characteristics through deposition process. However, representative TMDCs such as MoS2 and WS2 have tried many different disposition methods to overcome the limitations of their high process temperature (≥750°C). Due to their high process temperature, these materials can not be directly applied onto flexible polymer substrates. On the contrary, Tin disulfide (SnS2) is post transition metal sulfide and has low process temperature (<350°C), which is low enough to directly deposit on polymer substrates, and exhibits comparable characteristics with MoS2 and WS2 because of similar hexagonal layered structure. Therefore, we have developed low temperature process of few layer SnS2 thin films with atomic layer deposition method for obtaining 2D material characteristics and investigated the electrical properties by fabricating thin film transistors (TFTs).

In this study, SnS2 thin films were grown by atomic layer deposition with tetrakis(dimethylamino)tin (Sn[N(CH3)2]4, TDMASn) and hydrogen sulfide (H2S, 99.9%) at 150 °C. Subsequently, the post deposition annealing process up to 350°C was performed in 4% H2S gas ambient. We then identified the crystal structure and chemical bonding using X-ray diffractometer (XRD) and X-ray photoelectron spectroscopy (XPS), and the number of SnS2 layers was examined by atomic force microscopy(AFM), Raman analysis and high resolution-transmission electron microscopy (HRTEM). To investigate the switching characteristics of few layer SnS2 thin films, we fabricated bottom gate TFTs using few layer SnS2 thin films as active channel layer. As a result, few layer SnS2 TFTs showed n-type characteristics with on/off current ratio 8.32 x 106, mobility 0.08 cm2/Vs and 830 mV/decade of subthreshold swing.

**Multiphysics Modeling of Atmospheric Plasma Deposition of Zirconia**
Arash Tourki Samaei and Santanu Chaudhuri; University of Illinois Chicago, United States

The appeal of microwave-assisted atmospheric plasma for surface modification and embedding of chemistry is thwarted by the lack of predictive link between the process parameters, plasma chemistry, surface plasma reactions, and growth of functional layers with control over morphology and phase. The atmospheric plasma deposition of zirconia on a natively grown aluminum oxide layer offers an advanced, robust and cost-effective processing without a vacuum chamber in ambient air. Here, we present a comprehensive multiphysics modeling of the plasma deposition to study the physics of the processing and the metal oxide growth on the substrate. An organometallic evaporation model is adapted for predicting evaporation rate of precursor. This model calculates the growth rates and film thickness of zirconia and demonstrates strong dependency among growth rates and processing parameters including flow rates at different inlets and torch-substrate distance. This optimization study can help to enhance the performance of the experiments and achieve higher growth rate of metal oxide on substrate.

**Improvement of Reverse Leakage Current Characteristics of Si-Based Homoepitaxial InGaN/GaN Light Emitter for MEMS Applications**
Keun M. Song1, Moonsang Lee2, Hyun Uk Lee2 and Jaekyu Kim3; 1Korea Advanced Nano Fab Center, Korea (the Republic of); 2Korea Basic Science Institute, Korea (the Republic of); 3Hanyang University, Korea (the Republic of)

We report the nature of reverse leakage current characteristics in InGaN/GaN light emitting diodes (LEDs) on freestanding GaN (FS-GaN) crystals detached from a Si substrate for the first time, using temperature-dependent current-voltage (T-I-V) measurement. Based on T-I-V measurement results, carrier transport mechanism of the reverse leakage current is analyzed in the
InGaN/GaN LEDs. Their conduction mechanism can be divided into variable-range hopping and nearest neighbor hopping (NNH) around 360 K, which is enhanced by Poole-Frenkel emission. The analysis of T-I-V curves of the homoepitaxial LEDs yields an activation energy of carriers of 35 meV at -10 V, about 50% higher than that of the conventional ones (Ea = 21 meV at -10 V). This suggests that our homoepitaxial InGaN/GaN LEDs bears the high activation energy as well as low threading dislocation density (about 1 × 106/cm2), effectively suppressing the reverse leakage current. We expect that this study will shed a light on the high reliability and carrier tunneling characteristics of the homoepitaxial InGaN/GaN LEDs produced from a Si substrate and also envision a promising future for their successful adoption by MEMS community.

Significant development of high luminescence efficiency in InGaN/GaN LEDs has offered new futuristic applications such as automotive headlamps, traffic signals, displays, and general lighting. Despite their rapid advances and successful applications in lighting sources, improved efficiency, functionality, and flexibility in LEDs must still be obtained to use LEDs in emerging industries such as the internet of things (IoT), bio-applications, and wearable devices. Furthermore, integration of GaN and Si process enables tremendous new possibilities to Si-based MEMS and system designers.

In this work, we demonstrated homoepitaxial InGaN/GaN LEDs on FS-GaN substrate, which was grown by metal-organic chemical vapor deposition and detached from a Si substrate. To compare the reverse leakage current characteristics in InGaN/GaN LEDs fabricated using FS-GaN grown from a Si substrate, conventional InGaN/GaN LEDs with corresponding structures and the peak emission wavelength were fabricated on sapphire substrate. All the LED structures were fabricated with conventional lateral chip process. We performed temperature-dependent reverse leakage current measurement of InGaN/GaN LEDs. Based on T-I-V measurement results, we will discuss carrier tunneling characteristics of the homoepitaxial InGaN/GaN blue LEDs produced from a Si substrate.
its processability due to increased thermal stability and insolubility. In order to overcome these issues, PEDOT formed with the hydrophilic stabilizing anion Poly(styrenesulfonic acid) (PSS) has been widely used as a solution processable form of PEDOT. However, PSS-stabilizing anions have recently been correlated to anomalous currents in electrolytic capacitors, anisotropic conductivity, and decreased crystallinity. In addition, slurries of pre-polymerized PEDOT limit its infiltration and growth in high aspect ratio structures. Vapor-phase deposition processes are therefore promising methods to increase PEDOT film performance and applications. Until recently, vapor phase synthesis of Poly(3,4-ethylenedioxythiophene) (PEDOT) has relied on solid oxidants which require complex heating and dosing schemes for sequential layer-by-layer processes. Until now, vapor-phase PEDOT deposition has therefore been limited to to vapor phase polymerization (VPP) and oxidative chemical vapor deposition (oCVD) processes.

This work introduces a novel oxidative molecular layer deposition (oMLD) process using the volatile liquid oxidant, antimony(V) chloride (SbCl$_5$), to deposit high performance PEDOT thin films with nanometer precision. Using a home built, hot wall, viscous flow reactor, semi-metallic PEDOT thin films have been deposited with record breaking thin film conductivity of 6700 S cm$^{-1}$ at moderate deposition temperatures (150 °C). In addition to producing high performance PEDOT thin films, the protocol developed in this work has been used to explore the effects of reactor parameters on PEDOT nucleation and growth as well as film characteristics, moving towards greater control over PEDOT performance. Furthermore, this facile oMLD process has enabled the study of substrate dependent nucleation and growth, thereby moving towards an enhanced understanding of PEDOT selective deposition.

8:45 AM FF05.07.03
Device Integration of Ultrathin oCVD PEDOT Films in Perovskite Solar Cell Meysam H. Gharahcheshmeh, Mohammad Mahdi Tavakoli, Edward F. Gleason, Maxwell Robinson, Jing Kong and Karen K. Gleason; Massachusetts Institute of Technology (MIT), United States

Impressive values and systematic tunability of the optoelectronic properties of poly(3,4-ethylenedioxythiophene) (PEDOT) are demonstrated using single-step all-dry process. With the volatile oxidant, vanadium oxytrichloride (VOCl$_3$), pure face-on orientation results from oxidative Chemical Vapor Deposition (oCVD) without any post-deposition rinsing. In contrast, predominately edge-on orientation previously resulted with the solid oxidant FeCl$_3$ at the similar oCVD process conditions and a post-deposition rinsing step is required. At growth temperatures compatible with direct deposition on plastic substrates (140 °C), using the single-step oCVD process with the volatile VOCl$_3$ oxidant, we obtained ~four-fold improvement of direct current conductivity to optical conductivity ratio ) and ten-fold improvement of electrical conductivity as compared to oCVD PEDOT produced using FeCl$_3$. Indeed, the maximum =$50$ for this mechanically flexible polymer exceeds the benchmark for commercial transparent conductors. Varying only the partial pressure of the VOCl$_3$ oxidant induces systematic variation of the b-axis lattice parameter in the oCVD PEDOT crystallites from 6.98 to 7.02 Å and 6.97 to 7.01 Å for films grown at the deposition temperature of 110 °C and 140 °C, respectively. The lowest value correlates with the highest electrical conductivity, largest optical band gap (2.9 eV), and lowest degree of disorder as characterized by the Urbach band edge energy. The utility of the optimized oCVD PEDOT is demonstrated as a hole transport layer (HTL) for the fabrication of an inverted perovskite solar cell (PSC). This device achieves a power conversion efficiency (PCE) of 18.04%, higher than the 16.20% PCE for the control structure having a spun-cast PEDOT:PSS HTL. More significantly, incorporating oCVD PEDOT, rather than PEDOT:PSS, increased device stability approximated two-fold over a 42-day evaluation period.

9:00 AM *FF05.07.04
Development of Devices Based on Stimuli-Responsive Thin Films Deposited by iCVD Anna Maria Coclite; Graz University of Technology, Austria

Stimuli-responsive materials are characterized by dynamic switching of their properties depending on external stimuli (e.g. light, pH, temperature, humidity). In particular, hydrogels change their size and shape when exposed to aqueous environments. Functional and responsive surfaces have been successfully deposited by initiated Chemical Vapor Deposition (iCVD) on a variety of substrates. iCVD allows to obtain stimuli-responsive thin films with high chemical specificity and this is important to obtain a large responsiveness amplitude. In addition, the thin film form allows obtaining fast response.

Fast response and large signal amplitude are fundamental requirements for good sensors. Fast and ultra-fast
humidity sensors based on the optical detection of the change in thickness of the iCVD hydrogels will be shown. The setup was designed without electric components in the vicinity of the active sensor layer and is therefore applicable in harsh environments such as explosive or corrosive ones. The implemented sensor prototype delivered reproducible relative humidity values and the achieved response time for an abrupt change of the humidity was about three times faster compared to one of the fastest commercially available sensors on the market.

Another case of study will be presented in the field of multi-stimuli-responsive materials. A chemical functionalization of the hydrogel surface was performed to add multiple stimuli-responsive functionalities and obtain a smart material that responds to two stimuli at the same time. Modifying the hydrogel surface with solution-based methods is often problematic because of the damages caused by the permeation of solvents in the hydrogel. This issue is completely bypassed by the use of solvent-free techniques, like iCVD. Such polymers were used as drug encapsulants to achieve controlled drug release upon stimuli, with possible application as wound dressings.

9:30 AM FF05.07.05
Functional Polymer Thin Films with Tailored Properties by Initiated Chemical Vapor Deposition Stefan Schröder, Wiebke Reichstein, Maximilian Burk, Adrivit Mukherjee, Cenk Aktas, Thomas Strunskus and Franz Faupel; University of Kiel, Germany

Initiated chemical vapor deposition (iCVD) is a solvent-free, cost efficient synthesis technique to deposit conformal polymeric thin films. The properties of these organic films can be precisely modified by the deposition parameters. The use of different comonomers facilitates copolymerization, which for instance, enables further control over the crosslinking degree and film functionality. This opens a wide field of possible applications, like surface functionalization, functional dielectrics and drug delivery systems. Here, we demonstrate the tailored synthesis of hydrogel-, organosilicon- as well as fluoropolymers and their respective applications for conformal coatings on porous 3D structures, superior functional electret layers, photoswitchable copolymer films, drug delivery systems with barrier layers and adhesion promotion by use of various comonomers within one iCVD process.

SESSION FF05.08: Deposition of 2D Materials, Sulphides and Nitrides I
Session Chairs: Elisabeth Blanquet and Steven George
Wednesday Morning, December 4, 2019
Hynes, Level 3, Room 310

10:15 AM FF05.08.01
Molybdenum Disulfides and Diselenides by Atomic Layer Deposition Raul Zazpe1,2, Jaroslav Charvot1, Richard Krumpolec3, Milos Krbal1, Jan Priekyl1, Filip Bures1 and Jan M. Macak1,2; 1University of Pardubice, Czechia; 2Brno University of Technology, Czechia; 3Masaryk University, Czechia

The success of graphene opened a door for a new class of chalcogenide materials with unique properties that can be applied in the semiconductor technology [1]. Monolayers of two-dimensional transition metal dichalcogenides (2D TMDCs) possess a direct band gap [2] that is crucial for optoelectronic applications. Additionally, the direct band gap can be easily tuned by either chemical composition or external stimuli. Next to the optoelectronic applications, where a monolayer planar structure is necessary to employ, a layer of standing flakes, which possesses a large surface area, can be used for hydrogen evolution [3] a photodegradation of organic dyes [4] or as electrodes in Li ion batteries [5].

In principle, TMDCs can be prepared by various top-down (e.g. exfoliation) and bottom-up techniques, such as chemical vapor deposition (CVD) and atomic layer deposition (ALD) growth techniques [1]. MoS2, a typical representative of TMDCs, has been widely studied for many applications. Recently, the possibility to employ ALD as a technique to grow MoS2 has been reported. In these works (CH3)2S2 [6] or H2S [7, 8] were used as the S precursor and Mo(CO)6 [6], MoCl5 [7] or Mo(thd)3 [8] as the Mo precursors. From the practical point of view, MoSe2 is even more interesting than MoS2 since MoSe2 possesses a higher electrical conductivity than MoS2 [9, 10]. Recently, we have shown that ALD deposition of MoSe2 [11] or Mo-O-Se [12] using ((CH3)3Si)2Se as the Se
precursor and the MoCl₅ or Mo(CO)₆, respectively, as the Mo precursors is feasible. The presentation will focus on the synthesis of MoS₂ and MoSe₂ by ALD, their characterization and applications in various fields. Experimental details and some recent photocatalytic and hydrogen evolution results will be presented and discussed.

Patterned Growth of Graphene and Hexagonal Boron Nitride Heterostructures Using a “Gettering” CVD Approach Irfan Haider Abidi¹,², Barbaros Oezylmaz¹ and Zhengtang Luo²; ¹National University of Singapore, Singapore; ²The Hong Kong University of Science and Technology, Hong Kong

Two dimensional (2D) materials have reshaped the research interest in the field of electronics and aspired the researchers to develop ultrathin optoelectronic devices. However, in order to steer the progress on a fast track, the synthesis of high-quality 2D materials with desired architect is imperative. In this work we have demonstrated a precursor “gettering” approach for chemical vapor deposition (CVD) to directly grow patterned graphene as well as hexagonal boron nitride (hBN) on Cu substrate using a predesigned mask. Our proposed method is advantageous to the previous reports, which generally involved several post-growth complicated lithographic steps to obtain the desired architect of graphene films. Moreover, the quality of films grown via our method comprises of high quality in terms of layer homogeneity. Interestingly, taking advantage of the same growth substrate (Cu), we have constructed lateral heterostructures of graphene and h-BN through sequential feeding of respective precursors, in one-step CVD process. However, lateral heterostructures growth have been demonstrated previously but those are rather randomly distributed or others require multiple growth steps and complicated lithographic route. Therefore, our method is providing a unique strategy of one-step facile CVD process to build such patterned growth of graphene arrays and their heterostructures that can be integrated with crafting the nanoelectronic circuitry.

10:45 AM FF05.08.03
Wafer Scale MOCVD Grown BN for Encapsulation of 2D Devices Michael Snure¹, Shivashankar Vangala¹ and Gene Siegel²; ¹Air Force Research Laboratory, United States; ²KBR, United States

Due to the amazing and diverse properties of two dimensional (2D) materials, including semiconducting, metallic, insulating, and magnetic, there has been a great interest for more than a decade. A commonality among this class of layered materials is their ability to be thinned and stabilized down to one layer thick. The ability to achieve this thickness with minimal property degradation or even enhancement has generated continued interest for numerous applications. In these atomically thin materials, interactions with the environment, including the substrate and other 3D device elements, greatly degrade properties. Scattering from charged impurities, roughness, and phonons will reduce transport properties affecting device performance. The best solution has been the use of a thin van der Walls (vdW) buffer layers, like hBN. Of the available vdW materials, hBN is one of the only insulators, and due to is dielectric properties, high surface optical phonon energy, and atomically smooth surface, it has been the most successful and widely used material for preserving and protecting the intrinsic properties of 2D materials (graphene, phosphorene, MoS₂, ...). Here, we investigate the application of few-layer sp²-BN as a weakly interacting substrate, passivation layer and dielectric for 2D devices. By metal organic chemical vapor deposition (MOCVD), we grow
few layer wafer scale (2") sp²-BN on sapphire with excellent uniformity. To study this materials application as a weakly interacting encapsulation layer, we use transferred graphene to fabricate arrays of field effect transistors (FET) and investigate impacts on material and device performance compared to conventional dielectric substrates. As a substrate for graphene, MOCVD BN on sapphire results in graphene with a more that 2x increase in mobility and 10x reduction in sheet carrier density compared to on sapphire due to the lower interface doping and SO phonon energy. Through control of MOCVD process conditions, including temperature, pressure and V/III ratio, we can vary BN thickness and surface morphology, which we have used to investigate the role of BN morphology on transport properties. We also explore BN as a passivation layer for protection of conducting 2D layers from the ambient environment and oxidation. Finally, we discuss the use of BN in a 2 layer dielectric stack with atomic layer deposition Al₂O₃ allowing us to form high quality gates without the need for Al seeding.

11:00 AM FF05.08.04
Catalyst Engineering for Scalable 2D Film Control—The Dark Secrets of Bulk Oxygen and Integrated Pathways for Single-Crystal Growth Oliver Burton¹, Vitaly Babenko¹, Vlad-Petru Veigang-Radulescu¹,², Barry Brennan², Andrew Pollard² and Stephan Hofmann¹; ¹University of Cambridge, United Kingdom; ²National Physics Laboratory, United Kingdom

The controllable, reproducible and scalable growth of graphene and related 2D materials remains the foremost challenge for both research and any technologies exploiting their unique properties. While chemical vapour deposition (CVD) has become the most widespread method for 2D material film growth, even basic process parameters remain not well understood due to the manifold, complex parameter space. Here we focus on widely used Cu as process catalyst and reveal the role and control of residual bulk oxygen, as well as showing new integrated process pathways, for achieving uniform Cu(111) epitaxial layers. While oxidation is widely used to remove impurities in metal catalysts and to control the nucleation density of graphene[1], we show that minute concentrations of residual bulk oxygen can significantly deteriorate the quality of as-grown graphene highlighted by an increased Raman D/G ratio, increased propensity to post-growth etching and increased fraction of multi-layer graphene nucleation[2]. Starting from commercial Cu foils, we show that a simple hydrogen annealing step after the initial oxidation allows us to lower the residual oxygen level as measured by time-of-flight secondary ion mass spectrometry to produce graphene of significantly higher quality. This can be effectively combined with a short hydrocarbon exposure time of 10 min to achieve near full mono-layer graphene coverage, suitable for emerging industrial applications. We show that residual oxygen can have an equally significant impact on Fe catalysed h-BN CVD[2,3], and discuss the underlying mechanisms with parallels to well-known processes in metallurgy, catalysis and vacuum science. We further demonstrate the scalable deposition of ultra-low roughness single crystal Cu(111) and 2D material growth within a single synthesis step. The total synthesis from catalyst to 2D film takes less than 2 hours, during which there is no exposure to atmospheric conditions, circumventing the most common source of contaminants. A matching rapid and scalable method of transfer is devised and further improvements for device integration will be discussed[4,5].

11:15 AM FF05.08.05
CVD Strategy for Transition Metal Dichalcogenides Monolayers Wei Sun Leong; Massachusetts Institute of Technology (MIT), United States

Since 2011, 2D semiconductor monolayers such as transition metal dichalcogenides (TMD including MoS₂, WS₂, MoSe₂, WSe₂, etc), have attracted tremendous attention owing to their extraordinary properties, setting the stage for new breakthroughs in fundamental nanoscience and applications, from electronics to biosensors. To date, various techniques have been explored to obtain TMD monolayers, and among them, chemical vapor deposition (CVD) synthesis using transition metal oxide and chalcogenide solid precursors is the most commonly adopted approach in many laboratories. In particular, the transition metal oxide precursor was placed at the center of a furnace while the chalcogenide precursor at the upstream of the furnace, with targeted substrate facing down and put above the
crucible containing transition metal oxide precursor. Notably, the amount of precursor used in previous reports is normally surplus, which very often gives rise to chemical reactions between the precursors in each of their containers during synthesis, due to the diffusion of both precursors at the growth temperature. Thus, typically one growth chamber is dedicated to the growth of only one type of TMD to avoid cross-contamination (unless the chamber is used for hetero-TMD structures growth). In another words, the number of TMD that can be synthesized in a lab is limited by the number of CVD setup available in the lab.

We addressed this challenge by redesigning the CVD setup and pruning the amount of precursor used. We have been able to simultaneously synthesize different types of TMD on separate substrates using the same growth chamber. Through computational fluid dynamics modelling, we found that gas species trapped within those slanting substrates in our CVD setup are unable to escape from the trap, and thus avoiding the cross-contamination issue. The synthesized TMD films exhibit high-quality as confirmed by Raman, PL, XPS, AFM, and STEM analyses. Field-effect transistors fabricated on our TMD monolayers exhibit high electron mobility (64 cm²/V·s for MoS₂ and 21 cm²/V·s for WS₂ at room temperature) and large on-off current ratio (10⁷). Remarkably, our devised CVD technique has two advantages: (1) a CVD setup can be used to grow multiple TMD monolayers, which saves a lot of cost and space; (2) Multiple types of TMDs can be synthesized on separate substrates in one CVD cycle.

We also proposed a two-step CVD strategy to construct TMD-only synthetic electronics that can perform logic operations. The backbone of synthetic electronics relies on the possibility to chemically synthesize heterogeneous junctions between conductor and semiconductor, with perfect lattice matching. Interestingly, we found that our one-dimensional, solely TMD made, conductor-semiconductor junctions with large lattice mismatch exhibiting good electrical transport behaviors. We measured contact resistance as low as 500 Ωµm and a Schottky barrier height as small as 30 meV, both among the best values reported to date for contacts to 2D TMDs. Through a combination studies of STEM and second harmonic generation imaging, we confirmed that the semiconductor TMD monolayers nucleate from the vertexes of multi-layered TMD conductor and evolve into monolayer polycrystals. This is an unconventional non-edge epitaxy growth mechanism, and further studies are conducted to understand the interface physics of these lateral TMD junctions. In short, our CVD strategy enables the fabrication of ultrathin, flexible electronics, without the use of complex and costly device fabrication processes.

11:30 AM FF05.08.06
Formation of Micrometer Sized, Hierarchical h-BN Superstructures from Combined PECVD and MOCVD Processes Anja Sutorius¹, Daniel Studler¹, Robert Frohnhoven¹, Yakup Günüllü¹, Yogendra K. Mishra² and Sanjay Mathur¹; ¹University of Cologne, Germany; ²University of Kiel, Germany

Two dimensional materials namely graphene, MoS₂ and borophene went into focus of scientists all over the world due to their interesting properties (e.g. conductivity, flexibility) and possibility of large scale processability. However, the fabrication is bound by the surface chemistry and geometry of the used substrates, as well as the chemical interaction (adsorption and desorption) between substrate and precursor. In this regard, the formation of 2D materials on hierarchical superstructures is very difficult to achieve. Plasma enhanced CVD (PECVD); however, offers a way to overcome the chemical and geometrical restrictions, since the technique is not only able to activate the surface through heavy ion bombardment, but furthermore offers far-from-equilibrium phase formation at room temperature without substrate restrictions.

Here, we report the formation of three-dimensional, hollow h-BN superstructures, as obtained from a combined PE- and MOCVD deposition of B-N bond carrying single-source precursor molecules on ZnO host structures. Through the combination of plasma power, process temperature and time, we were able systematically study h-BN growth on these host materials to clearly demonstrate the suitability of the process for the formation of three-dimensional superstructures from two dimensional materials.
Revisited Thermal and Plasma Enhanced Atomic Layer Deposition Processes of Metal Nitrides—Challenges and Opportunities Elisabeth Blanquet, Arnaud Mantoux, Frederic Mercier, Raphael Boichot, Michel Pons and Carmen Jimenez; University Grenoble Alpes, France

Metal nitrides films stand out as candidates for many strategic industrial applications as they exhibit superior functional properties such as mechanical, electrical and thermal properties. Complementary chemical vapor deposition techniques from High Temperature Chemical Vapor Deposition (HTCVD) to Thermal and Plasma Enhanced Atomic Layer Deposition (T-ALD and PEALD) have been investigated to fabricate metal nitrides thin films. In each case, one of the major challenges is the synthesis of high quality, pure (with no oxygen contamination) material. Among ALD developments, efforts have been focused on the exploration of different precursor molecules, chemical reactions as well as growth processes sequences and conditions.

In this presentation, the examples of aluminum nitride (AlN) and niobium nitride (NbN) deposition process development will be presented. Aluminum nitride (AlN) is a semiconductor material with a wide bandgap, excellent thermal conductivity, high electrical resistance and good behavior towards oxidization and abrasion. AlN films are attractive for many applications in energy, electronic or optoelectronic devices. For instance, thin films are used in piezoelectric transducers and microwave filters applications, in resonators, as passivating coatings, as AlN substrate in high power applications. NbN films are mainly used for single-photon detectors (SSPDs), superconductive radio frequency (SRF) cavities due to their superconducting properties.

We report on the optimizing routes and strategies to obtain the best compromised film properties on these two systems.

Relationship between the Gas-Phase Reactions Occurring within an Electron Cyclotron Resonance- (ECR) Microwave- (MW) CVD Process and the Properties of Hydrocarbon Films Jesús M. García Figueroa and David R. Harding; Laboratory for Laser Energetics and Department of Chemical Engineering, United States

Increasing the energy that is coupled into a plasma by adding a magnetic field of 875G to it to make it ignite at the electron cyclotron resonance- (ECR) frequency (2.45 GHz) changes the gas-phase chemistry that occurs in standard plasma-assisted CVD processes. Films are formed as gas-phase reaction products at significantly higher ion energies (15–30 eV) and, at substrate temperatures that are appreciably lower than those that can be achieved without the electron-cyclotron augmentation. This phenomenon greatly affects the films’ properties.

In this study, the plasma ECR-MW-CVD technique is applied to make different types of hydrocarbon films, of variety of sp\(^3\), sp\(^2\), and sp content, and densities (1.1 to 3.2 g/cm\(^3\)), at substrate temperatures that range from 30 to 200\(^\circ\)C. The role that the composition of the gases (methane, hydrogen, and argon) in conjunction to the plasma power has on the films’ properties is discussed in the context of the enhanced gas-phase chemistry that occurs in the ECR-MW environment. The elemental composition of the films is determined from FTIR and Raman. Their surface morphology, in particular: their smoothness and texture, which are critical for the application that uses these materials as ablators for laser fusion experiments, are observed using SEM and AFM. Other films’ properties that are affected by the energetic species in the ECR-MW environment are determined via gravimetry, nanoindentation, and ellipsometry. The presentation shows the relationship that exists between the chemistry happening near the gas/substrate interface within the ECR-MW environment and the films’ properties.

This material is based upon work supported by the Department of Energy National Nuclear Security Administration under Award Number DE-NA0003856, the University of Rochester, and the New York State Energy Research and Development Authority.

Novel Approach for Conformal Chemical Vapour Phase Deposition of Ultra-Thin Conductive Silver Films
Sabrina M. Wack, Renaud Leturcq, Petru Lunca-Popa and Noureddine Adjeroud; LIST, Luxembourg

The present work demonstrates a novel approach for the conformal deposition of ultra-thin conductive silver (Ag) films on complex substrates. Using an original multi-step plasma-enhanced approach, we demonstrate the deposition of conductive silver films with thickness down to 11 nm. Conductive ultra-thin Ag films are commonly deposited by physical vapour deposition techniques (metal evaporation or sputtering). However, these are line-in-sight methods that do not allow conformal deposition on substrates with complex morphology (e.g. trenches) [1]. Non-line-in-sight methods such as the ones based on chemical vapour phase deposition (Chemical Vapour Deposition-CVD or Atomic Layer Deposition-ALD) usually produce non-electrically-conductive films for thickness below 20-50 nm due to island formation by Volmer-Weber growth mode for metal layers on oxide-based substrate [2]. Moreover, conductive ultra-thin silver films based on ALD (down to 22 nm) [3], require low-temperature deposition (below 120°C), with a very narrow process temperature window (about 10°C).

The deposition is based on Ag(fod)(PEt3) as silver precursor, and H2 plasma as reducing agent. An acceptable process temperature window (> 30°C), and a deposition temperature larger than 120°C for enhanced uniformity and deposition rate have been demonstrated. In these conditions, highly uniform deposition on bent and batched samples have been performed. 20 nm thick films exhibit a resistivity down to 40 μΩ.cm. The resistivity increases up to 1.4 mΩ.cm when reducing the thickness down to 11 nm. The critical thickness below 11 nm is thus very close to the state-of-the-art for sputter-deposited thin films [4], and well below the 22 nm obtained with ALD [3]. The obtained Ag thin films also demonstrate a high reflectance up to 94% and a low absorbance of 3% in the infrared region for a film thickness of 26 nm, showing the high quality of the films. This quality is confirmed by morphological analysis using scanning electron microscopy and atomic force microscopy, as well as by the structural (X-ray diffraction) and chemical (energy dispersive X-ray spectroscopy) properties. This new processing approach opens a very interesting path for the use of ultra-thin silver films for electronic and optoelectronic applications.

Low-Temperature Self-Limiting Growth of β-Ga2O3 Films on Flexible Substrates via Plasma-Enhanced ALD
Saidjafarzoda Ilhom1, Adnan Mohammad1, Deepa R. Shukla1,2, Brian Willis2 and Necmi Biyikli1; 1The University of Connecticut, United States; 2University of Connecticut, United States

Wide-band gap semiconductors have attracted great research attention due to their unique properties such as operation at much higher voltages and frequencies than conventional semiconductors. Our target is to engineer these materials for device applications in flexible and wearable technologies, which generally require lower deposition temperatures. Towards this goal, we have investigated the low-temperature self-limiting growth of Ga2O3 films on various substrates including glass and Kapton via inductively-coupled plasma-enhanced atomic layer deposition. Extended 300-cycle long runs were carried out to grow thin films on Si(100), glass, and Kapton using triethyl-gallium (TEG) as metal precursor and variants of Ar/O2 plasma (Ar/O2 with different partial pressures and O2-only with different flow rates) as metal precursor and oxygen co-reactant, respectively. Growth experiments have been performed within 150 - 400 °C substrate temperature range at 300 W rf-plasma power. Ex-situ ellipsometry was employed to measure the thickness and optical properties of the films. When O2-only plasma was used, the thickness of the films ranged between 19.32 - 16.88 nm and the as-grown refractive indices stayed fairly close between 1.73 - 1.71 within the scanned temperature range. However, addition of Ar gas to the plasma drastically reduced the refractive index of the films from 1.72 to 1.54, reminding of a possible plasma re-deposition of carbon-rich reaction byproducts or increased incorporation of oxygen. X-ray diffraction (XRD) showed that the as-grown Ga2O3 films exhibit amorphous structure irrespective of substrate temperature in this study. Furthermore, the effect of post-growth thermal annealing is investigated on the enhancement of crystalline quality (which indicates conversion from amorphous to monoclinic β-Ga2O3 crystal phase) and electro-optical properties of the films. Also, X-ray photoelectron spectroscopy (XPS) measurement results of the Ga2O3 samples grown under varying plasma (Ar/O2, O2-only) will be discussed, which provides additional insight into the elemental composition of the films that might
help to understand the changes in the structural, optical, and electrical properties under varying plasma chemistry. A comparative material properties analysis based on the substrate utilized will be carried out which will reveal how the film properties of as-grown Ga2O3 are affected by the substrate material. A future outlook will be provided to overcome the challenges to achieve device quality layers on low-temperature compatible flexible substrates.

Synthesis of Hexagonal Boron Nitride Using Microplasma Vianney Mille1, Hiba Kabbara1, Alexandre Tallaire2, Salima Kasri1, Ovidiu Brinza1, Claudia Lazzaroni1 and Guillaume Lombardi1; 1LSPM CNRS UPR3407, France; 2Institut de Recherche de Chimie Paris - IRCP UMR 8247, France

In this presentation, we propose an alternative synthesis method to deposit thin film material hexagonal boron nitride (h-BN) assisted by microplasma source. h-BN thin films are the focus of interest for electronic, optoelectronic applications due to its wide band gap semiconductor. In other hand, microplasmas have attracted growing attention in recent years because of possible applications in other fields such as surface treatment, light sources and nanomaterial synthesis [1]. They can be generated at high pressure which is a favourable condition to better dissociate N2 molecules, a prerequisite to the synthesis of nitride materials at lower temperatures compared to conventional processes. Our deposition reactor is composed of two chambers and the micro-plasma is located at the junction between them. The plasma source consists of an anode-dielectric-cathode sandwich through which one hole of 400 μm in diameter are drilled. The higher pressure chamber (several tens of mbar), favors the production of high density plasma, and consequently high nitrogen dissociation, while the lower pressure chamber (several mbar) limits the nitrogen recombination. The polarizable and heating substrate holder is located in the lower pressure chamber where the boron precursor (BBr3) is injected. The polarization of the substrate holder allows the discharge to be expanded from the hole to the substrate. Suitable conditions can be defined to achieve h-BN thin film synthesis and we report the growth of h-BN on 2 inch-silicon substrates at temperatures below 1000°C. The deposited films are then characterized by XRD and Raman spectroscopy to evaluate the phase purity and quality, and by SEM and TEM to observe the surface morphology and the crystallinity of the material.

Electron Enhanced Atomic Layer Deposition (EE-ALD) Steven M. George; University of Colorado, United States

Electron enhanced atomic layer deposition (EE-ALD) can dramatically reduce the temperatures required for film growth. Temperature reduction is possible because of electron stimulated desorption (ESD) of surface species. The desorption process creates highly reactive surface sites. Precursors can then adsorb efficiently on the reactive surface sites. Our work has demonstrated the EE-ALD of GaN [1], Si [2], BN [3] and Co at room temperature.

Film growth has been performed using alternating exposures of chemical precursors and low energy electrons. In situ ellipsometry measurements have monitored linear film growth versus number of reaction cycles. Additionally, we have observed the dependence of the EE-ALD growth rates on electron energy. Maximum growth rates have varied from 0.3 Å/cycle for Si films at 100-150 eV [2] to 3.2 Å/cycle for BN films at 80-160 eV [3]. Recent measurements have also obtained growth rates of 1.0 Å/cycle for Co films at 140 eV.

Co film growth was performed using sequential cobalt tricarbonyl nitrosyl (CTN, Co(CO)3NO) exposures and low energy electrons. The electrons desorb the CO and NO ligands from CTN on the surface and produce active sites for additional CTN adsorption. A hot filament electron flood gun was initially used as the electron source. One difficulty with the electron flood gun is the long cycle times of > 500 seconds. Much of this cycle time is consumed protecting the flood gun filament from precursor exposures and the long duration of the electron exposure due to the limited current of the electron gun. The cycle time could be reduced significantly using a more robust and higher flux electron source.

A new hollow cathode plasma electron source (HC-PES) has been developed to reduce the cycle time during EE-ALD. The HC-PES has a >600X increase in electron current compared with the electron flood gun. The HC-PES also eliminates the warm-up and cool-down time of the filament of the electron flood gun. The electron current from the HC-PES can be switched from nanoamps to milliamps in < 10 ms. The HC-PES is also chemically insensitive.
and reduces the need for pumping out the chamber following CTN exposures. This presentation will highlight Co EE-ALD performed using this new HC-PES.

GaN is the most significant binary member of the wide bandgap III-nitride material family, with a bandgap energy of 3.4 eV, and is heavily commercialized in applications such as blue light emitters for white-light LEDs, UV photodetectors, high-electron mobility transistor (HEMT)-based transistors for high-speed, high-frequency, and high-power electronics. Molecular beam epitaxy (MBE) and metal-organic chemical vapor deposition (MOCVD) are the well-known high-temperature epitaxial growth methods used for GaN deposition, whereas thermionic vacuum arc (TVA), pulsed laser deposition (PVD), reactive magnetron sputtering are among the low-temperature GaN deposition techniques. With the advent in plasma-assisted atomic layer deposition (PA-ALD) within the last decade, an increasing interest has been focused on the low-temperature self-limiting growth of III-nitride films using PA-ALD. While a few number of groups have been active in the film growth and material characterization aspects, reported device applications have been quite limited. In this study, we aim to demonstrate that finely tuned PA-ALD processes can be utilized to synthesize crystalline GaN layers on temperature-sensitive flexible substrates, which can function as electronic device layers for thin-film transistors (TFTs). We have grown GaN thin films at temperatures less than 200°C on Si, glass, and flexible polymeric substrates using PA-ALD featuring capacitively coupled hollow-cathode stainless-steel plasma source. GaN deposition experiments were carried out using two different organometallic gallium precursors: trimethylgallium (TMGa) and triethylgallium (TEGa) to investigate optimal experimental parameters for high crystalline quality for each precursor molecule. The growth process was conducted within an in-situ ellipsometer-integrated compact PA-ALD reactor having a base pressure of 20 mtorr. RF-plasma parameters (power, exposure time, plasma gas composition) and substrate temperature were mainly studied as variable process parameters for each deposition process. For the film thickness and optical constants (refractive index and absorption coefficient), in-situ multi-wavelength and ex-situ spectroscopic ellipsometry measurements and data fitting analysis were carried out. Synthesized GaN films turned out to be transparent non-absorbing within the visible spectrum along with refractive index values approaching 2.2 at 632 nm. The elemental composition was determined using x-ray spectroscopy (XPS). Below detection limit carbon along with relatively low oxygen concentration (< 5 at. %) was observed within the bulk of ALD-grown GaN films. For the structural characterization of the grown films, grazing-incidence x-ray diffraction (GIXRD) analysis was conducted to analyze crystalline quality and crystal grain size. XRD analysis showed single-phase hexagonal wurtzite GaN crystal structure with (002) dominant crystalline orientation. X-ray reflectivity (XRR) was used to comprehend the surface roughness and film density. High-resolution transmission electron microscopy (HR-TEM) analysis confirmed the crystalline structure of GaN films with grain sizes larger than 10 nm. As proof-of-concept device application, we will present our metal-semiconductor-metal (MSM) photodetector characterization results which were fabricated on GaN device layers grown on glass and flexible polymeric substrates. A comparative analysis will be carried out to understand the influence of substrate material as well as the impact of mechanical stress on the flexible device performance. A future outlook will be provided to improve material and device characteristics towards implementing ALD-grown III-nitride layers for flexible/wearable device technology.

**Magnetic Field-Assisted Chemical Vapor Deposition—New Pathways for Functional Materials**

Daniel Stadler¹, Vanessa Rauch¹, David N. Mueller², Peter Tutacz¹, Thomas Brede³, Michael Frank¹, Tomas Duchon², Thomas Fischer¹, Margret Giesen², Claus M. Schneider³, Cynthia A. Volkert¹ and Sanjay Mathur¹; ¹University of Cologne, Germany; ²Research Center Jülich, Germany; ³Georg-August-University, Germany

Temperature is the key parameter for controlling the phase and film morphology during chemical vapor deposition (CVD), since precursor decomposition, growth rate and obtained phases are depending on the very same. Anyhow, far from equilibrium phases and morphologies are not accessible solely by temperature but also by the application of external electric and magnetic fields. While electric fields often result in additional heating of the specimen, static magnetic (DC) fields do not lead to additional temperature gradients inside the samples and thus offer additional control on phase and morphology of the as-obtained films. In this presentation, magnetic field-assisted CVD (mfCVD) will be presented as novel and selective tool for the phase selective deposition of (magnetic) transition metal oxides and nitrides. The field-matter interplay at various temperatures and field strengths will be highlighted and consequences on physical, morphological and chemical properties of unaltered films will be discussed. Electron microscopy will demonstrate selective influence of the pristine film morphologies, while X-ray diffraction and absorption measurements will reveal changes in the obtained phase evolution and chemical surrounding. Electric, magnetic and catalytic property measurements of oxide films formed in different field environments will finally show the potential of mfCVD as additional manufacturing technique for the synthesis of functional materials.

**Atomic Layer Deposited Nanolayers for Silicon Photovoltaics**

Bart Macco, Jimmy Melskens and Erwin Kessels; Eindhoven University of Technology, Netherlands

Thin films are ubiquitous in the preparation of crystalline silicon solar cells. With the introduction of the PERC technology also the method of atomic layer deposition (ALD) has been introduced in high volume manufacturing in photovoltaics. Currently, the technique is quickly gaining market share for the deposition of ultrathin Al₂O₃ nanolayers for rear side surface passivation. The advantages of ALD are that it is scalable, that it is well suited to prepare high quality and uniform nanolayers, and that it is a "soft" deposition technique preventing interface damage. In this presentation the state of the art of ALD for silicon photovoltaics will be discussed as well as some ongoing developments and potential new applications. This includes new materials for surface passivation, nanolayers for passivating contacts, transparent conductive oxides as well as applications of ALD for polysilicon passivating contact solar cells.

**9:30 AM FF05.10.02/EN11.10.02**

**Thermally Stable Passivating Hole-Selective Contacts Using Atomic Layer Deposited Molybdenum Oxide with Thin Aluminum Oxide**

Geoffrey Gregory, Zhengning Gao, Titel Jurca, Parag Banerjee and Kristopher Davis; University of Central Florida, United States

One high efficiency crystalline silicon (c-Si) solar cell that has potential to be cost-competitive with Al-BSF devices while maintaining the passivation quality of PERC structures is the silicon heterojunction. Most notably is the Heterojunction with Intrinsic Thin-layers (HIT) solar cell, which chemically passivates the surface of the c-Si with intrinsic hydrogenated amorphous silicon (a-Si:H) while allowing charge carriers to conduct through the contact. Doped a-Si:H layers then create the potential gradient necessary for carrier diffusion and charge collection to occur.

Even with it's high performance and simplified fabrication process, the HIT solar cell has potential to be improved upon. The a-Si:H layers produce parasitic absorption of high energy light. Many groups have also found the a-Si:H contacts to be sensitive to annealing treatments above 200°C. This limits the processing space for the metallization...
In this work we use Atomic-Layer-Deposited (ALD) MoOx as a hole-selective contact to c-Si in combination with thin SiOx and Al2O3 passivation layers to study the solar cell parameters of carrier selective contacts without the use of a-Si:H. While the optical properties of MoOx present a significant reduction in parasitic absorption compared to a-Si:H, the temperature stability of the material is still in question. Many groups have been unable to anneal MoOx based contacts above 120°C without degrading the electrical properties of the contact. We show that by using a thin Ni capping layer before Al metallization, the contact remains stable up to 300°C with contact resistivities below 10 mΩ-cm². This presents significant improvements on the thermal budget of the MoOx processing sequence and will allow for more appropriate contact formation steps.

Using Ultraviolet Photoelectron Spectroscopy we measure a work function of 6.2 eV in our 5nm MoOx contact. We simulate the band-bending and hole concentration at the c-Si surface as a function of the MoOx contact work function and show that our films exhibit sufficient hole-selective properties. Additionally, High Resolution Transmission Electron Microscopy images show that when a thin Ni capping layer is not used prior to Al metallization, a 2-3 nm Al2O3 layer forms at the Al/MoOx interface. This insulating interlayer contributes to a large barrier to hole transport, making the Al/MoOx contact incompatible with high efficiency heterojunction solar cells. The Al/Ni/MoOx contact, however, exhibits no such interlayer. This suggests that Ni may act as a diffusion barrier to O species during solar cell fabrication.

Finally, we show that by using a thin (~1 nm) Al2O3 passivation layer at the MoOx/c-Si interface, we are able to achieve a minority carrier lifetime of over 1 ms on n-type c-Si.

Recently, Yang et al. have reported 22.1% efficient c-Si solar cell by applying an atomic-layer-deposited (ALD) TiOx thin layer as electron contact to n-type base [1]. The origin of the electron selectivity of TiOx has been ascribed to the asymmetric current flow at the (n) c-Si/TiOx interface where the conduction band offset is much lower than the valence band offset. On the other hand, we recently found that TiOx can be tuned from electron to hole selectivity by controlling the ALD condition etc. [2]. This offers an interesting possibility that TiOx can be used as a hole selective contact alternative to the widely-used p-type a-Si:H and transition-metal oxides such as MoOx, WOx and V2O5. In this contribution, we show for the first time that TiOx thin layers can act as efficient passivating hole selective contacts.

TiOx thin layers were deposited by thermal-ALD on c-Si (FZ, 1 Ωcm, (100), planer, n-type). First, carrier selectivity of the deposited TiOx was studied by measuring Voc of solar cells. To decouple the carrier selectivity from its surface passivation an intrinsic a-Si:H buffer layer was inserted between c-Si and TiOx. A standard SHJ structure of either (i-n) a-Si:H/ITO or (i-p) a-Si:H/ITO stack was formed as a counter electron or hole contact, respectively. It is found that Voc of the solar cell is 200-400 mV higher when using our TiOx as hole contact than using it as electron contact. The SPV measurement showed that the TiOx induces large band bending (~900 mV) with respect to (n) c-Si while almost no band bending is created when deposited on (p) c-Si. This implies the presence of the negative fix charge in the TiOx, which is considered as one of the origins of the observed hole selectivity of the TiOx. Furthermore, we found that the carrier selectivity of TiOx depends significantly on the work function (WF) of the capping metal (or TCO) contact. The Voc is increased monotonically with increasing the WF of the capping layer when using TiOx as hole contacts. This indicates that band bending in (n) c-Si is significantly influenced by the WF of the capping layer, as it is well-known in the MIS contact system. By using an ITO/TiOx/i a-Si:H stack as an emitter layer on (n) c-Si, we obtained a relatively high Voc of 650 mV. Furthermore, the TiOx is also found to act as a good passivation layer with respect to c-Si. An effective lifetime of >1 ms was obtained by depositing TiOx on (n) c-Si without a-Si:H buffer layer. By optimizing both the surface passivation and the hole selectivity of the TiOx layer, we attained solar cell efficiencies of >18%, demonstrating that TiOx has potential of working as an efficient passivating hole selective contact. We discuss the origin of the hole transport in the TiOx which contradicts to the previous transport model based on the band alignment at the TiOx/Si interface.

Hf Doped ZnO Engineering for Various Solar Cells Architectures

Boulos Alfakes1,1, Juan E. Villegas2, ChunYu Lu1,1, Ibraheem Almansouri1 and Matteo Chiesa1,3,1; 1Khalifa University of Science and Technology, United Arab Emirates; 2New York University, United Arab Emirates; 3UiT The Arctic University of Norway, Norway

The excellent electrical, optical and structural tunability of doped zinc oxide (ZnO) makes it a very good candidate for the replacement of indium-based material in the manufacturing of transparent conductive oxides. In this work, we present a comprehensive investigation of ALD grown hafnium doped ZnO within the context of its integration in different solar cells architectures. Specifically, we focus on the low range doping region, where Hf substitution is believed to be the key for band gap tunability without negatively effecting the carrier transport behavior. Scanning and transmission electron microscopy (SEM and TEM), x-ray diffraction, Kelvin probe force microscopy, Hall-effect measurements, spectrophotometry and ellipsometry were utilized to provide conclusive evidence of the suitability of Hf doped ZnO in different solar cells architectures. A band gap increase is being observed, as well as an increase in transmittance with doping. Electrically, doping is causing a decrease in resistivity and in work function. These results are interpreted in light of first-principles density functional theory simulation (DFT) to elucidate the mechanisms responsible for the electronic and electrical properties of Hf doped ZnO. DFT calculations predict a modification in the band structure of ZnO when Hf is substituted and/or embedded in the ZnO matrix as HfO2 phases. The experimentally measured and theoretically calculated modifications in the properties of the ZnO with Hf doping, validates its compatibility with different solar cells architectures.

Fabrication of Sb2S3 Planar Thin-Film Solar Cell with Vapor Transport Deposition (VTD) Method

Yiyu Zeng, Kaiwen Sun, Jialiang Huang, Micheal Nielsen, Martin Green and Xiaojing Hao; University of New South Wales, Australia

Antimony sulphide (Sb2S3) is another attractive photovoltaic material in the chalcogenide group and has drawn a great attention worldwide in the last decade. In contrast to the widely investigated and commercially competitive thin film solar cells such as CuInxGa1-xSe2 and CdTe, Sb2S3 is non-toxic and exists naturally as stibnite minerals, with both while Sb and S are bothas earth abundant elements. Sb2S3 is a binary compound with a single phase, consisting of linked one-dimensional ribbons. Such a ribbon structure provides a preferential pathway for electron transfer if withalong the desired orientation. Antimony sulphide has high absorption coefficient of α>105 and a bandgap of ~1.7eV, making it a suitable top cell candidate for tandem solar cells with silicon to overcome the single-junction Shockley-Queisser efficiency limitation. In the last decade Sb2S3 has been widely utilized as an efficient sensitizer in dye sensitized solar cells fabricated by chemical bath deposition. However, the CBD method is time-consuming with many undesirable oxide by-products, which usually require complex post treatment for the removal of these residuals.Moreover, reported high efficiency Sb2S3 solar cells have utilized unstable and expensive organic hole transport materials such as P3HT Spiro-OMeTAD, and PEDOT:PSS. While inorganic hole transport materials such as NiO and CuSCN have been investigated, the results have not been promising. Recently, Lijian et al. used V2O5 as the hole transport layer (HTL) and obtained a PCE of 4.8%, demonstrating the highest efficiency of a fully inorganic planar Sb2S3 solar cells up to date. However, the open circuit voltage of such the record cell is 550 mV, which indicates a large Voc deficit implying there is still much work to be done to improve the Sb2S3 absorber quality and interface engineering. Recently, a push towards dry vacuum-based methods, such as the thermal evaporation and atom layer deposition, have been employed to grow high quality Sb2S3 and Sb2Se3 in a relatively clean environment. Additionally, the rapid thermal evaporation (RTE) method has been recognized as an effective and reliable method to grow Sb2S3 thin films, achieving an efficiency of 3.5% with a high Voc of 710mV when using CdS as electron transport layer (ETL). However, the reported orientation of the Sb2S3 is not well controlled when deposited by the RTE method. In this work, we report the first fabricated Sb2S3 thin films with vertical orientation by VTD method. To better understand the key factor that enables the vertical growth of Sb2S3, we use the RTE method as a reference, which does not create vertically aligned Sb2S3 crystals on a CdS buffer layer. We achieved the an efficiency of 4.73% with a high Voc of 710 mV by using the iTO/CdS/Sb2S3/Gold configuration via VTD method compared to 370 mV using RTE method. We propose a simple model to describe the growth process.
Atomic-Layer-Deposited ZnO as a Full-Area Passivating, Contacting and Antireflection Layer for c-Si Solar Cells
Bart Macco, Marc Dielen, Bas van de Loo, Jimmy Melskens and Erwin Kessels; Eindhoven University of Technology, Netherlands

The field of c-Si photovoltaics has strongly diversified in recent years with the advent of a wide variety of novel passivation and passivating contact materials. Recently, we have demonstrated excellent surface passivation using stacks of ultrathin (~1.5 nm) RCA SiOₓ capped with ALD ZnO/Al₂O₃, with an implied open-circuit voltage (V_{oc}) of 725 mV on planar c-Si(n) wafers.[1] Within this SiOₓ/ZnO/Al₂O₃ stack, the RCA SiOₓ enables chemical passivation, similar as in poly-Si passivating contacts. The Al₂O₃ layer on top serves as a dense capping layer: It prevents effusion of H from the ZnO upon annealing, which is needed to hydrogenate the SiOₓ.

The unique aspect of the (doped) ZnO is that it is suited as an antireflection coating (simulated J_{sc} of 41.6 mA/cm²) which is also conductive (< 1 mΩcm). Therefore, if a proper tunnel contact between c-Si/SiO₂/ZnO can be made, the ZnO could serve as a full-area passivating, antireflective and lateral transport layer on the front side of a c-Si solar cell. In this work, we demonstrate several crucial steps to enable this application in industrial cells by looking into the influence of texture and doping level, oxide preparation method, metal contacting and thermal stability.

Firstly, we verified that the stack also passivates on textured c-Si(n) wafers (V_{oc} = 728 mV) and that its passivation on n⁺ diffused surfaces (100 Ω/sq) is on par with industrial SiNx. The stack is thermally stable up to ~550 °C, which is not firing-compatible, but allows for a much higher paste curing temperature than for HIT-type cells.

Secondly, we show that the SiOₓ can be prepared in many ways (RCA, LTO, UV/O₃, NAOS) which all yield good passivation. UV/O₃ however yields the best passivation and is a room-temperature, single-sided treatment which allows for accurate control over the oxide thickness (< 1.65 nm).

Thirdly, in order to be able to contact the ZnO by metal, we can selectively remove the insulating Al₂O₃ capping layer from the ZnO after hydrogenation by a wet-etch. Interestingly, no proper tunnel contact (>10 Ωcm²) can be made on 3 Ωcm c-Si(n) wafers, whereas a “first-try” value of ~0.1 Ωcm² was obtained on n⁺ diffused surfaces (100 Ω/sq). This contact resistivity is sufficiently low to use ZnO as a “hybrid” homo/heterojunction contact on n⁺ surfaces: the n⁺ doped Si surface provides electron-selectivity and facilitates tunneling, whereas the ZnO provides full-area passivation and aids in lateral transport, potentially allowing for higher Ohmic FSFs.

Ongoing work focuses on the effect of the doping levels of both the c-Si and ZnO and the integration of the ZnO on the front of a PERC-type cell.

Controllable Fixed Charge Densities of TiO₂–Based Passivation Layer in c-Si Solar Cells
Dohee Kim and Jihun Oh; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Surface passivation of crystalline Si (c-Si) is a key enabler for achieving high efficiency c-Si solar cells. While an Al₂O₃ surface passivation layer grown by atomic layer deposition (ALD) is known for excellent surface passivation for p-type Si from the negative fixed charges in the Al₂O₃ layer, low refractive index of Al₂O₃ demands an additional anti-reflection coating to suppress optical reflection, which leads to extra capital cost in c-Si solar cell manufacturing. Therefore, the multi-functional passivation layer that can provide both the high level of passivation quality and optimum optical property is necessary for high efficiency and cost-effective silicon solar cells.

Here, we designed the multifunctional Al-doped TiO₂ passivation layer using ALD single process for low cost high efficiency silicon solar cells. TiO₂ film grown by ALD is a promising candidate for front multifunctional passivation layer of p⁺-emitter/n-base structure due to negative fixed charge densities and appropriate refractive index for anti-reflection coating of silicon solar cell. ALD process allows to control the composition accurately and provide excellent passivation quality with thin films. In this work, we controlled the Al concentration in TiO₂ film with amorphous phase from 0 to 15.5 % by adjusting the cycle ratio of Al₂O₃ to TiO₂ in ALD process. We then successfully demonstrated that the fixed charge densities of Al-doped TiO₂ passivation layer can be controlled from -8×10¹¹ cm⁻² to -3×10¹² cm⁻² by varying the amount of Al concentration. As a result, we achieved implied V_{oc} up to 709 mV with 15nm thick Al-doped TiO₂ on n-Si by maximizing field-effect passivation. We also investigated the
The growth of oxides by atomic layer deposition (ALD) over lead-halide perovskites in solar cells is attracting increasing attention for improving environmental and mechanical stability. A wide range of materials have now been investigated, including SnO$_2$, TiO$_2$, Al-doped ZnO and zinc tin oxide. These oxide overlayers have led to unencapsulated perovskite solar cells achieving stable performance for 4500 h in ambient air. However, the range of growth temperatures that can be used to grow the oxide overlayers over the perovskite films is restricted to typical values of only 60 - 100 °C due to the low stability of the perovskites. This limits the mobility and density of the oxide films achievable. In this work, we show that we can open up the processing window of oxides grown over lead-halide perovskites by using atmospheric pressure chemical vapor deposition (AP-CVD). This technique yields oxide films with similar uniformity, density and electronic properties as ALD films at similar growth temperatures, but with orders of magnitude higher growth rates [1]. We investigate the growth of TiO$_x$ over thermally-sensitive CH$_3$NH$_3$PbI$_3$ films. We achieve a growth rate of 1.19 ± 0.04 nm s$^{-1}$ at a deposition temperature of 150 °C, which allows 7 nm TiO$_x$ films to be grown in 6 s (compared to >30 min for ALD). We show that this rapid deposition enables TiO$_x$ to be directly grown on CH$_3$NH$_3$PbI$_3$ films without damage to the bulk or surface, as shown by our X-ray diffraction, X-ray photoemission spectroscopy and time-resolved photoluminescence measurements. Indeed, we show that the TiO$_x$ overlayers can be grown at temperatures exceeding 180 °C without a significant drop in efficiency in CH$_3$NH$_3$PbI$_3$ solar cells. These results can be generalised to triple-cation perovskite devices, as well as to AP-CVD SnO$_2$ overlayers. In particular, we show that the conformal nature of the oxide overlayers lead to perovskite devices with improved performance (reaching 19.7% for triple-cation perovskite devices using a 60 nm SnO$_2$ overlayer). Our work demonstrates AP-CVD to be a versatile technique for growing high-quality oxides over a wide range of processing conditions.

Reference
engineering key interfaces within electrochemical cells. This presentation will describe our efforts to address challenges associated with lithium metal and silicon anodes. Thin films are integrated as ultrathin solid electrolytes in Li metal batteries and as protective coatings on Si anodes to limit undesirable side reactions.

Key requirements for electrolytes in solid-state lithium metal batteries are a large electrochemical stability window and low area-specific resistance (ASR). Solid electrolytes must also possess robust mechanical properties to accommodate large-scale production and integration into conventional lithium battery cell designs. To realize these properties, 50 nm-thick films of lithium phosphate oxynitride (Lipon) were deposited onto microporous polymer separators (Celgard) using RF magnetron sputtering. These separators provide a low ASR due to the thin, dense Lipon film; the total resistance of the separator was determined to be 40 Ω cm² in alkyl carbonate electrolytes, which is much lower than traditional ceramic electrolyte membranes, such as those fabricated from Garnet and NASICON-class of solid electrolytes. Furthermore, these composite separators inhibit chemical cross-diffusion and reaction between anode and cathode in both Li-S and Li-LiMn₂O₄ cells. Both the performance of these hybrid separators in practical lithium-metal batteries and fundamental studies of ion transport at the Lipon-liquid electrolyte interface will be presented.

Silicon is also an intriguing next-generation anode offering charge capacities comparable to lithium metal, yet significant challenges arise from the >300% volume expansion of Si during lithiation. To address continual electrochemical reduction of lithium ion battery electrolyte on Si anodes, nanoscale, conformal polymer films were synthesized as artificial solid electrolyte interface (SEI) layers. Initiated chemical vapor deposition (iCVD) was employed to deposit poly(1,3,5,7-tetravinyl-1,3,5,7-tetramethylcyclotetrasiloxane) (pV4D4) onto silicon thin film electrodes. 25 nm-thick pV4D4 films on Si electrodes improved initial coulombic efficiency by 12.9% and capacity retention over 100 cycles by 64.9% relative to untreated electrodes. pV4D4 coatings also improved rate capabilities, enabling higher lithiation capacity at all current densities. Post-cycling FTIR and XPS showed that pV4D4 inhibited electrolyte reduction and altered the SEI composition, with LiF formation being favored. This work will guide further development of polymeric artificial SEIs to mitigate electrolyte reduction and enhance capacity retention in Si electrodes.

2:00 PM FF05.11.02
Atomic Layer Deposition of Alumina on CVD Silicon Nanostructures—Towards the Development of 3D Ultrastable Aqueous Si Microsupercapacitor
Pascal Gentile1, Anthony Valero1,1, Dorian Gaboriau1,1, Adrien Mery1 and Said Sadki2,1; 1CEA Grenoble, France; 2Université Grenoble Alpes, France

In this work Chemical vapor deposition (CVD) and Atomic Layer Deposition (ALD) has been combined to elaborate electrodes for MicroSuperCapacitors (µSCs) devices. A great deal of attention has been focused on µSCs, for which large series of nanostructured active materials have been developed. We have demonstrated through comprehensive investigations the interest of doped silicon nanostructures grown by CVD with Vapor Liquid Solid (VLS) method as electrodes materials for µSCs using ionic liquid electrolytes [2,3]. The fine morphological tuning of the nanostructure allowed by the bottom-up approach enables specific designs of electrode architectures, with a considerable leeway compared to other techniques. Such latitude allows optimizing porosity and ionic and electronic pathways while keeping robust mechanical and thermal performances, depending on the target application. Si Nanostructures (SiNs) such as Si nanowires and Si nanotrees have displayed excellent electrochemical performances being stable over than 1 million cycles of galvanostatic charge/discharge under a 4 V wide electrochemical windows in EMI-TFSI ionic liquid, with large power densities of 10 mW.cm⁻² and good capacitance values of 0.5 mF.cm⁻² at high current density of 0.5 mA.cm⁻² [4].

However a major silicon weakness which was still hindering its use with aqueous electrolytes is the native uncontrolled growth of silica when subjected to ambient atmosphere. Here we have developed a highly conformal passivation coating of a nanometric high-k dielectric layer of Al₂O₃ based on the rising ALD technique. ALD has proven to allow a nanometric thickness control of the deposited layer while being highly conformal and covering. Electrochemical stability performances in ionic liquid, were enhanced allowing symmetric 2 electrodes devices to reach an unprecedented cell voltage of 5.5 V [5], improving energy and maximum power densities compared to pristine nanostructured silicon. The cyclability was also largely enhanced, with only 3% capacitance fade after 10⁶ galvanostatic charge/discharge cycles at 4 V, and no degradation even after several 10⁶ resilience cycles over a 5 V window [5]. Moreover, the protective alumina layer enables the use of aqueous electrolytes for nanostructured Si based µSCs, which significantly increases the specific power of the devices up to 200 mW.cm⁻² at 0.5 mA.cm⁻² while keeping the capacitance performances at 0.5 mF.cm⁻². Furthermore the system is remarkably able to retain
99% of its initial capacitance after 2 billion galvanostatic charge-discharge cycles at high current density of 0.5 mA.cm\(^{-2}\) in an aqueous electrolyte of Na\(_2\)SO\(_4\).

Eventually we have realized a composite SiNs-Alumina-conducting polymer as electrodes for pseudocapacitive device. This device exhibits promising performances with a specific energy of 2 Wh.kg\(^{-1}\) and a power density of 300 W.kg\(^{-1}\) at a current density of 1 A.g\(^{-1}\). The µSCs was able to retain 80% its initial capacitance after 50,000 galvanostatic charge-discharge cycles at 0.5 A.g\(^{-1}\) [6].

Atomic Layer Deposition of Hf-Doped ZnO Thin Films with Enhanced Thermoelectric Properties Jenichi Clairvaux Felizco1, Taneli Juntunen2, Jarkko Etula2, Camilla Tossi2, Mutsunori Uenuma1, Yasuaki Ishikawa1, Yukiharu Uraoka1 and Ilkka Tittonen2; 1Nara Institute of Science and Technology, Japan; 2Aalto University, Finland

ZnO has been a well-explored oxide thermoelectric material owing to its low toxicity, high abundance and good chemical stability. Among the deposition techniques used for ZnO thin film fabrication, atomic layer deposition (ALD) is recently gaining attention due to its excellent film uniformity and precise thickness control down to the Angstrom level. It is also an ideal technique for depositing doped ZnO for thermoelectric applications because optimum electrical properties can be achieved by actively controlling the dopant levels. However, reports on the thermoelectric properties of doped ZnO fabricated by ALD have been limited to a few dopants such as Al and Ga [1-2]. Herein, the thermoelectric properties of ALD Hf-doped ZnO (HZO) thin films are reported for the first time. On Si and glass substrates, ALD growth was performed by sequential pulsing of diethylzinc (DeZn) and H\(_2\)O to form the ZnO, and gas pulsing of tetrakis(dimethylamido)hafnium(IV) (TDMAHf) and O\(_2\) to incorporate the dopants. Three supercycles of ZnO and dopant were deposited, wherein one supercycle is composed of varying nominal dopant amounts (0%, 1%, 2%, 3% and 4%). The deposition temperature was 443 K and nitrogen was used as the carrier gas. Thermoelectric properties were measured from 303 to 453 K (heating) and back (cooling) to observe hysteresis. Below 453 K, pure ZnO sample exhibited higher \(\sigma\) compared to all the HZO samples. However, at 453 K, an increase in electrical conductivity of HZO thin films was observed when a minimum of 3% Hf was added. A maximum of 94.9 S/cm was reached for 4% HZO, which was higher than in pure ZnO. In addition, a large hysteresis was observed with the pure ZnO sample during the cooling scan, leading to a sixfold decrease in electrical conductivity. The Seebeck coefficients are almost similar for the ZnO and HZO samples throughout all temperatures during the heating scan, but a large hysteresis was likewise observed during cooling for the pure ZnO and the lightly doped (1% and 2%) HZO. The 3% and 4% HZO samples displayed minimal hysteresis, leading to a highly stable power factor throughout both heating and cooling stages. A maximum power factor of 157 \(\mu\)W/mK\(^2\) was obtained for the 3% HZO sample at 453 K, exceeding that of pure ZnO. Doping with 3% Hf therefore leads to an enhanced thermoelectric power factor as well as improved stability compared to pure ZnO thin films deposited by ALD.

ALD Process Control towards Fabrication of Reliable Nano-Sized Memristive Devices Hehe Zhang, Alexander Harddegen, Felix Cüppers, Stephan Aussen and Susanne Hoffmann-Eifert; Forschungszentrum Jülich GmbH, Germany

Redox-based resistive random access memory (ReRAM) devices are intensively investigated as artificial synapses in neuromorphic applications due to their simple fabrication, switching performance and energy efficiency. For the realization of high-density synaptic networks with large connectivity two concepts are pursued. In the stacking of two-dimensional (2D) passive crossbar arrays, the number of stacked layers is limited by patterning issues. Therefore, blocks with even larger numbers of integrated synapses require real 3D stacking of the memory cells. At this end, atomic layer deposition (ALD) becomes the unique deposition method of choice. Due to its surface reaction
controlled characteristic, ALD enables a conformal and pinhole-free coverage of the structured electrodes by ultra-thin metal oxide layers with high structural uniformity. The performance of nanoscale devices from ALD grown oxide thin films is thus a key factor for future 3D ReRAM architectures. Today’s nano-sized ReRAM devices contain resistive switching layers from metal oxide films of a few nanometers in thickness. The precise control of the layer thickness directly affects the electroforming voltage necessary for the onset of the resistive switching, and also the switching reliability. In addition, the layer’s microstructure and the stoichiometry have to be controlled. Therefore, the device performance strongly depends on the precise control of the film growth behavior.

This talk focuses on the comparison of thin film properties obtained for the most studied oxides in ReRAM research, namely, TiOx, Al2O3, TaOx, and HfOx, fabricated from two different ALD processes, this is, thermal ALD using water vapor and plasma-enhanced ALD utilizing a remote oxygen plasma as the oxygen source. Conformal reproducible growth of a few nanometer-thick oxide films onto structured bottom electrodes is the challenge. Characterization combines structural film analysis with electrical device characterization providing feedback for the ALD parameter optimization. By this means reliable 2D micro- and nanoscale ReRAM devices were fabricated. The oxide layer(s) are stacked between a Schottky electrode and an ohmic electrode. Engineering of both interfaces is carried out to further improve the cell reliability. Especially, for the TiOx-based devices it turned out to be advantageous to add a thin Al2O3 tunneling barrier between the Pt Schottky electrode and the oxide layer to gain the control over leakage. Further, it has been shown that the insertion of a thin TiOx layer between the Ti ohmic electrode and the HfOx switching layer reduces the variability in the resistance values and the set voltage. Here, the character of different oxides and the effect of stack order from combination of several oxide films is discussed, aiming at an interface design and a tuning of the switching behavior enabling a more rational design of ReRAM devices.

Sequential Infiltration Synthesis of Nano-Porous Alumina for Resistive Switching Memory with Ultra-High On/Off Ratio and Low Voltage Operation
Bhaswar Chakrabarti1,2,3, Khan Alam4,5, Thomas Gage3, Leonidas Ocola1, Ralu Divan1, Daniel Rosenmann1, Abhishek Khanna1, Benjamin Grisafe1, Toby Sanders6, Suman Datta6, Ilke Arsalan6, Supratik Guha1,3 and Abhinav Prakash1; 1The University of Chicago, United States; 2Indian Institute of Technology Madras, India; 3Argonne National Laboratory, United States; 4King Fahd University of Petroleum and Minerals, Saudi Arabia; 5University of Notre Dame, United States; 6Arizona State University, United States

Resistance switching in metal-insulator-metal structures has been extensively studied in recent years due to potential applications in non-volatile memory technology as well as alternative computational frameworks1,2. Despite their scalability (10 nm), device density (4F2), high switching speed and endurance, resistive memories still suffer from considerable performance trade-offs between low voltage operation, high on/off ratio and device variability. In this work we report for the first time sequential infiltration synthesis (SIS) as a pathway to develop ultra nanoporous oxide thin films for high performance conductive-bridge resistive memory. SIS is a recently developed modified atomic layer deposition (ALD) process whereby the inorganic precursor molecules for oxide growth infiltrate a polymer thin film matrix.3,4 In this work we grow nanoporous alumina at 95°C, using Poly (methyl methacrylate) (PMMA) as the polymer phase and trimethyl aluminium (TMA) and water as the ALD precursors. Nanoporous alumina with 5 nm pore size and ~ 70% porosity is obtained after removing the polymer phase by rapid thermal annealing for 20 minutes in a mixture of O2/Ar/N2. Crossbar resistive memory devices of size ranging from 200x200 nm² to 1 µm² are fabricated with Pt as the bottom electrode, nanoporous alumina as the switching layer and Ag as top electrode. The nanoporous alumina devices demonstrate ultra-low operating voltages (~±550 mV) and ultra-high on/off ratio (> 10⁹) in addition to pulse endurance up to 1 million cycles and high temperature (125 °C) retention for up to 10⁴ seconds. The combination of ultra-low operating voltages and extremely high on/off ratio shows the best performance reported so far. In addition, the devices also exhibit low intrinsic variability with standard errors ~2% for the operating voltages, <2% for the on-state resistance and <10% for the off state resistance values. Combining high resolution transmission electron microscopy, 3D tomography and electrical characterizations we argue that the presence of high internal free surface area results in ultra-low power operation.

Atomic Layer Deposition of Metals and Oxides onto Structured Si to Fabricate Efficient Photoanodes

Maxime Dufond¹, Maimouna Diouf¹, Gabriel Loget², Chiara Cozzi³, Giuseppe Barillaro³, Jean-Manuel Decams⁴, Sandra Haschke⁵, Julien Bachmann⁶, and Lionel Santinacci¹; ¹CNRS, Aix-Marseille Univ., France; ²CNRS, Univ. Rennes 1, France; ³University of Pisa, Italy; ⁴Annealsys SAS, France; ⁵University of Erlangen-Nuremberg, Germany; ⁶Saint Petersburg State University, Russian Federation

Water photosplitting is a promising way to transform the sunlight into a storable and transportable energy source. Among numerous semiconductors, Si can be used as photoanode because it absorbs in the visible range and its electronic structure is suitable to drive water photooxidation [1]. Though, Si suffers from a strong corrosion at high pH and it exhibits a high reflectivity. The present approach consists of depositing oxide and metal thin films to protect the surface and to enhance the Si electroactivity. To further improve the photoelectrode performances, various surface structuring methods are used to enlarge the light absorption, to increase the active area and to improve the charge collection.

Since Atomic Layer Deposition (ALD) is a well-adapted technique to coat both planar and tortuous surfaces, it has been used to grow a thin protective layer of TiO₂ on Si. An exhaustive investigation of the influence of the deposition parameters onto the final photoelectrochemical properties has revealed the crucial impact of the nature of the precursor (titanium isopropoxide, TTIP or tetrakisdimethylamidotitanium, TDMAT) as well as the effect of the process temperature. A perfect stability is reached when the TiO₂ layer is grown using TDMAT at 150°C. This has been ascribed to the easier Ti–N bond breaking during the TDMAT pulse. A detailed electrochemical study has also shown that Si oxidation and etching can proceed through the TiO₂ thin film at open circuit potential (ocp) under low illumination.

To increase the photocurrent and to lower the overvoltage, a co-catalyst must be added. Metallic Ni has been deposited by PVD or electrodeposition [2,3] but the quality of the films is not fully satisfying on tortuous substrates. In the present work, Ni has been deposited onto the TiO₂-covered Si according to a two-step process: (i) conformal ALD of NiO from Ni(CpEt)₂ and O₃ and (ii) the reduction to Ni by annealing under H₂ atmosphere. The efficiency of such multilayered photoelectrodes is drastically improved using significantly less Ni and the photoanodes exhibit a long term stability.

This approach has been extended to structured Si surfaces such as macroporous [4], nanospikes [5] and micropillars [6]. The use of those simple electrochemical structuring methods has led to enhanced water photooxidation on oxide-covered Si. It has been confirmed using another protective layer: Fe₂O₃. Iron oxide is grown by ALD using Fe(CpBu)₂ and O₃. In this later case, the photocurrent is increased by a factor 20 when using Si nanospikes as substrates.

This work shows clearly how various, well-controlled, ALD processes and surface structuring methods can be combined to optimize the photoanode properties. The electrochemical investigations give new insight on the photoelectrochemical phenomena occurring at the solid/liquid junction in both operating conditions and at ocp.

In the past decade, inorganic semiconductor light-emitting diodes (LEDs) based on the gallium nitride (GaN) material system were established in many everyday devices as an integral part of modern communication and consumer electronics. The conventional GaN-based LED technology relies on p-n junctions with embedded indium gallium nitride (InGaN) quantum wells which are used to obtain emission in the blue spectral range. However, the p-doping of GaN involves challenges leading to low conductivity of the p-GaN of several S/cm at high defect densities. Today, the technological difficulties of p-doping have not yet been completely overcome and gain new relevance by the development of three-dimensional (3D) LED structures to further increase the efficiency of LEDs.

In this work, we replaced p-GaN of conventional GaN-LEDs with a p-conductive poly(3,4-ethylenedioxythiophene) (PEDOT) by using oxidative chemical vapor deposition (oCVD) to obtain novel hybrid-LED architectures based on inorganic and organic materials. In comparison to classical wet-deposition techniques, e.g. spin-coating of PEDOT:PSS, we observed conformal, pin-hole free, ultrathin (<100 nm) coatings of oCVD-PEDOT on planar and nano-rod GaN-LED surfaces by using gaseous monomer (EDOT) and oxidant (FeCl₃). We observed stable, blue (~450 nm) electroluminescence (EL) for an applied voltage of > 3 V under ambient conditions for planar hybrid-LED structures which are directly fabricated on full 2"-wafers. We determined the current-voltage profiles of the hybrid-LEDs and obtained diode characteristic behavior. In comparison to conventional p-GaN LEDs the hybrid-LED configuration provides a more intensive, areal light emission which is attributed to the improved lateral conductivity of oCVD-PEDOT with ‘face-on’ orientation of the polymer backbone. Our results demonstrate the feasibility of oCVD for producing and integrating a highly p-conductive transparent polymer thin film into planar LED devices.

Membrane-based organic solvent separations promise a low-energy alternative to traditional thermal separations but require advanced materials that operate reliably in chemically aggressive environments. While inorganic membranes can withstand demanding conditions, they are costly and difficult to scale. Polymeric membranes, such as polymers of intrinsic microporosity, are easily manufactured into form factors consistent with large-scale separations (e.g., hollow fibers), but perform poorly in aggressive solvents. Here, a new post-fabrication membrane modification technique, vapor phase infiltration (VPI) is reported that infuses polymer of intrinsic microporosity 1 (PIM-1) with inorganic constituents to improve stability while generally maintaining the polymer’s macroscale form factor and microporous internal structure. The atomic-scale metal oxide networks within these hybrid membranes protect PIM-1 from swelling or dissolving in organic solvents including: tetrahydrofuran, dichloromethane, and anisole. This atomic-scale metal oxide network further decreases the molecular weight cutoff (MWCO; the smallest molecular weight the membrane “successfully” rejects) in n-heptane and toluene from a MWCO of about 600 g/mol for pristine PIM-1 thin film composite membranes to 204 g/mol for hybrid AlOx/PIM-1 membranes. The hybrid membranes further retain this MWCO and high levels of rejection (>95%) in solvents that traditionally swell or even dissolve pristine PIM-1 (such as ethanol and tetrahydrofuran). The decrease in MWCO and increase in stability of AlOx/PIM-1 hybrid membranes allows them to perform separations not only between solutes and solvents, but also separations of more challenging systems such as those comprising multiple solvents. For example, the hybrid AlOx/PIM-1 membranes are capable of enriching the toluene concentration in a mixture of 90 wt% toluene, 5 wt% 1,3,5-triisopropylbenzene, and 5 wt% 1,3-diisopropylbenzene from 90.0 wt% to 97.8 ± 0.3 wt% toluene. In this talk, we will discuss the chemical mechanisms of the infiltration process that we believe create the hybrid structures necessary to support this enhanced stability and separation performance.

Vapor-Phase Inorganic Infiltration into Hierarchically Self-Assembled Block Copolymer Thin Films Generates Three-Dimensional Electroactive ZnO Nanomesh

Ashwanth Subramanian1, Gregory Doerk2, Kim Kisslinger2, Daniel H. Yi1, Robert B. Grubbs1 and Chang-Yong Nam1,2; 1Stony Brook University, United States; 2Brookhaven National Laboratory, United States
Infiltration synthesis, an emerging material hybridization technique derived from atomic layer deposition (ALD), utilizes the infiltration of vapor-phase organometallic precursors into polymeric templates to generate organic–inorganic hybrids with uniquely enhanced material properties. A subsequent removal of organic matrix from the hybrid further generates functional inorganic nanostructures directly converted from the starting polymeric template, providing a new inorganic nanopatterning methodology. Fundamentally, the infiltration synthesis is mediated by the binding reaction between infiltrating Lewis-acidic organometallic precursors and Lewis-basic functional groups available in the polymer matrix. Hinging on this principle, self-assembled block copolymer (BCP) thin films (e.g., poly(styrene-block-methylmethacrylate) (PS-b-PMMA)) enable an area-selective infiltration of inorganic components owing to the intrinsically available, spatial chemical contrast (i.e., chemically reactive domains being spatially separated from non-reactive domains). While the infiltration synthesis of nanopatterned AlOx is routinely performed by infiltrating trimethylaluminum (TMA) into BCP templates, other more functional metal oxides, such as ZnO, are not readily amenable to the nanopatterning by infiltration synthesis unless a pre-infiltration of insulting AlOx (i.e., “AlOx-priming”) is applied, due to relatively weaker binding affinities between precursors (e.g., diethylzinc (DEZ) for ZnO) and active polymer templates. In this work, we report the infiltration synthesis of optoelectrically active, three-dimensional (3D) pristine ZnO nanomesh architectures by combining a modified infiltration synthesis protocol called micro-dose process with hierarchically stacked self-assembled polystyrene-block-poly(2-vinylpyridine) (PS-b-P2VP) BCP thin films. The combination of new infiltration protocol and more reactive BCP template with 3D hierarchical self-assembly not only obviates the need of AlOx-priming but also generates a new 3D ZnO nanomesh structure, which exhibits optoelectrical functionality, featuring stack-layer-number-dependent electrical conductance resembling the percolative transport originating from the intrinsic morphological network connectivity of the lamellar BCP pattern with symmetric block ratio. The results not only illustrate the first demonstration of electrical functionality based on the ZnO nanoarchitecture directly generated by the infiltration synthesis in self-assembled BCP thin films but also present a new, large-area scalable, metal oxide thin film nanoarchitecture fabrication method utilizing industry-compatible polymer solution coating and ALD. Given the large surface area, 3D porosity, and readily scalable fabrication procedures, the generated ZnO nanomesh promises potential applications as an efficient active medium in chemical and optical sensors.

Atomic Layer Processing—A Toolbox for Fabricating Novel Functional Hybrid Materials Mato Knez1,2; 1CIC nanoGUNE, Spain; 2IKERBASQUE, Spain

Atomic layer processing is an umbrella term for several processing techniques that base on atomic layer deposition (ALD). Those include thin film coatings with inorganic or organic materials, atomic layer etching and polymer infiltration strategies.

The ALD process can be seen from various perspectives. On the one hand, it allows controlled deposition of thin films on a variety of substrates and in this way enables a modification of a given functionality of a surface or even introduction of a new functionality. On the other hand, it may be seen as a chemical reactor that allows precise dosing of a chemical, allowing for chemical interaction and modification of the substrate. Considering both points of view, the process opens large variation possibilities for a design of novel functional materials for emerging applications and devices. Among those functional materials hybrid materials play an increasingly important role. Hybrid materials are in most cases blends of inorganic and organic materials and are considered to be key for the next generation of materials research. The main goal while fabricating such materials is to bridge the worlds of polymers and ceramics, ideally uniting the most desirable properties within a singular material. Furthermore, in a well performing hybrid material the individual components will add value to their counterpart in a synergistic way. In this talk, some approaches will be discussed that show great promise for establishing ALD as the method-of-choice for innovation in technological fields beyond the microelectronics industry. Rather than growing thin conformal films, the ALD process technology is applied to controllably grow nanoparticles on functional substrates adding value to their chemical or electrochemical properties. In an adapted processing mode, the ALD processing technology also allows infusing metals into polymeric substrates, which leads to novel material blends that cannot easily be obtained in other ways. In either of those cases the chemical or physical properties of the initial substrate are improved or new functionalities added. With some showcases, this talk will discuss approaches towards non-traditional application of ALD to fabricate novel materials with great promise in energy storage, catalysis, personal protection or flexible electronics. We will show examples where mechanical and electronic properties of polymeric materials have been significantly improved through nanoscale coatings and infiltration. Those polymers include natural polymers such as spider silk, collagen, etc. as well as technical polymers such as Kevlar, polyaniline and...
polythiophene. The characterization of the resulting material has been done by means of various spectroscopies, microscopies and modelling by density functional theory.

SESSION FF05.12: Devices and Applications Enabled by ALD/CVD II
Session Chairs: Karen Gleason and Sven Van Elshocht
Friday Morning, December 6, 2019

8:30 AM FF05.12.01
On the Origin of the High Conductivity of Intrinsic ALD-ZnO Daniel Hiller¹ and Dirk König²; ¹The Australian National University, Australia; ²University of New South Wales, Australia

ALD-ZnO thin films can achieve conductivities of ≤3 mOhm cm without any intentional doping such as by supercycling ALD-Al2O3 to deposit Al-doped ZnO (AZO). Whereas the latter allows for conductivities down to the 10^-4 Ohm cm range, the mobility of ALD-AZO is significantly reduced by impurity scattering and the free carrier absorption is increased, which induces e.g. optical losses when applied to solar cells. Generally, two different models for the n-type conductivity in ZnO are discussed in the literature: intrinsic ZnO point defects and hydrogen. However, ZnO deposited or grown by methods other than thermal ALD rarely reach the very high conductivity range that is essential for its application as transparent conductive oxide (TCO). Hence, ALD appears to introduce a very efficient intrinsic doping mechanism into the material unlike the other methods. We will show via T-dependent Hall-measurements that the intrinsic doping is so high that it induces a semiconductor-to-metal-transition (Mott transition). By means of isotope studies (deuterium vs. hydrogen) the origin of the ~1 at% H-concentration in the ALD-ZnO thin films is determined. Using a comprehensive range of structural-chemical characterization methods (FTIR, NRA, NMR, c-AFM, XANES at the O and Zn K-edges) the bonding configuration of H in ZnO is studied in detail. Finally, different models for the incorporation of H into the ZnO network and their resulting density of states (DOS) are simulated by density functional theory (DFT) to explain the very high conductivity of ALD-ZnO.

8:45 AM FF05.12.02
Molecular Layer Deposition of Metal-Organic Thin Films with Resistive Switching Properties for Neuromorphic Computing Mikko Nisula and Christophe Detavernier; Ghent University, Belgium

Recently, artificial neural networks (ANN) have revolutionized the field of artificial intelligence with human-like performance in fields such as computer vision and speech recognition. However, the current computers with von Neuman -architecture are ill-suited for the massively parallel operations required for ANNs resulting in high energy consumption. Neuromorphic computing aims to greatly improve the energy efficiency by emulating the functionality and interconnectivity of the biological neural networks on the hardware level. In biological neural networks, communication between neurons is facilitated by synapses that enable combined memory and processing. Development of brain-like computers requires materials and devices that have the same functionalities as the real synapses.

Metal-organic hybrid materials (coordination polymers) present an interesting candidate for this task. Their electronic conductivity can be modulated electrochemically by controlling the oxidation state of the material, and can be used to model the synaptic weight. The interplay of the metal and organic constituents enables the tuning of the electric/electrochemical properties towards low device conductance and low power consumption. Additionally, as the redox reactions are coupled with the motion of an associated counter ion, the difference in the electron and ion mobilities could potentially be harnessed to simulate various time dependent synaptic functionalities such as short- and long-term memory. However, currently the poor processability of coordination polymers limits their applicability for nanotechnology applications.

Here we demonstrate that Molecular Layer Deposition (MLD) is extremely well suited for this application. As an extension to ALD, MLD expands the self-limiting gas-surface reactions to hybrid organic-inorganic materials with the implementation of volatile organic molecules as the co-reactant. As a solvent-free, gas-phase processing technique it is in principle also compatible with the existing CMOS processing methods. As a proof-of-concept, we
developed a novel MLD process for Cu-dithiooxamidate based thin films. The growth and composition of the films is characterized with spectroscopic ellipsometry, XRR, XRD, XPS, AFM and FTIR. The resistive switching properties are explored in simple two-terminal devices arranged in cross-bar arrays of variable node sizes. The deposition process is shown to comply with the principles of ALD with surface saturation limited growth. Excellent thickness uniformity and low surface roughness (RMS < 0.3 nm) can be realized over large area substrates. The solid-state devices demonstrate an oxidation state dependent dynamic conductance range spanning over one order of magnitude. In pulsed operation mode similar to biological neurons, the devices demonstrate many of the basic synaptic functionalities. The rate of change in the device conductance is dependent on the excitation frequency and amplitude, thereby emulating spike-rate and spike timing dependent plasticity (SRDP and STDP). Furthermore, both volatile and non-volatile changes in device conductance can be realized to mimic the short and long-term plasticity (STP and LTP) of the biological synapse.

9:00 AM FF05.12.03
PbI₂ Deposition from Solution-Atomic Layer Deposition for Photovoltaic Application Maïssa Barr¹, Ceyla Asker¹, Soheila Nadiri¹, Karen Forberich², Felix Hoga³, Tobias Stubhan³, Hans Egelhaaf⁵, Christoph J. Brabec² and Julien Bachmann¹; ¹FAU-CTFM, Germany; ²i-MEET, Germany; ³ZAE Bayern - Erneuerbare Energien, Germany

We propose and demonstrate a novel thin film deposition technique by transferring the principles of atomic layer deposition (ALD), known with gaseous precursors, towards precursors dissolved in a liquid. The technique can also be considered as a generalization of already established methods such as the ‘layer by layer’ growth or the ‘successive ion layer adsorption and reaction’ (SILAR). 'Solution ALD' (sALD) shares the fundamental properties of standard ‘gas ALD’ (gALD), specially the self-limiting growth and the ability to coat conformally deep pores. It has been already shown that it is possible to transfer standard reactions from gALD to sALD such as TiO₂ deposition. However, sALD also offers novel opportunities such as overcoming the need for volatile and thermally robust precursors.

In the following the targeted field is photovoltaic. A great deal of interest has appeared on a new generation of material for solar cells application. Among them the perovskites are particularly interesting and the most studied one is CH₃NH₃PbI₃ (MAPI). The existing deposition methods such as spin coating or vapor-deposition techniques do not allow a control at the atomic level. ALD has been used to deposit PbS but it needed a two-step conversion method to obtain a perovskite. Therefore, a new process based on sALD is developed to deposit PbI₂. It allows the use of inexpensive lead salt and it is easy to process. Then, the PbI₂ can be easily converted to MAPI. The PbI₂ deposition was achieved with Pb(NO₃)₂ and LiI via s-ALD on large samples (up to 10 cm*10 cm). The ALD behavior has been shown. The influence of the deposition parameters on the morphology, the crystalline structure and the chemical composition has been investigated by scanning electron microscopy, atomic force microscopy, grazing incidence x-ray diffraction and x-ray photoelectron spectroscopy. The growth of PbI₂ has been studied on different oxides with various chemical pre-treatments. Later, the obtained PbI₂ has been converted to MAPI by vapor annealing. The influence of the temperature, the time and the type of gas on the conversion has been investigated the different substrates. Furthermore, the influence of the ALD parameters on the properties of the perovskite layer has been studied. Thus, the perovskite layer has been integrated into a solar cell.

9:15 AM FF05.12.04
Lithium-Containing Thin Films by Atomic Layer Processing John Hennessy; Jet Propulsion Laboratory, United States

We report on the development of lithium compounds by atomic layer deposition and atomic layer etching for space applications related to far ultraviolet telescope mirrors and energy storage devices. Lithium fluoride is a promising next generation mirror coating material for astrophysics instruments and initial ALD prototype mirrors have exceeded the performance and stability of legacy PVD systems. We have also investigated improvements in stability obtained by the use of nanolaminates with ALD aluminium fluoride. Our HF-based approach to the deposition of these materials has also led to thermal atomic layer etching methods that can be implemented on the same aluminum mirror systems to gently remove native oxide from the aluminum surface. Exploring an interaction between trimethylaluminum and HF has been shown to greatly enhance the etch effect on aluminum oxide as a function of substrate temperature. Planned flight demonstrations of these coatings on NASA sounding rocket and CubeSat missions will be discussed.
The same material system is also a promising battery interface material, and this talk will present initial results on
the passivation of Li-metal anodes using this ALD approach. The use of ALF₃, LiF, and intermediate phases of the
two have been investigated for their ability to improve cycling stability and capacity in test cells. The same
interactions with alkali materials observed in etching experiments is shown to influence the behavior of atomic layer
processing approaches on Li-metal anodes.

9:30 AM FF05.12.05
Atomic Layer Deposition as a Tool to Produce Photonic Materials for High-Temperature Applications Kaline
P. Furlan¹², Robert Zierold², Alexander Y. Petrov³, Robert Blick², Manfred Eich³, Gerold A. Schneider⁴ and Rolf
Janssen¹; ¹TUHH, Germany; ²University of Hamburg, Germany; ³Technische Universität Hamburg-Harburg,
Germany

Highly-porous ceramics are employed in a variety of technological applications, such as filtration, catalysis, heat
insulation and photonics. Photonic materials for high-temperature applications are expected to perform while being
exposed to temperatures higher than at least 800 °C. Nonetheless, this exposure usually causes detrimental
morphological changes with associated impairment of the photonic properties. Such properties are defined during
the fabrication process and are related not only to the material composition but also to the structure present at
different scales. 3D inverse opal photonic crystals (PhCs) are usually produced by the infiltration of a polymeric
template either by sol-gel, colloidal routes, chemical vapor deposition or atomic layer deposition (ALD). Hereby, we
demonstrate the production of ceramic-based photonic materials by combining the controlled self-assembly of
monodisperse particles with ALD. A variety of ceramic PhCs produced via ALD will be presented and their
behavior when exposed to high temperatures depicted. By specifically designing and controlling the ALD process,
materials with tailored composition are obtained which present a photonic stopgap even after exposure at 1400 °C, a
remarkable achievement concerning temperature stability. At last, an example of additive manufacturing combined
with colloidal assembly (AMSA) will be presented as a demonstration of large area templating, which in
combination with ALD creates new possibilities for photonic and highly-porous materials production.

ZnO Nanotube-Based Gas Sensors and Metal-Chalcogenide Memristors by Atomic Layer Deposition with an
Oxygen Plasma and Annealing Processes Sungkwon Cho, Kyungsub Lee and Seonghoon Lee; Seoul National
University, Korea (the Republic of)

ZnO nanotubes with a wall thickness on the order of nanometers were produced by atomic layer deposition (ALD)
with an organic template, using diethyl zinc as Zn precursors and water as O precursors. The organic template was
removed by an O₂ plasma process and a thermal annealing process, with the wall structure of the ZnO nanotubes
maintained during the removal of the template. We investigated the response and selectivity of a ZnO nanotube to
ethanol and hydrogen gases as a function of its wall thicknesses. The ZnO nanotubes with a wall thicknesses of 10
nm showed the highest gas response (defined as the ratio of electrical resistances, R_air/R_gas, under air atmosphere to
the mixed air atmosphere with ethanol vapor) of 1184 toward 100 ppm at 450°C. The ZnO nanotube with a wall
thickness of 10 nm was wholly depleted and thus highly responds to the adsorption of chemical species on its
surface. Accurate control of the wall thickness of the ZnO nanotubes is crucial to make ZnO nanotube sensors with
high response. The memristor is considered as the one of the promising candidates for next generation gas sensor,
nanoelectronic computing device. Metal-chalcogenide memristors with small thicknesses and high ionic mobility
were fabricated with ALD, shadow mask patterning technique, and metal electrode deposition.

Novel Material and Process Options for Future Technology Nodes in Semiconductor Industry Sven Van
Elshocht; imec, Belgium

As dimensions have been shrunk close to the limits of what is physically possible, novel materials as well as
alternative device concepts and architectures are increasingly required. Examples of such materials can be logic gate
spacers with lower dielectric constants, alternative channel materials with a higher mobility or metals with
decreasing resistivity to name a few. These are being added to the widening list of novel materials with every new
technology node. In addition and independent of the application, there is an ongoing trend of 3D integration: logic
(FinFET), DRAM (trench or pillar capacitors) or NAND Flash (staircase 3D NAND) are examples of the how
devices have been innovated into the third dimension to enable a continued area scaling and related performance
benefit. Such 3D architectures imply the need for conformal deposition techniques such as atomic layer deposition.
In addition, to reduce the level of edge placement error, self-aligned process schemes and the use of selective
deposition is being explored.
In this presentation, we will discuss how the semiconductor landscape is evolving and how material innovation is an
absolute must. We will highlight some of the material options that are being considered and touch upon selective
deposition to facilitate integration schemes.

11:15 AM FF05.12.09
Oxidative Chemical Vapor Deposition Enabled Poly(3-methylthiophene) Coating on Horizontally Aligned
Carbon Nanotubes for Flexible Supercapacitors with Ultrahigh Areal Capacitance Yue Zhou1,2;
1Massachusetts Institute of Technology, United States; 2South Dakota State University, United States

Together with the development of flexible and wearable devices, there is a growing demand of flexible energy
storage devices as power sources. Supercapacitors, bridging the gap between batteries and capacitors, are very
promising among the candidate power solutions. However, one of the key challenges for wide application of such
flexible supercapacitors is that the maximum current density allowed for them is not high enough. The issue is
partially induced by the structure of the electrode materials. Traditionally, randomly aligned carbon nanotubes are
used as electrode material for supercapacitors, hindering the ion transport inside the electrode and therefore limiting
the current density it can achieve. In this work, we demonstrate that horizontally aligned carbon nanotubes (CNTs)
exhibits superior ion transport inside the electrodes, and therefore significantly enhance the maximum current
density. At the same time, conjugated polymers with pseudocapacitive characteristics have drawn much attention for
the application of supercapacitors to enhance their capacitance. We for the first time, demonstrate oxidative
chemical vapor deposition (oCVD) synthesis of a conjugated polymer, poly(3-methylthiophene) (P3MT). With only
one methyl as the side group of the thiophene ring, P3MT demonstrates higher density of effective conjugation
(polythiophene structure) than other modified polythiophene-like polymers, such as PEDOT and poly(3-
hexylthiophene). In this way, the lighter repeating unit increases specific capacitance. With oCVD, we also
demonstrated conformal coating of P3MT on CNTs with an average thickness of ~5 nm. The resulting device
exhibits high areal capacitance of 3.1 F cm-2 at 5 mA cm-2, with areal capacitance shown to remain high at 1.8 F cm-
2 even at a current density of 200 mA cm-2, which is much improved compared to the state-of-the-art devices.
Furthermore, little change in cell performance is observed under high strain, demonstrating the mechanical and
electrochemical stability of the electrodes.

How Atomic Layer-Deposited Oxides Can Push Artificial Photosynthesis towards Terawatt Scale Won Jun Jo,
Georgios Katsoukis and Heinz Frei; Lawrence Berkeley National Laboratory, United States

Solar-driven CO₂ conversion needs to reach at least a 10 terawatt scale to have impact on the global fuels market. To
realize this unprecedented level of CO₂ fixation using H₂O as electron source, we have adopted a unique method of
leveraging atomic layer deposition (ALD) into the seamless constructions for photocatalytic nanotube arrays, which
are designed for gas-phase CO₂ reduction using sunlight and water. Specifically, such arrays have a large number of
ALD-grown core (Co₃O₄)-shell (SiO₂) nanotubes operating as independent photosynthetic units under ambient
conditions. The SiO₂ nanoshell serves as a H⁺ transmitting and O₂ impermeable membrane to spatially separate H₂O
oxidation catalysis by Co₃O₄ inside of the tube from CO₂ reduction catalysis by Cu nanoparticles outside of the tube.
This inherent product separation geometry allows to address long-standing scientific barriers of optimizing the
combinations of photoactive materials (thermodynamic efficiency) and minimizing charge transfer losses and
unwanted reactions (quantum efficiency) of artificial photosynthetic systems.
Performance evaluation and stepwise improvement of photocatalytic efficiency of the array include the optimization of the nanowall composition for structural stability, as well as quantitative evaluation and mechanistic understanding of charge-carriers (proton and electron) transfer across the core-shell nanotube wall using atomic resolution imaging, infrared spectroscopy, and electrochemical methods. Photocatalytic efficiency of the fully functionalized nanotube array is measured by time-resolved product monitoring through infrared, optical and mass spectroscopy. This measurement is further underpinned by mechanistic framework derived from parallel photocatalytic and photoelectrochemical studies using cm²-scale planar analogs of the core-shell nanotube walls in H-cell configuration.

Characterizing the Robustness of β-SiC Coatings for Applications in Magnetic Fusion Energy
Tyler Abrams¹, Stefan Bringuier¹, Sean Gonderman¹, Dmitry Rudakov², Gregory Sinclair³, Ezekial Unterberg⁴, Robert Wilcox⁴ and Leo Holland¹; ¹General Atomics, United States; ²University of California, San Diego, United States; ³Oak Ridge Associated Universities, United States; ⁴Oak Ridge National Laboratory, United States

Spectroscopic measurements of the gross erosion of crystalline silicon carbide (β-SiC) coatings, fabricated via chemical vapor deposition (CVD), have been measured under D and C ion bombardment using the DIII-D National Fusion Facility [1]. These measurements reveal that the physical sputtering of silicon from these SiC coatings is reduced by a factor of ~10 relative to pure Si material in the low ion impact energy range (50-300 eV) relevant to magnetic fusion devices. This result is consistent with TRIM.SP and MD modeling [2] predicting a suppression of Si physical sputtering from β-SiC due to the enhanced surface binding energy imparted by Si-C chemical bonds. A 2-5x reduction in the C chemical erosion rate from SiC is observed relative to ATJ graphite, the standard wall armor material used in DIII-D and many magnetic fusion experiments. The near-elimination of C chemical sputtering from SiC confirms and extends previous studies on high-flux linear plasma devices [3]. No evidence of Si chemical erosion via silane (Si, D) compounds is observed, but some Si II emission persists below the ion impact energy threshold for Si physical sputtering, suggesting that a chemical release mechanism is present.

SiC samples of 100-200 μm thickness were prepared via CVD on ATJ graphite substrates in the General Atomics Nuclear Technologies & Materials Laboratory. These materials were exposed to energetic (50-300 eV) D ion bombardment up to a fluence of 2x10²³ m⁻². Transient plasma pulses with D ion impact energies of 1-2 keV and heat fluxes up to 10 MW m⁻² were also utilized for thermal shock testing. These materials were tested in the DIII-D tokamak using a removable sample exposure probe known as the Divertor Materials Evaluation System (DiMES). In-situ measurements of Si and C gross erosion were conducted using line emission spectroscopy and the S/XB method [4]. No macroscopic damage to the SiC coatings was evident upon post-mortem visual inspection and detailed morphology analysis revealed no detectable change to the surface roughness before and after exposure. Microstructural analysis via SEM indicated features with characteristic size < 5 μm were not preserved, potentially due to evaporation and/or viscous flow processes. Energy Dispersive X-Ray Spectroscopy analysis revealed a slight enrichment of the Si surface concentration, relative to C, after plasma exposure. This result is corroborated by the spectroscopically inferred Si gross erosion measurements, which are quantitatively consistent with TRIM.SP physical sputtering predictions under the ad hoc assumption of a 5% Si enrichment fraction of the SiC surface. These results imply potentially favorable erosion properties for crystalline β-SiC under low impact energy hydrogenic ion bombardment characteristic of magnetic fusion energy devices. In conjunction with the robust neutronic properties of SiC at high temperatures, these results motivate serious consideration of SiC as wall armor material in future high power-density magnetic plasma confinement devices.

The tutorial will provide the attendees with a short course in advanced experimental and computational techniques as applied to the study of reactive materials. In the experimental section, additive manufacturing techniques, specifically direct ink write (DIW), are discussed in this context. The content will cover the tools, safety considerations for using this technique with reactive materials, challenges associated with material development, and toolpath development. The goal of this section is to provide 3D printing novices with the background to start working in this area, while also providing experienced users with advanced tips and tricks to improve the quality of their prints.

The computational section will focus on the use of molecular and atomistic modeling as they pertain to reactive materials. This content will contain a review of modern tools and state-of-the-art techniques for the modeling of energetic materials and their combination into a multi-scale approach to describe material behavior. The potential of these modeling approaches for the future of energetic materials, from manufacturing issues to advanced modeling of combustion fundamentals and applications, is also presented.

The Early Stages of Subcritical Reactions in Al/Ni Multilayers Studied by Combined Nanocalorimetry and Sub-Millisecond X-Ray Diffraction

Tobias Neuhauser¹, Gemma Tinti², Harald Leiste¹, Nicola Casati², Michael Stüber¹ and Karsten Woll¹; ¹Karlsruhe Institute of Technology, Germany; ²Paul Scherrer Institut, Switzerland

Subcritical reactions comprise phase transformations in reactive nanolaminates leading to the point of ignition and typically occur under high heating rates above 500 K/s. Harnessing the reaction attributes and the specific metallurgy of subcritical reactions in metallic nanolaminates represents a promising pathway for creating novel types of thin film nanocomposites. Based on this notion we develop so called “Pulsed Metallurgy”. The nanolaminates with their microstructure serve as templates which are transformed into nanocomposites via millisecond short temperature pulses. Thermal pulsing enables us to precisely control the precipitation of hard intermetallic compounds in the soft metallic matrix at the nanoscale. The pulse shape defines the amount as well as morphology of the intermetallic phase. Here, we present first design guidelines for thin film composites based on Al-rich Al/Ni nanolaminates. For the chosen system, we require fundamental knowledge on the thermodynamics and kinetics of the underlying phase transformations during subcritical reactions. Especially, the effect of high heating rates on the phase transformation is explored. We performed chip-based nanocalorimetry and time-resolved X-ray diffraction with synchrotron radiation to in situ explore the phase transformations. In addition to the thermodynamic/kinetic information, this allows us to trace structural changes with a temporal resolution of up to 50 µs. Heating rates from 10 K/s up to 10,000 K/s are chosen to determine the onset and the growth rate of intermetallic phases. Effects of chemical composition are studied. Complementary kinetic studies are performed under isothermal conditions. The analysis of two dimensional X-ray diffraction data gives further insight in the structural evolution during the reaction and their influence on the reaction mechanism. Selected Al/Ni multilayer samples are finally characterized via electron microscopy. Eventually, the calorimetry in combination with the structural data enables us to derive guidelines for microstructure development of Al-based thin film nanocomposites.

Reactive Composites of Boron with Bismuth Fluoride and Bismuth—Preparation, Ignition and Combustion

Siva Kumar Valluri, Karthick Kumarasen Ravi, Mirko Schoenitz and Edward L. Dreizin; New Jersey Institute of Technology, United States

Despite the thermodynamic advantages of boron, its long ignition delay and burn time hinder its widespread application as a practical fuel. The ignition is delayed by the nascent shell of hydrolyzed oxide acting as a diffusion barrier protecting the boron core. The combustion at higher temperatures occurs at the oxide-free boron surface; the rate of this heterogeneous reaction is relatively low. To address these shortcomings, modifying the chemistry of the oxidative process encompassing ignition and combustion, by introducing fluorination was found to be effective. The addition of fluorides like bismuth fluoride (BiF₃) and cobalt fluoride (CoF₂) depressed the ignition temperatures and improved burn times of micron-sized boron-fluoride composites. The focus of this work is to introduce small quantities of bismuth fluoride as an oxidizer to maintain the thermodynamic potential of boron while improving its ignition and combustion rates. Towards this end, different boron-bismuth fluoride composites, (100-x) B-xBiF₃, with 5, 10, 30 and 40 wt. % of bismuth fluoride were prepared. Composites with 10, 30 and 40 wt. % of BiF₃ were prepared by arrested reactive milling. Additionally, composites with 10 and 5 wt. % of BiF₃ were prepared by the solvent based chemical deposition technique. The milled samples were found to have a small quantity of reduced Bi and were contaminated by iron from the milling media and vial walls. Based on recent work, the iron introduced by milling is expected to accelerate combustion of boron. Here, a similar effect of reduced bismuth left behind after fluorination, on boron’s combustion behavior was explored experimentally. Milled boron-bismuth composites were prepared including 92B-8Bi and 69B-31Bi, containing bismuth and iron content comparable to the boron-fluoride composites, 90B-10BiF₃, and 60B-40BiF₃ respectively. A systematic reduction in ignition temperatures with the content of BiF₃ was observed with all milled composites igniting at much lower temperatures than boron. At a heating rate of 2500 K/s, milled composites 90B-10BiF₃, 70B-30BiF₃, and 60B-40BiF₃ ignited at 650, 600 and 580 °C respectively. The coated sample 90B-10BiF₃ ignited in a range of temperatures, with an average of 650 °C, while 95B-5BiF₃ did not ignite at temperatures under 1200 °C. The thermogravimetric analysis in aerobic conditions shows an oxidation step around 500 °C for all composites. The reference boron sample had an oxidative weight gain at a higher temperature, 710 °C. All the composite particles were heated and ignited by a CO₂ laser beam in air. They exhibited shorter burn times compared to similar-sized
boron particles. A reduction in burn-times with an increase in bismuth fluoride content was observed. For a particle of 1-micron size, boron had a burn-time of 2.1 ms. The milled composites 90B-10BiF₃, 70B-30BiF₃, and 60B-40BiF₃ exhibited burn-times of 0.38, 0.33, and 0.28 ms respectively, almost an order of magnitude faster than boron. The boron-bismuth composites were found to burn slightly faster than boron. Analysis of partially reacted products shows bismuth retained in particle till boron melting point. The combustion mechanism and reaction pathways involving the species will be discussed.

11:00 AM *FF06.01.03
Reactive Materials for Ceramics Fabrication Alex Mukasyan; Notre Dame University, United States

Phenomenon of self-sustained chemical reactions that sub-sonically propagate along the high-energy density material is widely used for fabrication of different ceramics [1,2]. The specifics of synthesis condition in such combustion front are as follows: short (0.1-10 ms) reaction time, high temperatures (2000-4000 K) and extremely high rate for temperature change (10⁴-10⁶ K/s). These features allow fabrication of materials with unique microstructures and properties. In this work, we report recent results on combustion synthesis (CS) of different materials including ultra-high temperature ceramics, high entropy ceramics, metastable phases, as well as cubic boron nitride. Special attention is paid to such novel synthetic routes as reactive spark plasma sintering (SPS), CS with mechanical stimulation, as well as solution combustion synthesis.

Specifically it is shown that SPS of reactive materials [3] allows one-step rapid fabrication of dense bulk nanostructured ceramics (e.g. SiC, B₄C, HfCN) with high mechanical properties. Application of similar approach in combination with high-energy ball milling permits production of high entropy carbides and nitrides. It is also demonstrated that CS in B-TiN reactive system under shock-wave conditions leads to formation of c-BN phase [4]. Finally, using self-sustained waves in reactive solutions of metal nitrates and different fuels (e.g. hexamethylenetetramine and glycine) allows synthesis of metastable metal nitrides phases [5].

11:30 AM FF06.01.04
Glassy Amorphous Organic Energetics Rajen Patel¹, Victor Stepanov¹ and Hongwei Qiu²; ¹U.S. Army Research Laboratory, United States; ²Leidos, United States

Glassy amorphous organic energetics is a new field offering several novel areas for study. While practical application might be limited due to low density and propensity to crystallization of amorphous energetics, the scientific opportunities are fertile. For example, they allow an in depth view of crystallization in real time, even of novel systems such as cocrystals, and the in situ characterization of pores, cracks and other gross defects as they form. The ability to quantify and characterize the crystallization of an organic material would not only be an important step in the science of crystallization, but could have broader application to the pharmaceutical, biological science, and energetic materials communities. Amorphous energetic formulations with relatively low excipient (i.e. polymer used to inhibit crystallization) loadings were studied as they crystallized. This allowed several key determinations to be made that linked porosity and crystallinity of the material during this dynamic process. This is especially critical, as porosity is a critical parameter in the sensitivity and mechanical properties of an explosive, two key drivers for future munitions applications. Furthermore, the results will have an impact on the study of crystallization from both a practical and theoretical standpoint.

11:45 AM FF06.01.05
**Shape and Size Effects on the Oxidation of Aluminum Powders** Pierre-Henry Esposito¹, Thomas Neisius², Renaud Denoyel¹ and Marie-Vanessa Coulet¹; ¹CNRS-Aix Marseille Univ, France; ²CNRS, Aix-Marseille Univ., France

Aluminum powders are commonly used in the formulation of reactive materials [1]. In those materials, there is a definitive interest in improving the reactivity of aluminum powders and the actual trend is to produce powders with a high specific surface areas (higher than 10m²/g) i.e. aluminium nanopowders. Without any consideration of the scale, aluminium particles are covered by a thin alumina layer whose thickness does not vary much with the particle size [2]. The enhanced reactivity due to the use of nanosized powders is proposed to be linked to size reduction effects of the particles and to the structural and microstructural characteristics of both the metallic core and this alumina layer.

The standard synthesis routes for nanopowders are atomization and wire electro-explosion techniques. Such techniques produce powders with spherical morphology. High-energy ball milling has been recently proposed as an alternative procedure to produce micro- or nano- aluminum powders. They possess a flake like morphology and have different reactivity compared to the spherical ones [3]. This technique has also been shown to be able to produce reactive composite materials [4].

In this contribution, we propose a comparative study of the oxidation mechanisms of aluminum powders as a function of their shape (spheres versus flakes) and size (micro versus nano). Thermogravimetric and differential thermal analysis performed under dry Air up to 1500°C are used to evaluate the oxidation behaviour of the powders. The morphology of the various powders is followed for different oxidation temperatures using gas adsorption, transmission electron microscopy (TEM) and energy filtered transmission electron microscopy (EFTEM) [5]. Finally, the oxidation mechanisms are studied using kinetically controlled thermal analysis [6]. In this mode, keeping the oxidation rate constant, the kinetics equations are simplified which facilitates the modeling of the experimental data. The observed differences between the oxidation mechanisms are discussed as a function of the shape and the size of the particles.

*The Direction Générale des Armées (DGA) and the University of Aix-Marseille (AMU) are acknowledged for funding the PhD of P.H. ESPOSITO.*

catalytic effect. Moreover, the graphene foam-based structures provide an additional benefit of increased thermal transport. It is well-known that heat transport also plays an important role in the combustion of solid fuels; higher thermal conductivity or diffusivity usually results in higher burn rates. Most solid fuels have a thermal conductivity in the range of 0.1-1 W/m-K, which is much lower than that of these graphene-based materials (up to a few thousand W/m-K). Indeed, carbon nanomaterials such as carbon nanotubes and graphene, because of their high thermal conductivity and large surface-to-volume ratio, have been used as nano-fillers to enhance the thermal conductivity of various composites and as heat exchangers in nano-electronic devices.

Motivated by the above, we explored the potential of GF structures, which were functionalized with a transition metal oxide manganese dioxide such as MnO$_2$ or CuO using a hydrothermal approach. The propellants we chose were Nitrocellulose (NC) and hybrid Ammonium Perchlorate-Nitrocellulose (AP-NC). For nitrocellulose with GF supported MnO$_2$, burn rate enhancements up to 9 times were obtained with the activation energies being lowered by 17%. However, without the use of GF as the supporting structure, using only MnO$_2$ oxide nanoparticles, burn rate enhancements only up to 2 times were obtained with the activation energies being lowered by 3.6%. Although, the presence of GF in itself does not have any catalytic effect on the propellant decomposition, the GF supported metal-oxide particles provided a more efficient contact between the propellant and the metal-oxide. This was in contrast to the traditional solid-fuel/metal-oxide mixture prepared in which a continuous contact between the propellant and the catalyst was not achieved because of the random mixing of metal oxide particles into the fuel matrix. For AP-NC, the CuO-functionalized GF micro-structures significantly enhanced the burn rates, up to 7 times the bulk value, which was attributed to the combined physical (increased thermal transport) and chemical (enhanced thermal decomposition) effects. TG (thermogravimetric) and DSC (differential scanning calorimetry) analysis showed the activation energy of AP-NC was lowered by 22% with the use of the CuO-functionalized GF structures.

2:15 PM FF06.02.02
Flexoelectricity in Al/Fluoropolymer Reactives Mikel J. Zaitzeff and Lori J. Groven; South Dakota School of Mines & Technology, United States

In the past few years there has been increased interest in the development of smart reactives. Towards that, the reactive system Al/THV, and Al/PVDF have been explored for their piezoelectricity and ability to be switched to a more sensitive state. Early work indicates that even non-piezoelectric composites could exhibit sensitization behavior, but it was not well explained. A possible explanation is the flexoelectric effect. Flexoelectricity in induced by an inhomogeneous strain gradient capable of switching, poling, and spontaneous polarization. This allows for the flexoelectric effect to produce similar effects as the piezoelectric effect without the need for a true piezoelectric. For example, unpoled PVDF has been found to exhibit the flexoelectric effect and in fabricated composites has been shown to have apparent $d_{33}$ coefficients on par with poled PVDF. In this effort THV and PVDF with various loadings of micron scale aluminum are considered and the flexoelectric coefficients measured. It is shown that THV exhibits a higher flexoelectric coefficient than PVDF and with inclusion of aluminum increases. PVDF exhibits a flexoelectric coefficient of 3.9, 5.2, and 6.1 nC/m at 0, 33, and 50 weight percent aluminum respectively. THV exhibits a flexoelectric coefficient of 5.1 and 7.0 nC/m at 0 and 33 weight percent aluminum respectively.

2:30 PM FF06.02.03
Development of Multimodal Antibacterial Surfaces Using Porous Amine-Reactive Films Incorporating Lubricant and Silver Nanoparticles Jieun Lee$^1$, Jin Yoo$^1$, Sanghyuk Wooh$^2$ and Kookheon Char$^1$; $^1$Seoul National University, Korea (the Republic of); $^2$Chung-Ang University, Korea (the Republic of)

Surface functionalization provides efficient strategy to significantly improve material surfaces to overcome the infectious problems from microbial fouling in many medical devices and food processing equipment. Anti-biofouling has been improved by passive or active ways. Passive antifouling strategies aim to prevent the initial adsorption of foulants, while active strategies aim to eliminate proliferative fouling by destruction of the chemical structure and inactivation of the cells. However, neither passive antifouling strategies nor active antifouling strategies can solely resist biofouling due to their inherent limitations. To achieve highly effective anti-biofouling surfaces, integration of bactericidal and bacteria-repellency is highly in demand. Herein, we successfully developed multimodal antibacterial surfaces for waterborne and airborne bacteria with the benefit of combination of anti-adhesion (passive) and bactericidal (active) properties of the surfaces. We elaborated multi-functionalizable porous amine-reactive (PAR) polymer films from poly(pentafluorophenyl acrylate) (PPFPA).
Pentafluorophenyl ester groups in the PAR films facilitate to create multiple functionalities through a simple post-modification under mild condition, based on their high reactivity towards various primary amines. To retain lubricant in films, porous structures of PPFPA films were developed by vapor-induced phase separation (VIPS) of polystyrene (PS)/PPFPA mixture and selective removal of PS. Attributing to excellent amine-reactive property of PPFPA, porous amine-reactive (PAR) films enable imparting versatile physiochemical functionalities on surfaces via sequential post-polymerization modification. Amine-containing molecules (i.e., amine-polydimethylsiloxane (amine-PDMS) and dopamine) and silver nanoparticles (AgNPs) were introduced on PAR films in serial order, followed by silicone oil infusion into PAR films.

Antibacterial efficiency of the developed surfaces was assessed for both Gram-negative bacteria (*Escherichia coli*, *E. coli*) and Gram-positive (*B. cereus and S. aureus*). We confirmed that lubricant-infused PAR films inhibit adhesion of not only waterborne bacteria but also airborne bacteria. To the best of our knowledge, this is the first study to utilize slippery surfaces as antibacterial surfaces for airborne bacteria. According to previous studies, contact-killing strategy is necessary to minimize airborne bacterial adhesion, the lubricant infused surfaces were insufficient to prevent airborne bacteria adhesion thoroughly. On the contrary, the AgNPs incorporated lubricant infused surface showed nearly perfect antibacterial efficiency for airborne bacteria owing to bacterial resistance of AgNPs. Furthermore, the L-infused Ag@DP-PAR possessing contact-killing activity has potential to be sustained longer than biocide-leaching system and to have lower toxicity. The aim of this work is to develop efficient and multimodal antibacterial surfaces toward both waterborne and airborne bacteria as the first proof of concept for application of PAR films with multi-functionalities by post-modification. Thus, the platform presented in this study suggests a new door to develop an effective multimodal anti-biofouling surface.

Preparation of Ti-Al-B Reactive Metal Powders from Titanium Borohydride Matthew Finn and Albert Epshteyn; U.S. Naval Research Laboratory, United States

Reactive materials aim to release large amounts of energy in a rapid yet controlled fashion. These materials include but are not limited to; thermites, intermetallics, or metal polymers which can be prepared from a variety of different metals and metal precursors. Titanium borides have drawn a great deal of interest as reactive materials; however, the high temperatures often required for their preparation results in materials with high hardness but low energy. Our group has previously reported a low temperature method for preparing hydrogen containing Ti-B materials from the decomposition titanium borohydride (Ti(BH₄)). This presentation details our work to optimize and expand upon this concept. Isolating and stabilizing the borohydride precursor affords greater control of the final materials. This allows for improved purity, more facile processing, and ultimately higher energy content. We can also control the inclusion of other metal additives such as aluminum. The resulting in Ti/Al/B materials have distinct properties compared to reactives prepared via other methods. The synthesis, processing, and characterization of these materials will be discussed.

3:30 PM FF06.03.02
Resodyn Acoustic Processing of Ni-Al for Cold-Spray Applications Ryan D. Macy, Michael J. Carter, Grant A. Crawford and Lori J. Groven; South Dakota School of Mines & Technology, United States

Metal-based reactive composites are a leading contender for use as structural energetic materials, but their utility is limited by low reactivity and relatively high ignition temperatures. Recent studies of the Ni-Al reactive system have shown that with the use of high-energy ball milling and subsequent wet grinding the ignition temperature can be tailored and be as low as 500 K. Therefore, we have extended this technique and demonstrate a processing technique using the Resodyn LabRam that allows bulk manufacture of reactive-composite powders suitable for cold spray use.
Following this, cold spray technology is demonstrated as a potential additive manufacturing technique to produce structural energetic materials. A baseline physical mixture of Ni-Al powder, milled Ni-Al nano-laminated composite particles, and other reactive composite particles are reported. Using a VRC high pressure spray system, nitrogen as the carrier gas and a deposit temperature of 100 °C, it is shown that the nanolaminate structure is retained and no pre-reaction occurs during deposition. The microstructure, mechanical properties, and combustion behavior of the as-deposited materials are also detailed.

Nanoporous Metals from Thermal Decomposition of Transition Metal Dichalcogenides Swarnendu Chatterjee, Yawei Li, Saad Intikhab and Joshua Snyder; Drexel University, United States

Development of nanoporosity on metals and alloys is a well-known pathway for making three dimensional high surface area structures especially useful for catalysis. Majority of the techniques are based on selective removal of a sacrificial metal from an alloy, a method known as dealloying. The driving force for the traditional electrochemical/chemical dealloying is difference of redox potentials and dissolution tendencies amongst the constituent metals. This limits the process to few noble metals e.g. Pt, Pd, Au etc. that can make homogeneous alloys with less noble metals. More recently liquid metal dealloying and vapor phase dealloying have been also identified to mimic the process of traditional dealloying based on difference of affinities of thermal dissolution in a liquid metal, and vapor pressures of the constituent metals, respectively. However, these are still restricted to few metals and the primary challenges lie with obtaining homogeneity in precursor alloy and limiting the pore size within 100 nm upon spinodal decomposition. Here, we present gas phase thermal decomposition of transition metal dichalcogenides (TMDs) as an alternative to dealloying that generates nanopores for a broader class of metals including refractory metals like W, Mo, Re etc. The chalcogen is removed from the surface by both reductive reaction with hydrogen and evaporation at elevated temperatures, which leads to the rearrangement and surface diffusion of the remaining metal atoms that evolve into an interconnected bicontinuous nanoporous network. Based on varying dynamics of pore formation and residual chalcogen contents for different TMDs, we have proposed a mechanism that emulates the decomposition process. The availability of vast library of TMDs having inherent atomistic homogeneity makes it a universal technique that can be utilized to make nanoporous metals.

How Synthesis and Processing Parameters Affect Reactivity of Sonochemically-Generated Ti-Al-B Reactive Metal Powders Albert Epshteyn, Matthew Finn, Rohit Jacob and Brian Fisher; U.S. Naval Research Laboratory, United States

Previously we demonstrated that the sonochemically-mediated decomposition of in-situ generated complex metal hydrides is a versatile methodology for the synthesis of unique metastable reactive mixed-metal nanopowders (RMNPs) that can be tuned for high energy content while also possessing other highly desirable solid fuel characteristics. In this latest iteration of our efforts to further improve the Ti-Al-B RMNP fuels, we made the effort to eliminate any parasitic impurities and focused on the sonochemically-mediated reaction process to evaluate the effects of the various synthetic and processing parameters on the final fuel properties. To that end we took the time to better purify the LiAlH₄, and then the syntheses were carried out using both the original approach of adding etheral solutions of LiAlH₄ and LiBH₄ to TiCl₄, as well as the reverse. We also employed a different approach of synthesizing the ether adduct of Ti(BH₄)₂, which was then reacted with LiAlH₄. The product powders were characterized for particle sizing and slow oxidation via thermogravimetric analysis, and subjected to careful elemental analysis via both ICP-OES of digests for metals content and combustion analysis for C, H, and N. New approaches were also explored in the compatibilization of the powders with HTPB cross-linking chemistry to produce RMNP-HTPB composites, the combustion behavior of which was then characterized in oxygen bomb
calorimetry, as well as heterogeneous strand-burn experiments. While the powders produced by different methods had similar elemental compositions, each of the newly produced materials reproducibly exhibited surprisingly unique combustion behavior.

Spherical Composite Powders Prepared by Mechanical Milling
Mehnaz Mursalat, Daniel Hastings, Mirko Schoenitz and Edward L. Dreizin; New Jersey Institute of Technology, United States

In energetic, pharmaceutical and other industries, dealing with spherical powders is attractive because of the ease of their handling and high flowability. Spherical powders are also of interest as feedstock materials for additive manufacturing. For metals, it is common to prepare spherical powders by atomization of melts, which is not suitable for most reactive materials. For non-metals, extrusion, spheronization, and emulsion polymerization are used, which are not compatible with many reactive materials sensitive to heating or having limited solubility in polymers. This work describes preparation of spherical composite powders of reactive materials by high-energy mechanical milling. Powders are ball milled in presence of two immiscible fluids (hexane and acetonitrile). It is observed that spherical composite powders are formed at a specific solid/liquid ratio, when the volume of solid is matched to that of acetonitrile. It is also found that the total volume of liquid must be at least twice as big as the volume of the solid powder. Reactive spherical powders were prepared with compositions of aluminum-rich thermites with copper and iron oxides as oxidizers, with an aluminum-boron composite as well as pure with aluminum, titanium, and boron. Additionally, spherical powders were prepared using fumed silica and iron oxide. Some of the formed spheres, such as those of fumed silica were not mechanically stable and easily fell apart, while others, such as those of aluminum or thermites were stable and could be easily handled. The powders were observed using optical and scanning electron microscopy. For selected powders, particle size distributions were measured. For both aluminum and boron the particle sizes became smaller at longer milling times. It is hypothesized that the spherical powders are formed from Pickering emulsions generated in the milling vial when the loaded liquid/solid mixture is mechanically agitated. Droplets of acetonitrile are expected to form in the continuous hexane phase and be stabilized by solid particles adsorbed to the hexane/acetonitrile interfaces. It is further hypothesized that because of the large amount of the loaded solid powder, the Pickering emulsion in this case coexists with a dense suspension of powder in hexane, the continuous phase. The presence of suspended powder makes it difficult to destabilize the emulsion droplets mechanically: when the surface is stretched and becomes unstable it rapidly adsorbs a suspended particle to become stabilized. The interaction of a dense suspension with Pickering emulsion droplets is proposed to lead to accumulation of the solid phase inside droplets, which causes formation of the spherical powders as observed here. Preparation, characterization, and reactivity of the prepared powders will be discussed.

SESSION FF06.04: Atomistic Modeling of Reactive Materials

Growth of Polycyclic Aromatic Hydrocarbons During Carbon-Fiber Processing from Density Functional Theory
Taishan Zhu1,1, Yanming Wang1,1, Jeramie J. Adams2, Jeffrey C. Grossman1 and Nicola Ferralis1;
1Massachusetts Institute of Technology, United States; 2Western Research Institute, United States

The growth of polycyclic aromatic hydrocarbons (PAH) is the chemistry dominating the formation of interstellar organic substances, various biogeochemical cycles and modern industry processes, but their mechanisms remain unclear. In this work, we study various cycloaddition mechanisms at intermediate temperatures (300-800 °C), including hydrogen abstract acetylene addition and polynuclear oligomerization, using first-principles approaches. Based on gas chromatography mass spectrometry measurements, we identify proxy molecules for heavy hydrocarbons such as coal tar pitch that is often used as a precursor for carbon-fiber processing. For a given molecular component and byproduct, rather than using the conventional bottom-up approach that hypothesizes growth from reactants, we develop a top-down framework to automatically enumerate all possible pathways through
splitting products to possible reactants, with molecular symmetry considered. These individual pathways are evaluated in a high-throughput manner, based on which a Bayesian description of cycloaddition mechanism is constructed. Moreover, the construction of such Bayesian mechanism at varying temperature reveals different mechanisms at different temperatures, suggesting different dominant pathways in the formation of large aromatic clusters in coal tar pitch processing leading to further insights towards the optimization of the synthesis of pitch-based carbon fibers. Moreover, the growth mechanisms could also give insights to other PAH chemical reactions, such as soot formation.

Modelling Energetics across Interfaces—Atomistic Molecular Dynamics Simulations of the Shock Loading of Reactive Nanolaminates Leah Granger¹, Jon-Paul Maria², Sergey Matveev³, Dana D. Diott¹ and Donald Brenner¹;
¹North Carolina State University, United States; ²The Pennsylvania State University, United States; ³University of Illinois at Urbana-Champaign, United States

Reactive inorganic nanolaminates containing metastable interfaces, such as those between metals and metal oxides, can undergo exothermic reactions when disturbed by heat or shock. While the chemical thermodynamics associated with reactivity in these systems is relatively straightforward, the mechanisms by which this chemistry is initiated are unknown. This is due in large part to the potential complexity of the dynamics and the challenges associated with experimental probes of dynamics at buried interfaces.

Using molecular dynamics simulations, we investigated the mechanisms by which the energy of a shock pulse delivered by a simulated flyer plate can initiate chemical mixing at a buried metal-metal interface. The simulations show plastic damage in the form of dislocations that are initiated at the edges of the flyer plate due to shear forces. This damage at the plate edges is consistent with recent experiments by Diott and co-workers in which the initiation of buried exothermic reactivity in a reactive nanolaminate is observed in a ring pattern that matches the flyer plate shape. Depending on the crystal orientation and the energy delivered by the flyer plate, the simulated dislocations can reach a buried interface. In the case of a Cu-Zr nanolaminate containing two buried layers with thicknesses of about 35Å, the dislocations were observed in the simulations to be terminated at the first interface, but with an elastic energy pulse that is transferred into subsequent layers. Hence the mechanisms by which energy is delivered across a series of buried interfaces may be different depending on the interface location with respect to the shock pulse. In these initial simulations little interfacial mixing was observed on a picosecond timescale. We will also discuss related simulations in which a simulated shock pulse is delivered across a buried metal-metal-oxide interface, where charge transfer and significantly exothermic chemistry play a large role that is missing from the dynamics of the buried metal interfaces.

This work was supported by the U.S. Department of Defense, Multidisciplinary University Research Initiative through the Army Research Office, Grant No. W911NF-16-1-0406.

Reactivity of Ni/Al and Ti/Al Nano-Composites—An Atomic-Scale Description Florence S. Baras and Olivier Politano; ICB, CNRS-Université Bourgogne Franche-Comté, France

Reactive materials based on metallic elements are produced by various methods. The basic method for the production of multilayer reactive nano-foils is the layer-by-layer magnetron deposition. The thickness of each layer may vary from several nanometers to microns, while the number of the layers "stacked" in one foil may vary from ten to thousands. An alternative and less expensive method for the production of reactive nano-foils is a mechanical method combining high-energy ball mill and cold rolling. The ball milled and cold rolled foils possess relatively high non-uniformity, intermittence, and tortuosity, as compared to the magnetron deposited films. However, nanometer-scale Ni and Al layers are present in the material. A very peculiar property of reactive multilayer nano-foils is that a reaction between pure metals initiated at one edge of the sample will propagate throughout the system in a self-sustained way. The heat released locally allows the reaction to proceed without any further supply of energy. During this talk, we will review the mean features of ignition and reaction in nano-layered metallic systems Me/Al, with Me=Ni or Ti. We will also give some insight into the effect of production by a mechanical method.

The understanding of the reaction mechanisms in reactive nano-composites relies on the study of reaction kinetics,
heat and mass transfer, as well as the dynamics of structural transformations. Besides the usual multi-physics description, the atomistic approach provided by Molecular Dynamics (MD) simulations becomes a useful tool in describing the behavior of reactive materials. MD simulations indeed give the basic atomistic steps leading to observed microstructure beyond any thermodynamic or kinetic modeling. MD simulations can be considered as a model that offers a counterpart to in-situ experiments to explore elemental mechanisms. In the case of nanometric metallic multilayers, MD proves to be a very appropriate method for numerical studies, as the accessible time and length scales are in the same range of magnitude as in “real” experiments. During this talk, we will review the main features of combustion synthesis in nanofoils considering Ni/Al as a model system [1]. The reactivity of Ti/Al nanofoils will also be analyzed. We will show how modeling and experiments are complementary approaches in order to detect intrinsic behaviors and reactive mechanisms.

In the second part of the talk, we will focus on the mechanical method of production. The idea here is to develop molecular dynamics simulations in order to study the possible elemental mechanisms (compaction, shear, plastic deformation, welding, fracturing,…) that can be observed during high energy ball milling. We will present our calculations to mimic the first impact due to grinding balls. A set of spherical Al and Ni (Ti) particles were submitted to a rapid compression. The compression produces compaction of the powder by removing empty spaces between the particles. Once the particles are compacted, they start to undergo plastic deformation. Indeed, the ductile Al mostly deforms whereas Ni remains more spherical. An increase in the number of atoms in mixing zones was observed. The detailed atomistic analysis allows us to follow the progressive amorphization, the formation of defects, the induced chemical mixing and the possibility of recrystallization due to this first hit. The ignition of such a system will be characterized.

Finally, we will show how large-scale MD simulations can handle more and more complex systems. We were able to consider complex nanostructures in order to understand the role of defects or intricate microstructure in nanostructured samples. As an example, we will show self-sustained propagation in a system made of disordered nanostructured grains.

The Role of Octylamine Ligands in the Stabilization of CuO Nanoparticles as a Determinant of the Al/CuO Redox Reaction Ségolène Palussière1,2, Jeremy Cure1, Pierre Fau2, Katia Fajerweg2, Myrtil L. Kahn2, Alain Esteve1 and Carole Rossi; 1University of Toulouse, LAAS-CNRS, France; 2University of Toulouse, LCC-CNRS, France

Among energetic materials, nanothermites are known for their high volumetric energy densities (up to 16 kJ/cm3), adiabatic flame temperature (> 2600 °C) and high reaction (burn) rates. One of the promising materials for integration into micro devices is Al/CuO nanocomposite because of its high enthalpy of oxidation-reduction reaction [1]. Increasing the contact surface between both components of the thermite composite should lead to improved properties. The control of the particles size, the morphology and the distribution of the nanoparticles inside the composite is therefore of paramount importance.

Recently, an original synthesis approach has been proposed to produce ultra-small CuO nanoparticles (ca. 5 nm) functionalized with octylamine ligands. This approach consists in the formation of the CuO nanoparticles by the
controlled hydrolysis and/or oxidation of an organometallic precursor (i.e. copper amidinate), in the presence of octylamine. [2] These usual ligands stabilize the CuO nanoparticles which can be beneficial to enhance the coating of Al particles with smaller CuO ones during the physical mixing. Thermally characterized by Differential Scanning Calorimetry (DSC), Al/CuO nanothermites thus produced react differently compared to those produced following the same mixing process but from commercial CuO nanoparticles.

Using a variety of characterization techniques, including microscopy, spectroscopy, mass spectrometry and calorimetry (ATG/DSC), the structural and chemical evolution of CuO nanoparticles stabilized with octylamine ligands are characterized upon heating. This enables us to depict the main decomposition processes taking place at the CuO surface at low temperature (< 500 °C) [3]: the ligands fragment into organic species accompanied with CO2 release, which promotes the CuO reduction into Cu2O and further Cu. Then an optimization process to overcome the ligands-induced CuO degradation at low temperature is proposed. Al/CuO nanothermite reaction is analysed, in terms of onset temperature and energy released.

Plasma-Based Synthesis of an Air Stable Polymer/Mg Nanocomposites for Hydrogen Storage Applications
Hui Liang1,2, Xi Geng2, Wenjiang Li2, Adriano Panepinto1, Minfang Chen2, Rony Snyders1 and Damien Thiry1;
1University of Mons, Belgium; 2Tianjin University of Technology, China

Hydrogen is considered as a promising alternative energy carrier due to its high energy density, great variety of potential sources, light weight and low environmental impact. Though the storage of hydrogen via Mg-based nanomaterials is very promising, the high reactivity of Mg towards oxygen leads to the easy formation of MgO, which blocks the penetration of hydrogen in the material, limiting the performance of the device.

In this work, in order to overcome this limitation, we propose to synthesize bilayer nanostructured Mg/polymer thin films using cold plasma-based processes. The process consists of two steps: (i) the synthesis of Mg nanostructured films by magnetron sputtering at grazing incidence and (ii) the coverage of the metallic nanostructured film by plasma polymerization from ethylene precursor. This method should allow (i) to control the porosity of Mg films by simply modifying depositions parameters such as temperature, incidence angle of the depositing particles (α) or pressure, and (ii) to avoid oxidation of the Mg-based nano-objects by protecting them with a highly cross-linked plasma polymer.

SEM characterization of the samples has revealed the presence of isolated Mg-based nanocolumns. Both the intercolumnar space (i.e. from 20 to 100 nm) and the diameter of the nano-objects (i.e. from 100 to 300 nm) depend on the incidence angle of the depositing particles. This evolution is directly related to the competition between surface diffusion and shadowing effect as confirmed by kinetic Monte Carlo methods. Mg-based nanostructures were homogeneously covered by a carbon/hydrogen-based plasma polymer which protects the films against oxidation. The obtained material reveals a high potential for efficient hydrogen storage.

Improving Boron for Combustion Applications
Kerrilee A. Chintersingh-Dinnall, Mirko Schoenitz and Edward L. Dreizin; New Jersey Institute of Technology, United States

Beyond their most common use for structural and catalytic purposes, metals are also great fuels due to their higher heats of combustion compared to traditional hydrocarbons. In particular, boron has been of interest as a high-energy density fuel additive in explosives and propellants. Some of the challenges are that boron particles tend to agglomerate, have lengthy ignition delays and very low combustion rates. Researchers have attributed the ignition delays to boron’s naturally occurring inhibiting oxide layer impeding further oxidation at low temperatures. For full-fledged combustion occurring at high temperatures when boron oxide is gasified, current studies report that boron particles burn in two consecutive stages; however, the actual reaction mechanism is poorly understood.

Despite many years of relevant research, quantitative combustion data on practically interesting, micron-sized boron particles are limited. Most proposed modifications to boron were designed to reduce its ignition delays by adding new chemical components and thus substantially diminished the energy density of the resulting composite material. Research aimed to accelerate boron combustion at high temperatures is generally lacking.

The motivation of this work was to achieve higher burn rates for boron powders without jeopardizing their
thermochemical performance, safety and stability and to develop an experimentally validated model adequately
describing oxidation kinetics for boron that can be used in practical simulations for a broad range of temperatures.
This study also was aimed to close the gap in data for combustion of fine boron particles in varying oxidizing
environments. Commercial boron powders were modified, and both as received and modified powders were used in
oxidation, ignition, and combustion experiments. Materials were prepared by mechanical milling or wet synthesis
techniques and burned in air, in hydrocarbon combustion products, and in steam/nitrogen environments. Combustion
and ignition characteristics were determined from optical measurements and images and described as trends of burn
times or ignition delays versus particle size. Strategies to modify boron’s heterogeneous reactions by functionalizing
its surface by organic solvents and using transition metals as “shuttle catalysts” have been explored. It was found
washing powders with acetonitrile removes hydrated surface oxide and reduces their ignition delays while not
leading to rapid aging and re-oxidation at ambient conditions. Doping boron with as low as 5 wt% of transition
metals (Fe or Hf) accelerates surface reaction rates leading to shorter particle burn times compared to the starting
commercial powder. A kinetic model was derived from low-temperature thermo-analytical measurements to
describe the oxidation of complex aggregated boron particles accounting for their surface morphology. Comparison
with particle combustion experiments showed that the same model can describe reactions at high temperatures
typical of full-fledged boron combustion, suggesting that the same heterogeneous reactions govern both ignition and
combustion of boron. Further, results suggest that the morphology of as received boron powders comprising micron-
sized agglomerates of finer primary particles does not always change to spherical droplets even at temperatures
exceeding the boron melting point. This leads to variation in burn rates and temperatures for various particles.

11:30 AM FF06.05.04
Tuning Reactivity of Al-CuO Thermites Prepared by Arrested Reactive Milling Using Liquid Process
Control Agents Mehnaz Mursalat, Mirko Schoenitz and Edward L. Dreizin; New Jersey Institute of Technology,
United States

Reactions in nanocomposite thermitites prepared by Arrested Reactive Milling (ARM) occur at the interfaces between
fuel and oxidizer and are affected by structure and properties of the interfacial layers formed during milling. For
many materials prepared by ARM, an organic process control agent (PCA) is used to limit cold welding which serve
as heat sink for the mechanically initiated exothermic reactions. While PCA directly controls shapes and sizes of the
powders being milled, the presence of an organic substance can also modify and functionalize the forming
interfaces, e.g., by forming carbide, oxycarbide, or nitride inclusions or even sublayers. Such possible effects are
explored here for Al-CuO thermitite. Previously, such thermitites were prepared by ARM using hexane as PCA. Here,
samples of Al-CuO thermitites were prepared using staged milling. In the first stage, Al and CuO powders were
individually pre-milled in acetonitrile, a polar PCA. The products were recovered, dried, and used in the second
stage milling, for which hexane served as PCA. In the second stage, pre-milled Al and CuO powders were combined
together or with respective as-received powders. The products were characterized by scanning electron microscopy,
thermal analysis and heated filament ignition experiments. Pre-milling CuO in acetonitrile did not affect properties
of the obtained thermitites. The samples including aluminum powder subjected to the first stage milling in acetonitrile
were found to ignite at a lower temperature and have stronger low-temperature exothermic reactions. When as
received aluminum was processed using hexane only, the ignition temperature did not depend on heating rate,
suggesting that the ignition was governed by a phase change occurring at the Al-CuO interface. Conversely, for
thermitites prepared using aluminum pre-milled in acetonitrile, the ignition temperature increased with heating rate,
suggesting that a reaction with thermally activated kinetics lead to ignition.

11:45 AM FF06.05.05
Functionally Grading Density in Thin Films of Energetic Materials for Detonation Wave Shaping Eric C.
Forrest, Robert Knepper, Michael P. Marquez and Alexander S. Tappan; Sandia National Laboratories, United
States

Physical vapor deposition (PVD) of energetic materials, including high explosives such as pentaerythritol
tetranitrate (PETN), has enabled an unprecedented level of control over energetic material morphology and
microstructure compared to traditional powder processing techniques. Previous research demonstrated the ability to
control the crystal orientation, grain size, and subsequent density and porosity of PETN films, through manipulation
of substrate surface energy alone. This has profound implications for initiation sensitivity and detonation wave
velocity in crystalline high explosives, which are strongly dependent on grain size, porosity, and unreacted explosive
material density, respectively.
In this study, we investigate novel methods to create functionally graded density in thin films of PETN for the purpose of detonation wave shaping. Specifically, we alter local substrate surface energy to attain desired morphology of PETN, with low surface energy areas used to create porous regions in the PETN film, and high surface energy areas to create denser regions. The technique is demonstrated with both simple linear geometries as well as more complex shapes using different masking and deposition techniques. Energetic film thicknesses range from approximately 10 µm to 100 µm, with relative, controlled density variations of 10-20% achieved in a single deposition. Characterization results for the energetic films, including scanning electron microscopy, surface profilometry, and X-ray diffraction, are presented. Scanning electron microscopy of surfaces and of fracture cross sections portrays the variation in microstructure and density achieved across PETN films. Pole figures taken at different locations on the energetic films demonstrate differences in crystalline orientation that contribute to observed density changes.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc. for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525. SESSION FF06.06: Applications of Reactive Materials II
Session Chairs: Michael Abere and Michael Zachariah
Tuesday Afternoon, December 3, 2019
Hynes, Level 3, Room 308

1:30 PM FF06.06.01
Neutralization of Chemical Warfare Agent Simulants DIMP and TEP Using Al/Mg/Zr Composite Metal Powders Preetom Borah¹, Rylie Lodes², Adam Sims², Nick Glumac² and Timothy P. Weihs¹; ¹John's Hopkins University, United States; ²University of Illinois at Urbana-Champaign, United States

Reactive composite metal fuels synthesized from varying amounts of Al, Mg, and Zr have previously shown promise in bio-agent defeat applications due to their high combustion efficiency, low ignition thresholds, and tunable combustion processes. Here, we report preliminary results on the efficacy of these powders for the related application of chemical agent defeat. Composite metal powders synthesized using high energy ball milling were ignited using PETN explosive charges in a combustion chamber containing chemical agent simulants Diisopropyl methylphosphonate (DIMP) and Triethyl phosphate (TEP), separately. Once the powders are ignited, the heat from combustion vaporizes the liquid simulant and then continues to burn. Burn times and reactive metal particle temperatures were evaluated using two-color pyrometry in conjunction with high speed videography. The concentration of DIMP and TEP were monitored over time, utilizing quantum cascade lasers (QCLs) for infrared spectroscopy, and we observe a reduction in the concentration of both species over the time period of microseconds. The composition of the powders was varied to monitor the effect of Al/Mg/Zr ratios on the rate of decomposition and the overall surrogate neutralization capability. Comparisons were also made between the synthesized composite powders and similarly sized Al powder. Lastly, scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were utilized to observe the microstructure of post-reaction oxide materials. Taken together, the collective data set demonstrates the ability of composite metal powders to neutralize these chemical agent surrogates.

1:45 PM FF06.06.02
Environmentally Friendly Time Delays Based on Reactive Nanolaminates Shane Q. Arlington, Joey Chen and Timothy P. Weihs; Johns Hopkins University, United States

Both commercial and military explosives frequently rely on time delays, devices which are triggered from some external event and, after a precisely controlled time, initiate detonation of the explosive charge. The design of these...
devices typically includes a delay column which controls the time between the external trigger and the propagated signal by means of a controlled exothermic reaction. Typically, these reactions involve hazardous materials such as lead oxides, chromates, and azides. While there has been a push to remove or mitigate the hazardous materials used in these delays, no comparable low-cost environmentally friendly alternatives have yet been widely adopted. Nanolaminates such as Ni/Al are known to react in a controllable and consistent self-propagating manner and can be fabricated with environmentally friendly materials. However, their reaction velocities are typically too high for chemical time delays manufactured into small and simple geometries. Here we present a method to dramatically reduce the reaction propagation velocity of nanolaminate films through architectural control of the sample substrates. By depositing reactive nanolaminates on woven polymeric meshes, we can reduce the velocity by orders of magnitude while maintaining the desirable levels of sensitivity, shelf-stability, and scalability of production of typical multilayer films. In this work, we explore the reaction behavior of these on-mesh delays as a function of the reactive thin film properties, as well as the properties of the underlying substrate. We will present a model for the underlying mechanisms of the interrupted propagation which slows the net velocity, and we propose designs for integrated delays based on these materials.

2:00 PM *FF06.06.03
Electromagnetic Control of Energetic Materials—A Prelude to Smart Energetics Travis Sippel; Iowa State University, United States

The future of energetic systems may require on-command tuning of energy output: In-mission control of solid rocket motor thrust to meet revised trajectories, dynamic control of countermeasure light emission to overwhelm advanced ordnance guidance systems, and in-flight sensitization/tuning of ordnance energy release. This talk presents recent materials fabrication strategies through which electromagnetic control can be designed into energetic materials. Materials strategies enabling localization of microwave energy deposition to the gas phase flame, the condensed phase, or the burning surface are discussed with application to solid propellant burning rate control, ignition, and extinguishment; dynamic control of pyrotechnic luminosity and color chroma; and thermites and propellants with thermally switchable microwave ignitability. Functional grading of the condensed phase as well as models of condensed phase absorption are also discussed. Finally, future directions and applications of dynamically controllable energetics are proposed, including synergies with other recent advances.

2:30 PM BREAK

3:00 PM FF06.07.01
Role of Grain Boundaries and Columnar Microstructures on Atomic Diffusion and Combustion in Ni/Al Nanolaminates Brandon Witbeck1,2 and Douglas E. Spearot1; 1University of Florida, United States; 2Air Force Research Laboratory, United States

Ni/Al nanolaminates are reactive composite materials with highly customizable combustion characteristics. These characteristics can be modified by altering system nanostructure through high precision synthesis techniques like physical vapor deposition (PVD). PVD has also been shown to form grains with diameters on the order of a single layer thickness and grain boundaries (GB) that may extend through the Ni/Al interface across multiple layers. The current work uses molecular dynamics simulations to investigate the effects of grain size and specific GB structures on Ni/Al nanolaminate combustion. Reaction rates are shown to increase with decreasing grain size on the same order of magnitude as increases caused by reductions in bilayer thickness, the fundamental attribute typically used to characterize nanolaminate combustion. Reaction peak temperatures are also shown to increase with decreasing grain size. To assess the role of specific GB structures, minimum energy GB structures are constructed and simulated in Ni/Al nanolaminate combustion. Effective diffusion coefficients are computed for each GB. Arrhenius descriptions of diffusion are constructed and shown to be a function of both GB structure and concentration, revealing stronger...
GB effects at temperatures below the Al melting point. Finally, GB effects on diffusion are shown to affect published continuum-scale calculations of both Ni/Al nanolaminate ignition temperature and combustion wave velocity.

**Effect of Bilayers Arrangement on Self-Propagating Reactions of Thermite Reactive Nanolaminate Films**  
Petra Hanusova and Jon-Paul Maria; The Pennsylvania State University, United States

Reactive nanolaminate (RNL) multilayer thin films, as a family of energetic materials, attract large attention recently due to the large storing capacity over a long term and its capability of tuning energy and power output. Despite the termite reaction has been known for decades, the fundamental transport mechanisms during oxygen exchange between reactants needs to be examined more carefully to understand how the released energy can be tuned and controlled. This work studies the phase transformations and properties of ZnO/Zr RNL films grown by physical vapor deposition (PVD) as the main synthesis method in producing well-defined interfacial areas and excellent control of reactant layer spacing and stoichiometry. Thermal annealing was performed to ignite the exothermic reaction between individual layers, and the resulting phase transformations and reaction products were analyzed by means of X-ray diffraction (XRD) analysis. We found that the RNLs reacted to completion, as seen by the presence of the terminal metal Zn and the terminal oxide ZrO₂, measured by XRD. Furthermore, XRD reveals that in the RNL films, adjacent layers react and form an intermetallic intermediate, which provides additional energy to the system and assists the thermite reaction to completion. In addition, differential scanning calorimetry (DSC) and ultrafast shock spectroscopy were used to study how numbers of layers and interface density influence the reactive and thermal behavior of RNLs. The DSC results showed the activation energy decreases with increasing numbers of bilayers. In other words, larger interfacial area, increases the RNL reactivity.

**Microstructural and Mechanical Property Characterization of Reaction Synthesis-Produced Aluminum Metal Matrix Composites**  
Ethan Sullivan¹, Jacob Nuechterlain², A. Polizzi², Jeremy Iten², Stephen Liu¹ and Marcia Domack³; ¹Colorado School of Mines, United States; ²Elementum 3D, United States; ³NASA, United States

Wrought aluminum alloys, particularly those exhibiting high strength, are already seeing extensive use in aerospace and automotive applications given their high strength-to-weight ratio. Additive manufacturing (AM) of these alloys has grown more commonplace in an effort to meet the demands of these industries while overcoming the limitations of conventional manufacturing processes. However, many alloys of this class possess a propensity for solidification cracking, resulting in reduced ductility and tensile strength, which tends to make them unsuitable for welding and AM processes. Also, especially for aerospace applications, higher stiffness and more robust high-temperature properties are desired of these alloys. Addition of ceramic particulates to an aluminum alloy matrix to form a metal matrix composite (MMC) has been shown to both mitigate solidification cracking and achieve these desired properties. For ideal minimization of solidification cracking and to ensure uniform mechanical properties, the reinforcement phase must be uniformly distributed and possess a small mean diameter. Reaction synthesis refers to the reaction between precursor materials to form nanoscale particles that act as grain refiners or material reinforcement. Particles are formed in-situ during welding and AM processing through an exothermic reaction. Reaction synthesis can be used to form ceramic or intermetallic products that serve as the reinforcing phase in a MMC. Reaction synthesis is also able to address the poor wettability of the ceramic phase with the aluminum matrix through the presence of much higher temperatures during the reaction.

In this work, aluminum-based reactive additive manufacturing (RAM) powder blend feedstocks are employed in welding, laser powder-bed fusion (PBF), and electron beam freeform fabrication (EBF³) processes to examine the effect of feedstock composition and morphology on microstructure and mechanical properties. Blended powder was the feedstock for the laser PBF process and powder core filled wire was the feedstock for welding and the EBF³ process. The RAM feedstocks were characterized using scanning electron microscopy and particle size analysis. X-ray diffraction confirmed the presence of ceramic and intermetallic secondary phases in material fabricated using the RAM feedstocks. Light optical microscopy and electron back-scatter diffraction were used to examine texturing and the extent of grain refinement among the various feedstock compositions and the different fabrication processes. ASTM subsize tensile and Charpy specimens were used to measure the tensile strength and impact energy of materials produced by each process. Finally, differential thermal analysis was used to compare the heat evolution
during solidification of the RAM powder feedstocks compared to inert aluminum powders.

**Tailoring Reaction Temperature and Propagation Velocity in Ni/Al Multilayers—Understanding and Preventing Substrate Quenching**  
Stefano Danzi, Maxence Menetrey, Jelena Wohlwend and Ralph Spolenak; ETH Zurich, Laboratory for Nanometallurgy, Switzerland

Ni/Al multilayers are reactive nanostructures consisting of alternating Ni and Al layers that can release heat through a self-sustained propagating exothermic reaction. Sparked by advances in physical vapor deposition, the renewed interest towards these materials propelled over the past two decades the development of applications where the multilayers’ heat release is targeted towards a specific functionality. Prominent examples include the development of miniaturized heat sources for micro-propulsion and on-demand healing of metal thin films. In many cases, however, Ni/Al multilayers are designed to work in intimate thermal contact with other components, or on a specific substrate, which act as heat sinks by extracting heat from the propagating reaction front. These conductive losses may reduce both the maximum temperature and the propagation velocity of the reaction until a point where the propagation is ultimately quenched, a process that so far has only been qualitatively observed. In this work, we study the influence of thin film heat sinks such as gold, copper and silicon, on the propagation velocity and temperature of the self-sustained heat wave produced by the NiAl intermetallic-forming reaction. Both the reaction temperature and propagation speed are shown to be linearly decreasing functions of the heat sink thickness up to a critical thickness for which the reaction propagation is completely quenched (~350nm for gold and copper, ~1.3µm for silicon). Further, we demonstrate that a multilayer Al₂O₃/Zr/Al₂O₃ thermal barrier between the heat source and the heat sink prevents reaction quenching and enables stable propagation in otherwise quenched conditions. The results of this study provide a detailed overview of the propagation behavior of Ni/Al multilayers on thin heat sinks and demonstrate that the reaction propagation can be critically controlled and eventually stopped by varying the thickness of a thin heat sink. Together with the introduction of a nanoscale thermal barrier, these results will facilitate the integration of Ni/Al multilayers as intrinsic heat sources on different substrates for applications in micro/nano-devices.

**In Situ High-Speed Simultaneous X-Ray Phase Contrast Imaging and Diffraction for Dynamic Temperature and Morphology Measurements**  
Ibrahim E. Gunduz; Naval Postgraduate School, United States

High-strain mechanical loading of polymer-bonded explosives can produce significant localized heating due to microstructural heterogeneities. Detailed in-situ observations of the processes governing the generation of heat in these materials are challenging, yet they are important for improving predictive modeling tools for safety and performance. Here we report on a novel high-speed, high-resolution in-situ synchrotron x-ray diagnostic, combining phase contrast imaging with diffraction during heating of an explosive particle in a binder. We demonstrate that the morphology changes can help identify heating mechanisms, whereas the measured diffraction spot shifts from the single crystal can be used to track in-situ temperatures, verified by thermal modeling based on infrared camera measurements on the outside surface of the samples.

4:30 PM FF06.07.06  
**Effects of Post-Processing on Sol-Gel Synthesized Hard Magnetic Nanoparticles**  
Keri A. Ledford, Jason H. Nadler and David Reid; Georgia Tech Research Institute, United States

Hard magnetic nanoparticles have been synthesized by a solution-based combustion method. Strontium hexaferrite (SrFe₁₂O₁₉) was prepared by a sol-gel approach that allowed stoichiometric control of the nitrate-citrate gel by complexing specific ratios of metal nitrates with citric acid, and the subsequent auto-combustion reaction resulted in nanometer range particles. Material structure was analyzed by x-ray diffraction (XRD), and the nanometer-range particle size and shape were characterized by scanning transmission electron microscopy (STEM) and dynamic light scattering (DLS). The effects of calcining on the crystal structure and particle coarsening were investigated and characterized by XRD, STEM, and DLS. The electromagnetic permeability of toroids, pressed from pre- and post-calcined nanopowders, were measured with a 7mm coaxial airline.
8:45 AM FF06.08.01
Microstructure and Mechanical Properties of Swaged High-Density Reactive Materials for Use in High-Velocity Impact Testing
Jesse P. Grant1, Kevin McNesby2 and Timothy P. Weihs3; 1Johns Hopkins University, United States; 2US Army Research Laboratory, United States

The need to counter weapons of mass destruction with reduced collateral damage in urban environments has necessitated the development of countermeasures containing pre-formed, dense reactive materials. A crucial first step in understanding the impact and combustion performance of high-density reactive materials compacts is to characterize the effect that processing has on the microstructure and mechanical properties of the compacts. Here, we discuss the fabrication and characterization of high-density, reactive metallic composites formed through radial forging (swaging). The composites are formed by mixing dense, elemental powders of tantalum or tungsten with ball-milled reactive composite powders comprised of aluminum, magnesium, and zirconium; these powder mixtures are then compacted to near theoretical density through room temperature mechanical swaging. We manipulate process parameters such as the size of the elemental and composite powders and the degree of swaging, and we characterize the impact on the resulting microstructures and mechanical properties of the dense composites. These properties will, in turn, be used to understand the fragmentation of the composites on impact, as well as their reaction products and energy release.

9:00 AM FF06.08.02
Shock-Induced Reaction Synthesis of Boron Nitride from Mechanically Activated GaN and B Nano-Composite
Wesley W. Chapman1, Josh Pauls2, Metin Örnek1, Alex Mukasyan2 and Steve Son1; 1Purdue University, United States; 2University of Notre Dame, United States

It has been shown recently that cubic boron nitride (c-BN) can be formed through the ultra-fast (0.1-5 µs) shock-initiated reaction of TiN and B, leading to the synthesis of TiB2 and BN. In this study, we have further investigated the synthesis of boron nitride using different precursor nitrogen sources, ZrN, GaN, Cr2N. The shock-induced reaction of a ZrN+3B system will be reported herein. The composite ZrN+3B nano-powders were produced through high-energy ball milling to provide intimate, homogenous, mixing and were subsequently shocked to ~20 GPa using a copper recovery capsule, copper flyer, and a PETN based explosive. X-Ray diffraction (XRD) and Fourier transform infrared spectroscopy (FTIR) has been used to identify the phases and chemical bonding characteristics of the shocked powder. XRD results confirm that the precursor powder system has successfully reacted and formed hexagonal BN (h-BN). FTIR spectra corroborated the formation of h-BN and revealed a band near 1100 cm⁻¹, which suggests the existence of c-BN or wurtzitic BN, or both. These results could pave the way for in-situ creation of impact resistant ceramics.

9:15 AM *FF06.08.03
Tuning the Breakup of Reactive Fragment Materials
Joseph Hooper; Naval Postgraduate School, United States

The reactive-fragment concept involves explosive or gun launch of a reactive material, which then travels some distance before impact on a target. Upon impact, the fragment should shatter into a fine debris cloud and begin combusting, creating either thermal or overpressure damage. These competing requirements create a challenge for material design, as the fragment must be sufficiently tough to survive energetic launch without failure but still brittle enough to break up catastrophically when impacting a target. The majority of materials that work well in this role are pure metal compositions that rely on aerobic combustion for energy release. Traditional powder metallurgy techniques like hot isostatic pressing have been the most widely employed for fabrication of reactive fragments.

In this talk I review several years of research (especially within the Navy) on the material properties, energy release,
and fragmentation of this subclass of reactive materials. The degree to which the material shatters on impact is critical for aerobic combustion, but efforts to rationally tune the energy release of reactive frags has been hindered by the lack of experimental fragmentation data. I will discuss our efforts to directly recover and analyze brittle debris from high-velocity reactive frag impact or explosive launch using soft catch media. This data has allowed the development of analytic fragmentation models which provide a first step towards more advanced continuum and mesoscale modeling efforts.

SESSION FF06.09: Advanced Manufacturing of Reactive Materials
Session Chairs: Michael Grapes and Timothy Weihs
Wednesday Morning, December 4, 2019
Hynes, Level 3, Room 308

10:15 AM *FF06.09.01

The mixing process of multimaterial systems can impart microstructure that can affect the overall material properties such as mechanical response and reactivity. In-line mixing has been implemented with a variety of feedstocks including siloxanes, sol-gel formulations, and reactive materials where the chemistry has been optimized for extrusion-based 3D printing. The behavior of the feedstocks requires additional characterization due to the complex fluid behavior present when introducing additional shear energy through mixing. This is especially true when mixing materials with vastly different densities, rheological behavior, and mechanical properties. The use of an active mixing printhead in 3D printing processes requires an understanding of how the processing dictates the microstructure and correlates to the resulting material properties. Characterization techniques such as mechanical testing and reactivity measurements are used to determine the connection between the microstructure due to the printing parameters, and the macro-scale behavior of printed structures. While in-line mixing has been utilized for a diverse set of materials, reactive materials are of special interest. Reactive materials benefit immensely from in-line mixing since the reaction kinetics can be controlled by printing parameters such as flow rate, mixing volume, and mixing speed. Additionally, the reaction is initiated in the mixing volume, reducing safety concerns when working with hazardous materials. An overview of multimaterial printing processes with an emphasis on reactive materials is presented.

10:45 AM FF06.09.02
Aqueous Dispersion of Hydrophobic Pigments at High Solids Concentrations Manish K. Mishra1,2, Alexander Katz1, Yijun Guo1, Antony V. Dyk3, James Bohling1, Ahmet Kusoglu2, Adam Z. Weber2, Kebede Beshah3, John Roper III1, Clayton J. Radke1 and Futiyani Wang1; 1University of California Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States; 3The Dow Chemical Company, United States

Controlling the surface chemistry of inorganic-oxide nanoparticles and their dispersion in water is an essential requirement for many technologies including ink and paint formulations. Competing requirements are typically encountered, when considering the necessity of water wettability of the nanoparticle surface in order to render low-viscosity aqueous dispersion on the one hand, and the need for water-barrier properties in the dried film on the other hand. Building on nearly a decade of advances in the surface modification and tailoring of surface chemistry of inorganic-oxide nanoparticles, which include poly(1→4)-β-glucan, alkylsilane-hexamethyldisilazane, and polysiloxane surface modification strategies, here we describe the synthesis of nanoparticles that exhibit a
combination of hydrophilic and hydrophobic character. These nanoparticles are hydrophilic in the wet state, and hydrophobic in the dry state, as characterized by capillary rise, contact angle, and water-uptake measurements. We describe the synthesis of such nanoparticles, and the importance of both electrostatic effects as well as steric effects of stabilization in aqueous dispersion, the latter characterized by $^{29}\text{Si}$ CP/MAS NMR spectroscopy and thermogravimetric analysis. We also study the flow behavior of the concentrated aqueous dispersion of modified-nanoparticles by rheometry, which reveals a low viscosity of the dispersions, thus making them ideal for applications.

**Development of a Dual Nozzle Vibration Assisted 3D Printer with Applications to Reactive Materials** Aaron Afriat, Monique S. McClain, Jeffrey F. Rhoads, Ibrahim E. Gunduz, Steve Son and John C. McCaw; Purdue University, United States

Vibration Assisted 3D Printing (VAP) is a new direct-write manufacturing approach in which a nozzle resonates to enable dynamic flow control with constant driving pressure. Recent work suggests that VAP is capable to print highly viscous composite materials and propellants with applications to variable geometry solid rocket propellant, gun propellant, biological materials, ceramics and more. Developing a dual-nozzle VAP printer integrates two materials in a variety of configurations to explore topics such as combined energetic materials. An open-source Fused Deposition Modeling (FDM) 3D printer is modified to incorporate two VAP printing heads, each including a transducer and a 5cc syringe in contact with an ultrasonic transducer tip. The transducers are connected to a function generator and linear amplifier to generate the vibration frequency and amplitude needed for extrusion. A dual output compressor generates back pressure to keep a constant flow of material. A UV light is also incorporated to cure UV-curable propellants. Either of the VAP heads can be swapped with a FDM head to incorporate hybrid VAP/FDM prints. Such application includes printing various geometries of a support structure for a reactive material. Developing a dual nozzle VAP is a desirable step to investigate a wider range of energetics applications as well as implementations outside of the field. Here we present initial results of a dual nozzle VAP printer with examples of potential applications.

**Using Architecture to Control Burn Properties of 3D Printed Al/CuO Thermite Structures** Elliot R. Wainwright$^{1,2}$, Kyle T. Sullivan$^1$ and Michael Grapes$^1$; $^1$Lawrence Livermore National Laboratory, United States; $^2$Johns Hopkins University, United States

Breakthroughs in additive manufacturing of energetic materials, particularly direct ink write 3D printing, have allowed for greater control of performance by manipulation of architecture and/or composition. Here, we demonstrate control over the self-propagating reaction properties of 3D printed Al/CuO thermite by generating lattice structures with various void contents and filament sizes. The thermite is produced via on-the-fly static mixing of constituent Al and CuO inks, decreasing the risk associated with handling such materials. By reducing the fundamental print width (i.e. filament size) and introducing even small amounts of engineered porosity, we show that energy release rates can be increased by more than 100x over full-density burn strips. We also report on unique channel structures, which display propagation velocities of over 100 m/s due to confinement of the hot gas and molten particles released by the thermite reaction. We present Ashby plots which demonstrate the design space for...
3D printed thermites and discuss the wide level of control we achieve over the energy release rate using architecture with a single thermite formulation.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-776741.

11:30 AM FF06.09.05
A Comprehensive Study to Investigate the Supramolecular Interaction of Low-Molecular-Weight Gelators and Ultraviolet-Curable Monomers Zuoxin Zhou, Lea Santu, Christopher Tuck, Derek Irvine, David Amabilino and Ricky Wildman; University of Nottingham, United Kingdom

Monomers containing acrylate/methacrylate functional groups have attracted intensive interest due to the ability to polymerize readily under ultraviolet exposure. However, it would have great benefits for many applications if a network could be pre-established to support the monomers. A promising approach is to use low-molecular-weight gelators, which are capable of forming a physical 3D network to entrap and immobilize liquids. This might potentially form a dual network, modifying physical properties (rheology, morphology and others) of composites. The aim of this study is to obtain comprehensive results via investigating the interaction between gelators and monomers.

Methodology: Nine thermo-responsive gelators (A-I) with different structures were investigated. Each gelator was mixed with 29 monomers at 10 mg/ml. Gel tests were performed using a Crystallisation Systems Crystal16. Samples were heated gradually from 20°C to 120°C and cooling back to 25°C. Light transmission was recorded for each sample to determine gelation temperatures. Gel stiffness was characterized using an oscillatory rheometer and xerogels morphology were characterised via SEM.

Statistical analysis has been performed to build the relationship between gelation and 10 monomer parameters including: molecular weight, atom account, partition coefficient, hydrophilic-lipophilic balance (HLB), polar surface area, refractivity, Reichardt’s polarity (E<sub>T</sub>(30)), Kamlet-Taft polarizability, hydrogen bonding donor, and hydrogen bonding acceptor. Hansen’s HSPiP software was also used to understand the gelation.

Results and Discussion: There were three bis-urea gelators that formed gels with a significant amount of monomers: A (20 monomers), B (18 monomers), C (12 monomers), and a cyclohexanone derivative (D) formed gels with 19 monomers. The bis-urea molecules provided strong hydrogen bonding as the driving force for molecules to self-assemble into fibrous network. However, the acrylate/methacrylate monomers may mediate the process of hydrogen bonding molecular recognition pathways. The cyclohexanone derivative was of particular interests because its supramolecular mechanism was primarily relying on π-π stacking and London dispersion force contributed by the alkyl chains. Linear symmetrical bis-ureas demonstrated their interaction with monomers was most influential by E<sub>T</sub>(30) (p value = 0.004, F value = 5.72). As for the remaining gelators, partition coefficient and HLB were the solvent properties that had the most significant impact on correlating gelator-monomer interaction.

The asymmetrical bis-urea exhibited morphologies of self-assembly into thick fiber bundles whereas the cyclohexanone derivative formed plate-shaped morphologies. However, the linear symmetrical bis-ureas formed intertwining flexible networks with primarily single-strand fibrils. The results indicated that hydrogen bonding tended to favor self-assembly into single-strand fibers whereas self-assembly via aromatic interaction lead to non-fibrous arrangement. The gels formed from bis-ureas and cyclohexanone derivative were in the same range of storage modulus with the highest achieved above 4000 Pa at 1 Hz and the lowest below 50 Pa. However, none of the gels formed from gelator C was above 800 Pa. Linear symmetrical bis-urea gelator with longer alkyl chain resulting in higher gelation temperature and lower stiffness due to partially forming crystalline precipitation. Extensive precipitation has been observed on the surfaces of the gels formed from L-cysteine-derived double hydrocarbon chain.

Model Materials to Develop Particle Chemistries for Reaction Assisted Additive Manufacturing Shane Q. Arlington, Shashank Vummidi Lakshman, Sara C. Barron, Jeffery B. DeLisio, Juan C. Rodriguez, Sharada Narayanan, Gregory Fritz and Timothy P. Weihs; 1Johns Hopkins University, United States; 2Charles Stark Draper Laboratory, United States

Recent developments in additive manufacturing have drastically improved the ability to rapidly prototype and assess product design and viability. However, for products with integrated electronics, the ability to 3D print devices incorporating electronic components is limited by the small number of conductive inks, such as nanosilver. As the
most common conductive ink, nanosilver's high surface diffusivity allows it to sinter at low temperatures, resulting in electric interconnects with low resistivity. However, that same surface diffusivity causes poor durability as the printed lines can fail due to electromigration even at moderate current densities. Here, we demonstrate a new pathway to creating stable, electrically conductive printer interconnects, wherein the powders used to formulate the ink have stored chemical energy which assists in the sintering process and produces a low-resistivity product phase. The particles contain pairs of elements, such as Zr-C, Ti-C, and V-C, that have high heats of reaction, embedded in a soft, low melting temperature and low resistivity matrix, such as Al or a Cu-Ag alloy. This technology allows for the use of stable conductive materials, such as carbides, which would otherwise necessitate very high processing temperatures. To investigate the selection of chemistries suitable for these reaction-assisted inks, samples with highly controlled composition and microstructure were generated via physical vapor deposition (PVD) and the effects of chemistry and ignition method on the product phases, resistivity, and microstructure were assessed. These PVD materials serve as model materials and provide a toolbox for tuning stoichiometry when developing commercially viable powders for reaction assisted additive manufacturing applications.

SESSION FF06.10: Reactive Behavior and Material Properties III

9:00 AM FF06.10.01
Interface Engineering with Metal Nanoparticles to Tune Ignition of Al/CuO Nanothermite Baptiste Julien, Jeremy Cure, Andrea Nicollet, Severine Vivies, Alain Esteve and Carole Rossi; LAAS CNRS, France

As typical energy storage materials, nanothermites which contain Al and oxide, have attracted much more attention for their broad potential applications in both civilian and military fields. They exhibit not only better combustion efficiencies and better ignitability compared to traditional monomolecular explosives but also the reaction outputs can be tuned thanks to the selections of fuels, oxidizers, architectures and reactant size allowing multiple actions. The performance and sensitivity of these materials are critically dependent on the properties of both active materials, Al and oxide, and their interfaces which control the reactants diffusion and thus reaction kinetics. Among nanothermites, sputter-deposited Al/CuO multilayers represent the state-of-the-art of energetic nanomaterials for tunable ignition to replace old hot-wire ignitor. To apply these 2D layered materials into products, it is now important to modulate the layers features in a controllable manner to fit the application requirements which are often contradictory in terms of ignition threshold, expected high for safety reasons, and reactivity. For example, decreasing the bilayer thickness below 150 nm permits to reach self-propagation velocities ~100 m/s but also led to instabilities and potential non-desired ignition, so that the materials can not be handled in a reliable manner. In this paper, we propose a new strategy based on utilizing uniformly distributed gold nanoparticles at the first interface to - upon thermal stimulation - generate reactive hot spots serving as ignition precursors. We first report a fast, low-cost and scalable approach to produce uniformly distributed gold nanoparticles onto the first sputtered CuO nanolayer using a photo-deposition method before sputtering the Al/CuO nanothermite on top. Then, we discuss the thermal-mechanical energy-transfer mechanisms that govern the initiation of redox reaction. Under thermal stimulation, Gold nanoparticles serve as localized-heat absorbers triggering locally the redox reaction and thus producing reactive micro-sized hot-spots. These hot-spots generate stress-induced mechanical rupture of the structure. The following disintegration of the layered material project Al droplets that burns into the environment. The ignition and flame characterization including emission spectra analyses as well as electronic microscopy observation completed in this work have allowed the construction of the following fundamental description of the ignition and reaction scenario in Al/CuO nanolaminates being ignited upon ultra-fast ramping. Upon heating the redox reaction begins between the Al and CuO reactant layers in the bulk material. In the reaction zone, the temperature quickly increases and produces localized highly stressed zones (hot-spots) leading to the disintegration of the nanolaminate before the entire Al reservoir has reacted. This explains why the observed flame temperature is above the Al vaporization point and, even, in some particular conditions, above the Al2O3 vaporization point. When the multilayer structure breaks apart, it disperses in the ambient unreacted, melted Al and CuO. Both continue to react, now with the additional possibility for unreacted Al to burn with environmental oxidizers such as those found in air.
Finally, we provide a perspective on the advantages of using gold nanoparticles as ignition triggers and suggest design strategies for highly efficient, stable while tunable Al/CuO nanothermites for commercial applications.

9:15 AM FF06.10.02
The Transition between Oxidation Mechanisms for Aluminum Clusters and Nanoparticles Kyle R. Overdeep, Claron J. Ridge, Yan Xin, Tonya N. Jensen, Scott L. Anderson and C. Michael Lindsay;
1University of Dayton Research Institute, United States; 2Air Force Research Laboratory, United States; 3Florida State University, United States; 4The University of Utah, United States

Micron-scale and nanometer-scale aluminum (nAl) particles are often considered attractive choices for fuels in energetic materials. In general, reaction rates increase as particle size decreases, owing to the increased surface area and reduced diffusion lengths between reactants. The oxidation behavior for aluminum nanoparticles >10 nm has been widely studied, and so has the oxidation behavior of clusters <1 nm (primarily for catalysis applications). These two regimes exhibit vastly different reaction mechanisms, but there is no experimental work observing oxidation behavior for intermediate size particles from 1-10 nm. The present study investigates this transition regime by producing unpassivated aluminum particles of this size range using Superfluid Helium Droplet Assembly (SHeDA), and then oxidizing the particles by rapidly transferring them from ultra-high vacuum (UHV) to ambient air. Scanning Transmission Electron Microscopy with EDS (STEM/EDS) and X-ray Photoelectron Spectroscopy (XPS) showed that particles < 4 nm vaporize upon oxidation while particles > 4 nm do not. We have hypothesized that this is a critical diameter, based on a rapid decrease in cohesive energy at this size, and is the threshold between the oxygen-etching mechanism of clusters and the heterogeneous oxidation of nanoparticles.

From Synthesis to Application—Al/Zr-Based Reactive Composite Metal Fuels Elliot R. Wainwright and Timothy P. Weihs; Johns Hopkins University, United States

The introduction of novel reactive metal fuels into various explosive, pyrotechnic, and agent defeat applications requires an understanding of how ignition, combustion, and large-scale performance properties are coupled and how they depend on powder properties. Here, we will discuss the last five years of research on Al and Zr-based composite metal fuel powders that are synthesized via the scalable method of high energy ball milling. We will describe the entire lifecycle of these materials, including their synthesis, initiation, and combustion at both the individual particle and macroscopic fireball scales. These composite fuels are unique in that they have independently tunable ignition and combustion properties that includes a two-stage burn process (vapor then condensed phase). The composite metal powders demonstrate a significant decrease in ignition thresholds and substantial increases in combustion efficiency and burn time relative to pure Al powders of similar or smaller sizes. Through collaborations with a variety of research groups at ARL, NSWC-IHEODTD, Argonne National Lab, and several universities, we have explored the fundamental ignition and combustion mechanisms of these composites using multiple methods such as laser-induced plasmas, heated filaments, and explosive launch tests. In this presentation, we will summarize the results of these collaborations, as well as our own work, characterizing the dependence of ignition and burn mechanisms on powder parameters that include microstructure, size, chemistry, and environment.

Algorithm-Improved High Speed and Non-Invasive Confocal Raman Imaging of Two-Dimensional Materials
Sachin Nair, Jun Gao, Qirong Yao, Michael H. Duits, Cees Otto and Frieder Mugele; University of Twente, Netherlands
Confocal Raman microscopy is an important tool to characterize two dimensional (2D) materials, but the low flux of generated Raman scattered photons significantly hinders its expanding applications. For metastable materials such as graphene oxide (GO), the low signal flux is aggravated by the requirement of an extremely low laser dose to avoid or minimize laser-induced sample damage. In this work, we introduce algorithm-improved Confocal Raman Microscopy (ai-CRM), a fast and non-invasive confocal Raman microscopy (CRM) method based on a combination of an electron multiplying charge-coupled device (EMCCD), and principal component analysis (PCA) guided data de-noising. Using graphene and GO as a proof-of-concept, we demonstrate that ai-CRM can increase the Raman scanning rate by at least one order of magnitude with respect to state-of-the-art works. Meanwhile, GO can be imaged at a laser dose that is 2 to 3 orders of magnitude lower than previously reported, to the extent that the influence of laser illumination on the properties of the material can be avoided. We show that ai-CRM enables fast and spatially resolved quantitative analysis, such as mapping the defect density of graphene sheets. It is also demonstrated that the method can be extended to fast imaging of other 2D materials including Molybdenum Sulfide (MoS$_2$), Tungsten Sulfide (WS$_2$) and Boron Nitride (BN), and the three-dimensional distributions of nano-composite materials. Since ai-CRM is based on general mathematical principles, it is cost-effective, facile-to-implement and universally applicable to many other materials as well as other hyperspectral imaging methods such as surface-enhanced Raman scattering, hyperspectral infrared microscopy, and photo-luminescent microscopy.

**10:45 AM FF06.11.02**  
**Non-Contact Density and Thermal Conductivity Measurements of Encased Organic Thin Films and Thin-Film Explosives** Elbara O. Ziade$^1$, Christopher Perez$^2$ and Eric C. Forrest$^1$; $^1$Sandia National Laboratories, United States; $^2$Stanford University, United States

Vapor-deposited thin-film explosives provided a pathway to fundamentally understand the physics of explosives initiation and detonation. However, the physical properties of vapor-deposited thin-films deviate from their bulk counterparts and must be carefully characterized. Specifically, density, which is a primary physical parameter in detonation performance, varies depending on the substrate and across the thickness of a vapor-deposited thin-films. A gravimetric measurement of density can be obtained by dividing the measured mass of the thin-film by its measured volume. Unfortunately, variations in film thickness and limitations in balance resolution result in large uncertainty in these calculations and limit our ability to reliably measure density.

In this work, we present a novel method for non-contact technique for density and thermal conductivity measurements of encased organic thin-films and thin-film explosives. Four films of indomethacin and an array of varying thickness pentaerythritol tetranitrate (PETN) thin-films were vapor-deposited on silicon and fused silica substrates. The samples with encased with aluminum and gold thin-films and the density of the samples was measured with Frequency Domain Thermoreflectance (FDTR). Our results are compared to those obtained through gravimetric measurements and are in good agreement and prove to be a more reliable method for local density measurements of thin-film explosives and demonstrate the applicability of our technique for future microenergetics research.

**11:00 AM *FF06.11.03**  
**Direct Observation of Shock-Induced Energetic Material Decomposition** Keith A. Nelson; Massachusetts Institute of Technology, United States

We have developed methods for laser-driven shock loading of energetic materials and direct observation of shock-induced energetic material decomposition [1-3]. Small RDX crystallites embedded in polymer hosts are subjected to focusing quasi-2D shocks, and shock propagation and material responses are observed with a multi-frame camera that can record up to 16 frames in a single event with as little as 3 ns between frames. The results from many shocked crystals consistently show decomposition occurring initially along a single well-defined crystalline plane, with additional decomposition following depending on the shock pressure that is reached. Chemical and physical decomposition are apparent from the images and from photoemission that is also measured in real time. Post-mortem SEM and ultra-small-angle x-ray scattering reveal shock-induced voids whose sizes and shapes depend on the extent of chemical as well as physical decomposition.

Increases in RDX sensitivity also are observed under some conditions. When multiple crystallites are in contact, decomposition occurs preferentially at the regions of contact where stress localization is likely. Multiple shocks also have profound effects on sensitivity, with the extent of decomposition induced by a first weak shock far less than the decomposition induced by a second weak shock delivered to the same crystal as the first. The method is well suited...
11:30 AM FF06.11.04
Mass Spectrometric Study of the Formation of Key Intermediates in Iron Oxide Synthesis Flames Yasin Karakaya and Tina Kasper; University of Duisburg-Essen, Germany

Synthesis of functional materials in flame reactors is a reliable method to produce pure nanoparticles or coatings with unique physical and chemical properties, which are of great interest to a wide field of applications as additives, e.g. in edibles and medicine. The properties of flame-synthesized nanoparticles strongly depend on the particle size. The size can be influenced, for example, by the temperature of the synthesis and precursor concentration. The network of chemical reactions of the precursor decomposition interacts with the flame chemistry and forms key intermediates that are involved in particle growth. Consequently, the fundamental understanding of the decomposition of the iron based precursor to key intermediate species and stable products and the inception of particles during flame synthesis is of major importance for planned synthesis processes. Time-of-flight mass spectrometric in-situ measurements of iron pentacarbonyl doped model flames can identify which species occur in the synthesis flames. This information is the first step in generating a reaction model of the chemical processes in flame synthesis.

In this study, the decomposition of iron pentacarbonyl (Fe(CO)5) and the reaction pathways in laminar H2/C2H4/O2/Ar synthesis flames at low pressure are investigated. For a chemically controllable synthesis and functionalization of tailored iron oxide particles in flames, gaseous intermediates that act as building units during particle formation have to be identified. The analysis of the neutral intermediates is performed with aid of electron ionization molecular beam mass spectrometry (EI-MBMS). The extraction of a representative sample from the particle-laden flow of a synthesis flame by using an intrusive sampling technique for the mass spectrometric analysis is an ongoing challenge, because easily condensing iron containing species can obstruct the sampling probe. As a result, species with the structure Fe-O-H are still difficult to detect. Naturally occurring cationic iron containing species can be extracted from the flame with a novel sampling technique, which reveals cationic reaction pathways in the flame. The sampling of naturally occurring cations from flames allows measurements with high sampling efficiency for iron containing intermediates, thus overcoming one of the major difficulties in the EI-MBMS work. Here, cations with the structure Fe(OH)2+/Fe(OH)2H+ revealing the presence of neutral Fe(OH)2 and the cations Fe(OH)3+/Fe(OH)3H+ allude to the presence of Fe(OH)2 and hydroxide clusters with the structure Fe2O3H+. This study sheds some light on the gap between precursor decomposition and formation of nascent particles in iron oxide synthesis flames. Data sets with concentration profiles of neutrals and cations are provided for the validation of kinetic reaction mechanisms in combustion synthesis processes.

Laser Ablation of Natural Carbonaceous Materials—Chemistry, Tunability and Applications Xining Zang, Cuiying Jian, Nicola Ferralis and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Polyaromatic carbonaceous materials (such as coal, tar, and pitch) are a family of materials with extremely rich chemistry and complex structures, representing a massive opportunity for their use in a range of potential applications. However, a deeper understanding of their electronic and structural properties at the microscopic scale is essential before they can be utilized in applications that require targeted properties and performance as well as large-scale manufacturing. In this talk, we present our recent work using laser ablation as a processing tool to induce extremely high local temperatures in thin films of natural carbon materials. Our results reveal the laser thermal
effect can control the H:C ratio, sp2 concentration, and graphitic stacking which are key structural fingerprint
determining the electrical properties of processed carbon materials. The laser ablation of carbonaceous materials
involves two key steps dehydrogenation and restacking behavior of polyaromatic hydrocarbons (PAHs). The broad
tunability of the two factors result in a wide distribution of carbon materials crystallinity from amorphous to highly
graphitic, with a sequential broad distribution of conductivity up to $10^5$ S/m. Semiconducting carbonaceous
materials require relative high H:C, while highly graphitized carbon is desired for conductivity electrodes. Both
experimental and simulation results indicate a graphitic cluster formation mechanism of NPAHs involving aromatic
corea, alkane “glue” molecules, and additive aromatic agents. These results shed light on the potential of natural
carbon to be utilized in active components, and can be used to guide the tuning of their electrical, structural and
chemical properties, paving the way towards their use far beyond simply disposal or burning.

Characterization of Frontally Polymerizable Adhesives Daniel S. Camarda1, Matthew J. Lampe1, Alan J. Lesser1,
Dennis Volleberg2, Mark D. Minnichelli3 and Anna M. Mueller-Cristadoro3; 1University of Massachusetts Amherst,
United States; 2Eindhoven University of Technology, Netherlands; 3BASF, Germany

Frontal Polymerization is a reaction that, following initiation, releases sufficient energy to further polymerize,
creating a spatially propagating wave front. The present work utilizes this process in epoxy formulations where
frontal polymerization is driven by the exotherm released from cationic ring opening of the epoxide monomers.
Accordingly, this technology is advantageous in creating high-T_g, high-performing thermosets in that curing takes
place without the use of costly energy sources or VOCs. Frontally polymerizable epoxies are envisioned to have
relevance in a variety of applications where mechanical strength and chemical resistance is required. More
specifically, the use of frontally polymerizable epoxies as adhesives is investigated herein.

In this paper, the adhesion performance of a frontally polymerized formulation to a wide range of substrates is
investigated. Results discussing the influence of substrate properties, adhesive morphology, and boundary conditions
on adhesion will be presented in this work. Adhesion testing utilized a lap shear configuration and the shear stress
distribution was calculated using a shear lag model. This model was formulated to enable the calculation of the
stress distribution when adhering two substrates with different material properties. Consequently, an adhesion
investigation was facilitated where adhesion to one substrate was exceptional thereby promoting failure at another
material interface. Further, in all cases at least one interface was selected to be transparent, allowing for in-situ
measurements of the polymerization propagation rates and resulting morphology. Herein, the mechanisms of
adhesion to the various substrates will also be discussed.

A Reaction Violence Test for Safety Screening of Thermites Kyle T. Sullivan and Eric Avalos; Lawrence
Livermore National Lab, United States

The reaction mechanisms in thermite powders is a highly complex process, and involves various non-equilibrium
and equilibrium processes as fuel and oxide particles react to form mixed-phase products on a rapid time scale.
Understanding this process involves understanding of the various length and time scales and how they contribute to
the reaction processes. Fundamental studies can help better our understanding of the reaction mechanisms,
specifically as they pertain to safety and performance. In this work, we present a small scale test designed to
evaluate the reaction violence of thermites at the formulation scale. A small charge is placed at the sealed end of a
clear, acrylic tube, and ignited. This results in rapid entrainment and flow of the powder. The velocity of this flow
can give a relative ranking of the pressurization, as intermediate gases are released and drive this flow. The burn
time of the dispersed powder can yield information about the thermal profile, which is important to know when
evaluating heating effects such as damage to a target or safety shielding requirements. The test can easily be
modified as-needed, but is an important first step in evaluating the safety characteristics of new materials, and towards developing a better fundamental understanding of how the material attributes can control this behavior. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-760652.

In Operando High-Speed Microscopy and Thermometry to Track Reaction Propagation

Dylan Kline1,2, Haiyang Wang2 and Michael R. Zachariah2; 1University of Maryland, United States; 2University of California, United States

Understanding structure-function relationships is exceedingly difficult because the characteristic length scale of the microphysics (composition and thermal gradients) is usually much smaller than the characteristic length scale of the measurement. To address this mismatch we employ a new high-speed microscopy/thermometry capability that enables ~ μs time and ~ μm spatial resolution as applied to highly exothermic reaction propagation. This enabled us to directly observe reactive sintering and the reaction front at high spatial and temporal resolution.

We show the usefulness of this approach for three specific examples. An important proposed mechanism in nanothermites reactions – reactive sintering – plays a significant role on the combustion performance of nanothermites. Experiments on the Al + CuO nanocomposite system reveals a reaction front thickness to be ~30 μm and temperatures in excess of 3000 K, resulting in a thermal gradient in excess of 10⁷ K m⁻¹. The local microscopic reactive sintering velocity is found to be an order of magnitude higher than macroscale flame velocity. In this observed mechanism, propagation is very similar to the general concept of laminar gas reaction theory in which reaction front velocity ~ (thermal diffusivity x reaction rate)¹²⁻¹

In a second example, recent studies have demonstrated a counterintuitive result in that additives with thermally insulating properties – notably SiO₂ particles – can enhance the propagation rate in solid propellants. Using high-speed microscopy and thermometry on 3D printed solid propellant films containing both thermally conducting (graphite) and insulating (SiO₂) to investigate the role of these additives on film propagation rate. It was found that addition of SiO₂ particles increased the effective surface area of the reaction front through inhomogeneous heat transfer in the films, and that such corrugation of the reaction front area on the micron scale manifests itself as a global increase in the propagation rate on the macro scale. Graphite additive was observed to have a substantially lower burning surface area and propagation rate, suggesting that the effect of reaction front surface area is larger than the effect of thermal diffusivity for low-weight percent additives in solid propellants. In the last example we will demonstrate how the use of microwaves can be used to initiate and moderate burn rate using metal coated nanoparticles that optimize absorption.

In-Depth Understanding of Reactive Aluminum/Aluminum Iodate Hexahydrate Nanoparticles via Advanced Material Characterizations

Chi-Chin Wu1, Jianguo Wen2, Scott D. Walck3, Jennifer L. Gottfried1 and Rose A. Pesce-Rodriguez4; 1U.S. Army Research Laboratory, United States; 2Argonne National Laboratory, United States; 3Service Engineering Inc., United States

Metallic nanoparticles, such as nano-aluminum (nAl), are promising candidates as the next generation energetic additives for improved combustion and detonation effects in explosive/propellant formulations. Their high theoretical energy content and potentially rapid burning of nAl, enabled by the high surface area to volume ratio, are very desirable characteristics for energetics. This work aims to enhance fundamental understanding of the chemical and structural properties for reactive aluminum-aluminum iodate hexahydrate (AIH) composite nanoparticles. The composites were produced by treating commercial nAl particles (60-100 nm average particle diameter) with helium and argon inert plasmas using custom-designed atmospheric dielectric barrier discharge reactors followed by subsequent mixing with acidic iodic solution (HIO₃) to form the energetic oxidizing salt, aluminum iodate hexahydrate (AIH) on the nAl surface. High resolution transmission electron microscopy (HRTEM) micrographs revealed unique miniature crystalline structures within the amorphous alumina (Al₂O₃) shell surrounding the crystalline Al core and at the outermost particle surface with only one to two monolayer thickness. Elemental maps obtained from scanning TEM (STEM) experiments demonstrated distinctly different distributions of AIH crystallites on the nAl surface for the nAl-AIH composites produced by different gases during the plasma treatment. X-ray photoelectron spectroscopy and Fourier transform infrared spectroscopy were used to study surface functional
groups of the nAl-AIH nanoparticles. This paper emphasizes the significance of exploiting advanced materials characterizations to enhance in-depth understanding of reactive nAl-AIH composites by revealing the plasma-dependent altered surface chemical and structural properties.

Analytical Prediction of Spin Band Widths in Co/Al Nanolaminates Michael J. Abere1, Catherine Sobczak2 and David P. Adams2; 1Lawrence Livermore National Laboratory, United States; 2Sandia National Laboratories, United States

The propagation of sputter deposited Co/Al nanolaminates is known to have a bilayer thickness dependent instability. The specific 2D instability observed involves the transverse propagation of a band in front of a stalled front commonly referred to as a “spin band.” Previous laser ignition studies have revealed that preheating to the point of pre-reaction removes enough stored chemical energy to slow propagation. Here, a single step diffusion limited reaction model is implemented into a time dependent heat spreading model to calculate the magnitude of pre-reaction ahead of a propagating front. To determine the amount of stored chemical energy lost as a function of pre-reaction thickness, films with product phase diffusion barriers were grown and characterized. This pre-reaction model is combined with an analytical calculation of propagation velocity, which allows for a prediction of quench length. The energy-depletion based model for spin band width is then tested on normally stable bilayer designs where instabilities have been induced through the addition of diluent product phase layers within the reactant layers.

This work was supported by the Sandia National Laboratory Directed Research and Development (LDRD) program. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under Contract No. DE-NA0003525. This work describes objective technical results and analysis. Any subjective views or opinions that might be expressed in the paper do not necessarily represent the views of the U.S. Department of Energy or the U.S. Government.

3:30 PM *FF06.13.02
3D Simulations of Reaction Front Dynamics in a 1:1 Co/Al Reactive Multilayer System David Kittell, Michael J. Abere and David P. Adams; Sandia National Laboratories, United States

Reactive multilayers are uniformly structured materials that may be ignited to produce rapid and localized heating. While this class of material is well-known, and has long been studied for a variety of applications (e.g. joining, brazing, or near-net shape forming of intermetallic parts), only recently have the related thermochemical reactions been implemented in large 3D computer simulations. Original modeling efforts through the early 2000s considered flame propagation in one dimension; this approach is useful to compare with the measured reaction front velocities and flame front thicknesses. Such 1D models provide physical insights into the material behavior, as velocity and front thickness are varied experimentally by controlling the multilayer periodicity and total film thickness. However, high speed videography has shown that the reaction fronts can be non-planar [1], for certain periodic spacings (i.e. bilayer), ambient temperatures, gaseous environments, as well as other design conditions. In particular, various instability modes have been observed, including auto-oscillation of the reaction front (1D instability), spinning reaction fronts (2D or 3D instability), and chaotic reaction propagation (3D instability). Such behavior may only be explored in large finite element analysis (FEA) codes (e.g. [2]), where the current state-of-the-art is thought to be on the order of 10 to 100 million elements for a reactive thermal analysis on modern high-performance computing resources.
In this work, an empirically-driven reduced order model for 1:1 Co/Al multilayers is implemented in Aria, a Galerkin FEA code developed by Sandia National Laboratories, and part of the SIERRA computational framework. The reduced model is a diffusion-limited reaction model based on the one by Hardt and Phung [3]; this model has been previously used to predict the ignition delay, propagation velocity, and quench limits for different Co/Al and Al/Pt multilayer designs [4]. Now, the reaction model is coupled to empirical thermophysical property data obtained from years of testing at Sandia. This includes: an anisotropic thermal conductivity model, mixture heat capacity, melting and phase change with formation enthalpies, piecewise continuous diffusivity with an Arrhenius dependence on temperature, and bilayer-dependent species concentration profiles. To summarize this implementation, we present the most up-to-date model fits for 1:1 Co/Al and the associated equations which are assumed to govern the reaction front dynamics. Next, large 3D simulation results show that the fully detailed model is able to predict planar as well as non-planar fronts, which are then examined for their heating rates and thermal gradients. From these simulations, it is hypothesized that real instabilities originate from nucleation sites. In order to artificially induce this nucleation, we show numerical initiation schemes that break the symmetry of the calculation, with different boundary conditions and multilayer edge geometries. Finally, one case of a spinlike reaction front is discussed in greater detail to compare and contrast with the mechanism originally proposed in [5].

**Modelling the Thermal Aging of Al/CuO Thermites in the Form of Nanolaminate Thin Films and Its Effect on Performances**

Guillaume Lahiner¹, Mehdi Djafari Rouhani¹, Nicolas Richard², Carole Rossi¹ and Alain Esteve¹;

¹LAAS-CNRS, France; ²CEA-DAM, France

Nanoenergetic materials deposited in the form of nanolaminates have been developed for welding purposes or as micro-initiators. One major advantage lies in their ability to be integrated on a chip via conventional MEMs fabrication techniques such as sputter deposition. Their integration and miniaturization in circuits open a number of new functional perspectives in miniaturized systems (security, actuation, local heat source...). One of the main obstacles to use these materials and deploy them at a large-scale is to guarantee and preserve their performance and safety under long term storage. To this end, predicting and quantifying the impact of thermal aging on nanolaminate structures and their energetic performance is of crucial importance.

Recently, an experimental investigation dedicated to the identification of a reaction scenario of Al/CuO nanolaminate at very low heating rate, typically used in Differential Scanning Calorimetry (a few tens of degree per sec.) has been proposed, establishing a number of basic mechanisms [1]. From low to medium range temperatures (<500°C), we evidenced that degradation of the nanolaminate is governed by the transport of oxygen across the growing layer of Al2O3 separating Al and CuO, exhibiting multiple steps with corresponding structural variants in the interface. On this basis, we developed a heterogeneous reaction model [2] integrating an ensemble of basic reaction mechanisms (oxygen diffusion, structural transformations, polymorphic phase changes) as the simulation core of a modelling platform, NICAM (for Nanolaminates Ignition Combustion and Aging Model) to: (i) simulate accelerated thermal aging, (ii) predict the effect of aging on nanolaminate performance in terms of combustion, flame propagation and initiation delay. We discuss “in silico” experiments with varying parameters such as layer thicknesses, stoichiometric ratio, initiation power, substrate thermal conductivity, or the size of the heating zone. For each case studied, we provide the nominal conditions of aging and how performance is altered, in terms of initiation delay, flame propagation and heat release.

[1] Structure and chemical characterization at the atomic level of reactions in Al/CuO multilayers, Iman Abdallah, James Zapata, Guillaume Lahiner, Benedicte Warot-Fonrose, Jeremy Cure, Yves Chabal, Alain Esteve, Carole
Interest in reactive nanocomposites has experienced massive growth due to the proclivity of these energetic materials to provide highly adaptable, attractive solutions to pyrotechnical problems requiring large amounts of energy in the form of heat or pressure. These nanothermites, constructed of a fuel-oxidizer pairing, produce extremely exothermic reduction-oxidation reactions with highly tunable properties including the gas production, flame temperature, burn rate, or visual effect. By adapting the thermite couple materials to produce the desired reactions, these nanoenergetic materials have applications in MEMS as heat sources or micro-initiators, the aerospace industry as solid propellant, propulsion systems, or space vehicle separation, mining time delay elements, among others. The study and characterization of different nanothermites and their reactions by experiment can be costly, difficult to standardize or quantify, and even dangerous to manufacture. Up to this point, many experimental studies and most numerical simulation of nanothermites have been based on the Al/CuO nanothermite due to the abundance of the materials and elevated base of understanding in the community, but it is not applicable for all possible domains. Computational modelization provides an economical, relatively quick, and safe method to characterize the different options available for these applications.

This work presents a novel phenomenological model based on the Deal-Grove diffusion/reaction scheme for mixed powder-based nanothermites. It is based purely on the condensed phase reaction, including diffusion of oxygen atoms across interfaces in addition to reactive sintering. These cause the initial agglomeration and melting of the mixed nanoparticles due to an external heating source that begins the self-sustaining reaction due to the exothermic reduction and oxidation of the metal oxide and metal fuel, respectively. With inputs such as the initial particle materials, size and nature, and associated properties, such as diffusion coefficient, the wetting contact angle of coalescence, the stoichiometric ratio, the compaction rate (as a percentage of the Theoretical Max Density), and the initiation method, results like the initiation delay, total burn time, and speed of steady-state propagation are produced. We first discuss the role of condensed phase mechanisms and sintering on the initiation of an Al/CuO mixture as a function of the heating ramp or initiation mode (resistive versus laser heating). This leads to a comparative study of the driving force in initiation between condensed or gas phase mechanisms. [1] A benchmark study is then completed on commonly used thermite couples, their initiation and propagation, with an emphasis on low-gas or gasless thermites for specific applications in mining or space domains. These simulated results are validated with available experiment where possible, with the hope that this information can provide a framework reference for new or existing applications looking for a certain range of pyrotechnical effects.

Quantum spintronics is an emerging field of spin coherence and spin correlations at or near room temperature, and their effects on a wide range of properties, including spin dynamics and light emission from color centers in solids, spin and charge transport in organic materials, spin-dependent transport in tunnel junctions, dynamic nuclear polarization, and animal sensing of magnetic fields. Room-temperature quantum spintronic systems can be much more sensitive to external perturbations than sensors that must be very near thermal equilibrium. Applications include sensing of magnetic fields in biological systems (e.g. color centers in diamond and other wide-band-gap semiconductors and insulators), control of light emission intensity from organic light emitting diodes (e.g. thermally-activated delayed fluorescence), spin injection, spin dynamics, and coherent optical interactions with single spins (color-center photonics). Highly sensitive room-temperature spin systems also feature prominently in proposals for very low power electronic logic.

This tutorial will provide an introduction to the materials and operating regimes that tend to exhibit room-temperature spin coherence and spin correlations, methods of calculating and measuring these properties, areas of initial application and critical open questions.

1:30 PM
**Theory of Quantum Spintronics** Michael Flatté, The University of Iowa

The theoretical criteria for a stable, room-temperature quantum coherent system will be described, and several examples will be presented. Methods of calculating the response of a quantum coherent system to external fields and perturbations will be presented, including density matrices, stochastic Liouville equations, and master equations. Recent progress in predicting specific quantum coherent systems, such as density functional theory for new color centers in wide-gap semiconductors, will be surveyed. The ideal performance of quantum spintronic devices will be compared with other sensors or information processing approaches.

2:15 PM
**Quantum Magnonics and Magnonic Materials** Ezekiel Johnston-Haperin, The Ohio State University

Magnon excitations of magnetic materials are of increasing interest for quantum applications due to their broad spatial extent and their potential to efficient coupling to systems ranging from isolated single spins to microwave and optical photons. One of the central challenges in this field is the identification of materials with sufficiently low loss to support these emerging applications. Critical materials constraints and the current state of materials development will be presented.

3:00 PM BREAK

3:30 PM
**Optical Coupling to Quantum-Coherent Spins** David Awschalom, The University of Chicago

Coherent coupling of light to spin coherent systems, especially for color centers in diamond and silicon carbide, will be described in detail. Nonequilibrium polarization/pumping, manipulation of the spin state, and efficient detection will be presented, along with criteria for pulse shaping that can be used for low-error manipulation of the spin state of a quantum coherent system.
The design, fabrication, and measurement of photonic devices that efficiently integrate a quantum coherent spin with a cavity will be described. Methods of manipulating the quantum spin to bring it into resonance with the cavity, such as through acoustic oscillations or electrical gates, will be presented. The figures of merit for spin-photon coupling will be derived and compared with state-of-the-art coupling of other quantum coherent systems.

**Electronic, Spin and Structural Properties of Er³⁺ Doped Yttria: Y₂O₃**  
Cuneyt Sahin¹,², Tian Zhong² and Michael E. Flatté¹,²,³; ¹University of Iowa, United States; ²The University of Chicago, United States; ³Eindhoven University of Technology, Netherlands

Rare earth ions in oxide materials have been extensively studied due to narrow transitions with long coherence times and high quantum efficiency between electronic levels of partially filled f-shells. This results in the fabrication of optical amplifiers with high quantum efficiency and optimal wavelength in telecommunication applications, high power solid-state lasers, and usage in optical storage, data, and quantum information processing [1]. Furthermore, yttrium oxide (Y₂O₃) as one of these oxide materials with a high dielectric constant has gained attraction for being an alternative for replacing silicon dioxide in metal-oxide-semiconductor devices [2].

Here we study electronic, structural, and spin properties of trivalent rare-earth element erbium (Er³⁺) impurities in the cubic bulk Y₂O₃ with a wide band gap of 5.8 eV. The primitive cell of the yttria has 40 atoms, however, a conventional bixbyite supercell with 80 atoms is used for impurity calculations. As one of the most promising dopants, Er³⁺ substitutes an yttrium atom at two symmetrically inequivalent and octahedrally coordinated cation sites (C₂ and C₃) with an equal probability. First, we compute structural parameters such as lattice constant and elastic properties within the density functional theory using a Monkhorst-Pack k-point grid of 2x2x2 for Brillouin zone integration, the generalized gradient approximation (GGA) with the Perdew-Burke-Ernzerhof exchange-correlation potential and the pseudopotential method in a plane wave basis. We also calculate the electronic band structure and the density of states of the bulk and doped yttria. The results of the electronic and structural calculations are in a good agreement with experimental measurements. Then we proceed to calculate the formation energies of Er³⁺ impurities as point defects at two different sites using the defect formation energy formula [3]. We
also investigate the formation energies of different charged states as a function of the Fermi level.

We also calculate individual defect properties such as level splittings and g-tensors using an effective crystal field Hamiltonian with Wybourne normalization and treat the Zeeman and hyperfine interactions as a perturbation. Group theoretical studies [4] show that the low crystal symmetry of Er\(^{3+}\) sites requires only a small number of crystal-field parameters to model energy levels of the dopants sufficiently. We show that g-tensor of the ground state that is calculated from this Hamiltonian is highly anisotropic with a large component along one direction. Presence of an abundant isotope of the \(^{167}\)Er with a non-zero nuclear spin and anisotropic g-tensor suggest that an experimental control of the spin dynamics of this system is possible through the Zeeman and hyperfine interaction.

We acknowledge funding from the Center for Emergent Materials, an NSF MRSEC under Award No. DMR-1420451 and by NSF EAGER Award No. 1843044.

1:45 PM MQ01.01.02
Nanoscale Structure of the Orbital Magnetic Moment of a Single Dopant Spin in a Semiconductor

Adonai R. Cruz\(^1\) and Michael E. Flatté\(^2,1\); \(^1\)Eindhoven University of Technology, Netherlands; \(^2\)University of Iowa, United States

The localized electron spin of a single impurity in a semiconductor is a promising system to realize quantum information schemes [1]. Coherent control of this spin depends on understanding the structure of the magnetic moment that couples the system with external fields. In this work we investigate the orbital contribution to the magnetic moment originated from the spin-orbit induced circulating current associated with the ground state of a single magnetic impurity in zincblende III-V semiconductor. This circulating current is dissipationless and represents an electron moving in a closed trajectory [2]. The orbital moment associated with the circulating current could be directly measured by the dc-magnetic field it produces through nanoscale magnetometry techniques provided by NV-centers in diamond [3].

In this project we developed a formalism employing Green's functions obtained by the Koster-Slater technique [4] with a sp\(^3\)d\(^5\)s\(^*\) empirical tight-binding Hamiltonian [5,6] to describe the host material. We calculated the circulating current and orbital moments of a single Mn dopant in GaAs. The spin-correlated orbital moments originates from the hybridization between the Mn(d\(^3\)) spin-polarized electrons and the As dangling bonds leading to t\(_2\)-symmetric triplet acceptor states in the band-gap above the valence band edge.

Electrical Manipulation of Isolated Quantum Spins Using Classical SiC Devices

Christopher P. Anderson\(^1\), Alexandre Bourassa\(^1\), K.C. Miao\(^1\) and David D. Awschalom\(^2,1\); \(^1\)The University of Chicago, United States; \(^2\)Argonne National Laboratory, United States

The neutral divacancy (VV0) in silicon carbide (SiC) exhibits robust spin coherence and a high-quality near-infrared spin-photon interface in a material compatible with mature fabrication techniques. Here, we make use of this
scalable semiconductor host and design electronic devices to manipulate embedded isolated quantum systems. Specifically, we create and isolate single VV0 defects in a commercial p-i-n diode [1]. This simple integration enables engineering of the defect’s charge environment and drastically reduces electric field noise. Surprisingly, the use of electrical gating results in mitigating spectral diffusion and achieving near-lifetime limited optical lines. Furthermore, by exploiting field confinement of the junction, we show that the optical transitions can be gate-tuned by nearly a terahertz. This geometry also provides a method for using electric fields combined with optical excitation to enable deterministic charge state control.

Applying gigahertz ac electric fields to SiC devices produces coherent interference in the form of Landau-Zener-Stückelberg fringes, arising from interactions between microwave and optical photons [2], even in the absence of a microwave resonator. We demonstrate lifetime-limited optical coherence and clock-like spin transitions that result in increased robustness against magnetic noise. Electrical driving of optical transitions offers advantages over spin-based coupling and points towards new types of hybrid quantum systems. These results reveal new opportunities for electrical manipulation of spin-based quantum systems in scalable SiC electronic devices.

This work was done in collaboration with S. L. Bayliss, A. L. Crook, P. J. Mintun, S. J. Whiteley, G. Wolfowicz, H. Abe, A. Gali, V. Ivady, T. Ohshima, G. Thiering, P. Udvarhelyi.

2:30 PM MQ01.01.04
Spin-Photon Interfaces Based on Tin-Vacancy Quantum Emitters in Diamond Matthew Trusheim, Lorenzo De Santis, Kevin C. Chen and Dirk Englund; Massachusetts Institute of Technology, United States

Inversion-symmetric quantum emitters in diamond, such as the silicon-vacancy, germanium-vacancy, and the recently-discovered tin-vacancy complexes, are promising candidates for quantum networking as their optical coherence is protected from electric field noise. Emitters containing a heavier element, such as Sn or Pb, are of particular interest as their large spin-orbit coupling reduces phonon scattering at easily achievable (non-3He dilution) temperatures, offering the possibility of long spin coherence – a key requirement for scalable quantum networks. Here we report on the development of coherent spin-photon interfaces based on Sn-vacancy emitters, including optical and spin coherence measurements and integration into nanophotonic devices. The narrow optical linewidths and long spin coherence times observed, combined with robustness to fabrication-induced damage, place the SnV among the best-known solid-state spin-photon interfaces.

2:45 PM MQ01.01.05
Quantum Emitters with Tailored Optical and Spin Physics Christopher J. Ciccarino1, Johannes Flick1, Isaac Harris1,2, Dirk R. Englund2 and Prineha Narang1; 1Harvard University, United States; 2Massachusetts Institute of Technology, United States

Color centers have emerged as leading solid-state “artificial atoms” for a range of technologies from quantum sensing to quantum networks. Concerted research efforts are now underway to identify new color centers that combine the favorable spin properties of the nitrogen vacancy (NV−) with the spectral stability of the silicon vacancy (SiV−) centers of diamond. Using a first principles approach, we investigate quantum defects in both 3D (diamond) and 2D (hexagonal boron nitride) hosts with the aim of unlocking and understanding the optical and spin physics. In diamond, we will discuss insights into Jahn-Teller interactions, including the product and dynamic Jahn-Teller distortions related to both group III and group IV color centers. Further, we show the instabilities and charge-states associated with each of these group III/IV defects and the implications in quantum information science related to both spin and spectral stability. In hBN, we discuss the origin of defect emission, in particular the importance of the level of theory invoked to describe charge states and defect-defect interactions.

3:00 PM MQ01.01.06
Vanadium Spin Qubits as Telecom Quantum Emitters in Silicon Carbide Gary Wolfowicz1,2, Christopher P. Anderson1, Berk Diler1, Oleg G. Poluektov2, Joseph F. Heremans2,3 and David D. Awschalom1,2; 1The University of Chicago, United States; 2Argonne National Laboratory, United States
Quantum emitters in the solid state with addressable spin registers are promising platforms for quantum communication, yet few emit in the narrow telecom band necessary for low-loss fiber networks. This scarcity is compounded by the low brightness and hard-to-engineer host materials of erbium ions, the prototypical telecom emitter, motivating the search for alternative systems.

Here we create and isolate single vanadium dopants in silicon carbide (SiC) with emission in the O-band (1278-1388 nm) and with brightness allowing cavity-free detection, in a commercial, wafer scale and CMOS-compatible material [1]. We demonstrate that their emission is stable and relatively narrow even near surfaces, showing strong promise for integration with nanoscale devices.

In ensembles, we characterize the complex physics provided by the $d^1$ orbital of these transition metals, including a systematic study of the five different sites available in the 4H and 6H polytypes of SiC. The optical transitions are observed to be sensitive to mass shifts from the distribution of nearest neighbor silicon and carbon isotopes, potentially enabling optically-resolved nuclear spin registers.

Optically detected magnetic resonance of ground state and excited spin transitions reveal a variety of hyperfine interactions with the vanadium nuclear spin and their related clock transitions for use as quantum memories. Finally, we demonstrate coherent quantum control of the spin state at 3.3 K, limited by thermal relaxation effects. These results provide a path for telecom emitters in the solid-state for quantum applications.

3:30 PM MQ01.02.01
Spin Filtering through Chiral Molecule Monolayers on Semiconductors Tianhan Liu¹, Longqian Hu¹, Eric Lochner³, Peng Xiong¹, Xiaolei Wang², Hailong Wang², Jianhua Zhao², Gang Shi², Fan Gao³, Honglei Feng³ and Yongqing Li³; ¹Florida State University, United States; ²Institute of Semiconductors, China; ³Institute of Physics, China

The effect of structural chirality-induced spin selectivity (CISS) has been observed in a host of nanostructures involving chiral molecule monolayers on noble metals.¹ Realizing CISS on semiconductors could open new pathways of spin injection and detection on semiconductors without using any magnetic materials. However, there has been no report of such experiments on planar semiconductor surfaces. Here, we report on the self-assembly of thiolated dsDNA and polyalanine monolayers on GaAs and its magnetic variant, (Ga,Mn)As, which is used as a spin analyzer to ascertain CISS through the chiral molecules. The monolayer assemblies on GaAs are studied by AFM and ellipsometry and compared with those on Au. On Au, "blocking" by hydrophobic alkanethiol self-assembled monolayers is necessary to achieve assembly of dsDNA oriented away from the substrate. The assembly on GaAs is made possible by an ammonium sulfide treatment for oxide removal and surface passivation,² on which the polyalanines form oriented SAM without any "blocking".

We further study the spin-selective electron transport across vertical junctions of (Ga,Mn)As/polyalanine/Au. The bottom (Ga,Mn)As electrode is epitaxially strained, resulting in perpendicular magnetic anisotropy. The micrometer scale junctions are formed in openings in a hardened PMMA layer on the (Ga,Mn)As defined by electron beam lithography. The native oxide on the exposed (Ga,Mn)As is removed by ion milling, followed immediately by
polyalanine monolayer self-assembly in a solution. The top Cr/Au electrodes are thermally evaporated under liquid nitrogen cooling. The CISS effect is evidenced by measuring the magnetoresistance of the junctions: Sweeping the perpendicular magnetic field at low temperatures, sharp changes in the junction resistance are observed at the coercive fields of the (Ga,Mn)As, indicating spin filtering of electrons from the Au electrode by the polyalanine monolayer. The spin polarization of the electrons from GaAs filtered by polyalanines may be determined quantitatively by spin-resolved superconducting tunneling with a thin Al counter-electrode.

Imaging Spin Dependent Properties of Individual Dopants through DC Magnetoresistance of Spin-Polarized Scanning Tunneling Microscopy Current
Stephen R. McMillan1,2, Nicholas J. Harmon3 and Michael E. Flatté1,2,4;
1University of Iowa, United States; 2The University of Chicago, United States; 3University of Evansville, United States; 4Eindhoven University of Technology, Netherlands

A detailed understanding of two-level quantum systems in complex environments is necessary for the development of quantum information and sensing applications [1,2]. Individual or small clusters of dopants with remarkably long coherence times are addressable via scanning tunneling microscopy (STM) and the exchange interaction between dopants can be measured [3-6]. Through the use of localized magnetic contacts, for instance a spin-polarized STM, the correlations between the dopant spin state and the magnetization of the tip yields insight into the coherent dynamics at the addressed site. We propose a method to dynamically probe the spin-dependent properties of a spin-1/2 dopant exchange coupled to a charge-stable spin-1/2 state in the presence of a milliTesla dc transverse magnetic field embedded in a weakly conducting host. Calculations of the magnetoresistance through the mediating dopant rely on a stochastic Liouville approach where the density matrix of the two-dopant system is tracked and a steady state solution is found. The MR in these systems provides signatures of the exchange interaction, hyperfine coupling, spin decoherence, and g-factor. An extension of the spin-1/2 case to a system with spin-1 is applicable to systems like the divacancy defect in silicon carbide.

We acknowledge support from DOE BES through Grant No. DE-SC0016447.

Quantum Coherent Single-Spin Dynamical Effects in DC Electrical Transport
Michael E. Flatté; University of Iowa, United States

A broad range of quantum-coherent spin centers have been identified in optically-accessible materials, especially including nitrogen-vacancy, silicon-vacancy, and germanium-vacancy centers in diamond, divacancies and transition-metal dopants in several polytypes of silicon carbide, and even spin centers in two-dimensional materials such as hexagonal boron nitride. Some of these materials, however, allow good electrical transport (such as silicon carbide), and other spin centers have been found in materials that cannot be easily probed optically. Some of these, such as dopants in silicon, have been probed using electron spin resonance techniques that require an rf field. Recently, however, it has become clear that dc techniques can electrically manipulate and measure the spin orientations of spin centers through the establishment and release of electrical transport bottlenecks. The key requirements of these approaches are a spin-polarized electrical contact and a small transverse magnetic field, however no ac field of any type is required. Some examples of the potential for this approach will be described, including the proposal to measure, at room temperature, the micro-eV-scale exchange and hyperfine fields between spins in a semiconductor using dc magnetoresistance, and the room-temperature observation of hyperfine interactions in a trap at the Si-SiOx interface in a MOSFET.

Aspects of this work were supported by DOE DE-SC0016447 and HDTRA1-18-1-0012.
Electrically Detected Electron Nuclear Double Resonance in a Transistor

Brian R. Manning¹, Ryan J. Waskiewicz¹, Duane J. McCrory² and Patrick M. Lenahan¹; ¹The Pennsylvania State University, United States; ²Keysight Technologies, United States

Electron paramagnetic resonance (EPR) techniques offer unrivaled analytical power in the identification of the physical and chemical nature of point defects in semiconductors and insulators. However, the sensitivity of conventional EPR is about 10 billion defects. This number greatly exceeds the number of performance-limiting defects in technologically relevant solid-state devices. Electrically detected magnetic resonance (EDMR) is at least 7 orders of magnitude more sensitive than its parent technique, EPR [1,2]. This enormous enhancement in sensitivity makes EDMR a powerful tool in the investigation of point defects in nano-scale electronic device. This sensitivity also makes EDMR potentially useful in various spintronic applications. Although EDMR is a powerful tool, its analytical power could be greatly enhanced with the addition of a nuclear magnetic resonance (NMR) component. The conventional double resonance technique known as electron nuclear double resonance (ENDOR) combines EPR and NMR and has the analytical power to provide detailed atomic scale information about paramagnetic defects in semiconductors and insulators [3]. The absolute sensitivity of conventional ENDOR is grossly inferior that of classical EPR, making the technique essentially impossible for studies of nano-scale electronic devices. This also makes the exploitation of long nuclear spin decoherence times quite difficult via classical ENDOR. We show that, by utilizing EDMR detection, ENDOR sensitivity may be enhanced by many orders of magnitude, opening possibilities for electrically detected ENDOR (EDENDOR) to contribute substantially to solid-state device physics, possibly including some spintronic applications. We have developed a sensitive EDENDOR spectrometer and demonstrate that it can provide reasonably high signal to noise spectra involving ^14N nuclear spins interacting with deep level defects in the base-emitter junction of a fully processed 4H-SiC bipolar junction transistor at room temperature. The EDENDOR spectrometer utilizes a single loop non-resonant antenna that is placed within a TE102 microwave cavity adjacent to the transistor to generate the NMR oscillating magnetic field. A frequency sweep is supplied to the NMR coil loop via an arbitrary waveform generator (AWG). To maintain constant power to the loop, a proportional-integral-derivative (PID) controller has been used to feedback a real time measurement of the power through the loop and adjust the output. This suppresses the non-resonant background which could otherwise obscure the EDENDOR response. To the best of our knowledge this is the first time ENDOR measurements have ever been made within a fully processed transistor.

Charge State Control of Single Spins in Semiconductor Devices

Christopher P. Anderson, Alexandre Bourassa and David D. Awschalom; University of Chicago, United States

Silicon Carbide (SiC) has recently established itself as a viable host for defect-based spin qubits, providing a diamond-like host for spins with silicon-like fabrication and doping control. In particular, neutral divacancies (VV⁰) in SiC have shown exceptional spin coherence and a viable telecom spin-photon interface for entanglement schemes. Here, we isolate for the first time single VV⁰ in functioning, doped, commercial semiconductor p-i-n devices and use the diode to control and tune these defects. In this talk, we focus in particular on the control of the charge state of the single spins in the device.

Controlling charge dynamics has allowed for key demonstrations in quantum sensing and communications. Additionally, the charge states of single spins can be utilized in spin-to-charge conversion, enabling single-shot optical readout and even electrical readout of single spins. However, the understanding and control of charge for single spins in SiC remains unexplored.

In this work, integration of single spins into the p-i-n device enables a demonstration of deterministic charge state
control of single VV$^0$ spin defects, and a careful study the defect’s photo-dynamics. These results allow for the stabilization of the desired charge state of the defect and reduce ionization and spectral hopping of the orbital structure. Furthermore, integration into the device allows for electrically gating of the single photon emission, and control of formation of these defects using fermi-level engineering.

Leveraging of the mature SiC semiconductor device technology creates exciting opportunities for electrical control, manipulation and readout of both the spin and charge degrees of freedom in these quantum emitters.

The Tin Vacancy Center in Diamond—An Interesting New Qubit Candidate? Christoph Becher; Saarland University, Germany

Quantum bits based on soli-state spins are promising and potentially scalable systems for the implementation of quantum technologies ranging from quantum information processing to quantum-enhanced sensing and metrology. Ideally, they combine individually addressable spins with very long coherence times, optical emission spectra with narrow homogeneous and inhomogeneous broadenings and bright single-photon emission. In this respect, impurity-vacancy color centers in diamond based on group-IV elements (SiV, GeV, SnV, PbV) have emerged as interesting systems promising to combine all desired favorable properties.

Both the SiV and the GeV center feature superior spectral properties, i.e. at liquid helium temperatures (4K), they exhibit a narrow zero phonon line (ZPL) with a four-line fine structure and close to lifetime-limited linewidths [1,2]. Furthermore, both allow for fast all-optical addressing and control of their spin states [3,4]. However, at temperatures around 4K both color centers exhibit spin coherence times (T2$^*$) of only a few ten nanoseconds due to phonon-induced decoherence processes [3,4] and the SiV reaches millisecond spin coherence times only at millikelvin temperatures and in pure samples [3,5]. A potential resort are vacancy defects with a heavier group-IV impurity atom, such as SnV and PbV centers, featuring a larger ground state splitting and thus less susceptibility to phonon-induced decoherence.

Here, we report on spectroscopy of SnV centers [6,7,8] where we find two charge states, i.e. SnV(-) and SnV(0), which both show promising optical properties. The SnV(-) features a ground and excited state splitting considerably larger (850 GHz and 3000 GHz, respectively) as compared to the SiV center, potentially enabling long spin coherence times even at liquid He temperatures. This defect is a bright single photon emitter, showing a narrow inhomogeneous distribution of zero phonon lines in a high-temperature annealed sample [6] and truly lifetime-limited transition linewidths down to 20 MHz. Furthermore, we determine the charge transition from the negative to the neutral charge state as a function of the excitation wavelength and find it to coincide well with theoretical predictions [9]. For the SnV(0) center we find emission lines that again agree well with theoretical calculations [10]. The neutral charge state is particularly interesting due to its potentially long electron spin coherence times.

Development of Scalable Technology for NV-Magnetometry and Photonics on Single Crystalline Diamond

Christian Giese¹, Patricia Quellmalz¹, Helge Gehring², Wolfram Pernice² and Christoph E. Nebel¹; ¹Fraunhofer IAF, Germany; ²University Muenster, Germany

The unique properties of the negatively charged nitrogen vacancy color center (NV⁻) in single crystalline diamond have been explored for developing new types of devices for photonics and scanning probe magnetometers with high sensitivity and spatial resolution over more than a decade. This growing field is in need of thin, free-standing ultraclean diamond devices with complex geometries. The fabrication of such structures in large numbers will be the topic of this presentation.

Free-standing diamond devices as photonic crystals or NV-scanning-probe heads are typically manufactured from diamond membranes of below 30µm thickness. The latter are expensive and available only in small numbers which makes a scaling of the production very challenging. In addition to this, the homogeneity in thickness below micron level is crucial for many applications and remains practically unachievable via polishing on large surfaces.

An alternative method based on so-called faraday-cage-angled-etch (FCAE) pioneered at the group of prof. Loncar at Harvard university is based on the capability to create free-standing diamond devices via dry chemical underetching. We have employed FCAE to create mechanical and optical components and will report on the characteristics of the devices investigated via SEM as well as optical and mechanical metrology.

Rapid, High-Resolution Magnetic Microscopy of Single Magnetic Microbeads

Julia M. McCoey, Robert W. de Gille, Babak Nasr, Jean-Philippe Tetienne, Liam T. Hall, David A. Simpson and Lloyd Hollenberg; University of Melbourne, Australia

Magnetic microparticles are used in a variety of research applications including cell sorting, targeted drug delivery and optical force traction microscopy. The magnetic properties of such particles can be customized for specific applications with the uniformity of individual magnetic microparticles having a significant bearing on their function. Prior to the study discussed here, most magnetic characterization techniques have quantified the magnetic properties from large bead ensembles. As such, there is a significant demand for magnetic imaging techniques to evaluate and visualize the magnetic fields from single beads. New insights into the magnetic uniformity, anisotropy, and alignment of magnetic domains can be found through measurements of the magnetic properties of single beads. Here, magnetic microscopy based on the nitrogen-vacancy centre in diamond is applied to image and characterize individual magnetic beads with varying magnetic and structural properties: ferromagnetic and superparamagnetic/paramagnetic, shell (coated with magnetic material), and solid (magnetic material dispersed in matrix). The magnetic microscopy described here probes both the fluctuating moments of the beads studied as well as their static magnetic moments. The single-bead magnetic images identify irregularities in the magnetic profiles from individual bead populations. Magnetic simulations account for the varying magnetic profiles and allow to infer the magnetization of individual beads. Additionally, this work shows that the imaging technique can be adapted to achieve illumination-free tracking of magnetic beads, opening the possibility of tracking cell movements and mechanics in photosensitive contexts.

Quantum Sensing of Atomically Thin Magnets Patrick Maletinsky; Basel University, Switzerland

The recent discovery of long-range magnetic order in atomically thin `van der Waals’ (vdW) crystals has attracted significant attention due to their fundamental and technological interest, including predictions of exotic magnetic phases and unique opportunities to control magnetism at the atomic scale. I will present recent experiments, where we employ a single-spin-based quantum sensing technology for quantitative, nanoscale probing of atomically thin vdW magnets. Specifically, I will describe experiments, where we employ a diamond-based, scanning probe quantum sensor to address magnetism in the prototypical vdW magnet CrI3, down to the level of atomic monolayers. Our approach enabled nanoscale imaging of magnetic domains, quantitative determination of CrI3’s layer-dependent magnetization, and revealed a delicate interplay between magnetic and crystalline order in CrI3. Next to addressing fundamental open questions in the nanomagnetism of atomically thin CrI3, our results yield attractive perspectives for future probing of dynamical properties of two-dimensional spin systems using single spin quantum sensors. Amongst other things, these could yield experimental evidence for the still elusive quantum spin liquid, which is believed to occur in monolayers of certain vdW compounds.

Imaging the Domain Pattern of In-Plane Layered Antiferromagnets using Diamond Magnetometry Martin S. Wornle, Pol Welter and Christian Degen; ETH Zurich, Switzerland

Antiferromagnetic materials are promising candidates for new memory devices with fast electrical writing and readout capabilities. Imaging the magnetic state of antiferromagnets on the sub-micrometer scale, however, is challenging because these materials do not exhibit a macroscopic magnetization.

In this talk, we will discuss the application of scanning diamond magnetometry for investigating the microscopic domain structure of in-plane layered antiferromagnets, like tetragonal CuMnAs. After introducing the basics of the technique, we will discuss models and concepts for analyzing the magnetic stray field emanating from the antiferromagnetic domains. We will further show that current pulses lead to changes in the domain pattern and analyze these changes as a function of the current amplitude and direction.

Metrology Driven Development of Point Defect Synthesis and Localization Nazar Delegan1, Samuel J. Whiteley2,3, Edward Bielejec1, David D. Awschalom2,3 and Joseph F. Heremans1,2; 1Argonne National Laboratory, United States; 2The University of Chicago, United States; 3Sandia National Laboratories, United States

The negative nitrogen-vacancy (NV-) defect in diamond has quantum spin properties observable from cryogenic temperatures to ~1000 K. Parallel to this, SiC based divacancy (VV) complexes photoluminesce in the telecom infrared range, extending their technological applicability. Both of these spin-based quantum sensors are known to be responsive to changes in local strain, electric, magnetic, and thermal fields. Building on this foundation, we discuss recent advances of defect 3D localization in the context of improving and controlling their spatial resolution and crystalline environment. This progress is fueled by nanoimplantation and nanoscale strain-sensitive X-ray imaging techniques. The insights provided serve to better understand the defect’s lattice surroundings, guide future synthesis efforts, improve the creation efficiency, and advance the goal maintaining coherence times of the spin states.

4:15 PM MQ01.03.07/EL05.07.07
First Principles Discovery and Understanding of Color Centers in Diamond for Quantum Information Science Isaac Harris1,2, Christopher J. Ciccarino2, Johannes Flick2, Dirk R. Englund1 and Prineha Narang2; 1Massachusetts Institute of Technology, United States; 2Harvard University, United States

Defect centers in diamond are promising candidates for applications such as quantum sensing, networking and computation. Previous work has experimentally identified several defects such as the NV– and group IV related defects. However none of these color centers have shown the ideal combination of optical transitions, coherence times, and ease of fabrication and integration, motivating an ab initio search of new color centers in diamond.

Towards this goal, we present first principles calculations of a new class of emitters, the group III-vacancies, which are theoretically shown to have a promising ground state structure for quantum applications, a noise insensitive optical transition, and are thermodynamically favored in intrinsic diamond. The ground state fine structure, as well as the excited electronic structure will be discussed in this talk. Further, we will show the electron-phonon coupling parameter calculations to determine the Jahn-Teller distortion, as well as the phonon sideband of the optical emission. Finally, we will discuss how the ab initio results compare with experimental quantities such as the ground state spin structure and optical emission properties.

4:30 PM *MQ01.03.08/EL05.07.08
Understanding and Mitigating Quantum Decoherence of Nitrogen-Vacancy Center Spins for High-Spatial Resolution Quantum Sensing Ania Bleszynski Jayich1 and Dolev Bluvstein2; 1University of California, Santa Barbara, United States; 2Harvard University, United States

The nitrogen vacancy (NV) center defect in diamond is emerging as a powerful quantum-enabled technology, in particular in the realm of sensing and imaging with ultra-high spatial resolution. The performance of these solid-state quantum sensors is highly dependent on their quantum coherence and charge-state stability, which are sensitive to their local environment. Surfaces are an important part of the defect's environment, in particular when targeting high spatial resolution sensing, which necessitates close proximity between the sensor and target. To identify and mitigate the deleterious environmental effects, I discuss several materials-based and quantum-control approaches. Specifically, I discuss the formation of highly-coherent NV centers via a gentle, bottom-up method of nitrogen delta-doping during chemical vapor deposition growth of diamond thin films followed by low energy (~ 150 keV) electron irradiation. I present measurements of the density and coherence properties of the NV centers formed in this way as a function of growth and irradiation parameters [1]. In the second part of the talk, I discuss the spin and charge state properties of shallow NV centers, and introduce techniques to mitigate decoherence due to paramagnetic surface spins [2] as well as charge state instabilities near surfaces [3]. These approaches to improved sensors will ultimately enable truly nanoscale spatial resolution imaging of magnetic, electric, and thermal fields in a variety of condensed matter and biological systems.

Ultrastrong Magnon-Magnon Coupling in YFeO$_3$ in Magnetic Fields up to 30 T
Takuma Makihara$^1$, Gary T. Noe$^1$, Xinwei Li$^1$, Kenji Hayashida$^1$, Nicolas Marquez$^1$, Xiaoxuan Ma$^2$, Zuanming Jin$^2$, Wei Ren$^2$, Guohong Ma$^2$, Shixun Cao$^2$, Motoaki Bamba$^{3,4}$ and Junichiro Kono$^{1,1}$; $^1$Rice University, United States; $^2$Shanghai University, China; $^3$Kyoto University, Japan; $^4$Japan Science and Technology Agency, Japan

There is currently much interest in studying quantum optical phenomena in solid state systems to realize large-scale quantum information processing applications. In addition to scalability, solid state systems can be intrinsically advantageous to atomic systems due to the vastly larger number of electrons and many-body interactions that lead to cooperative enhancement of quantum optical phenomena. One example is Dicke cooperativity, where a system of $N$ dipoles coupled to an optical field experience an enhancement of light-matter coupling strength by a factor of $N^{1/2}$ [1]. Thus, solid state systems are particularly well-suited for studying exotic quantum optical phenomena that occur in regimes of light-matter coupling that are inaccessible to atomic systems, such as the ultrastrong coupling regime [2].

We recently demonstrated the extension of ultrastrong coupling to matter-matter coupling. Namely, we observed Dicke cooperativity between Er$^{3+}$ electron paramagnetic resonance and a vacuum magnon field of Fe$^{3+}$ spins in Y$^{3+}$ doped ErFeO$_3$ samples, and the collectively enhanced coupling strength was in the ultrastrong coupling regime [3]. In this work, we further demonstrate matter-matter ultrastrong coupling between two magnon modes in YFeO$_3$. This rare earth orthoferrite is a canted antiferromagnet due to its two antiparallel spin sublattices slightly tilting towards each other, yielding a weak ferromagnetic moment. There are two distinct magnon modes in YFeO$_3$, referred to as the quasi-ferromagnetic (qFM) mode and the quasi-antiferromagnetic (qAFM) mode, corresponding to coherent spin precessions with terahertz (THz) frequencies. These magnons can be excited by magnetic dipolar interactions between the Fe$^{3+}$ spins and a THz pulse, after which they precess at their Larmor frequency [4]. We studied the magnon frequency as a function of applied magnetic field strength and the direction of the magnetic field, i.e., the angle with respect to the weak ferromagnetic moment. When the applied magnetic field strength was tuned between 0 T and 30 T and the direction was not aligned with one of the crystallographic axes, anticrossing between the qFM and qAFM magnon frequencies was observed, demonstrating ultrastrong magnon-magnon coupling.

THz time-domain spectroscopy studies of YFeO$_3$ up to 30 T were performed using our tabletop pulsed magnet that uniquely marries strong magnetic fields and diverse optical spectroscopies [5]. We characterized magnons in YFeO$_3$ at different angles between the applied magnetic field and the weak ferromagnetic moment, which points along the $c$-axis. Specifically, we measured transmitted THz waveforms for five different samples of YFeO$_3$ cut such that the magnetic field was directed in the $b$-$c$ plane and at an angle of 0, 20, 40, 60, and 90 degrees with respect to the $c$-axis. We observed clear anticrossing between the qFM and qAFM magnon frequencies as we tuned the magnetic field between 0 T and 30 T in samples with relative angles of 20, 40, and 60 degrees.

Using the Herrmann model, we calculated the qFM and qAFM magnon frequencies for our experimental geometry [6]. The applied magnetic field breaks the symmetries of the two modes, and the mixing of these modes causes anticrossing. We found excellent agreement between experimentally measured and calculated frequencies. Most importantly, the vacuum Rabi splitting was found to be a sizeable fraction of the resonance frequency, showing that the qFM and qAFM magnon-magnon coupling strength is in the ultrastrong coupling regime.

8:30 AM *MQ01.04.02
Enhancing the Interaction of Magnons and Optical Photons
James A. Haigh; Hitachi Cambridge Laboratory, United Kingdom

To build hybrid quantum interfaces based on magnons, it will be important to optimise the coupling strength to both optical and microwave fields. While magnons can be routinely coupled to microwave photons in a coherent way, there is still a long way to go to achieve similarly strong coupling in the optical domain. This is because the strength
of magneto-optical interactions through the Faraday effect are typically very weak. In order to strengthen the magneto-optical interaction, the magnetic material can be embedded in a high quality-factor optical cavity. Such devices have been used to demonstrate that the scattering of optical photons with magnons can be significantly enhanced [1]. I will present our measurements on resonant magnon scattering in yttrium iron garnet, and discuss whether the limit of strong coupling can be achieved. In addition, optimizing the optical coupling requires reducing the volume of magnetic material. Although this is in conflict with the requirements for strong microwave coupling, we have shown the coupling strength can be maintained through the use of low-impedance microwave resonators [2].

9:00 AM MQ01.04.03
Phono-Magnetic Analogs to Opto-Magnetic Effects Dominik M. Juraschek1,2, Sebastian Stepanow2, Prineha Narang1 and Nicola Spaldin2; 1Harvard University, United States; 2ETH Zürich, Switzerland

Over the past few years, it has become possible to control the magnetic order of materials on timescales smaller than a picosecond, promising application in advanced data storage and data processing in spintronic devices. One ingredient is the coherent excitation of spin waves, which can be achieved by driving the spins with the magnetic or electric field components of an ultrashort light pulse. The basic interaction of light with a magnetic material is described by the opto-magnetic effects, of which the most prominent examples are the inverse Faraday and inverse Cotton-Mouton effects. There, the irradiated light acts as an effective magnetic field on the spins of the magnetic ions in the material, and coherent collective precession of the spins is induced via an impulsive stimulated Raman scattering mechanism [1,2].

Here, we present an alternative route of exciting coherent spin waves by coupling the magnetic degrees of freedom to the crystal lattice. We introduce the phenomenology of the analog magneto-phononic and phono-magnetic effects, in which coherently excited vibrational quanta take the place of the light quanta. Here, the coherent lattice vibrations couple to the magnetic order through the spin-phonon coupling, and the underlying mechanism is ionic Raman scattering, which had been proposed already half a century ago, and has only been demonstrated within this decade in the context of nonlinear phononics. The mechanism is less dissipative and reduces parasitic electronic effects compared to impulsive stimulated Raman scattering due to the lower energy of the excitation at mid-infrared wavelengths compared to visible light. Using density functional theory calculations in combination with phenomenological modeling for the paradigm antiferromagnet nickel oxide (NiO), we show that the phono-magnetic effects can potentially overcome the efficiency of the established opto-magnetic effects [3].

9:15 AM MQ01.04.04
Solid-State Room-Temperature Masers—A Platform for Macroscopic Dicke States Jonathan Breeze1, Enrico Salvadori2, Juna Sathian3, Neil Alford1 and Christopher W. Kay3,4; 1Imperial College London, United Kingdom; 2University of Turin, Italy; 3University of Saarland, Germany; 4University College London, United Kingdom

The solid-state maser, invented in the 1950s, had a much less impressive career than its younger sibling the laser, mainly due to its dependence on cryogenic refrigeration and high-vacuum systems. Despite this, masers found niche application in deep-space communications and radio astronomy due to their unparalleled performance as low-noise amplifiers and oscillators.

In 2012, the first room-temperature solid-state maser was demonstrated, employing an high-Q cavity coupled ensemble of inverted triplet states in photo-excited pentacene molecules doped into a p-terphenyl host [1].

Since then, this new class of maser has been dramatically miniaturized [2], characterized on nanosecond timescales
and shown to exhibit Rabi oscillations and normal-mode splitting, hallmarks of the strong-coupling regime of cavity quantum electrodynamics [4]. Unfortunately, the $p$-terphenyl host is volatile, has very poor thermal properties and unfavourable triplet sublevel decay rates – so that only pulsed operation lasting less than a millisecond has been observed to date. Alternative inorganic materials containing spin-polarizable defects such as diamond nitrogen-vacancy (NV) centres and [5,6] and vacancies in silicon carbide [7] have been proposed due to their slow spin-lattice relaxation and spin dephasing rates. These materials have the additional advantage of excellent thermal and mechanical properties.

In this talk I will discuss the development of the organic pentacene solid-state room-temperature maser and how the quest for continuous operation naturally led towards diamond and nitrogen-vacancy centres. I will report on the recently reported continuous-wave room-temperature maser based on optically pumped charged nitrogen-vacancy (NV) defect centres in diamond [8]. I will also discuss prospects for the macroscopic quantum (Dicke) states and multipartite entanglement supported by masers [4,9] and the immediate challenges.

magnon density of states, magnon spin diffusion length, and magnon-phonon coupling. These properties are central to the design and fabrication of future generations of quantum coherent devices, and will help to guide the development of this emerging class of highly coherent magnetic materials.

10:30 AM *MQ01.05.02
Quantum-Enhanced Sensing in Magnonics with a Superconducting Qubit Dany Lachance-Quirion1, Samuel P. Wolski1, Yutaka Tabuchi1, Shingo Kono2, Koji Usami1 and Yasunobu Nakamura1,2; 1The University of Tokyo, Japan; 2RIKEN, Japan

The quantum regime of magnonics has been recently explored thanks to the strong and coherent interaction engineered between a superconducting qubit and the uniform magnetostatic mode, or Kittel mode, of a spherical ferrimagnetic crystal of yttrium iron garnet (YIG) [1-4]. With this architecture of quantum magnonics, single quanta of collective spin excitations, called magnons, have been resolved by using the qubit as a quantum sensor when the hybrid system reaches the strong dispersive regime [3, 4]. Here, we use this strong dispersive interaction to demonstrate novel protocols for quantum-enhanced sensing of magnons in a ferromagnetic crystal. First, we demonstrate a magnon detection sensitivity of about $10^{-3}$ magnons/$\sqrt{\text{Hz}}$ by using a simple quantum sensing protocol that relies on the dephasing of the qubit from the presence of magnons in the ferromagnetic crystal. In a second experiment, we entangle the Kittel mode with the qubit through a conditional excitation of the qubit, which we use to demonstrate the single shot detection of a single magnon with a detection efficiency of about 69%. This demonstration brings the equivalent of the single photon detector to the field of magnonics. Furthermore, using this conditional qubit excitation, we can perform tomography measurements of the vacuum and coherent states of the Kittel mode and thereby study the dynamics of magnons in the quantum regime. These measurements have enabled us to confirm the absence of a significant pure dephasing mechanism for the Kittel mode of YIG in the quantum regime. Finally, we discuss our progress towards preparing and characterizing quantum states of magnons, as well as our investigation regarding the origin of losses of the Kittel mode in the quantum regime [2, 5].

Fringe Fields and Spin Waves in V[TCNE]$_{x}$ Cylindrical Disks Denis Candido1,2 and Michael E. Flatté1,2,3; 1University of Iowa, United States; 2University of Chicago, United States; 3Eindhoven University of Technology, Netherlands

Through the application of a rf magnetic field in ferrimagnetic materials it becomes possible to create magnetostatic spin waves [1,2]. These collective excitations have been recently getting attention due to their applicability in both devices and fundamental research, which stems from the their long spin lifetimes and absence of ohmic losses. In this work we obtain the magnetostatic resonant modes of a ferrimagnetic V[TCNE]$_{x}$ disk [3] on top of a diamond substrate. Most importantly, we calculate analytically the spectrum, the fringe field and the magnetization obtained through the pinning condition at both top and bottom disk surfaces. In addition, we also perform the relaxation of the pinning condition and analyze its consequences in the spectrum, fringe fields and magnetization. We present our results for two different magnetic field directions: in plane and out of plane of the disk. The material is based on work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award Number DE-SC0019250.

11:15 AM MQ01.05.04
Dispersion Relations and Linewidths of 1D and 2D Magnonic Crystals of V[TCNE]$_{x=2}$ Kwangyul Hu$^1$ and Michael E. Flatté$^{1,2,3}$; $^1$University of Iowa, United States; $^2$University of Chicago, United States; $^3$Eindhoven University of Technology, Netherlands

The ferromagnet yttrium iron garnet (YIG) has attracted considerable attention for studying quantum magnonics for the advantages such as long spin lifetime [1], narrow ferromagnetic linewidth (FMR), low Gilbert damping constant [2] and high Q factor [3]. However, a specific superlattice substrate gadolinium gallium garnet (GGG) is required to fabricate high quality YIG thin films [4], preventing the broad application of YIG such as with silicon. Recent studies have revealed that an organic based ferrimagnet, V[TCNE]$_{x=2}$ is an excellent alternative to YIG. High quality V[TCNE]$_{x=2}$ can be grown on various flexible substrates such as glass, quartz and Si wafer using low temperature CVD [5]. This suggests that V[TCNE]$_{x=2}$ is an attractive magnonic media with the same advantages as YIG [6-8].

Here, we present the dispersion relations and linewidths of quasi one-dimensional and two-dimensional periodic magnonic crystals of V[TCNE]$_{x=2}$ calculated by using Landau-Lifshitz-Gilbert (LLG) formalism [9]. For the one-dimensional magnonic crystals, periodic layers of two alternating materials is studied. For the two-dimensional magnonic crystals, we considered infinitely long cylinders embedded in a host material forming a square lattice periodic structure. In both cases, V[TCNE]$_{x=2}$ combined with well known ferromagnets such as YIG and cobalt are considered. We focus on unit cells with a lattice constant of a=100nm in an external dipolar field of $H_0\mu_0=0.1T$. Our results can be extended to investigate other properties of V[TCNE]$_{x=2}$ such as spin wave propagation and their applications.

We acknowledge support from NSF EFRI NewLAW under Award No. EFMA-1741666.

Photodriven Quantum Teleportation of an Electron Spin State in a Covalent Donor-Acceptor-Radical System
Michael R. Wasielewski, Brandon Rugg, Matthew D. Krzyaniak, Brian T. Phelan, Mark Ratner and Ryan Young; Northwestern University, United States

Quantum teleportation is essential to the development of many aspects of quantum information science (QIS). Toward this goal, we demonstrate electron spin state teleportation in an ensemble of covalent organic donor-acceptor-stable radical (D-A-R) molecules. Following preparation of a specific electron spin state on R in a magnetic field using a microwave pulse, photoexcitation of A results in the formation of an entangled electron spin pair D\textsuperscript{+}-A\textsuperscript{-}. The spontaneous ultrafast chemical reaction D\textsuperscript{+}-A\textsuperscript{-} \rightarrow D\textsuperscript{+}-A\textsuperscript{-}R constitutes the Bell state measurement step necessary to carry out spin state teleportation. Quantum state tomography of the R and D\textsuperscript{+} spin states using pulse electron paramagnetic resonance spectroscopy shows that the spin state of R is teleported to D\textsuperscript{+} with high fidelity. This result affords the possibility that chemical synthesis can create complex nanostructures for QIS applications.

Low Damping Ferromagnetic Resonance in Electron-Beam Patterned, High-Q Vanadium Tetracyanoethylene Magnon Cavities
Andrew J. Franson\textsuperscript{1}, Na Zhu\textsuperscript{2}, Seth Kurfman\textsuperscript{1}, Michael Chilcote\textsuperscript{1}, Denis Candido\textsuperscript{1}, Kristen Buchanan\textsuperscript{4}, Michael E. Flatté\textsuperscript{3}, Hong Tang\textsuperscript{2} and Ezekiel Johnston-Halperin\textsuperscript{1}; \textsuperscript{1}The Ohio State
On-chip integration of patterned, low-loss magnetic materials and magnon cavities into microwave devices and circuits presents many challenges due to the specific conditions that are required to grow ferrite materials, driving the need for flip-chip and other indirect fabrication techniques. The low-loss ($\alpha = (3.98 \pm 0.22) \times 10^{-5}$), room-temperature ferrimagnetic coordination compound vanadium tetracyanoethylene ($V[TCNE]_x$) is a promising new material for these applications that is potentially compatible with semiconductor processing. Here we present the deposition, patterning, and characterization of $V[TCNE]_x$ thin films with lateral dimensions ranging from 1 micron to several millimeters. We employ electron-beam lithography and liftoff using an aluminum encapsulated poly(methyl methacrylate), poly(methyl methacrylate-methacrylic acid) copolymer bilayer (PMMA/P(MMA-MAA)) on sapphire and silicon. This process can be trivially extended to other common semiconductor substrates. Films patterned via this method maintain low-loss characteristics down to 25 microns with only a factor of 2 increase down to 5 microns. A rich structure of thickness and radial confined spin wave modes reveals the quality of the patterned films. Further fitting, simulation, and analytic analysis providing an exchange constant, $A_{ex} = (2.2 \pm 0.5) \times 10^{-15} \text{ J/m}$, as well as insights into the mode character and surface spin pinning. Below a micron, the deposition is non-conformal which leads to interesting and potentially useful changes in morphology. This work establishes the versatility of $V[TCNE]_x$ for applications requiring highly coherent magnetic excitations ranging from microwave communication to quantum information.

Noncollinear Magnetism in Complex Oxide Superlattices Jennifer E. Hoffman and Jason D. Hoffman: Harvard University, United States

Noncollinear magnetic textures give rise to interesting charge and spin transport properties, and allow for control of magnetism using small electric currents. While these textures have been observed in a number of bulk materials and in thin films, realizing non-collinear magnetism in heterostructures presents new avenues to control their properties using tailored interfaces and gate electric fields. We have discovered noncollinear magnetism in superlattices comprised of two metallic perovskites, La$_2$/3Sr$_1$/3MnO$_3$ (LSMO) and LaNiO$_3$ (LNO). The superlattices are synthesized using oxide molecular beam epitaxy and characterized with a variety of means, including x-ray and neutron scattering. We find that the angle between the magnetization of the LSMO layers varies in an oscillatory manner with the thickness of the intervening LNO. We demonstrate a memory device in one such superlattice, where the magnetic state of the noncollinear magnetism is reversibly switched between different orientations using a small magnetic field and read out in real time using a combination of the anomalous Nernst effect and anisotropic magnetoresistance measurements. Finally, we discuss the growth and characterization of additional complex-oxide-based systems and devices, such as LaVO$_3$.

2:00 PM MQ01.07.02
Electric Field Control of the Magnetic and Associated Metal-Insulator Transitions in Iridates
Juan Ignacio Beltrán1,2, Andrea Peralta2, Javier Tornos2, Fernando Gallego1, Carlos León2, Jacobo Santamaría2 and Carmen Muñoz2; 1Instituto de Ciencia de Materiales de Madrid, Consejo Superior de Investigaciones Científicas, ICMM (CSIC), Spain; 2Universidad Complutense de Madrid, Spain

Iridates are of great importance to investigate the realization of exotic quantum phenomena generated by non-negligible spin-orbit coupling. The strontium-based iridates, with the perovskite structure and a valence band derived from the 5d orbitals of Ir, exhibit electronic and magnetic ground states resulting from the subtle interplay of spin-orbit coupling, electron-electron correlation and dimensionality. Therefore, they are highly susceptible to small changes in the relative strength of the different interactions. In the Ruddlesden-Popper series Srm+1Ir2O3m+1 (m=1,2, … ∞), the two-dimensional compounds, m = 1 and 2, present an antiferromagnetic (AF) Mott insulating ground state, with canted planar and out of plane AF orderings, respectively. Conversely, the three-dimensional SrIrO3 is semi-metallic, non-magnetic and shows non-trivial topological features. Here, based on a multi-fold approach relying on magneto-transport measurements and first-principles calculations, we demonstrate the reversible tuning of the magnetic and electric ground state of thin SrIrO3 films by external electric fields. Ultra-thin epitaxial SrIrO3 films grown on SrTiO3 exhibit thickness dependent metal-insulator and associated magnetic transitions. Its ground state evolves from a magnetic insulator, for 1 or 2 unit cell (u.c.), to a paramagnetic semi-metal, for n > 3 u.c. thicknesses. Moreover, for the thicker metal films, an electric field perpendicular to the film drives a metal-insulator and a simultaneous paramagnetic to weak ferromagnetic transition. We explore the transitions in ultra-thin layers of SrIrO3, 3 < n < 8 u.c., by electric double layer techniques, which employ ionic liquid as gate dielectric, and prove that the metal-insulator and magnetic transitions are reversible. In addition, we show that the weak ferromagnetic behavior induced by the electric field arises from an underlying canted AF order within the basal plane. The orbital and spin moment canting rigidly tracks the staggered rotations of the IrO6 octahedra, which results in out-of-plane ferromagnetic spin components induced by the Dzyaloshinskii–Moriya interaction. We discuss the role of the orbital magnetism and Rashba spin-orbit interaction -due to the breaking of inversion symmetry- in the stabilization of the magnetic insulator state. The electric field, via the Rashba interaction, promotes a moment reorientation of the disordered paramagnetic state, which is at the root of the metal-insulator transition. This novel behavior is a consequence of the unique character of the semi-metallic SrIrO3 ground state, it illustrates the exotic spin interactions in iridates and points to a new paradigm for device structures in which magnetic states are reversibly manipulated by electric fields.

This work was supported by the Spanish Ministerio de Ciencia e Innovación through MINECO/FEDER Grants MAT2015-66888-C3-1R and RTI2018-097895-B-C41.

Mechanistic Insights into the Superexchange-Interaction-Driven Negative Thermal Expansion in CuO
Yuanpeng Zhang1,2, Marshall McDonnell2, Stuart Calder2 and Matt Tucker2; 1National Institute of Standards and Technology, United States; 2Oak Ridge National Laboratory, United States

Thermal expansion is an important consideration in many applied fields ranging from large-scale infrastructure building to high-precision instrumentation. Starting from the discovery of isotropic negative thermal expansion (NTE) in ZrW2O8 by Sleight, et al. in 1996 [1], NTE has been an intensely studied material phenomenon. For NTE, one, two, or all three dimensions of the material shrink with increasing temperature, which is counter to both our intuition and experience. NTE is believed to be connected with various origins, such as geometrical flexibility, ferroelectricity and magnetism [2]. Such connections then provide potential routes for controlling the thermal expansion utilizing NTE materials. Specifically concerning the superexchange driven NTE, increasing of atomic distances is beneficial for reducing the on-site Coulomb repulsion (through reducing, e.g. the p-d orbital overlapping) and therefore is potentially accounting for the expanding of lattice as T decreases (i.e. NTE). However, the lattice expansion in turn tends to reduce the magnetic coupling. Therefore, it brings in an outstanding question – how the interplay between superexchange interaction and lattice expansion proceeds as T decreases. Concerning the implication for tuning NTE of superexchange systems in general sense, it is important to resolve such a question. To this aim, we revisit the superexchange involved anisotropic NTE of CuO [3].

The negative thermal expansion (NTE) in CuO is explained via electron-transfer-driven superexchange interaction. The elusive connection between the spin-lattice coupling and NTE of CuO is investigated by neutron scattering and principal strain axes analysis. The density functional theory calculations show as the temperature decreases, the
continuously increasing electron transfer accounts for enhancing the superexchange interaction along – the principal NTE direction. It is further rationalized that only when the interaction along is preferably enhanced to a certain level compared to the other competing antiferromagnetically exchange pathways can the corresponding NTE occur. Outcomes from this work have implications for controlling the thermal expansion through superexchange interaction, via, for example, optical manipulation, electrons or holes doping, etc.

**Growth and Properties of Magnetic Heusler Epitaxial Thin Films**

Chris J. Palmstrom; University of California, Santa Barbara, United States

Heusler compounds have been predicted and experimentally shown to exhibit novel electronic and magnetic properties, such as half-metallic ferromagnetism, semiconducting and superconducting. The spin dependent transport across ferromagnet/semiconductor or ferromagnet/insulator interfaces depends critically on their structure and electronic properties, which include the semiconductor doping beneath the ferromagnetic contact, as well as the contact metallization. Interfacial reactions, the formation of non-magnetic interlayers, and conductivity mismatch have been attributed to low spin injection efficiency. In the case of epitaxial Fe3Ga/GaAs(001) interfaces, the interface reconstruction was found to depend on the GaAs(001) surface reconstruction and the Fe3Ga growth conditions. Co2MnSi is predicted to be half-metallic and we have demonstrated record high spin accumulation at Co2MnSi/GaAs(001) interfaces in lateral spin transport device structures and also investigated electronic structure tuning with Co2(Mn,Fe)Si/GaAs(001) heterostructures. The variation in the spin polarization in the GaAs is consistent with the Fermi level increasing in the Co2(Mn,Fe)Si films with the increase in the number of valence electrons per formula unit with the addition of Fe. This results in a sign change in the spin polarization between Co2MnSi and Co2FeSi contacts.

The magnetic damping and magnetoresistance were found to depend on the composition of Co2-xMn1+xSi films grown on MgO(001). Current-induced spin-orbit torque in Co2FeAl/Pt ultrathin bilayers have been investigated as a function of temperature. By substituting Fe for Ti, the half-Heusler CoTiSb can be controllably tuned from a semiconductor to ferromagnetic metal. We have also demonstrated, by both angle-resolved photoemission and magnetotransport measurements, Fermi level tuning of topological PtLuSb by substituting Au for Pt, which results in control of the dominant carrier type and density.

Using a combination of molecular beam epitaxy and in-situ scanning tunneling microscopy and x-ray photoelectron spectroscopy, we have investigated the surface atomic structure, the interface formation and growth mechanisms. Ab-initio theory and ex-situ transmission electron microscopy studies corroborate the Heusler/semiconductor interfacial atomic structure.

In this presentation, I will discuss the molecular beam epitaxial growth and tuning of properties of Heusler compounds with emphasis for spintronic and hybrid quantum interfaces.

**Spin-Orbit Torque Switching of Antiferromagnet and Ferrimagnet**

Feng Pan, Cheng Song, Xianzhe Chen and Xiaofeng Zhou; Tsinghua University, China
Antiferromagnets with zero net magnetic moment, strong anti-interference and ultrafast switching speed have potential competitiveness in high-density data storage. Electrical switching of antiferromagnets is at the heart of their device application \[1,2\]. The antiferromagnetic insulator NiO and metal Mn\(_2\)Au, which is manifested electrically via spin Hall magnetoresistance in NiO/Pt bilayers \[3\] as well as a combination of anisotropic magnetoresistance and spin Hall magnetoresistance in Mn\(_2\)Au/Pt bilayers \[4\]. The antiferromagnetic moments are switched towards the current direction, different from the vertical configuration in the fieldlike torque scenario in a Mn\(_2\)Au single layer \[5\]. Electric field is used to switch the magnetic moment of Mn\(_2\)Au films grown on piezoelectric Pb(Mg\(_{1/3}\)Nb\(_{2/3}\))\(_{0.7}\)Ti\(_{0.3}\)O\(_3\) (PMN-PT) (011) substrates. When the electric field is swept, the easy axis of Mn\(_2\)Au is switched between [100] and [0 1] directions of PMN-PT (011) at room temperature, exhibiting a butterfly-like switching feature. This feature indicates that the underlying mechanism is the electric field-induced ferroelastic strain. Such a transition of the easy axis leads to the change of threshold current for the field-like torque switching of Mn\(_2\)Au \[6\]. Recently, we also realize a bulk spin-orbit torque in ferrimagnetic CoTb, and provides a possible mechanism to explain this unusual phenomenon. Electrical switching of antiferromagnetic and ferrimagnetic moments pave the way for all-electrical writing and readout in antiferromagnetic spintronics.

I am grateful to the contribution by Prof. Yaroslav Tserkovnyak, Dr. Jia Zhang, Dr. Ran Cheng, Prof. Yonggang Zhao, and Dr. Wanjun Jiang.

**Spin-Orbit Torques in Mn\(_2\)Au/Permalloy Bilayers** Cheng Song\(^1\), Xiaolong Fan\(^2\), Wenwen Kong\(^2\), Xiaofeng Zhou\(^1\) and Feng Pan\(^1\); \(^1\)Tsinghua University, China; \(^2\)Lanzhou University, China

The global centrosymmetry plus broken sublattice inversion symmetry crystal structure of antiferromagnetic (AFM) Mn\(_2\)Au result in the Néel spin-orbit torque (NSOT) switching of its Néel vector direction. In this talk, I will present our recent progress on the spin-charge conversion and spin-orbit torques generated by Mn\(_2\)Au films, where its special crystal structure is strongly involved. Current-induced spin-orbit torques generated by Mn\(_2\)Au was measured in Mn\(_2\)Au/Permalloy bilayers with the spin-torque ferromagnetic resonance (ST-FMR). Unlike the spin-charge conversion in generally used heavy metal/ferromagnetic metal and AFM/ferromagnetic metal bilayers, we find that besides a spin polarization along transverse direction (y-axis), in Mn\(_2\)Au films there is a spin polarization along the film normal direction (z-axis), which is perpendicular to the charge current (x-axis). The AFM Mn\(_2\)Au broken sublattice inversion symmetry crystal structure induced unusual spin polarization along the film normal direction and subsequent in-plane field-like torque. The film thickness and angular dependence of the spin polarization along z-axis are thoroughly investigated. Our observation adds a different dimension to spin-orbit torque.

**Microscopic Dynamics and Optoelectronic Response of Type-I Weyl Semimetals from First Principles**
Christina Garcia, Jennifer Coulter and Prineha Narang; Harvard University, United States

The transition metal monopnictides TaAs, NbAs, TaP, and NbP have been well-studied in the past few years since they were first predicted and experimentally confirmed to be Weyl semimetals. Much work has been done in further characterization of these materials and probing of additional Weyl physics signatures, including studies of both linear and nonlinear optics. However, some of the microscopics of these systems relevant to designing complex device architectures utilizing the Weyl nodes’ linear dispersion in the bulk of the crystal are still not fully understood. In this talk, we address the temperature dependence of the linear optical responses in TaAs and NbAs. We present the real and imaginary parts of an experimentally relevant complex dielectric function for these materials as functions of frequency, temperature, and polarization direction, incorporating scattering rates calculated from first principles. From these we also present linear optical conductivity predictions which agree well with experiment where experiment exists for TaAs. Finally, we examine the effect of chemical potential on the optical...
conductivity, which can be used to understand the role of the Weyl nodes in these optical responses.

4:30 PM *MQ01.08.04
Topological Materials for Quantum Devices and Beyond Claudia Felser, Johannes Gooth and Kaustuv Manna; Max Planck Institute, Germany

Topological insulators, Weyl and Dirac semimetals and new Fermions are new quantum states of matter, which have attracted considerable interest from the condensed matter community. Heusler compounds are a remarkable class of materials which exhibit a wide range of extraordinary multi-functionalities including tunable topological insulators, half metallic ferromagnets and non collinear topological spin structures [1]. The required band inversion has already been unambiguously identified by angle-resolved photoemission (ARPES) and transport [2, 3]. Weyl and Dirac semimetals open up new research directions and applications that result from the large Berry phases that they exhibit: these lead to giant anomalous Hall effect (AHE), giant anomalous Nernst and spin Hall effects (SHE) and topological spin structures [4]. Examples discussed in the talk are Mn3Sn, Co3Sn2S2 and Co2MnGa. In the 2D limited we propose a Quantum anomalous Hall effect for Co3Sn2S2 [5, 6]. However the number of correlated materials with topological properties is limited. With Ta2Se8I a material with a competition between a Weyl semimetal and a charge density wave might open a new field “axion insulators” [7]

Tuning Optical and Spin-Valley Properties in van der Waals Heterostructures Bernhard Urbaszek1, Mikhail Glazov2, Marina Semina2, Xavier Marie1, Cedric Robert1, Scott Crooker3, Mateusz Goryca3, Shivangi Shree3, Bo Han1 and Honghua Fang1; 1Institut National des Sciences Appliquées de Toulouse, France; 2Ioffe Institute, Russian Federation; 3Los Alamos National Laboratory, United States

The optical properties of transition metal dichalcogenide (TMD) monolayers (MLs) are dominated by excitons, electron and hole pairs bound by Coulomb attraction [1]. In this talk we report recent results on linear and non-linear optical spectroscopy of these atomically thin semiconductors for applications in optoelectronics and spintronics. We discuss fundamental parameters such as the optical bandgap and the photoluminescence emission time and yield that can be tuned by changing the dielectric environment of the monolayers and using different substrate materials and heterostructure fabrication techniques [2,3]. We discuss the polarization dynamics of excitons and resident carriers in different TMD materials giving access to spin and valley physics, governed by very different physical processes in the case of excitons as compared to resident carriers [4].

2:00 PM *MQ01.09.02  
**Optical Measurements of Electron and Nuclear Spin Polarization in Semiconductors**  
Vanessa Sih; University of Michigan, United States

Greater control of nuclear spin polarization could provide breakthroughs in both classical and quantum information storage and processing. In this talk, I will describe optical pump-probe techniques that generate and measure an electron spin polarization that persists over several laser pulse repetition periods in a gallium arsenide epilayer. Spins excited from successive laser pulses interfere, either constructively or destructively, depending on the Larmor spin precession frequency, which is determined by both the applied magnetic field and nuclear Overhauser field, and we demonstrate a dynamic nuclear polarization that actively responds to the external magnetic field sweep direction, sweep rate, and magnitude of transverse electron spin polarization [1]. We show that the electron-nuclear spin system retains memory of the external field history, including interruptions and reversals in magnetic field sweeps. [1] “Observation of magnetic field sweep direction dependent dynamic nuclear polarization under periodic optical electron spin pumping,” M. Macmahon, J. R. Iafrate, M. J. Dominguez, and V. Sih, Phys. Rev. B 99, 075201 (2019).

2:30 PM MQ01.09.03  
**Exciton-Polaritons as a Tool to Control the Emission Characteristics of Exciton and Trions Bound to Te$_2$ in ZnSe**  
Anne-Laurence Phaneuf-L’Heureux, Mathias Pont and Sebastien Francoeur; Polytechnique, Genie physique, Canada

Te$_2$ molecules in ZnSe form a quantum defect that offers advantageous characteristics, including a high optical uniformity due to its atomic nature and a strong optical dipole moment matching those from semiconductor nanostructures, for the development of efficient spin-photon interfaces for applications in quantum optics, communications and networks. In this work, we demonstrate that excitons-polaritons generated in the ZnSe host material can be used to deterministically control the emission characteristics of excitons and trions bound to a single Te$_2$ molecule. In particular, the emission efficiency is increased by two orders of magnitude, indicating a very efficient coupling between free excitons and Te$_2$ bound states. Scanning the free-exciton band with a narrow-frequency tunable laser over the free exciton spectral region reveals strong in-phase oscillations with a period of about 1 meV in the bound exciton emission intensity, emission energy, and emission linewidth. These modulations are explained by the strong coupling naturally occurring in ZnSe between photons and free-excitons, or exciton-polaritons. This type of cooperative process whereby a host excitation is used to control the behavior of a single emitter has never been reported before. It allows deterministically controlling the emission properties and enables the development of new coherent control scheme, such as the rotation of spins without the need for an external magnetic field.

2:45 PM MQ01.09.04  
**Resonant Excitation of Excitons and Trions Bound to Te$_2$ Molecules in ZnSe**  
Mathias Pont, Anne-Laurence Phaneuf-L’Heureux and Sebastien Francoeur; Polytechnique, Genie physique, Canada

Te$_2$ molecules in ZnSe form an isoelectronic center capable of binding a single hole, an exciton, a positively charged exciton, or a biexciton. This defect offers two advantageous characteristics for the development of spin-photon interfaces for applications in quantum optics, communications and networks. It provides the optical uniformity of atomic defects composed of a few atoms, like NV or other color centers in diamond, and the remarkable optical dipole moments found in semiconductor nanostructure.

In this work, we perform resonant excitation on a single Te$_2$ molecule in ZnSe. Resonant excitation reveals the intrinsic absorption linewidth of exciton and trion states. It is found that the addition of ultra weak non-resonant above band gap excitation can be used to stabilize the environment by reducing charge fluctuations, thereby allowing the measurement of much narrower absorption linewidths. Resonant excitation also reveals the participation of several bulk phonons along with phonons that have been reported in ZnSe. They are associated with localized phonons bound to the Te$_2$ molecule. In addition, resonant excitation on single Te$_2$ molecules reveals exciton tunneling to a nearby Te$_2$ molecule. Tunneling efficiency depends sensitively of the energetic separation, the respective orientation of the two molecules and the angular nature of the optical excited and detected exciton.
wavefunctions. These results pave the way towards resonant fluorescence and quantum optics with atomic-sized defects in semiconductor materials.

3:00 PM MQ01.09.05
Gate-Controllable Spin Splitting and Giant Proximity Magnetoresistance in InAs Induced by a Magnetic Proximity Effect Anh Le Duc1,1, Kosuke Takiguchi1, Takahiro Chiba2, Tomohiro Koyama3,3, Daichi Chiba3,3 and Masaaki Tanaka1,1; 1The University of Tokyo, Japan; 2National Institute of Technology, Fukushima College, Japan; 3Osaka University, Japan

The magnetic proximity effect (MPE)[1], which occurs due to the magnetic coupling within a few monolayers at the interface of two magnetically dissimilar layers, is effective in incorporating magnetic effects into nonmagnetic (NM) materials. In particular, the MPE at ferromagnetic (FM)/NM interfaces, where the NM layer is a material with strong spin-orbit coupling—typically a heavy metal, topological insulator, or two-dimensional electron gas (2DEG) with a strong Rashba effect—, has attracted much attention as promisingly open routes toward realizing Majorana fermions without using a strong magnetic field. However, the magnetic coupling at the FM/NM interface is typically a short range (~1 nm), which limits the strength of the MPE and hinders the ability of electrical gating of the effect.

Here, we show that the magnetic coupling range of MPE in a NM/FM bilayer can be dramatically enhanced, at least by two orders of magnitude, to several tens of nm on the NM side by using a semiconductor quantum well (QW) as the NM layer. The bilayers under study consist of InAs (thickness \( t = 15 - 40 \) nm)/(Ga,Fe)Sb (15 nm, 20% Fe) grown on AlSb buffer/semi-insulating GaAs (100) substrates by molecular beam epitaxy. This bilayer system has several unique properties that are particularly suitable for demonstrating MPE: i) (Ga,Fe)Sb is a p-type ferromagnetic semiconductor (FMS) with a high Curie temperature \( T_C (> 300 \) K)[2,3], while InAs QW is a typical Rashba 2DEG system with high electron mobility. ii) The lattice mismatch between InAs and (Ga,Fe)Sb is only \( \sim 0.1\% \); thus, high-quality heterostructures can be epitaxially grown. iii) InAs/(Ga,Fe)Sb is a type-III heterostructure, i.e., the conduction band bottom of InAs is lower than the valence band top of (Ga,Fe)Sb at the NM/FM interface, which enables large penetration of the electron wavefunction into the (Ga,Fe)Sb side. iv) The resistivity of the (Ga,Fe)Sb layer is two orders of magnitude higher than that of the InAs 2DEG, particularly at low temperature. Therefore, the electrical transport in these bilayers is dominated (> 99%) by the InAs 2DEG. We fabricate field-effect transistor structures on these InAs/(Ga,Fe)Sb bilayers, and measure magnetotransport properties using a standard four-terminal method.

We demonstrate that a new giant magnetoresistance (~80% at 14 T), which we call proximity magnetoresistance (PMR), is induced in the InAs 2DEG due to the MPE from the neighbouring (Ga,Fe)Sb layer. This PMR is two orders of magnitude larger, and its dependence on the magnetic field direction has a unique symmetry, which is different from the MR observed in other NM/FM bilayers reported to date. The PMR magnitude can be controlled over one order of magnitude by a gate voltage \( V_g \). These results are explained by the penetration of the InAs 2DEG wavefunction into (Ga,Fe)Sb, which is effectively modulated by \( V_g \). By fitting our modified Khosla-Fischer model to these PMR data, we find that a spontaneous spin splitting \( \Delta E \) is induced in the InAs channel by the MPE from (Ga,Fe)Sb. The magnitude of \( \Delta E \) is largely modulated from 0.17 to 3.8 meV when applying \( V_g \) between \( \pm 3\) V. In principle, this gate-controlled spin splitting and the new PMR provide a mechanism to locally access Majorana fermions in InAs-based Josephson junctions[4], and introduce a new concept of magnetic-gating spin transistors in which the NM channel current is modulated by both electrical and magnetic means[5].

This work was partly supported by Grants-in-Aid for Scientific Research (Nos. 16H02095, 17H04922, 18H05345), the CREST Program (JPMJCR1777) of JST, Yazaki Foundation for Science & Technology, and Spin-RNJ.

Spin Pumping into Superconducting Materials through Cr/Fe Interfaces  
Murat Cubukcu¹, Alex Chan², Alexander Vanstone², Sachio Komori³, Juliet Thompson³, Kun-Rok Jeon³, Chiara Ciccarelli³, Mark Blamire³, Jason Robinson³, Lesley F. Cohen² and Hidekazu Kurebayashi¹; ¹London Centre for Nanotechnology, United Kingdom; ²Imperial College London, United Kingdom; ³University of Cambridge, United Kingdom

There is currently a great deal of interest in the research field of superconducting spintronics [1]. In particular, the generation of spin-polarised (triplet) Cooper-pairs is a central topic. Long-range transportation of triplet Cooper-pairs, compared to singlet Cooper-pairs within a neighbouring ferromagnet, has been measured in a number of magnetic Josephson junctions with spatially inhomogeneous magnetisation [1,2]. We have demonstrated generation of the triplet Cooper-pairs spin currents and detection by spin pumping experiments in Pt/Nb/NiFe samples [3]. The observed enhancement of spin relaxation (or Gilbert damping) in this case implies that when Nb turns superconducting, a spin channel opens allowing spin-pumped magnons in NiFe to be dissipated at the Pt sink layer. This is in stark contrast to the picture of singlet Cooper-pairs which are unable to carry away any angular momentum, leading to the reduction of Gilbert damping below $T_c$. A proposed driving mechanism is the interaction of the spin-orbit coupling in Pt and the magnetic exchange interaction through the Nb layer. In this presentation, we will show our study of applying the same measurement techniques to other material systems. Of particular interest is an Fe/Cr interface where spin-glass states are formed to generate spin misalignments [4]. We will describe how the Gilbert damping parameter behaves below and above $T_c$ and the implications for spin transport through the Fe/Cr/Nb interfaces, in terms of the triplet Cooper-pair generation.

Spin-Filtering of Triplet Cooper Pairs and Suppression in an S-Wave Superconductor  
Lesley F. Cohen¹, Sachio Komori², James Devine-Stoneman², Mark Blamire² and Jason Robinson²; ¹Imperial College, United Kingdom; ²University of Cambridge, United Kingdom

Spin selectivity in a ferromagnet results from a difference in the density of up- and down-spin electrons at the Fermi energy as a consequence of which the scattering rates depend on the spin-orientation of electrons. This property is utilized in spintronics to control the flow of electrons by ferromagnets in a ferromagnet/normal metal/ferromagnet pseudo spin-valve.

The feasibility of superconducting spintronics depends on a spin-sensitivity of ferromagnets to the spin of equal-spin triplet Cooper pairs generated at superconductor(S)/ferromagnet(F) heterostructures with magnetic inhomogeneity at the S/F interface (1). In this talk we report Nb/Cr/Fe/Cu/Fe/Cr/Nb triplet Josephson junctions in which Cr/Fe interfaces act as triplet generators (2) and where the magnetization-alignment between the Fe layers controls the critical current ($I_c$). Furthermore, we will discuss equivalent junctions in which the central layer of Cu is substituted for a 10-40 nm thick layer of superconducting Nb; in these junctions we observe a suppression of $I_c$ below the critical temperature of the central Nb layer indicating a blocking of triplet pairs by the Nb singlet density of states.

4:00 PM MQ01.10.03
Nodal Superconducting Exchange Coupling  
Jason Robinson and Sachio Komori; University of Cambridge, United Kingdom

The superconducting equivalent of giant magnetoresistance involves placing a thin-film superconductor between two ferromagnetic layers. A change of magnetization-alignment in such a superconducting spin-valve from parallel (P) to antiparallel (AP) creates a positive shift in the superconducting transition temperature [$\Delta T_c=T_c(P)-T_c(AP)$] due to
an interplay of the magnetic exchange energy and the superconducting condensate. The magnitude of $\Delta T_c$ scales inversely with the superconductor thickness ($d_s$) and is zero when $d_s$ exceeds the superconducting coherence length ($\xi$). In this talk I will discuss a superconducting spin-valve effect involving a different underlying mechanism in which magnetization-alignment and $\Delta T_c$ are determined by the nodal quasiparticle-excitation states on the Fermi surface of the $d$-wave superconductor $YBa_2Cu_3O_{7-\delta}$ (YBCO) grown between the insulating ferromagnet $Pr_{0.8}Ca_{0.2}MnO_3$. We observe $\Delta T_c$ values of 2 K with $\Delta T_c$ oscillating with $d_s$ over a length scale exceeding 100 $\xi$ and, for particular values of $d_s$, we find that the superconducting state reinforces an antiparallel magnetization-alignment. The results pave the way for all-oxide superconducting memory$^2$ in which superconductivity modulates the magnetic state.

**Spin-Dependent Phenomena across the Crystalline BaTiO$_3$-Germanium Interface** Yichen Jia, Cristina Visani, Charles H. Ahn and Frederick J. Walker; Yale University, United States

The epitaxial integration of functional oxides on conventional semiconductors using advanced molecular beam epitaxy opens new opportunities for coupling their unique properties with semiconductors for post-CMOS computing paradigms. Here we explore spin-dependent phenomena in Permalloy-BaTiO$_3$-Germanium heterostructures and demonstrate an interesting correlation between charge transport and magneto-resistive response across the crystalline BaTiO$_3$-Germanium interface. In the quantum tunneling charge transport region, we observe Hanle and inverted Hanle effect with a full width at half maximum of ~100 mT. The single Hanle peak evolves into a superposition of two peaks with opposite polarity and distinct linewidth when impurity-assisted charge transport becomes dominant. Our result serves as a step towards understanding the origin of the magnetoresistance in oxide tunnel junctions.

4:30 PM MQ01.10.05
**Transport Spin Polarization of Pt/ferromagnetic Insulator Bilayers** Michael S. Osofsky$^1$, Joseph Prestigiacomo$^2$, Peng Li$^2$ and Yuri Suzuki$^2$; $^1$Naval Research Laboratory, United States; $^2$Stanford University, United States

It has been shown that the anomalous Hall effect can be observed in platinum films deposited on a ferromagnetic insulator which implies the existence of a magnetic proximity effect [1]. One of the key features of ferromagnetic metals is a net spin polarization of the carriers at the Fermi energy which enable the functionality of spintronic devices. In this presentation we show that spin polarized carriers are indeed present in Pt films of various thicknesses that were deposited on magnesium aluminum ferrite (MAFO) using point contact Andreev scattering [2]. The results were obtained by extracting conductance vs. voltage data from I-V curves taken through contacts formed by driving a sharpened superconducting Nb tip into the Pt/MAFO samples. The resulting spectra were then analysed using a modified BTK theory of supercurrent conversion at a normal/superconductor interface to obtain the values of the transport spin polarization.

The authors acknowledge the support of the Basic Research Office of the Assistant Secretary of Defense for Research and Engineering under the Laboratory University Collaboration Initiative (LUCI) and Vannevar Bush Faculty Fellowship (funded by the Office of Naval Research through grant N00014-15-1-0045).

**An Electronically-Controlled High Mobility Spin-Polarized Electron Gas at Engineered Oxide Interfaces** Yunzhong Chen; Technical University of Denmark, Denmark
The emergent two-dimensional electron gas (2DEG) and magnetism at the SrTiO$_3$-based oxide interfaces open new avenues for spintronics. However, to date, the “marriage” between the ferromagnetism and the high mobility 2DEG remains elusive. The recent introduction of a magnetic buffer layer of EuTiO$_3$ at the conducting interface gives rise to spin polarization but lowers the electron mobility significantly. Based on our former finding of charge transfer induced modulation doping at oxide interfaces, herein, we inserted a ferromagnetic insulating BaFeO$_3$ (BFO) buffer layer at the epitaxial LaAlO$_3$/SrTiO$_3$ (LAO/STO) interface and achieved a high mobility spin polarized 2DEG when the BFO is as thin as 1 unit cell (uc). Element-specific X-ray magnetic circular dichroism (XMCD) measurements reveal a paramagnetic nature of both the 1uc-BFO buffer layer and the 2DEG. Nevertheless, the spin polarization of the single band 2DEG is found to be enhanced strongly as electrons are depleted from the interface which is dramatically different from the multiple band spin polarized 2DEGs. The unique high mobility spin polarized 2DEG provides an intriguing material platform to design all-oxide spintronic devices.

**TUTORIAL**

Introduction to Ion Trap and Superconducting Qubits and Their Material Challenges

Sunday Morning, December 1, 2019
Hynes, Level 2, Room 202

Ion trap and superconducting qubits are two of the most popular quantum computing platforms in academia and industry but the performance of the qubits can be severely limited by their surrounding material quality. Surface defects, dielectric loss, anomalous heating in surface traps, unwanted coupling to spins and defects - all these material properties influence coherence times, the time qubits retain their quantum properties, which put the ultimate limit on the ability to run algorithms in quantum computing processors.

The tutorial will overview the basics of ion trap and superconducting qubits and the history of material development for these two quantum computing platforms. The tutorial will provide good opportunities for material scientists, who wants to engage in quantum information science, to learn about quantum computing devices and the ongoing challenges in the material research for quantum computation.

8:30 AM
Frederick Wellstood, Joint Quantum Institute, University of Maryland
In this tutorial, we will overview the basics of superconducting qubits and their material structures. Key concepts related to their material properties such as coherence times will be introduced as well as the characterization methods. The history of the superconducting qubit material research will be reviewed as well as the current challenges with future directions.

10:00 AM BREAK

Selective Area Epitaxy of a Materials Platform for Scalable Quantum Computing
Leo Kouwenhoven;
Microsoft/Delft University of Technology, Netherlands

Nanoscale hybrid III-V semiconductor/superconductor heterostructures have demonstrated potential to advanced quantum transport physics, in particular to host the elusive Majorana quasiparticles. Virtually all progress on the materials side in the last 6 years has relied on high quality vapor liquid solid growth of III-V free-standing nanowires functionalized at a later stage by ex-situ deposited Al. Despite these early successes a more robust,
scalable materials platform is still missing to enable the future topological quantum computer. Here I will report on our progress in using molecular beam epitaxy (MBE) to grow both III-V semiconductor nanowire networks and a high quality epitaxial s-wave metal superconductor, using selective area epitaxy. I will first introduce the current state of the art, advantages and challenges of the selective area approach and MBE with respect to other growth techniques and geometries. Fundamental knowledge gained by growth studies will be applied to obtain reproducible, high yield advanced high spin-orbit III-V nanowire/superconductor networks. I will present low temperature transport experiments that characterize the quality of the materials.

9:00 AM MQ02.01.02
Lattice-Matching Strategy for Coherent Interface Design of Josephson Junction—Al/AlOx/Al vs Re/Al2O3/Re Chang-Eun Kim, Keith Ray and Vincenzo Lordi; Lawrence Livermore National Laboratory, United States

Amorphous aluminum oxide-based tunnel junctions have been widely adopted for fabricating superconducting qubit devices, but further improvement is hindered by potentially fundamental limits of uniformity and interactions with intrinsic tunneling two-level-systems (tTLS) originating from amorphous AlOx and disordered interfaces. The amorphization and disordering are inevitable due to large lattice mismatch between crystalline aluminum oxide and the aluminum substrate. The Re/Al2O3/Re material stack has well-matched lattice parameters, and prior work has demonstrated reduced TLS density. We aim to understand the materials property of these interfaces, detailing their thermodynamic property such as interfacial energy and work of adhesion; and structure-related electronic properties such as fundamental energy gap, ionic charge transfer, and local dipole formation. The results show how the lattice-matching strategy improved several microscopic properties of the tunnel barrier junction, laying out a strategy to develop more coherent superconducting quantum computing components. (Prepared by LLNL under Contract DE-AC52-07NA27344.)

Atomic-Scale Fabrication of Donor-Based Quantum Devices in Silicon Xiqiao Wang1,2, Ranjit Kashid1, Jonathan Wyrick1, Pradeep Namboodiri1 and Richard Silver1; 1National Institute of Standards and Technology, United States; 2University of Maryland-College Park, United States

Donor-based qubits in silicon have attracted broad interest as a promising candidate for scalable solid-state quantum computing. Central to the scalability and performance of this quantum system is atomically precise control of dopant confinement and single dopant placement in silicon. Atomically precise fabrication in silicon has enabled atom-by-atom control and characterization of quantum materials properties for quantum information processing and quantum simulation applications, such as high-fidelity spin readout/initialization and tunable exchange coupling in multi-qubit gate operations.

Success in atomically precise fabrication is a direct consequence of controlling materials properties at the atomic scale. This presentation will present our recent advances to address critical challenges in atomically precise fabrication and characterization of donor-based quantum devices in silicon by using enhanced STM-based hydrogen lithography to define atomically precise dopant-based devices, and by suppressing atomic-scale dopant movement during device encapsulation overgrowth. We will report on STM-defined single electron transistors that can be used as charge sensors, where the source/island/drain tunnel coupling can be controlled with atomic-precision for the optimization of charge sensing performance. We will present resonant tunneling spectroscopy analysis of STM-defined single and few donor quantum dots with atomically defined tunnel gaps. Finally, we combine single/few donor quantum dots with atomically defined single electron transistors as charge sensors and report our recent results in atomic-scale control of tunnel coupling between few-donor quantum dots and single electron charge sensors to illustrate the impact of atomically defined tunnel coupling on single electron charge sensing and spin selective-readout.

9:30 AM *MQ02.01.04
Towards PAMBE Grown Nitride Superconductors for Epitaxial Josephson Junctions and Quantum Circuits Christopher Richardson; University of Maryland, United States

Low microwave loss superconducting circuit components are a necessity of fabricating high-fidelity
superconducting qubits. Accordingly, significant research has focused on making high-quality planar resonators from elemental and nitride superconductors. Josephson junctions are the nonlinear component of superconducting qubits, that also need to be high performance. Interestingly, superconducting qubits all use Josephson junctions fabricated from aluminum and aluminum oxide using the double angle evaporation process. Details of this alternative design will be presented.

Plasma assisted Molecular beam epitaxy (PAMBE) is used to grow niobium titanium nitride alloys (Nb,Ti₁₋ₓN) and wide bandgap nitride (AlN) superconductors directly on sapphire wafers. This combination of nitride materials provides sufficient degrees of freedom that synthesis of an epitaxial Josephson junction may be possible. Growth results of Nb,Ti₁₋ₓN films on c-plane sapphire substrates, and initial trilayer NbTiN/AlN/NbTiN (superconductor-insulator-superconductor) Josephson junction structures on sapphire will be presented along with structural analysis and results from superconducting IV and microwave-loss measurements.

Protecting Superconducting Qubits from Phonon Mediated Decay Yaniv J. Rosen, Matthew Horsley, Sara Harrison, Eric Holland, Allan Chang, Tiziana Bond and Jonathan DuBois; Lawrence Livermore National Laboratory, United States

For quantum computing to become fault tolerant, the underlying quantum bits must be effectively isolated from the noisy environment. It is well known that including an electromagnetic bandgap around the qubit operating frequency improves coherence for superconducting circuits. However, investigations of bandgaps to other environmental coupling mechanisms remain largely unexplored. We present a method to enhance the coherence of superconducting circuits by introducing a phononic bandgap around the device operating frequency. The phononic bandgap blocks resonant decay of defect states within the gapped frequency range, removing the electromagnetic coupling to phonons at the gap frequencies. We constructed a multi-scale model that derives the decrease in the density of states due to the bandgap and the resulting increase in defect state T₁ times. We demonstrated that emission rates from in-plane defect states can be suppressed by up to two orders of magnitude. We combine these simulations with full master equation simulations to demonstrate the suppression of qubit energy relaxation even when interacting with 200 defects states.

10:45 AM *MQ02.02.02
3D Integration to Enable High Coherence and Connectivity for Superconducting Qubits Danna Rosenberg¹, J. Mallek², D. Yost¹, M. Schwartz¹, R. Das¹, J.L. Yoder¹, G. Calusine¹, E. Golden¹, B. Huffman¹, Alexander Melville¹, A. Sevi¹, W. Woods¹ and W.D. Oliver¹,²; ¹Lincoln Laboratory, Massachusetts Institute of Technology, United States; ²Massachusetts Institute of Technology, United States

As the field of superconducting qubits progresses, it will become increasingly important to use 3D integration to address large arrays of qubits. Traditional 3D integration methods pose challenges for superconducting qubits, because these qubits are vulnerable to losses introduced by bulk dielectrics and at interfaces. To overcome these challenges, we are developing a novel three-tier stack where an interposer with superconducting through-silicon vias (TSVs) isolates sensitive qubits from a potentially-lossy readout and interconnect chip. This isolation prevents degradation of the qubit coherence time, and the high-aspect ratio superconducting TSVs enable dense circuitry to control and read out the qubits. The components of the three-tier stack are bonded using indium bump bonds, providing both structural support and a galvanic connection between the three chips. I will present our work developing and characterizing 3D integration components including indium bumps and TSVs, and I will discuss recent demonstrations incorporating superconducting TSVs in qubit control and readout circuitry.

Microfabricated Ion Traps for Quantum Information Science  
Susan Clark, Matthew Blain, Raymond Haltli, Craig Hogle, Daniel Lobser, Melissa Revelle, Christopher Yale and Peter Maunz; Sandia National Laboratory, United States

Trapped ion systems have many advantages that make them promising quantum computing platforms. They are well isolated from the environment, feature high-fidelity quantum operations, and exhibit basically no idle errors. Microfabrication enables the realization of complex traps that allow one to precisely control large ion chains, move qubits through the trap, and reconfigure the trapped ion quantum processor, which are necessary features for building large scale systems capable of performing complex algorithms. However, microfabricated surface traps bring unique challenges. Proximity of ions to trap structures can lead to electric field noise which induces anomalous heating of ions in the trap. Routing through traps to make complex electrode patterns leads to higher capacitances and thus higher thermal dissipation on the device. Also, complex RF geometry can lead to excessive micromotion and AC Stark shifts, which can vary or broaden the energy levels used to perform gates. Reducing these sources of error is essential to further improve the fidelity of trapped ion quantum processors.

We will present Sandia’s ion-trap microfabrication capabilities and introduce ion trap designs that are being used in the leading trapped-ion groups, as well as our characterization and mitigations for these sources of error. We show exquisite classical control of ions as well as high-fidelity quantum operations, demonstrating the viability of microfabricated surface electrode ion traps for quantum information processors.

SNL is managed and operated by NTI under DOE NNSA contract DE-NA0003525. SAND2019-6322 A

8:00 AM MQ02.03.01
Quantum Spin System in a Semiconducting Diode  
Alexandre Bourassa¹, Christopher P. Anderson¹ and David D. Awschalom¹²; ¹The University of Chicago, United States; ²Argonne National Laboratory, United States

The neutral divacancy (VV⁰) in silicon carbide (SiC) is a candidate solid state qubit which promises a combination of long spin coherence and near-infrared emission in a material which is already optimized for state-of-the-art scalable semiconductor manufacturing. Here, we use this mature host material to integrate quantum states into classical electronic devices.

First, we show that we can create and isolate single divacancy in p-i-n diodes. We then perform spin manipulation and readout of these single defects inside the junction and demonstrate high fidelity Rabi oscillations (with >98% contrast). This allows us to measure a long spin coherence time (T₂) which persist inside the device.

Second, we use the diode to confine the electric field in the i-layer which allows us to Stark tune the single photon emission frequency by almost a terahertz. Furthermore, since this field is applied along the defect axis, the tuning does not change the symmetry of the orbitals which minimizes unwanted spin flip rate.

Finally, we show how we can use charge depletion in the junction to drastically reduce electric field noise at the defect. This allows us to effectively eliminate spectral diffusion and obtain an optical linewidth approaching the
lifetime limit of the emitter (a 50x enhancement). Moreover, we show that this optical line is very stable and fluctuates by less than a linewidth over many hours.

Overall, these results demonstrate the power in integrating quantum states into engineered classical electronics devices.

Er Doped Y₂O₃ on Silicon—Development and Characterization of a Scalable Quantum Memory Platform
Manish Kumar K. Singh¹, Abhinav Prakash¹,², Tijana Rajh², Gary Wolfowicz¹,², Yizhong Huang¹,², Christina Wicker¹, Alan Dibos², Jianguo Wen², David D. Awschalom¹,², Tian Zhong¹,² and Supratik Guha¹,²; ¹University of Chicago, United States; ²Argonne National Laboratory, United States

Rare earth ions (REI) have a spin-optical interface that enables storage of optical quantum information in the long-lived nuclear spin levels. Further, a microwave resonator can couple to the spin transitions inductively, making REI suitable for quantum memory and transduction applications. In the case of Er³⁺, the optical excitation matches the telecom transmission wavelength (~1.55 um), making it technologically attractive. When embedded in a crystalline host, the full 5s and 5p orbitals of the REI shield the intra 4f electrons from the crystal field effects from the host. This results in very narrow transition linewidths and high spectral stability, making it an ideal candidate for solid state quantum memory. Long coherence times of 1.3s in Er:YSO [1] bulk single crystals have been demonstrated. However, very little has been done in this regard when it comes to demonstrating thin films that could be integrated into scalable devices.

Using molecular beam epitaxy (MBE), we demonstrate the growth and characterization of high quality single crystal thin films of Er:Y₂O₃ on Si 111. Using optical and electron paramagnetic resonance spectroscopy, we confirm that Er substitutes for Y at both C2 and C3 sites in the bixbyite structure of Y₂O₃. We obtain a photoluminescence linewidth of 7.9 GHz and 5.1 GHz for the 1536 nm transition (4I13/2 → 4I15/2) at 4 K and 7 mK, respectively. We will discuss the role of the microstructure (carried out using extensive electron microscopy), the use of buffer layers, the Y₂O₃/Si and the Y₂O₃/air interface, and the optimization of these parameters that led to the demonstration of narrow optical linewidth of Er³⁺. We also discuss the gains resulting from using enriched ¹⁶⁷Er (91.5%) as the dopant.

In order to transfer the growth processes for compatibility with compact, optically modulated solid state devices, it is necessary to develop these heterostructures on silicon-on-Insulator (SOI) wafers—preferably (but not necessarily) oriented along <100>—so that they may be integrated with silicon photonics based optical waveguides. We demonstrate the growth of Y₂O₃ on Si 100 with a Y₂O₃/Si(110)//Si(100) epitaxial relationship. We will also report on the demonstration of full SOI/Er:Y₂O₃/Si overlayer heterostructures and the quality of optical waveguides fabricated using this platform.

Integrated Photonic Devices and Materials for Scalable Trapped-Ion Quantum Logic
Karan Mehta, Chi Zhang, Maciej Malinowski, Thanh-Long Nguyen and Jonathan Home; ETH Zürich, Switzerland

Trapped-ion quantum systems are a promising platform for large-scale quantum information processing, with all relevant operations having been demonstrated with the highest fidelities in any qubits to date [1,2], and fully connected systems with of order 10 qubits [3]. Given this established set of basic operations, methods to allow their robust implementation at a large scale, while also significantly reducing error rates, will play an increasingly central role in work towards realizing useful quantum processors.

A major element of this in the context of trapped-ion qubits will be the integration of optics used to control many
ions in parallel into the ion traps themselves [4]. This enables stable beam delivery, tight focusing to µm-scale spots for individual ion-addressing and efficient power usage, and straightforward parallelization. I will describe our recent work at ETH developing on these ideas [5], in devices with efficient fiber coupling on multiple channels directly to waveguides on trap die (2 dB coupling loss measured at 729 nm wavelengths), and low-loss routing and emission to ions trapped 50 µm above the surface of the chip. I will present our work towards realizing multi-qubit quantum logic in these devices, a few novel beam arrangements utilizing such optics, and observations on relevant noise sources present owing to the various materials near the ions.

Our current experiments are based on integrated devices for light at red and near-IR wavelengths, and use modulators off-chip. In longer-term systems there will be considerable interest in compact integrated modulators, including for blue and near-UV wavelengths, able to be implemented within the trap chip. This will motivate research on thin-film material systems suitable for integrated electro- and acousto-optic devices at short wavelengths; these would additionally have broad applicability beyond quantum information.

9:00 AM MQ02.03.04
Aluminum Gallium Arsenide Photonic Waveguides for 780 nm Optical Delivery for Quantum Sensors Based on Ultra-Cold Atoms of Rubidium Jessica O. Maclean1, Mark Greenaway2, Richard Campion1, Mark Fromhold1 and Chris Mellor1; 1University of Nottingham, United Kingdom; 2Loughborough University, United Kingdom

An on-chip approach to optical delivery for portable quantum sensors is described. The optical design, epitaxy, nanofabrication and measurement of polarisation-maintaining, deep-etched aluminium gallium arsenide (AlxGa1-xAs) waveguides for near-infra-red 780 nm light was achieved, in an analogous approach to earlier work at (1300-1550) nm wavelengths [1]. Material characterisation techniques were developed to infer improved optical quality and reduced optical loss intrinsic to the material, grown by Molecular Beam Epitaxy (MBE). High, continuous-wave optical power densities were guided with low polarisation noise and photonic waveguide performance was stable over time. The optical loss was measured to be below 4.3(±0.4) dB cm⁻¹ corresponding to an attenuation coefficient, α, of 1.0 (±0.08) cm⁻¹ for single mode waveguides and demonstrating improved performance data [2]. The polarisation extinction ratio was better than −19 (±1) dB for orthogonal polarisations. These novel components illustrate the feasibility of passive photonic integrated circuits for the 780 nm wavelength. Future work will investigate the optical switching properties of these structures. The ultimate aim of the work is the creation of waveguide-based photonic circuits for compact cold atom sensors based on the D2 hyperfine transition of 87Rb at 780.24 nm [3]. Further applications include free-space short-wave communications, hybrid quantum systems [4] and epitaxial structures transparent to shorter wavelengths for other cold atom species and trapped ions. To this end, recent experiments examined device functionality as a function of wavelength.

Thermodynamic Performance Limits for Optical Microcavities Christopher L. Panuski, Ryan Hamerly and Dirk R. Englund; Massachusetts Institute of Technology, United States

High quality factor ($Q$), small mode volume ($V$) optical microcavities are coveted for a variety of applications, including low-energy nonlinear optics and precision sensing. Recent theory and fabrication advances have led to the experimental realization of resonators featuring subwavelength mode confinement and quality factors exceeding 10 million. These continued improvements lend a natural question – is there any limit to the highly sought-after $Q/V$ ratio? Here, we show that the presence of thermo-refractive noise (TRN) – stochastic perturbations of the cavity material’s index of refraction due to fundamental temperature fluctuations – imposes a fundamental bound of the achievable cavity performance. Specifically, our results reveal a mode volume-dependent limit to an “effective quality factor,” which accounts for both intrinsic decay and resonant frequency noise. We compare this performance bound in various common integrated photonics materials systems, and explore the implications for proposed all-optical quantum information schemes. These results thus illustrate the importance of considering thermal noise in state-of-the-art microcavities, but also inform the choice of materials and processes which minimize its performance impact.

Design and Fabrication of Large-Scale Defect-Free Arrays of Artificial Atoms Coupled to Photonic Waveguides Tsung-Ju Lu1, Noel Wan1, Kevin C. Chen1, Michael Walsh1, Matthew Trusheim1, Lorenzo De Santis1, Eric Bersin1, Isaac Harris1, Sara Mouradian1, Edward Bielejec2 and Dirk Englund1; 1Massachusetts Institute of Technology, United States; 2Sandia National Laboratories, United States

Atom-like emitters in diamond are among the promising qubits for quantum computing and information processing. In particular, the silicon vacancy (SiV) and germanium vacancy (GeV) centers are outstanding emitters due to their long spin coherence times and narrow optical transitions. Here, we describe the design and fabrication of diamond waveguide arrays containing single SiV and GeV centers coupled to aluminum nitride photonic circuits. A high-yield qubit creation process along with deterministic photonic nanofabrication produces unity coupling of emitters to single-mode diamond waveguide arrays. These arrays are subsequently assembled on aluminum nitride photonic waveguide arrays for on-chip routing and manipulation of photons. The combination of these advances allows the initial demonstration of a 72-channel solid-state spin qubit microphotonic chip for large-scale manipulation of quantum information.

9:45 AM MQ02.03.07
Narrow Optical Linewidths in Implanted Erbium Ions Paul Stevenson, Christopher M. Phenicie, Sacha Welinski, Brendon C. Rose, Stephen A. Lyon, Robert J. Cava, Nathalie P. de Leon and Jeffrey Thompson; Princeton University, United States

Erbium ions are a promising resource for long-range quantum communication applications. Optical transitions operating at 1.5μm minimize propagation loss in optical fibers, enabling communication on the 100 km scale, while electron and nuclear spin degrees of freedom can be used as a local quantum memory. However, currently known hosts for Er$^{3+}$ ions contain atoms with nonzero nuclear spin, which leads to magnetic noise that dephases the Er$^{3+}$ electron spin.

We present a new approach to incorporating Er$^{3+}$ into nuclear spin free materials via ion implantation while achieving narrow (~4GHz) inhomogeneous optical linewidths. By implanting Er$^3$ into crystalline hosts of appropriate symmetry, we are able to significantly reduce the effect of inhomogeneous broadening on the optical linewidths, observing few GHz linewidths prior to thermal processing. We use a hybrid optical-ESR technique to unambiguously relate optical and spin degrees of freedom in the system. These results present a general route forward for incorporating Er$^{3+}$ and other ions into non-standard crystalline hosts.

Long Distance Quantum Networks Based on Color Centers in Diamond  Nathalie P. de Leon; Princeton University, United States

Color centers in diamond are promising candidates for quantum networks, as they can serve as solid state quantum memories with efficient optical transitions. Prior work has focused on the NV- center in diamond, which exhibits long spin coherence times and has narrow, spin-conserving optical transitions. However, the NV- center is prone to spectral diffusion, and over 97% of emission is in an incoherent phonon side band, severely limiting scalability. Alternatively, SiV- exhibits excellent optical properties, with 70% of its emission in the zero phonon line and a narrow inhomogeneous linewidth. However, SiV- suffers from significant interaction with phonons, with spin coherence times limited by an orbital relaxation time (T1) of around 40 ns at 5 K.

Informed by the limitations of NV- and SiV-, we have developed new methods to control the diamond Fermi level to stabilize the neutral charge state of SiV, thus accessing a new spin configuration. SiV0 exhibits a spin T1 of around 1 minute at 4 K, coherence time (T2) approaching 1 second, over 90% of emission in the zero phonon line, and near-transform limited optical linewidths, making it a promising candidate for applications in quantum networks.

Magneto-Optical Properties of Neutral Group-IV Vacancy Color Centers in Diamond from First Principles  Adam Gali1,2 and Gergo Thiering1; 1Hungarian Academy of Sciences, Hungary; 2Budapest University of Technology and Economics, Hungary

The neutral silicon-vacancy color center has S=1 spin with long longitudinal spin relaxation time, close-to-unity Debye-Waller factor, and its optical transition is intrinsically resistant against stray electric fields. These properties are attractive in quantum communication applications. Unlike the negatively charged silicon-vacancy color centers, the magneto-optical properties of the neutral silicon-vacancy center is not well understood. Furthermore, the other neutral XV split-vacancy complexes in diamond, where X and V labels a group-IV impurity atom of X = Si, Ge, Sn, Pb and the vacancy, are practically unknown, although the negatively charged counterparts can be fabricated in diamond.

Our first principles calculations reveal the charge state stability of the neutral XV split-vacancy complexes in diamond which may guide the experiments to create these centers. In addition, we develop and apply ab initio theory to quantify the strength of electron–phonon coupling for neutral XV complexes in diamond, and find a significant impact on the corresponding optical properties of these centers. Our results show good agreement with recent experimental data on the prospective neutral SiV quantum bit, and reveals the complex nature of the excited states of neutral XV color centers in diamond. We predict the zero-phonon-line of neutral XV color centers in diamond and other magneto-optical properties.

A 72-Channel Diamond Quantum Memory Array Integrated in a Microphotonic Chip  Noel Wan1, Tsung-Ju Lu1, Kevin C. Chen1, Michael Walsh1, Matthew Trusheim1, Lorenzo De Santis1, Eric Biersin1, Isaac Harris1, Sara Mouradian1, Edward Bielejec2 and Dirk R. Englund3; 1Massachusetts Institute of Technology, United States; 2Sandia National Laboratories, United States

Optically active spins coupled to single-mode diamond optical waveguides are efficient spin-photon interfaces for quantum networks. In a previous abstract, we described the unity creation, coupling and integration of single silicon vacancy (SiV) and germanium vacancy (GeV) in diamond waveguide arrays with a large-scale photonic integrated
circuit (PIC) in aluminum nitride. Here, we present the detailed characterization of our 72-qubit quantum memory chip. Single-photon emission from 72 distinct optical channels are routed in the PIC and coupled to optical fibers. We performed low-temperature laser spectroscopy of the emitters, confirming that lifetime-limited optical transitions from both SiV and GeV centers are preserved following nanofabrication, micromanipulation and heterogeneous integration. With qubit energy and spin control, this fiber-coupled quantum photonic circuit establishes the prospects for high-efficiency, multiplexed quantum repeaters on a chip.

Noise Resilient Entanglement Creation of Remote Quantum Memories Hyeongrak Choi and Dirk Englund; Massachusetts Institute of Technology, United States

Entanglement is a core component in quantum information science including quantum computing and quantum repeater. Indistinguishability of two sub-systems is a prerequisite for measurement-based entanglement, and thus, its creation process is very susceptible to any kinds of local noise. In this work, we propose a noise resilient entanglement protocol based on detuned Rayleigh scattering of photons from atomic memories. In principle, near unity fidelity is possible in the presence of noise, and only limited by the energy splitting of state selective transitions. The protocol make use of a cyclic transition and is compatible with ancillary memory spins such as nuclear spins. The combination of these properties enables fault-tolerant quantum repeater with quantum error correcting nodes.

Ab Initio Radiative Lifetime of Point Defects in Hexagonal Boron Nitride Shiyuan Gao, Hsiao-Yi Chen and Marco Bernardi; California Institute of Technology, United States

Point defects in hexagonal boron nitride (hBN) have recently emerged as potential single-photon emitters due to their high brightness, strong zero-phonon line and room temperature stability. However, the atomic structures of the point defects to which light emission in hBN has been attributed are still unknown. Several candidate defect structures have been proposed using density-functional theory (DFT) calculations, which have so far focused on the defect formation energy, structure, symmetry, and electronic energy levels; yet, direct comparisons with experiments remain inconclusive. In this talk, we present first-principles calculations of the optical excitation energy and radiative lifetimes of various defects in monolayer hBN; our results are obtained from DFT plus the GW-Bethe-Salpeter Equation (BSE) method, which properly accounts for dielectric screening and excitonic effects, and can provide accurate radiative lifetimes. We find that the radiative lifetimes of various defect structures can differ by an order of magnitude due to microscopic details such as the defect optical transition dipoles and spin polarization. We identify several defects with optical transitions close to the 2 eV value found in experiments, including an NV-like defect with a two-level structure with 2.4 eV optical transition and a 72 ns radiative lifetime, as well as defects with ~20 ns radiative lifetimes. Our results provide a new approach for identifying promising defect structures for single photon emitters and quantum technology applications.
materials and epitaxial synthesis techniques that can yield quantum engineered hybrid materials platforms of interest in this context. Examples include magnetically-doped topological insulators that host robust quantum anomalous Hall insulator or axion insulator phases [2] and oxide-topological insulator interfaces that allow erasable spatial patterning of magnetic and chemical potential landscapes at the mesoscale [3]. Finally, we provide a perspective on the potential opportunities and the daunting challenges for experimentally realizing topological quantum computing platforms using these hybrid quantum materials [4].

Quantized Superconductor-Semiconductor Nanowire Junctions Sabbir A. Khan1, Ajuan Cui1, Charalampos Lampadaris1, Martin E. Cachaza1, Jung-H. Kang1, Lukas Stampfer2, Joachim E. Sestoft2, Filip Krizek2, Yu Liu1, Thomas S. Jespersen2 and Peter Krogstrup1; 1University of Copenhagen, Denmark; 2Niels Bohr Institute, University of Copenhagen, Denmark

One-dimensional hybrid superconductor/semiconductor (SU/SE) nanowires are promising material platforms for gatable superconducting device measurements.1,2 In this research we grow stacking-faults-free InAs, InSb and InAs0.3Sb0.7 nanowire networks with epitaxial Al shadowed junctions in single-step growth process using molecular beam epitaxy (MBE). We compare different material systems and discuss associated pros and cons. We also study the formation of superconductor/semiconductor junctions and characterize the structural and electrical properties of the junctions. We show optimized junctions provide enhanced transport properties exhibiting repeatable quantized conductance for all three type of wires and potential host for Majorana bound states. Furthermore, we characterize both in-situ and post-growth processed junctions in a single nanowire and demonstrate in-situ SU-SE junctions exhibit clean surface morphology and enhanced electrical transport.

2:30 PM MQ02.04.04
Evidence for Helical Hinge Zero Modes in an Fe-Based Superconductor Mason Gray1, Josef Freudenstein1, Shu Yan F. Zhao2, Ryan O’Connor1, Samuel Jenkins1, Narendra Kumar1, Marcel Hoek1, Abigail Kopec1, Takashi Taniguchi3, Kenji Watanabe3, Ruidan Zhong4, Genda Gu4 and Kenneth Burch1; 1Boston College, United States; 2Harvard University, United States; 3National Institute for Materials Science, Japan; 4Brookhaven National Laboratory, United States

Combining topology and superconductivity provides a powerful tool for investigating fundamental physics as well as a route to fault-tolerant quantum computing. There is mounting evidence that the Fe-Based Superconductor FeTe0.55Se0.45 (FTS) may also be topologically non-trivial. Should the superconducting order be s±, then FTS could be a higher order topological superconductor with Helical Hinge Zero Modes (HHZM). To test the presence of these modes we’ve fabricated normal-metal/superconductor junctions on different surfaces via 2D atomic crystal
heterostructures. As expected, junctions in contact with the hinge reveal a sharp zero-bias anomaly that is absent when tunneling purely into the c-axis. Additionally, the shape and suppression with temperature are consistent with highly coherent modes along the hinge, and are incongruous with other origins of zero bias anomalies. Furthermore, additional measurements with soft-point contacts in bulk samples with various Fe interstitial contents demonstrate the intrinsic nature of the observed mode. Thus we provide evidence that FTS is indeed a higher order topological superconductor.

Computational Database of Topologically Non-Trivial Materials Using Spin-Orbit Spillage Kamal Choudhary; National Institute of Standards and Technology, United States

The Majorana fermion based topological quantum computing (QC) has immense potential for decreasing decoherence, which is one of greatest challenges for conventional QC. However, very few topological materials are known to date. To accelerate the identification of topological materials, we present a novel methodology to identify topologically non-trivial materials based on band inversion induced by spin-orbit coupling (SOC) effect. Specifically, we compare the density functional theory (DFT) based wavefunctions with and without spin-orbit coupling and compute the ‘spin-orbit-spillage’ as a measure of band inversion. Due to its ease of calculation, without any need for symmetry analysis or dense k-point interpolation, the spillage is an excellent tool for identifying topologically non-trivial materials. Out of 30000 materials available in the JARVIS-DFT database, we applied this methodology to more than 4835 non-magnetic materials consisting of heavy atoms and low bandgaps. We found 1868 candidate materials with high-spillage (using 0.5 as a threshold). We validated our methodology by carrying out conventional Wannier-interpolation calculations for 289 candidate materials. We demonstrate that in addition to $Z_2$ topological insulators, this screening method successfully identified many semimetals and topological crystalline insulators. Importantly, our approach is applicable to the investigation of disordered or distorted as well as magnetic materials, because it is not based on symmetry considerations. We discuss some individual example materials, as well as trends throughout our dataset, which is available at the websites: https://www.ctcms.nist.gov/~knc6/JVASP.html and https://jarvis.nist.gov/.

Low Loss Superconducting Circuits for Quantum Computing Vivekananda Parampalli Adiga; IBM T.J. Watson Research Center, United States

Low loss microwave circuits are an essential ingredient that enables superconducting quantum processors. Most of the present day superconducting quantum computers rely on qubits and resonators with long life times to demonstrate basic quantum computing applications. To reach the goal of a fault tolerant universal quantum computer with superconducting circuits, coherence times still need to improve several orders of magnitude. Some improvements will likely come from better designs, fabrication processes, and materials used to build quantum processors. In this talk I will discuss the history of coherence improvements in qubits and current challenges in achieving low loss quantum circuits.

2:00 PM *MQ02.05.02
Materials Developments for Superconducting Quantum Circuits David Pappas; National Institute of Standards and Technology, United States

Rapid progress in being made towards optimizing materials to increase coherence superconducting quantum circuits. In particular, both intrinsic and extrinsic materials and effects have been studied. In the former, new techniques to
study the effects of dielectric loss and the role of defects in and around junctions have been devised as well as new ideas for mitigating these effects and designing new types of qubits. For the latter, extrinsic causes of decoherence including the effects of radiation, quasiparticles, piezoelectricity, trapped flux, and excess photons. In this talk a general review of coherence and fabrication techniques for this circuits will be given with a few examples from the general literature. So of our work on intrinsic effects will be discussed, including studies of long-term measurements of highly coherent, non-tunable superconducting transmon qubits. Measurements of relaxation and dephasing are used to understand the low-frequency burst noise in coherence times and qubit transition frequency, leading to information about the microscopic origin of the intrinsic decoherence mechanisms in Josephson qubits. Progress towards a test-bed for studying loss in superconducting resonators and the associated analysis and interpretations will be presented. Interlaboratory comparisons of these analysis will be presented.

Growth and Characterization of a Novel Si/SiGe Heterostructure for Quantum Dot Qubits Thomas W. McJunkin1, Evan R. MacQuarrie1, Samuel F. Neyens1, Brandur Thorgrimsson1, Joelle Corrigan1, John P. Dodson1, Leah Tom1, Donald E. Savage1, Max G. Lagally1, Robert Joynt1, Mark Friesen1, Susan N. Coppersmith1,2 and Mark A. Eriksson1; 1University of Wisconsin–Madison, United States; 2University of New South Wales, Australia

In recent years, silicon-based quantum dots have been shown to be a promising avenue for quantum computing. However, the near-degeneracy of the two low-lying valley states in silicon quantum wells can inhibit the formation of distinct quantum states. Motivated by the desire to increase the magnitude and tunability of this valley splitting, a Si/SiGe heterostructure is grown with a thin layer of SiGe embedded within the silicon quantum well. The Si/SiGe heterostructure is grown via UHV-CVD on a linearly graded SiGe alloy with a final germanium concentration of 29%. STEM measurements reveal the quantum well structure to consist of a ~10 nm silicon layer, followed by a thin ~1 nm SiGe layer, and subsequent ~2 nm layer of pure silicon. Above this quantum well, a ~35 nm layer of SiGe with 29% germanium is grown to separate the quantum well from the surface. The intent of this ~1 nm layer of SiGe, positioned just below the upper interface of the quantum well, is to modify the valley splitting of electrons in a 2-dimensional electron gas (2DEG) that reside near this interface. By varying an external vertical electric field, the electron wavefunction can be moved on and off this spike in germanium concentration, modifying the magnitude of the valley splitting.

We report electronic measurements of both Hall bars and electrically gated quantum dot devices that are fabricated on this heterostructure. Shubnikov-de Haas (SdH) and quantum Hall (QH) measurements reveal a peak transport mobility in excess of 100,000 cm²/(V s) at 6 x 10¹¹ cm⁻² carrier density. We report SdH and QH measurements over a wide range of carrier density and magnetic field in the form of a fan diagram. Valley splitting values are measured in the quantum dot device by magneto-spectroscopy, in which a few-electron dot transition is measured while an in-plane magnetic field is swept. Measuring at the second, third, and fourth electron transition in the quantum dot, we find valley splittings of 29, 48, and 65 μeV, respectively. To measure tunability of valley splitting, nearby gate
voltages are changed to vary the vertical electric field at constant charge occupation. We find that both the lowest lying valley splitting and the valley splitting in the first excited orbital can be tuned over a factor of 2 by means of such changes in gate voltage. Additionally, we report modeling of the applied electric field at the dot in support of experimental results.

8:45 AM *MQ02.07.02
Isotope Materials Engineering for Silicon Quantum Computing Kohei M. Itoh; Keio University, Japan

A series of recent high-impact researches on silicon-based quantum computers [1] has proven that it is crucial to prepare high quality silicon matrixes that are free of background nuclear spins. For example, electron spin qubits placed in a natural silicon substrate decoher quickly due to their interaction with background $^{29}$Si nuclear spins that exist with the natural abundance of 4.7%. On the other hand, electron spin qubits placed in zero-nuclear-spin $^{28}$Si stable isotope matrixes show much extended coherence time leading to increase in the possible quantum gate operation number and gate fidelity [1].

This talk will review the state-of-the-art in silicon isotope materials engineering [2] followed by in-depth discussions on how not only the background $^{29}$Si nuclear spins but also the mass fluctuation caused by co-existence of $^{28}$Si, $^{29}$Si, and $^{30}$Si isotopes can affect the properties of both electron and nuclear spin qubits placed in silicon. While majority of the results that will be presented are obtained in the present author’s group, some significant and relevant results achieved under the projects supported by the MEXT - Quantum Leap Flagship Program in Japan are also introduced.

This work has been supported by the Center for Spintronics Research Network, Keio University. The author acknowledges fruitful collaborations with Satoru Miyamoto, Noritaka Usami, Yusuke Hoshi, Seigo Tarucha’s group, Mark Eriksson’s group, Andrew Dzurak’s group and Andrea Morello’s group.

9:15 AM *MQ02.07.03
Quantum Computing with Silicon and Germanium Menno Veldhorst and Luca Petit; Delft University of Technology, Netherlands

Semiconductor quantum dots constitute a promising platform for quantum computation. More than two decades of intensive research has led to impressive demonstrations of single-shot initialization and readout, coherent control, and coupling of single electron spins. Group IV materials have emerged as leading platforms, since they can be isotopically enriched to remove nuclear spin decoherence to provide excellent quantum coherence.

I will present our efforts on silicon and germanium quantum devices and discuss the opportunities in these systems. In silicon, these include operation at elevated temperatures for hot-qubit operation, enabling to integrate classical electronics on the same chip for scalability and superior control. In germanium, I will show fast single and two qubit logic, and semiconductor-superconductor devices for novel hybrid quantum hardware. Moving forward, I will discuss our vision to increase the number of qubits toward practical quantum information.

9:45 AM MQ02.07.04
Transport in Ultra-Scaled Ge Quantum Dots Masiar Sistani1, Jovian Delaforce2, Cecile Naud2, Roman Kramer2, Olivier Buisson2, Minh Anh Loung2, Martien Hertog2 and Alois Lugstein1; 1Technische Universität Wien, Austria; 2Université Grenoble Alpes, France

Metal-semiconductor-metal heterostructures are attractive for both fundamental studies of low-dimensional nanostructures as well as future high-performance low power dissipating nanoelectronic and quantum devices. Most notably, they bear enormous potential for a vast array of key components for quantum computing such as SQUIDs, oscillators, mixers and amplifiers. In this context, combining high carrier mobilities and leveraging strong quantum
confinement effects due to a more than five times larger exciton Bohr radius compared to Si, Ge occupies an exceptional position for the development of novel quantum devices in the post Si era. Here, we demonstrate that utilizing a thermally induced exchange reaction between single-crystalline Ge nanowires and Al pads, monolithic Al-Ge-Al nanowire heterostructures with ultra-small Ge segments contacted by self-aligned, quasi-1D, crystalline Al leads can be fabricated without lithographic constraints. High-resolution transmission electron microscopy and energy dispersive X-ray spectroscopy proved the composition and perfect crystallinity of these metal–semiconductor nanowire heterostructures. Integrating such nanowire heterostructures as active channels in electrostatically gated field-effect transistor devices, provides a platform for the systematic investigation of electrical transport mechanisms in ultra-scaled Ge nanowires. In contrast to common short channel devices, the 1D monolithic metal-semiconductor-metal architecture effectively prevents screening of the gate electric field by lithographically defined contacts and thus enables perfect electrostatic control of field effect devices. We will demonstrate ballistic transport as well as quantum ballistic transport phenomena, which were systematically investigated depending on the Ge channel length and nanowire diameter. Temperature depending measurements in the range between 5 K and 300 K of the resistivity and gate-dependent conductance measurements including a detailed bias spectroscopy study revealed transport through spin-degenerate 1D sub-bands in ultra-scaled Ge channels up to room temperature. Finally, we will present low temperature (400 mK) DC spectroscopy measurements, revealing the high gate-tunability of hole transport in ultra-scaled Ge channels monolithically integrated in Al-Ge-Al nanowire heterostructures. In particular, we will show the ability to tune the Ge segment from a completely insulating regime, through a low conductive regime, that exhibits properties of a single-hole transistor, to a superconducting regime, resembling a Josephson field effect transistor with a maximum critical current of 15 nA. The experimental proof of exchanging Cooper-pairs between superconducting Al leads through a gate-tunable Ge channel, mediated by the superconducting proximity effect is the first demonstration of superconductivity induced in a pure Ge channel.

10:30 AM MQ02.07.05
Measurement of the Strain Induced Modulation of Tunnel Barriers in Nanoscale Silicon Quantum Devices
Ryan Stein1,2, Joshua Pomeroy3, Neil M. Zimmerman3 and M. D. Stewart4; 1University of Maryland, United States; 2Joint Quantum Institute, United States; 3National Institute of Standards and Technology, United States

For quantum dots (QD) in the silicon MOS system, the local potential is a defining factor in device performance. Silicon-based devices experience a local potential modulation at the edge of lithographically defined gates due to mechanical strain. The strain originates in the mismatch of the coefficient of thermal expansion (CTE) between silicon and the gate material as well as the intrinsic strain from the deposition process. The resulting potential modulation is large enough to alter the tunnel coupling or induce unintentional QDs at low temperatures. Here, we present measurements of the barrier height in tunnel junction devices defined by aluminum and titanium gates. These measurements reveal the difference in barrier height between the two materials due to strain. Our results agree with COMSOL simulations which use the CTE value achieved in the deposition and strongly disagree with simulations which use the bulk CTE value. These results show that using simulations alone as a guide towards improving devices performance is inadequate thus highlighting the need for more experimental work.

10:45 AM MQ02.07.06
Atomically Sharp, Tensile Strained Ge Light-Hole Quantum Well on Si
Simone Assali, Aashish Kumar, Samik Mukherjee, Jérôme Nicolas, Patrick Del Vecchio, Anis Attiaoui and Oussama Moutanabbir; Ecole Polytechnique de Montreal, Canada

Highly tensile strained Ge quantum well (QW) is a long-sought-for low-dimensional system to investigate and develop hole spin-based qubits and high hole mobility electronics. Under tensile in-plane biaxial strain, light-hole (LH) occupies the top of the valence band and the LH-HH splitting can exceed 100s meV. Moreover, when the tensile in-plane biaxial strain exceeds 1.5% only LH is confined in the QW thus minimizing LH-HH interactions. With this perspective, this work provides the first experimental demonstration of the epitaxial growth of tensile strained Ge QW on Si substrates. Sn-rich GeSn layers are used as barriers to achieve high tensile in-plane biaxial strain and engineering the band structure for LH confinement. We will discuss the epitaxial growth of this tensile-strained GeSn/Ge/GeSn heterostructure exhibiting atomically-sharp interfaces and in-plane biaxial strain above 1.5
% grown on a lattice-mismatched Ge$_{0.86}$Sn$_{0.14}$ substrate. The sharpness of the interfaces across the Ge/GeSn heterostructure will be addressed using EELS and atom probe tomography (APT) measurements. A tunable s-Ge layer thickness ranging from ~13 nm down to ~1.2 nm is achieved. The pseudomorphic nature of the s-Ge layer will be discussed based on TEM/STEM and XRD-RSM measurements, while dislocations are mainly observed in the low Sn content buffer layers.[1,2] Ongoing work focuses on band structure calculations and low-temperature magneto-electric transport measurements to probe the confined LH states in the grown s-Ge QWs.[3]

Single and Two Spin Qubits with High Fidelity Limited by Environment Noise in Si Quantum Dots
Seigo Tarucha; RIKEN, Center for Emergent Matter Science, Japan

To date various materials have been used to fabricate spin qubit devices for quantum computation. Some devices are advantageous for fast qubit operations and others for low noise operations or weak decoherence. Among them isotopically purified silicon is one of the appropriate choices to achieve high-fidelity in single and two-qubit gates. So far we have used quantum dots (QDs) made in GaAs, natural Si/SiGe, and isotopically purified 28Si/SiGe materials to implement high-fidelity spin qubits and study the decoherence mechanisms. Decoherene generally arises from coupling of spin to the environment, which is a source of magnetic and charge noise. In this talk I will first discuss the noise source to the electron spin in the GaAs, natural Si, and 28Si QDs equipped with a micro-magnet. We measure the noise dynamics of the environment to fluctuate the Zeeman field or Larmor precession on the spin, and assign the fidelity limiting factor to nuclear spin noise in GaAs and natural Si, while 1/f-like charge noise in 28Si. For the 28Si/SiGe the highest fidelity of 99.93% has been achieved, and to further raise the fidelity it is crucial to eliminate the charge noise. We have developed a feedback technique to suppress the low frequency magnetic noise in GaAs QDs, and then observed enhancement of the decoherence time but limited by the 1/f-like charge noise same as in 28Si/SiGe QDs. Secondly I will discuss cross-correlated noise in Si QD spin qubits. We used the Ramsey interference protocol to evaluate the power spectral densities of correlated and anti-correlated noise between two Rabi frequencies. We observed positively cross-correlated noise in the low-frequency range. Such noise correlation between qubits may influence two-spin entanglement control and quantum error correction performance.

11:30 AM MQ02.07.08
A Group IV Platform for Light-Hole Qubits
Patrick Del Vecchio, Anis Attiaoui, Simone Assali and Oussama Moutanabbir; École Polytechnique de Montréal, Canada

For decades, Si-compatible low-dimensional systems and quantum devices have been exploiting either tensile strained Si or compressively strained Germanium (Ge) quantum wells (QWs), which are the only group IV systems that can currently be routinely obtained using SiGe as growth template and barrier layers. For quantum information, the former has been used as the building block for electron spin qubits, whereas the latter has been explored in new schemes for hole spin qubits. Herein, we present a third low-dimension system consisting of highly tensile strained Ge QW integrated on an optically active platform and discuss its basic properties experimentally and theoretically. The growth of tensile strained Ge QW is achieved using direct bandgap GeSn as barrier layers grown on silicon wafers. This heterostructure yields high tensile strain in Ge QW and band structure corresponding to a sizable light hole-heavy hole (LH-HH) splitting exceeding 100 meV. Unlike compressively strained Ge, the top of the valence band is occupied by LH in tensile strained Ge. Interestingly, by tuning the tensile strain above 1.5%, only LH can be confined in the QW and LH-HH mixing can be strongly reduced. We also found a high LH g-factor anisotropy in the GeSn/Ge/GeSn QW, with $g = 21.8$ for in-plane B-field and $g = 0.69$ for perpendicular-to-plane field.

These properties lay the groundwork to implement LH spin qubits with potentially easier manipulation due to the combined effects of the large Rashba-type spin-orbit interaction (SOI), the absence of Dresselhaus SOI, and the spin $\frac{1}{2}$ of LH. Indeed, for quantum computing, tensile strained Ge QW combines all the sought-for advantages of Ge in...
qubits including: (i) high hole mobility; (ii) holes have much stronger spin-orbit coupling, which can be exploited to achieve much faster spin manipulations; (iii) the fourfold degeneracy of the valence band, which is not compatible with the two-level system at the core of quantum system, is eliminated by introducing strain and quantum confinement in the QW. This leads to a reduced hole effective mass and a large intrinsic splitting between LH and HH bands, which can enable high mobilities and tunnel rates in addition to eliminating the need for smaller quantum dot size; and (iv) a reduced hyperfine interaction with surrounding nuclear spins for improved quantum coherence as Ge can be purified to remove nuclear spin-full $^{73}$Ge impurities.

Ongoing work includes transport measurements of the fabricated QWs, which will give a clear description of the hole mobility within the structure. Additionally, a detailed discussion of the mechanisms of spin manipulation within such heterostructures will be presented, including various spin manipulation schemes such as EDSR and g-tensor modulation resonance.

11:45 AM MQ02.07.09
InAs-EuS-Al Hybrid Nanowires Yu Liu and Peter Krogstrup; University of Copenhagen, Denmark

Material development holds promise as the basis of topological quantum computing with Majorana fermions. These quasiparticles have been predicted to be formed in semiconductor nanowires coupled to conventional superconductors. This prediction was followed by a series of experiments providing strong evidence. However, in the current system, an external magnetic field along the NW axis is always needed to realize Majorana states.

Therefore, in order to integrate and scale up qubit devices, it is aimed to induce a self-sustaining parallel magnetic field on semiconductor–superconductor hybrid NWs. Composite materials using ferromagnetic insulators (FMIs) in close proximity to a semiconductor – superconductor structure have been proposed as a solution to reach a zero-field topological state, where the effective Zeeman splitting is induced by an magnetic exchange coupling by the FMI. In this work, we grow epitaxial semiconductor – ferromagnetic insulator – superconductor InAs-EuS-Al hybrid nanowires in-situ in the molecular beam epitaxy system. The results show the superconducting hard gap, the hysteretic evolution of density of states as a function of magnetic field and the shape-defined magnetic single domain structures based on well-controlled epitaxy, which suggests that this highly ordered material system is a promising platform for scalable topological quantum computing.

References
of 600 mK. We compare the measured $Q$ data to a model based on loss from the interaction of the superconducting resonator with lossy two-level systems and separately to a model we have developed based on non-equilibrium quasiparticles accumulating in regions of the TiNx film with a lower superconducting gap (D). To distinguish between these competing models, we will also discuss results where we apply superconducting pair-breaking infrared light directly to the resonator device and measure the loss.

8:30 AM MQ02.08.02
(S)TEM Characterization of Josephson Junctions in Qubits Xiaotao Liu1, John M. Kreikebaum2, Stefano Cabrini1, Frank Ogletree1, Virginia P. Altoe1, Irfan Siddiqi2 and Andrew M. Minor2,1; 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States

The development of predictable superconducting circuits incorporating Josephson Junctions (J-Junctions) is essential for developing scalable quantum computing devices. Here we report on atomic resolution analysis of J-Junctions consisting of two polycrystalline Al layers separated by a barrier layer of amorphous AlOx. Samples were also probed with analytical (S)TEM techniques such as EDS and EELS, and correlated with the performance of the device. Our results demonstrate that both the top-Al and the bottom-Al layers comprise columnar grains of around 30 nm with a AlOx barrier layer approximately 3-5 nm thick. Our analysis will discuss how the e-beam evaporation process effects the microstructure of the resulting layers. For instance, the roughness of the Al/AlOx interface seems to be related to grain boundaries in the Al layers. The effect of residual strain will also be discussed, correlated with device performance and analysis of the local strain field with scanning nanobeam diffraction (4D-STEM).

8:45 AM MQ02.08.03
Evidence for Majorana Bound States in an Iron-Based Superconductor Shivu Zhu1, Dongfei Wang1, Lingyuan Kong1, Peng Fan1, Hui Chen1, Wenyao Liu1, Lu Cao1, Yujie Sun1, Yuyang Zhang1, Shixuan Du1, John Schneeloch2, Ruidan Zhong2, Genda Gu2, Liang Fu3, Hong Ding1 and Hong-Jun Gao1; 1Institute of Physics and University of Chinese Academy of Sciences, Chinese Academy of Sciences (CAS), China; 2Brookhaven National Laboratory, United States; 3Massachusetts Institute of Technology, United States

Majorana bound states (MBSs) are spatially-localized zero-energy fractional quasiparticles with non-Abelian braiding statistics that hold great promise for topological quantum computing. By using scanning tunneling microscopy/spectroscopy (STM/STS), here we report the observation of MBSs in a single material platform of high-$T_c$ iron-based superconductors, FeTe$_{0.55}$Se$_{0.45}$, which combined advantages of simple material, high-$T_c$, and large ratio of $\Delta/\Delta_F$. We observed a sharp zero-bias peak inside a vortex core that does not split when moving away from the vortex center. The evolution of the peak under varying magnetic field, temperature, and tunneling barrier is consistent with the tunneling to a nearly pure MBS, separated from nontopological bound states [1]. We further investigated the MBS and observed a conductance plateau feature, which is protected by the Majorana particle-hole symmetry [2]. The observations not only prove a strong evidence of MBSs in this iron-based superconductor, but also offer a single-material platform for Majorana braiding at relatively high temperature.

9:00 AM *MQ02.08.04
Anomalous Charge Noise in Superconducting Qubits Robert McDermott; University of Wisconsin-Madison, United States

We have used Ramsey tomography to characterize charge noise in a weakly charge-sensitive superconducting qubit. We find a charge noise that scales with frequency as $1/f^\alpha$ over 5 decades with $\alpha = 1.93$ and a magnitude $S_q(1 \text{ Hz}) = 2.9 \times 10^4 \text{ e}^2/\text{Hz}$. The noise exponent and magnitude of the low-frequency noise are much larger than those seen in prior work on single electron transistors, yet are consistent with reports of frequency noise in other superconducting qubits. Moreover, we observe frequent large-amplitude jumps in offset charge exceeding $0.1e$; these large discrete charge jumps are incompatible with a picture of localized dipole-like two-level fluctuators. The data reveal an unexpected dependence of charge noise on device scale and suggest models involving either charge drift or fluctuating patch potentials. We describe follow-on experiments to systematically explore the dependence of charge noise on device geometry.

Demonstrating Ultra-Stable Aluminum Oxide SETs as Potential Charge Sensors for Quantum Computing
Yanxue Hong1,2, Ryan Stein1,2, Neil M. Zimmerman2, M. D. Stewart2 and Joshua Pomeroy2; 1University of Maryland, United States; 2National Institute of Standards and Technology, United States

In spin-based quantum computing, the spin readout is achieved through spin-to-charge conversion and single-electron charge detection. Often, single-electron transistors (SETs) capacitively coupled to the qubit are used for sensing the charge transition. Since the SET control curve is sensitive to the electrostatic environment, the local charge stability is of great importance. Although metallic SETs are simple to fabricate, historically they were found to be very unstable, preventing use as charge sensors. We revisit this challenge by using plasma oxidized aluminum oxide (AlOx) tunnel barrier based SETs. We have successfully overcome the charge offset drift issue previously seen in metallic Al/AlOx/Al SETs. The long-term charge stability presented here are better than any other reported metallic SETs, with standard deviation of ≪ 0.01 e over 7.5 days. To evaluate the charge sensing ability, we plan to couple the plasma oxidized Al/AlOx/Al SET to a quantum dot and sense the charge of the quantum dot. By modeling in FastCap and using the data, a 1 e charge change on the quantum dot will cause a measurable current shift in the SET control curve. This charge sensing measurement will be a significant step for the application of ultra-stable Al/AlOx/Al SETs in a quantum computing architecture.

10:15 AM MQ02.08.06

Phosphorus dopants placed with atomic precision using scanning tunneling microscopy-based hydrogen depassivation lithography on silicon (Si:P) have long been considered a leading pathway to both high-performance conventional and quantum electronic devices. However, the realization of practical Si:P device architectures requires low processing temperatures to keep the carefully placed dopants from diffusing.

Among recent developments in the field are advanced molecular beam epitaxy (MBE) techniques and integration of microfabrication processes like ion implantation and surface gates. Much of this effort has focused on preserving the atomic fidelity of Si:P devices by minimizing P dopant diffusion and segregation. However, the incorporation of vacancies and contaminants into both the P dopant layer and Si capping layer also significantly impacts the performance of resulting devices and must often be balanced with the need for low process temperatures. An improved understanding of the whole material system is necessary for optimization of devices and systems, particularly for integration with conventional CMOS technology.

Here, we report on the presence and influence of atomic defects in both the dopant layer and Si overgrowth, the techniques available for characterization of these defects, and the influence of defects on the properties of the resulting Si:P devices. Using a combination of optical spectroscopy, transport measurements, and transmission electron microscopy, we relate the appearance of defects in the Si:P and Si films to parameters of the fabrication process and the electronic characteristics of the resulting devices. This is directly applicable to the next generation of digital electronics at the atomic limits of precision and has implications for quantum applications.

Direct Probing of the Electronic Structure of Hybrid InAs/Al Interfaces Sergei Schuwalow1,2, Niels B
Hybrid epitaxial semiconductor-superconductor materials have recently shown promise as a platform for topological quantum computing applications. Targeted engineering of their key ingredient, the electronic hybridization, requires detailed understanding of the electrostatic properties, in particular the alignment between the band edges of the semiconductor and the Fermi level, in the vicinity of the interface. In this work we use a combination of angle-resolved photoelectron spectroscopy (ARPES) measurements, Schroedinger-Poisson (SP) calculations and a core level fitting procedure to obtain the band offset and other fundamental electronic structure parameters of a promising materials platform for topological Majorana devices, the buried InAs(100)/Al interface. Furthermore, we demonstrate how starting from the investigation of the pristine InAs(100) surface, this combined approach makes it possible to access the electrostatic properties of any heterostructure with the same substrate on which a sequence of core level spectra can be obtained. To verify the validity of our approach we compare the result with the first direct observation of a buried InAs/Al electron accumulation layer.

Materials and Surface Considerations for High-Fidelity Trapped-Ion Quantum Information Processing John Chiaverini; MIT Lincoln Laboratory, United States

Atomic ions arrayed and manipulated via electromagnetic fields form the basis for one of the leading candidate systems for quantum computing, with potential applications in quantum sensing and communications as well. While ion traps based on a combination of radio-frequency and static electric fields applied to microfabricated electrode structures have emerged as a powerful platform for this technology, electric-field noise originating from the electrode surfaces of small traps can limit quantum operation fidelity. Though the mechanisms behind this noise are not completely understood, recent experiments have uncovered evidence that is helping to constrain possible theories. I will describe our experimental work utilizing temperature variation and ion-milling treatment of microfabricated traps made from multiple materials in order to better understand and potentially mitigate ion heating due to electric-field noise.

11:15 AM MQ02.08.09
Supercurrent in All-Van-der-Waals Josephson Tunnel Junctions Qing Li1,1, I-Jan Wang1, Megan Yamoah1, Kenji Watanabe2, Takashi Taniguchi2, Simon Gustavsson1, Terry P. Orlando1,1, Pablo Jarillo-Herrero1 and William D. Oliver1,1,3; 1Massachusetts Institute of Technology, United States; 2National Institute for Materials Science, Japan; 3Massachusetts Institute of Technology (MIT) Lincoln Laboratory, United States

Van der Waals (vdW) materials and their heterostructures have been extensively studied and broadly applied, owing to their extraordinary and versatile electronic properties in combination with epitaxially-precise interfaces. While vdW heterostructures have been well investigated via DC transport and optical techniques, experimental exploration in the microwave regime has heretofore been relatively limited. This has left an unexplored potential for incorporating the advantages of vdW materials into the circuit quantum electrodynamics (cQED) platform of relevance to advancing quantum technologies.

Two-level-systems (TLS) are identified as a major coherence-limiting factor that exist both within and at the interface of amorphous oxide found in current qubit devices. To investigate the concentration of TLSs in vdW dielectric materials, we recently studied the microwave loss of hexagonal boron nitride (hBN), a dielectric that can be used to both encapsulate qubits and to serve as the tunneling barrier of Josephson junctions. We were able to extract a lower bound for the hBN quality factor of ~3x10^8, at least two orders of magnitude higher than that of amorphous dielectric materials such as AlOx or SiOx commonly used in current quantum devices.

Motivated by these promising results, in this work, we fabricate and characterize high-quality, all-vdW Josephson junctions, a key component in superconducting quantum circuits. VdW heterostructures consisting of 2D transition metal dichalcogenide (TMD) superconductors and thin layers of hBN are assembled together in an inert (argon-filled) environment, which promotes pristine materials with atomically flat interfaces. These procedures may significantly reduce the number of two-level-systems. We measure the vdW tunnel junction in temperature well
below the superconducting gap and characterize its DC and AC Josephson response. We expect these efforts will lead to high-coherence qubit devices with small form factors.

8:00 AM *MQ03.01.01
Topological Physics in HgTe-Based Quantum Devices Laurens Molenkamp, Julius-Maximilians-Universität Würzburg, Germany

Suitably structured HgTe is a topological insulator in both 2- (a quantum well wider than some 6.3 nm) and 3 (an epilayer grown under tensile strain) dimensions. The material has favorable properties for quantum transport studies, i.e. a good mobility and a complete absence of bulk carriers, which allowed us to demonstrate variety of novel transport effects.

A novel development is the use of wet etching technologies to fabricate HgTe based nanostructures. This approach allows a much higher transport quality in nanodevices. We have fabricated quantum point contacts, which show remarkable spin selective transport behavior. Additionally, we have developed a gate-training technique, which pushes the scattering length for the quantum spin Hall effect well above 100 mum. A further recent development is the realization that van Hove singularities in the valence band may give rise to remarkable transport effect, such as e.g. the realization of a n=-1 quantum Hall plateau at fields as low as 20 mT.

Another regime we can study is topological superconductivity, which can be achieved by inducing superconductivity in the topological surface states of these materials. Special emphasis will be given to recent results on the ac Josephson effect. We will present data on Shapiro step behavior that is a very strong indication for the presence of a gapless Andreev mode in our Josephson junctions, both in 2- and in 3-dimensional structure. An additional and very direct evidence for the presence of a zero mode is our observation of Josephson radiation at an energy equal to half the superconducting gap.

Controlling the strain of the HgTe layers strain opens up yet another line a research. We have recently optimized MBE growth of so-called virtual substrates ((Cd,Zn)Te superlattices as a buffer on a GaAs substrate), that allow us
to vary the strain from 0.4% tensile to 1.5% compressive. While tensile strain turns 3-dimensional HgTe into a narrow gap insulator, compressive strain turns the material into a topological (Weyl) semimetal, exhibiting clear signs of the Adler-Bell-Jackiw anomaly in its magnetoresistance. In quantum wells, compressive strain allows inverted energy gaps up to 60 meV.

8:30 AM *MQ03.01.02
New Progress in Quantum Anomalous Hall Effect Qi-Kun Xue1,2; 1Tsinghua University, China; 2Beijing Academy of Quantum Information Sciences, China

The quantum anomalous Hall (QAH) effect is a quantum Hall effect induced by spontaneous magnetization, and occurs in two-dimensional insulators with topologically nontrivial electronic band structure which is characterized by a non-zero Chern number. It was first experimentally observed in the thin films of magnetically doped (Bi,Sb)2Te3 topological insulators (TIs) in 2013, more than thirty years after the discovery of the first quantum Hall effect by Klaus von Klitzing. In this talk, I will report on some recent experimental progresses in this direction. By co-doping of Cr and V into (Bi,Sb)2Te3 TI films and developing intrinsic magnetic topological insulator, we are able to significantly increase the observation temperature of QAH effect. More interestingly, we can construct other topological states of matter such as axion insulator, quantum spin Hall insulator and QAH insulator of high Chern number by growing QAH insulator-based heterostructures.

9:00 AM MQ03.01.03
Experimental Verification of Magnetic-Field-Induced Topological Phase Transition in Fe-Doped Topological Insulator (Bi,Sb)nSe3 Thin Films Junichi Shiogai1, Yosuke Satake1, Grzegorz P. Mazur2, Shojiro Kimura1, Satoshi Awaji1, Kohei Fujiwara1, Tsutomu Nojima1, Kentaro Nomura1, Seigo Souma1,2, Takaomi Sato3,4, Tomasz Dietl2,4, Qi-Kun Xue1,2; 1Tsinghua University, China; 2Beijing Academy of Quantum Information Sciences, China

Thin film synthesis of the emergent quantum materials is a prerequisite technique to observe novel topological phases such as quantum Hall [1] or quantum anomalous Hall (QAH) state [2-5] and exotic proximity effects at hetero-junction with magnets and superconductors [6]. The QAH phase accompanying a dissipation-less chiral edge channel has been achieved in one example of three-dimensional topological insulator (3D-TI), (Bi,Sb)2Te3 with a magnetic dopant Cr or V, which fulfills two requirements: (i) inducing an exchange gap by magnetic impurity doping and (ii) tuning Fermi level (EF) into the gap by electrostatic gating in a thin film form [2]. A representative 3D-TI Bi1-xSbxTe3 is another candidate platform to study such an exotic topological phase because of an inherently large bulk insulating gap [7]. However, by comparing with a well-investigated (Bi,Sb)2Te3 3D-TI compound, there has been little progress on EF tuning technique in (Bi1-xSbx)2Se3 probably owing to a low solubility limit of Sb below x ~ 0.5 [8], making it difficult to study the Dirac feature of this system by electrical transport measurements. To date, we have developed a buffer layer technique to stabilize rich Sb-doped (Bi1-xSbx)2Se3 in molecular beam epitaxy. With precise tuning of Bi/Sb composition ratio and thickness in a field-effect transistor (FET), we materialized the EF tuning across the charge neutral point (CNP) [9,10].

In this study, based on these established EF tuning techniques, we investigate magneto-transport properties of Fe-doped (Bi1-xSbx)2Se3 heterostructures. The Fe-doped sample with EF tuned around CNP behaves like an insulator at zero magnetic field. By sweeping a perpendicular magnetic field, topological phase transition emerges from Anderson insulator to QAH state [11]. A clear insulator-to-metal transition was observed in magnetoresistance with a large Hall resistance by application of a high magnetic field up to 24 T. Furthermore, a (Bi1-xSbx)2Se3-based FET exhibits the large Hall resistance approaching the quantized value (h/e2) at around 14 T. With these set of the data, we concluded that a magnetic-field-induced QAH state was verified in Fe-doped (Bi1-xSbx)2Se3 thin films. Combining well-regulated growth technique for precise tuning of EF and high-field transport measurements sheds light on the hidden topological phases in a wide variety of emerging quantum materials.

Experimental Realization of Thin-Film LaAlGe—A Type II Weyl Semimetal

Niraj Bhattarai1,2, Rajendra P. Dulal3, Andrew Forbes1,2, Christopher Gassen1,2, Ian Pegg1,2 and John Philip1,2; 1The Catholic University of America, United States; 2The Vitreous State Laboratory, United States; 3Chapman University, United States

The rare-earth based ternary compounds RAlGe (R=La, Ce, Pr) are Weyl semimetals, in which LaAlGe exhibits type II Weyl semimetal behavior with space-inversion symmetry breaking. In this article, we report the growth, characterization, and transport measurements of LaAlGe thin films grown by molecular beam epitaxy. Extensive analysis of the longitudinal resistivity shows that the system displays semimetallic behavior. An upturn at a temperature below 35 K is observed in the resistivity curve due to weak localization. Observed resistivity behavior and a leap in activation energy gap from 1.67 meV to 103 meV suggest a near room temperature semimetal-to-semiconductor transition. We also observed a positive longitudinal magnetoresistance at and below 30 K and an ordinary Hall effect with nearly temperature independent Hall coefficient between 10 and 200 K. Furthermore, electrons are the majority of the charge carriers in our thin film samples.

Single-Layer Mott Insulator 1T-TaSe2—Exotic Orbital Texture and Spin Liquid Behavior

Yi Chen1, Wei Ruan1, Shujie Tang2, Meng Wu1, Amy Y. Liu1, Joel E. Moore1, Zhi-Xun Shen2, Steven G. Louie1, Patrick A. Lee4, Sung-Kwan Mo3 and Michael Crommie1; 1University of California, Berkeley, United States; 2Stanford University, United States; 3Lawrence Berkeley National Laboratory, United States; 4Massachusetts Institute of Technology, United States

Mott insulating behavior is induced by strong electron correlation and can lead to exotic states of matter such as unconventional superconductivity and quantum spin liquids. Recent advances in van der Waals material synthesis enable the exploration of novel Mott systems in the two-dimensional (2D) limit. Here we report characterization of the local electronic properties of the single-layer Mott insulator 1T-TaSe2 via spatial- and momentum-resolved spectroscopy involving scanning tunneling microscopy (STM) and angle-resolved photoemission. Our combined experimental and theoretical study indicates that electron correlation induces a robust Mott insulator state in single-layer 1T-TaSe2 that is accompanied by novel real-space orbital texture. By placing single-layer 1T-TaSe2 onto a metal, we observe a strong Kondo resonance peak at the Fermi level, verifying the existence of local moments in this 2D Mott insulator. Finally, STM dI/dV imaging at the Hubbard band edges reveals a new incommensurate superstructure with a wavevector close to 2k_F of a half-filled spinon band, indicating a possible formation of a spinon-related density wave.

Challenges in Synthesis and Characterization of Topological and Quantum Materials

David A. Tennant; Oak Ridge National Laboratory, United States

Quantum materials are rapidly advancing but still present great challenges. Topological quantum materials in particular are receiving great attention as they provide potentially robust routes to quantum information processing that are protected against decoherence processes. Among key challenges are the prediction and realization of magnetic materials in the form of magnetic Weyl semimetals and quantum spin liquids as ways of realizing exotic quasiparticles such as Majorana fermions that can be used for application. These materials present new experimental challenges in terms of identifying their quasiparticles and demonstrating quantum coherence in their ground states states. Here I will show how we are using the integrated application of machine learning along with experiment and synthesis to advance the discovery and understanding of these materials.

Polarized Raman Spectroscopy of Single Nanoflakes of the Type-II Weyl Semimetal NbIrTe4

Iraj A. Shojaei1, Congcong Le2, Brenden Ortiz2, Giriraj Jnawali1, Seyyedesadaf Pournia1, Samuel Linser1, Howard E. Jackson1, Leigh M. Smith1, Fuchun Zhang2 and Stephen Wilson3; 1University of Cincinnati, United States; 2University of the Chinese Academy of Sciences, China; 3UC Santa Barbara, United States
We make detailed polarized micro-Raman spectroscopy measurements of single nanoflake of the layered ternary compound NbIrTe$_4$. Thin 10 to 100 nm thick layers were exfoliated from single crystals and dispersed onto a silicon substrate. The a and b crystalline axes lay in the plane of the nanoflake with the c-axis perpendicular to the layer. Micro-Raman spectra were taken in the backscattered geometry using both 633 nm and 514 nm laser light with the incoming and outgoing light parallel to the c-axis with the scattered light polarization selected to be both parallel and perpendicular to the incoming laser polarization. Our results indicate strongly anisotropic Raman peaks which are consistent with the broken inversion symmetry of the crystal, which is an essential enabling condition for a Weyl semimetal. The large orthorhombic unit cell of this material has 24 atoms and belongs to the space group Pmn2$_1$ (point group c$_{2v}$) which predicts 69 active Raman modes with A$_{1,2}$ and B$_{1,2}$ irreducible representations. Since our excitation is parallel to the c-axis we can only detect the A$_{1,2}$ modes. Density Functional Theory (DFT) calculations for the A$_{1,2}$ modes show close correspondence with both the frequency and symmetries of the modes detected in our measurement. The normal mode vibrations for each mode are also determined. All A$_1$ modes have vibrations in the bc-plane of the crystal structure, so they include out-of-plane vibrations, while the A$_2$ modes show atoms which vibrate only along the a-axis of the lattice structure, with in-plane vibrations. Fits to the rotational symmetry of each mode allow us to extract the relative electron-phonon constants for each mode. Some evidence is seen that the electron-phonon interaction is modified for the different energy excitation conditions.

11:00 AM MQ03.01.08
Circularly Polarized Transient Reflectivity in the Type II Weyl Semimetal NbIrTe$_4$ Samuel Linser¹, Giriraj Jnawali¹, Seyyedesadaf Pournia¹, Iraj A. Shojaei¹, Howard E. Jackson¹, Leigh M. Smith¹, Congcong Le², Fuchun Zhang², Brenden Ortiz² and Stephen Wilson³; ¹University of Cincinnati, United States; ²UC Santa Barbara, United States; ³University of the Chinese Academy of Sciences, China

Weyl semimetals have recently attracted intense research interest for exhibiting chiral Weyl nodes which are displaced in momentum space because of band crossings. When photoexcited with circularly polarized light transport measurements have been shown to be consistent with a chiral anomaly where the number of particles with a given chirality are not conserved. Though such photogalvanic measurements have confirmed the presence of chiral nodes in Weyl semimetals, little is presently understood about the dynamic behavior of the chiral particles. We exfoliate single thin flakes from a bulk crystal of NbIrTe$_4$ which is a ternary variant of WTe$_2$ with broken inversion symmetry. DFT calculations have shown that there are 16 Weyl nodes in the Brillouin zone, eight lying in the k$_z$ = 0 plane and eight lying in the k$_z$ = ±0.2 plane. We excite the flake with laser pulses incident along the c crystal axis, which is normal to plane of the flake defined by the a and b axes. The thin flake is excited by a near-infrared (NIR) 1.5 eV 140 fs pump laser pulse, and probed by a delayed circularly polarized mid-infrared (MIR) pulse with an energy which can be tuned from 0.3 to 1.2 eV. We show that the transient reflectivity response of the NbIrTe$_4$ exhibits distinct dynamics depending on the circular polarization of the MIR probe pulse. The peak response at zero time has opposite phase for probe pulses of opposite handedness. This initial strong polarized response decays rapidly within 1 ps, but the weaker remaining signal decays slowly within 500 to 1000 ps before reaching equilibrium. The dynamics of the polarized transient reflectivity do not respond to the circular polarization of the NIR pump pulse. We suggest that the distribution of the chiral particles is perturbed by the modulation of the Fermi level caused by the strong NIR pump pulse.

We acknowledge the financial support of the NSF through grants DMR 1507844, DMR 1531373, and ECCS 1509706. S.D.W. acknowledges the support of NSF DMR 1505549.

11:15 AM MQ03.01.09
Detection of the Photogalvanic Effect in NbIrTe$_4$—A Type II Weyl Semimetal Seyyedesadaf Pournia¹, Giriraj Jnawali¹, Iraj A. Shojaei¹, Samuel Linser¹, Howard E. Jackson¹, Leigh M. Smith¹, Brenden Ortiz², Stephen Wilson³, Congcong Le² and Fuchun Zhang³; ¹University of Cincinnati, United States; ²UC Santa Barbara, United States; ³University of the Chinese Academy of Sciences, China

We investigate the optically driven transport properties of NbIrTe$_4$, which is a candidate type II Weyl semimetal.
which lacks spatial inversion symmetry. DFT calculations show that this ternary analog to WTe$_2$ exhibits 16 Weyl nodes, eight in the $k_z = 0$ plane and eight in the $k_z = \pm 0.2$ plane. A 100 nm flake of this material was exfoliated from a bulk crystal and dispersed on a Si++/SiO$_2$ substrate. 300 nm thick Ti/Al metal pads were deposited on two sides of the nanoflake by photolithography, metal deposition and liftoff. The device was mounted on a gold chip carrier, and after wire bonding, it was placed on the cold finger of an optical cryostat. A tunable polarized infrared laser was used to excite the device parallel to the c-axis normal to the flake. The I-V measurement shows that the resistivity of the device is about 2 mm.$\Omega$W at 300K and 0.2 mm.$\Omega$W at 10K. The photocurrent measurement with light linearly polarized along the “a” and “b” crystal directions shows photoresponse with different magnitudes in these two directions. Using a quarter wave plate for excitation between 1000 and 3000 nm (0.4 to 1.2 eV), the photoresponse was measured for a full rotation, with different amplitudes seen for right hand and left hand circular polarizations, revealing the circular photogalvanic effect which is consistent with the chiral nature of the Weyl nodes in this material.

We acknowledge the financial support of NSF through grants DMR 1507844, DMR 1531373, DMR 1505549 and ECCS 1509706.

11:30 AM MQ03.01.10
Electron-Phonon Coupling and the Decay of Chirality in Weyl Semimetals
Gavin Osterhoudt$^1$, Jennifer Coulter$^2$, Christina Garcia$^2$, Yiping Wang$^1$, Vincent Plisson$^1$, Bing Shen$^1$, Ni Ni$^3$, Prineha Narang$^2$ and Kenneth Burch$^1$; 1Boston College, United States; 2Harvard University, United States; 3University of California, Los Angeles, United States

Weyl semimetals are a class of recently realized topological semimetals characterized by three-dimensional linear dispersions known as Weyl nodes. A key feature of these materials is the low energy excitations in the vicinity of the Weyl nodes possess a chirality – their spins and momentum are locked either parallel or anti-parallel to one another. As such, considerable research attention has been focused on investigating these novel electronic properties. Despite this, little effort has been directed towards an understanding of their vibrational properties or the coupling between the two systems. In this talk we present experimental and computational results which reveal the interplay between the vibrational and electronic systems for the prototypical type-I Weyl semimetals NbAs and TaAs. In temperature dependent Raman measurements of phonon linewidths we observe an unusual dominance of electron-phonon based scattering of optical phonons into electron-hole pairs. Computational calculations of the mode resolved electron-phonon coupling strength not only confirm the presence of this scattering channel, but reveal other phonon mediated scattering channels which connect the disparate Fermi surfaces in the vicinity of the Weyl nodes.

11:45 AM MQ03.01.11
Synthesis of Cd$_3$As$_2$ Epilayers on II-VI Semiconductor Platforms via Molecular Beam Epitaxy
Anthony Rice and Kirstin M. Alberi; National Renewable Energy Lab, United States

The three-dimensional Dirac semimetal Cd$_3$As$_2$ has exhibited a number of interesting properties, including linear dispersion in the bulk electronic structure, Fermi arc surface states and giant magnetoresistance [1-3]. Many of these discoveries were made in bulk single crystal material due to the relative ease of synthesis. Epitaxial thin films have also been instrumental in detecting the quantum Hall effect and studying the influence of confinement on its properties [4]. Future investigation of Cd$_3$As$_2$ properties and devices will increasingly benefit from synthesis in thin film form and will critically depend on our ability to control defects, dopants, surfaces and interfaces during the growth process.

Here, we present a framework for imparting control during the growth of high quality Cd$_3$As$_2$ epilayers by molecular beam epitaxy. Our approach consists of three tactics to improve the electron mobility. The use of lattice-engineered II-VI Cd$_{1-x}$Zn$_x$Te buffer layers grown on GaAs substrates with a small degree of miscut reduces extended twin and dislocation defects. Growth from elemental Cd and As$_2$ sources rather than a Cd$_3$As$_2$ compound source allows for careful control of the chemical potential during growth and the resulting point defect populations. Illumination of the growth surfaces of both the II-VI buffer layer and Cd$_3$As$_2$ epilayer with a broadband source is further found to improve surface smoothness. Together, these methods have produced electron mobilities as high as
18,000 cm²/Vs in bulk epilayers even though growth is carried out at substrate temperatures no higher than 120 C. We will discuss the underlying mechanisms as well as prospects for using them to probe various aspects of defect physics in Cd₃As₂.

SESSION MQ03.02: Advanced Characterizations for Emerging Quantum Materials

Scattering Studies of Lattice Dynamics Coupled to Charge and Spin Degrees-of-Freedom Olivier Delaire:
Duke University, United States

A detailed understanding of lattice vibrations is needed to build microscopic theories of transport and thermodynamics in emerging quantum materials. The interplay between phonons and other degrees-of-freedom of charge and spin has long been known to be critical in ferroelectrics/multiferroics, metal insulator transitions, as well as some aspects of superconductivity, including at high pressures or in nematic phases. Large deviations from harmonic potential energy surfaces, as in the Landau double-well picture, also give rise to interesting anharmonic phonon properties characterized by extensive interactions between phonon quasiparticles and pronounced renormalization effects, which can be tuned to zero temperature at ferroelectric quantum critical points. Further, phonons directly modulate the potential seen by electrons and offer a means to control the electronic structure and its topology, either thermally or via coherent excitations. I will highlight recent developments and achievements in studies of phonons in emergent quantum materials. In particular, I will discuss scattering techniques such as inelastic neutron / x-ray scattering, which can map phonon dispersions and linewidths throughout the Brillouin zone, and time-domain spectroscopies that can probe coupling mechanisms and far-from-equilibrium regimes. In addition, first-principles simulations of phonons can often be directly compared to these experiments and provide further insights into phonon couplings to charge, spin and orbital degrees of freedom.

Probing Broken Symmetries of Quantum Materials by Resonant Ultrasound Spectroscopy Paula Giraldo-Gallo¹, Jose A. Galvis³, Albert Migliori³, Fedor F. Balakirev³, Jon B. Betts³, Shimpei Ono⁴, Stephen Hayden⁵, Ross D. McDonald³, Brad J. Ramshaw⁶, Arkady Shekhter¹ and Gregory S. Boebinger¹; ¹Universidad de Los Andes, Colombia; ²Universidad Central, Colombia; ³Los Alamos National Laboratory, United States; ⁴Central Research Institute of Electric Power Industry, Japan; ⁵University of Bristol, United Kingdom; ⁶Cornell University, United States; ⁷Florida State University, United States

Determining the broken symmetries at a thermodynamic phase transition is an essential tool for understanding, or at least constraining, the microscopic mechanisms that lead to novel ground states in quantum materials. Resonant Ultrasound Spectroscopy (RUS) is a characterization technique that measures the spectrum of mechanical resonances of a solid, which allows the determination of its elastic tensor, a thermodynamic quantity that contains symmetry specific information of the ground state. Tracking the evolution of the elastic tensor through a phase transition allows determining which symmetries are broken in the transition, and to propose better suited order parameters.

In this talk I will present RUS measurements of unconventional superconductors and charge density wave compounds. I will focus on the La₂-xSrₓCuO₄ cuprate superconductor, for which we observe a strong softening of the C₆₆ elastic shear moduli, associated with the B₂₃ symmetry channel, as temperature is decreased and an
orthorhombic to tetragonal structural phase transition is approached. The temperature dependence of this softening is consistent with a Curie-like temperature dependence. This softening persists even for Sr compositions for which the tetragonal to orthorhombic structural transition is not seen. The B2g softening is truncated by the opening of the superconducting gap, evidenced by the stiffening of C66 below Tc. These observations suggest an electronic nematic origin for this softening, similar to what has been observed in Ba-pnictide superconductors.

Ultrasensitive Nanoscale Calorimetry for the Characterization of Emerging Quantum Materials Charles T. Harris, Peter Sharma, Lisa A. Tracy, Rupert Lewis and Tzu-Ming Lu; Sandia National Labs, United States

Properties relevant to quantum materials are characterized by the material’s ground states and excitations. Complementary to electrical and optical measurements, heat capacity measurements performed on quantum materials can reveal information about the material’s density of states. Many emergent materials that are synthesized in the laboratory exist at nanometer length scales, and performing heat capacity measurements on these materials in the monolayer limit presents a formidable challenge. Typical commercial calorimeters require bulk samples and operate between 300K to 2K. Microfabricated calorimeters, compared to commercial systems, possess a significantly smaller thermal mass, and because of this drastically reduced size, they inherently have greater sensitivity to thermal signals. Here we present a method of performing ultrasensitive calorimetry on nanoscale quantum materials. Our microfabricated calorimeter possesses an intrinsic heat capacity that is 1000 times lower than state-of-the-art thin-film calorimeters and has been designed to operate over a wide temperature range, permitting measurements of low-energy excitations that occur at sub-Kelvin temperatures. Our calorimeter design also facilitates transmission electron microscopy measurements, allowing structure-property correlations on the same material of interest. In this presentation, I will explain the design and operation of this ultrasensitive calorimeter, present heat capacity measurements, and discuss various nanoscale material loading techniques, including the opportunities and the challenges inherent to these measurements.

Correlative Total Tomography of III-As Nanowire Quantum Wells—Deconvolving Structure-Property Relationships at the Nanoscale Megan O. Hill1, Jonas Lähnemann2, Jesús Herranz2, Oliver Marquardt2, Guanhui Gao2, Ali Al Hassan3, Arman Davtyan1, Stephan O. Hruszkewycz1, Martin V. Holt2, Chunyi Huang1, Irene Calvo-Almazán1, Uwe Jahn2, Ullrich Pietsch2, Lutz Geelhaar2 and Lincoln J. Lauhon1; 1Northwestern University, United States; 2Leibniz-Institut im Forschungsverbund Berlin e.V., Germany; 3Naturwissenschaftlich-Technische Fakultät der Universität Siegen, Germany; 4Argonne National Laboratory, United States

Ternary III-As nanowire (NW) heterostructures provide a path to quantum confined structures of zero, one, and two dimensions integrated on Si, making them candidates for quantum-enabled applications including single photon emission and manipulation of Majorana Fermions [1,2]. Tomographic imaging of nanoscale composition is necessary to determine the confinement potentials of charge carriers and to understand and optimize growth. Furthermore, correlated analysis of nanoscale properties is needed to develop quantitative understanding of the influence that composition, strain, phase, and defect structure has on band structure. We have used a novel combination of characterization methods to correlate the 3-D structure of (In,Ga)As quantum wells (QWs) on GaAs NWs with their spatially varying optical properties at the nanoscale. While these classes of heterostructures are being developed both as quantum wires and emitter structures, we focus here on emission due to the significant interest in efficient compact and near-IR lasers for on-chip optical interconnects. Towards that end, spatially resolved cathodoluminescence (CL) was used to investigate the emission of InGaAs QWs grown on GaAs NWs that switched from the zincblende (ZB) to wurtzite (WZ) phase along their length, leading to brighter and blue-shifted emission in the WZ region. Electron backscatter diffraction and nano-probe based x-ray diffraction (nanoXRD), directly correlated with CL, established this correlation. Synchrotron-based nanoXRD was also used to probe position-dependent strain along multiple crystallographic directions with 25-50 nm spatial resolution. Atom probe tomography (APT) was then used in direct correlation with CL to image the composition and morphology of the embedded (In,Ga)As QWs. APT revealed that the In mole fraction is significantly reduced in WZ compared to ZB QWs, while the QW thickness is unchanged. Correlated measurements of composition, morphology, strain, and structure were combined as input for band structure calculations, leading to a predicted emission shift of 95 meV between the WZ and ZB region that is in reasonable agreement with the CL results (70-80 meV shift). This correlative analysis, using an array of advanced characterization tools, ultimately enabled deconvolution of complex spatial variations in electronic structure in a way not previously possible, and can be extended to a range of buried
quantum heterostructures. To explore the limits of the methodology, we will also discuss the application of coherent x-ray diffraction imaging to non-destructively image strain in embedded radial QWs as small as 8 nm in diameter.

Imaging Effects of Electronic Correlations in Twisted Bilayer Graphene Stevan Nadj-Perge; California Institute of Technology, United States

Twisted bilayer graphene with a twist angle close to 1° features isolated flat electronic bands that form a strongly correlated electronic system. Here we investigate properties of this system by probing local tunneling density of states using scanning tunneling microscopy and spectroscopy. We show that the flat bands get highly deformed when they are aligned with the Fermi level using electrostatic gating. At half filling of the bands, we observe the development of gaps originating from correlated insulating states. Near charge neutrality, we find a previously unidentified correlated regime featuring a substantially enhanced flat band splitting that we describe within a microscopic model predicting a strong tendency towards nematic ordering. Our results provide basis for microscopic understanding of correlated quantum phases in small angle twisted bilayer graphene.

Experimental Determination of the Ionization Energies of MoSe2, WS2 and MoS2 Using Photoemission Electron Microscopy Taisuke Ohta1, Morgann Berg1, Thomas Beechem1, Calvin Chan1, Kunital Keyshar2, Xiang Zhang2, Robert Vajtai2, Gautam Gupta2, Pulickel Ajayan2 and Aditya D. Mohite2; 1Sandia National Laboratories, United States; 2Rice University, United States; 3Los Alamos National Laboratory, United States

The energy positions of the valence and conduction electronic states with respect to the vacuum level are essential parameters to evaluate how the band gaps of semiconductors or Fermi-levels of metals would line up with respect to each other. Defined as an energy separation between the vacuum level and the highest occupied electronic states, the ionization energy is of particular importance for atomically-thin transition metal dichalcogenides (TMD) to predict the performance of their heterostructures as well as their interfaces with metal contacts. Ionization energies have been investigated based on theoretical calculations, but to the best of our knowledge, no systematic experimental confirmation is reported for the wide range of TMDs and other emerging quantum materials, despite their importance.

Here we present a new approach to study the electronic properties of prototypical TMDs, MoSe2, WS2, and MoS2 monolayer and multilayer flakes, supported on thick silicon oxide (SiO2) film, using a photoemission electron microscopy combined with a deep ultraviolet (DUV) illumination. We determine the band alignments of monolayer to multilayer junctions in these four materials, and show that the ionization energy decreases from MoS2, WS2, to MoSe2 as predicted by density functional calculations. We further extend this experimental approach to quantify Schottky barriers at the TMDs-metal contacts. This work reveals a new metrology approach to conduct systematic studies of electronic properties of TMDs.

Scanning Tunneling Microscopy of Nanomaterials, New Yang-Mills Observe-on Regge Beta Decay and Relativistic Dark Matter Stephen Sharma1,2; 1University of California, Berkeley, United States; 2University of
Motivating experimental and theoretical physics is a desire for grand unification and practical solutions to real world problems. The highest resolution visualization of nanomaterials comes from the scanning tunneling electron microscope (STM). It probes quantum states through a conducting stylus. Further investigation into the collapse of the wavefunction necessitates the creation of a new particle that solves a problem in Yang-Mills symplectic rotations. From Clebsch-Gordon coefficients and the resultant Green’s functions fields, a single source particle is uncovered, the observe-on. This unification means that the neutrino does not exist. Regge theory and angular momentum at the quantum scale imply funny SU(2) particle states that carry the Fermi-Curie deconvolution. When applying this rotational correction to galactic cores, the perturbation to the mass density length contraction generates a pseudo-energy and pseudo-central force from a frame dragging effect. This is dark matter. This work is a theoretical exploration into ideas central to hyperspace Aharonov-Bohm dimensions, dark matter, Yang-Mills theory, quantum STM experiments, fusion, and the connections that make emergent properties like the scientific endeavor a conscious entity. New s-matrix theory and string geodesic landscapes discard quantum loop theories. Really, though, this is an experimental thrust into tunneling and how quantum probes unify with relativity to allow scientists to predict the properties of particles and surfaces with unique electronic and nuclear states beyond the standard model.

4:30 PM MQ03.02.08
Direct Imaging Revealing Halved Ferromagnetism in Tensile-Strained LaCoO₃ Thin Films Dechao Meng¹, Qiyuan Feng², Jinghua Guo³, Chao Ma⁴, Xiaofang Zhai⁵, Qingyou Lu² and Yalin Lu²; ¹China Academy of Engineering Physics, China; ²University of Science and Technology of China, China; ³Lawrence Berkeley National Laboratory, United States; ⁴Hunan University, China

The enigma of the emergent ferromagnetic state in tensile-strained LaCoO₃ thin films remains to be explored because of the lack of a well agreed explanation. The direct magnetic imaging technique using a low-temperature magnetic force microscope (MFM) is critical to reveal new aspects of the ferromagnetism by investigating the lateral magnetic phase distribution. Here we show the experimental demonstration of the rare halved occupation of the ferromagnetic state in tensile-strained LaCoO₃ thin films on SrTiO₃ substrates using the MFM. The films have uniformly strained lattice structure and minimal oxygen vacancies beyond the measurement limit. It is found that percolated ferromagnetic regions with typical sizes between 100 nm and 200 nm occupy about 50% of the entire film, even down to the lowest achievable temperature of 4.5 K and up to the largest magnetic field of 13.4 T. Preformed ferromagnetic droplets were still observed when the temperature is 20 K above the Curie temperature indicating the existence of possible Griffiths phase. Our study demonstrated a sub-micron level phase separation in high quality LaCoO₃ thin films, which has substantial implications in revealing the intrinsic nature of the emergent ferromagnetism.

SESSION MQ03.03: Quantum Phenomena in Epitaxial Thin Films, Heterostructures and Interfaces
Session Chairs: Olivier Delaire and Julia Mundy
Tuesday Morning, December 3, 2019
Hynes, Level 2, Room 203

8:00 AM *MQ03.03.01
Probing Topological Magnetic Interfaces with Next-Generation Neutron Reflectometry Alexander Grutter; National Institute of Standards and Technology, United States

Whether it originates in crystallinity, magnetism, or electronic structure, interfacial symmetry breaking represents one of the most powerful tools for the realization of new quantum materials with advanced functionality. Mismatches in band topology and time reversal symmetry across interfaces have been harnessed to open gaps in the surface states of topological insulators or to induce topological transitions. Heterostructures interfacing
superconductors with a quantum anomalous hall insulator (QAHI) have been reported to exhibit signatures of Majorana fermions, while two-dimensional systems with strong spin-orbit interactions have long been suspected of harboring skyrmions at interfaces with perpendicular magnetic materials. In all of these cases, our understanding of the underlying physics has hinged critically on the ability to precisely understand and isolate the properties of the interface from the bulk of the system. By decomposing the magnetic and electronic properties on a layer-by-layer and element-resolved basis, new quantum material systems may be robustly understood and designed. In this talk, I will discuss our recent progress in combining depth-resolved information from polarized neutron reflectometry with element-specific information from soft X-ray spectroscopy to design and control magnetic interfaces in topologically nontrivial systems such as (Bi,Sb)2Te3/antiferromagnet and Bi2Se3/oxide heterostructures. I will focus in particular on the new capabilities enabled by CANDOR, the new polychromatic neutron reflectometer at the NIST Center for Neutron Research. A highly intensity-limited technique, the application of neutron reflectometry has been critically hampered by the long measurement times necessary to probe the trace magnetic signal in systems such as superconductors and QAHIs. By implementing a polychromatic beam with multiplexed energy analyzing detectors, CANDOR allows for multiple orders of magnitude intensity gains, allowing even more sensitive measurements to be performed in hours instead of days.

8:30 AM MQ03.03.02

Resolving Interfacial Charge Transfer in Buried Monolayers with Resonant X-Ray Reflectometry Ryan Need1, Patrick Marshall2, Susanne Stemmer2 and Stephen Wilson2; 1University of Florida, United States; 2University of California Santa Barbara, United States

More and more frequently, the interfaces between electronic thin films are playing critical roles in the operations and functions of our electronic devices. As we move towards new computing paradigms, it’s the interfaces of quantum materials with strongly coupled degrees of freedom and complex phase behavior that show the greatest potential to revolutionize the ways we store, process, and transfer information. Yet, the same coupled degrees of freedom that give quantum materials their unique and desirable properties place stringent requirements on the local structure and composition at the interfaces, where the presence of unintended defects can diminish spin polarized currents and destroy coherent quantum states. However, characterizing the physics at these interfaces, which are often buried deep below the sample surface, remains difficult. Addressing this challenge requires a technique capable of measuring the local electronic structure with high-resolution depth dependence.

In this talk, we show how linearly polarized resonant X-ray reflectometry (RXR) can be used to visualize charge transfer in complex oxide superlattices with atomic layer resolution. From our RXR measurements, we extract valence depth profiles of SmTiO3(SmTO)/SrTiO3 (STO) heterostructures with STO quantum wells varying in thickness from five SrO planes to a single SrO plane. At the polar-nonpolar SmTO/STO interface, an electrostatic discontinuity leads to approximately half an electron per area unit cell transferred from the interfacial SmO layer into the neighboring STO quantum well. We observe this charge transfer as a suppression of the t2g absorption peaks that minimizes contrast with the neighboring SmTO layers at those energies and leads to a pronounced absence of superlattice peaks in the reflectivity data. Our results demonstrate the sensitivity of RXR to electronic reconstruction in the monolayer limit and establish RXR as a powerful means of characterizing charge transfer at the buried interfaces of quantum materials.

8:45 AM MQ03.03.03

Heterogeneity in the Epitaxial Thin Film with Full Field X-Ray Diffraction Microscopy Zhan Zhang1, Nouamane Laanait2, Seohyoung Chang3, Hua Zhou1, Han Xu4, Zhenlin Luo4, Dillon Fong1 and John Freeland1; 1Argonne National Laboratory, United States; 2Oak Ridge National Laboratory, United States; 3Chung-Ang University, Korea (the Republic of); 4University of Science and Technology of China, China

Epitaxial thin films, especially the oxide thin films, have been studied extensively due to their emerging properties and potentials in various applications, such as energy storage and data storage. Many factors, such as the chemical state, the strain state, and presence of the external field, can affects the thin film structure, which in turn influences the properties. While the unit cell level atomic structures of such thin film materials are fairly well known/defined, the recent interests are steered towards how the unit cells and nano-sized domains are organized into the macroscopic functional materials. This so-called meso-scale structure turns out to be not that simple due to the spatial inhomogeneity in the thin film as it minimizes the total energy in response to the internal and external
stimulant. Availability of spatial-resolved and/or time-resolved structures of such systems would be critical to a better understanding and eventually designing function-oriented new materials. A diffraction based, full field X-ray microscopy method, the X-ray reflection interface microscopy (XRIM), has been adopted to study the surfaces, buried interfaces, and thin film material systems at meso-scale, with sub-nanometer + sensitivity in the surface normal direction and <80 nm lateral resolution.

With the penetrating power of hard X-rays, XRIM can emphasize the features at different depth from the top surface by choosing proper scattering conditions, making it an excellent candidate to study the films in-operando in real time. Combined with the reciprocal space mapping (RSM), the spatially resolved structure evolution can be identified. A few examples will be discussed to demonstrate the capability of XRIM method and its potential applications in a broader field.

9:00 AM MQ03.03.04
Exploring Buried Layers and Interfaces Using Angle-Resolved Hard X-Ray Photoelectron Spectroscopy Anna Regoutz; University College London, United Kingdom

Modern materials science often concerns not isolated, bulk materials, but materials as part of larger, complex thinfilm-based heterostructures. The final behaviour of such systems is in many cases dominated by the interfaces between materials and cannot usually be inferred from the bulk characteristics of the individual components.

One of the main challenges complicating a full understanding of such complex systems is the availability of direct characterisation methods for buried layers and in particular the interfaces between them. We greatly lack direct probes for chemical states and electronic structure at interfaces, which present a special challenge for physical characterisation techniques due to their spatial confinement, the fact that by their nature interfaces are buried beneath a variety of overlayers, and the starkly different behaviour of chemical species at interfaces compared to surfaces and the bulk. Advanced X-ray spectroscopy methods can tackle some of these issues, and X-ray Photoelectron Spectroscopy (XPS) in particular can deliver great insight as it combines both qualitative and quantitative information on elemental distributions, chemical environments, and valence states.

Here, we present a systematic study using angle-resolved hard X-ray photoelectron spectroscopy (AR-HAXPES) to study buried layers and interfaces. Hard X-rays provide increased depth information and using an angle-resolved approach, highly depth-resolved information monitoring elemental and electronic structure changes across thin films stacks and interfaces is possible. Well defined 4H-SiC/SiO₂ heterostructures are used as a test system representing a complex, defect rich system, in which knowledge of the precise nature of defects is limited. The samples were treated in a variety of nitrogen-containing atmospheres (N₂, NO, NH₃ and NO+NH₃) after the initial fabrication procedure, which leads to different distributions and chemical states of nitrogen across the heterostructures, which can compensate defects in particular at the interface. SiC is a wide band gap semiconductor, that is widely used for power electronic applications and therefore of great interest in itself.

Clear differences are observed in HAXPES spectra after high temperature treatments and across the heterostructures. Angle-resolved Si 2s and 1s, C 1s, O 1s, and N 1s core level spectra are analysed to give a complete picture of chemical environments present in the oxide and carbide layers and particularly at and around the interface. In addition, valence band spectra are used to provide an insight into changes in the electronic structure of the materials. Ultimately, we show that AR-HAXPES can be applied to the investigation of buried features and interfaces and related phenomena.

9:15 AM MQ03.03.05
Tuning the Electronic Properties of the 4D Transition Metal Oxide LaRhO₃ Juan Jiang, TaeKyung Lee, Sangjae Lee, Sohrab Ismail-Beigi, Frederick J. Walker and Charles H. Ahn; Yale University, United States

Perovskite transition metal oxides exhibit various novel properties due to the interactions of strongly correlated electrons. These interactions are well known in the 3d transition metal oxides, such as LaCoO₃, where multiple spin states can be observed. Electronic correlations are expected to change as the transition metal is changed from Co to Rh in the same column of the periodic table. To explore these changes, we grow high quality La₁₋ₓSrₓRhO₃ thin films with Sr concentrations as high as 50% on both LaAlO₃ and SrTiO₃ substrates by molecular beam epitaxy. Systematic changes in both structure and electronic transport have been observed that can be directly tied to the

10:00 AM  MQ03.03.06
Couplings at Oxide Interfaces in Perovskites and Double-Perovskites Marta Gibert; University of Zurich, Switzerland

Complex-oxide heterostructures have garnered much attention as a path to couple the rich variety of properties of these materials, but also for the many routes they offer for the stabilization of novel behaviors. Understanding the electronic and structural reconstructions occurring at interfaces is therefore key for the success of interface engineering. In the last years, control of the structural couplings of the oxygen sublattices during epitaxy synthesis is arising as a very powerful route to manipulate the states of matter in complex oxides. Whereas this strategy is starting to settle as one of the main mechanisms governing interfacial couplings in oxide heterostructures, we show here a system where, despite first glance prognosis, the dominant coupling is instead electronic in nature. The chosen heterostructures are high quality epitaxial NdNiO3/SmNiO3 superlattices and the occurring of the metal-insulating transition (single or double depending on the layer period) is the interesting functionality investigated. I will also focus on the family of double-perovskite compounds A2NiMnO6 (A being a rare earth cation), which is characterized by an insulating ferromagnetic behavior, with the end member La2NiMnO6 displaying a Curie temperature approaching room temperature (≈ 280K). The magnetism of these double-perovskite thin films will be investigated down to few unit cells. All thin films and superlattices are grown by off-axis magnetron sputtering.

10:30 AM MQ03.03.07
Order Parameter Control in Perovskite Nickelates via Oxygen Vacancies Zhen Zhang and Shriram Ramanathan; Purdue University, United States

The electronic structure and electromagnetic properties of perovskite nickelate quantum materials are highly sensitive to orbital occupancy and strain. In this work, we will discuss how oxygen vacancies can be injected into perovskite nickelates such as NdNiO3 in a reversible and controlled manner and can cause massive electronic phase changes by which the charge carriers are localized within unit cell dimensions. The distribution of oxygen vacancies can further be controlled spatially by bias voltage in a solid-state device creating functionally graded quantum systems. We will present experimental results combining variable temperature electronic transport and X-ray spectroscopic data to illustrate how the Ni-site orbital filling influences multiple order parameters such as electronic band gap, optical gap and spin ordering. These studies suggest the potential of nickelates as model systems for fundamental understanding of strong electron interactions by controlling concentration of oxygen vacancies and further their potential use in electronic switches.

10:45 AM MQ03.03.08
Tunable Resistivity Exponents in the Metallic Phase of Epitaxial Nickelates Qikai Guo1, César Magèn2, Saeedeh Farokhipoor1 and Beatriz Noheda1,3; 1Zernike Institute for Advanced Materials, University of Groningen, Netherlands; 2Instituto de Ciencia de Materiales de Aragón (ICMA), CSIC-Universidad de Zaragoza, Spain; 3Groningen Center for Cognitive Systems and Materials, Netherlands

The tunable resistivity of materials undergoing metal-insulator transitions (MIT) holds great promise for resistive switching applications, such as adaptable electronics and cognitive computing. Among the materials with MIT, rare-earth nickelates (RENiO3 with RE denoting a trivalent rare earth element) present a very interesting case because their MIT can be controlled by using different RE elements or by epitaxial strain [1-3]. Moreover, it has been reported that eliminating the MIT in nickelates by orbital engineering would give rise to a superconducting state, which could be more robust than that of the cuprates [4]. Thus, it becomes important to have an accurate picture of the relevant electron interactions in the intermediate temperature regimes, just before the MIT takes place. However, despite the vast amount of recent works, transport in nickelates is not yet fully understood. Based on different scaling exponents of the resistivity as a function of temperature reported in this material, various hypotheses, such as bad metal, Fermi-liquid (FL), non-fermi liquid (NFL), or even the crossover between FL and
NFL, had been proposed to describe the intriguing behavior of nickelates. However, the issue of matching these different hypotheses in one material rises the question on how to interpret the experimentally obtained apparent exponents.

Here, by investigating a series of NNO films grown on different substrates, we reveal an evolution of the resistivity-temperature apparent power law exponent of the metallic phase as a function of epitaxial strain and the associated induced disorder. Our experimental results support recent theoretical predictions by Patel et al. [5], which propose that the combined effect of electron interactions and disorder can give rise to a continuous variation of the exponents. These results demonstrate that the assessment of FL or NFL behavior based on the measurement of exponent of the power law temperature dependence of resistivity should be preceded by a detail analysis of the disorder.

11:00 AM MQ03.03.09
Complex Oxides at Weakly Coupled Interface—Epitaxy and Electrical Property Jian Shi; Rensselaer Polytechnic Institute, United States

Among various efforts to integrate quantum technology-associated complex oxides materials (e.g. nonlinear and strongly correlated oxides) on electronic substrates, thin film epitaxy has been regarded as one promising solution due to its feasibility for mass production, controllability over film dimension and high-density device integrability. However, most epitaxial oxides grown on Si are populated with defects such as grain boundaries and dislocations. The fundamental challenge lies in the fact that Si and most oxides have large lattice mismatch, which brings significant strain energy when film is below critical thickness but leads to populated misfit dislocations and threading dislocations when film is above its critical thickness. In this talk, to tackle these issues, I will show how we design and develop unconventional epitaxy approaches featured by weakly-coupled film-substrate interface. The model materials in this talk include correlated oxides and nonlinear electro-optic oxides. I will also show how the weakly-coupled complex oxides behave differently from films produced by conventional epitaxy under external stimuli.

11:30 AM MQ03.03.10
Accessing Novel Correlated Materials with Entropy Stabilization Synthesis Alessandro R. Mazza, Yogesh Sharma, Elizabeth M. Skoropata and T. Zac Ward; Oak Ridge National Laboratory, United States

Disorder is an important aspect of correlated quantum systems. As examples, it can be used to manipulate superconductivity, stabilize quantum spin liquid states, and enable scaling of non-fermi liquid responses. While synthesis of new quantum materials is generally focused on creating perfect crystals comprised of only a few elemental building blocks, we will present our recent efforts to create high quality crystals with a high degree of configurational elemental disorder on sublattice sites. The intent is to gain knowledge of how maximizing local microstates might enable the emergence of new and unexpected macrostates. Complex crystal structures comprising two or more sublattices, such as those in the perovskite family, are particularly promising. This is due to the nearest neighbor cations on one configurationally disordered sublattice being tied together by an intermediate common and uniform anion sublattice.

As an example, we present our recent stabilization of single crystal epitaxial films of the ABO3 perovskite La(Cr0.2Mn0.2Fe0.2Co0.2Ni0.2)O3. XRD and STEM-EELS studies confirm crystallinity, epitaxy, and full site mixing of the 5 B-site elements (no single element clustering). Experimental results from neutron studies, XMCD, and SQUID magnetometry demonstrate unexpected long-range magnetic ordering which is highly tunable through lattice symmetry modification.

11:45 AM MQ03.03.11
Regaining a Dimension—Mechanically-Transferrable 2D InAs Nanofins Grown by Selective-Area-Epitaxy Jakob M. Seidl1, Jan G. Gluschke1, Xiaoming Yuan2,3, S Naureen2,4, Naeem Shahid2,5, Hoe Tan2, Chennupati Jagadish2, Adam Micolich1 and Philippe Caroff6; 1University of New South Wales, Australia; 2The Australian
Semiconductor nanowires have seen great success for the last two decades and have opened the doors to a multitude of device applications [1]. However, emerging quantum devices often require more elaborate geometries that go beyond single one-dimensional wires. Selective-area-epitaxy (SAE) can overcome this limitation because it offers an approach to growing nearly arbitrary shapes, as demonstrated recently [2-4]. Most SAE-grown nanostructures are bound to their growth substrate which, while attractive for large scale processing, makes few-sample fabrication costly and challenging. We report on growth and electrical characterization of free standing InAs nanofins grown by selective-area-epitaxy [5]. Their rectangular footprint can be deliberately tuned to give structures ranging from 1D nanorods to thin 2D nanosheets with good height control. The high aspect ratio allows us to mechanically transfer them to device substrates where they lie flat and can be fabricated into devices with multiple contacts, top- and back-gates. Our devices show excellent prospects for fabrication into more sophisticated devices, e.g., by adding functional elements like superconducting contacts or by top-down patterning them into desired shapes after growth. InAs nanofin growth proceeded via metal-organic vapor phase epitaxy (MOVPE) on an InP (111B) substrate covered with a SiOx mask. During growth, nucleation occurs in lithographically pre-patterned rectangular openings in the SiOx. As with SAE growth of nanowires, the crystal retains the shape given by the rectangular openings if their long axis is aligned correctly relative to underlying crystallographic axes. Rectangular nanofins with typical width 1-4 μm, height ~ 4 μm and thickness < 85 nm were grown. After mechanical transfer to a prepatterned substrate these nanofins were fabricated into field-effect transistor devices with multiple ohmic contacts, a global back-gate and local top-gates. Low-temperature (T = 300 mK) electrical characterisation shows reliable contact performance with resistances below 10 kΩ. Hall measurements give electron densities of $1.5 - 7 \times 10^{17}/\text{cm}^3$ with good density control via the back-gate. We obtain field-effect mobilities of up 4400 cm²/Vs, systematically higher than transport mobilities extracted from Hall effect data, yet similar to what is found in InAs nanowires [6]. Reproducible quantum interference is visible in the magnetoconductance at large and small magnetic field scales. A robust weak anti-localisation (WAL) peak is visible around B = 0 T, which evolves with back-gate voltage. Fitting to this peak gives phase-coherence lengths $L_\phi = 200-600$ nm and spin-relaxation lengths $L_{SO} = 150-350$ nm. We see no signs of quantum-Hall effect in our accessible field range ($B \leq 2$ T).

Observation and Manipulation of Coupled Order Parameters and Domains in Magnetoelectric Multiferroics
Tsuyoshi Kimura; The University of Tokyo, Japan

In multiferroics having two or more ferroic orders simultaneously, multiple order parameters coexist in a system, sometimes couple with each other, and exhibit nontrivial crossed phenomena such as magnetoelectric effect. To date, various mechanisms have been proposed for the origin of multiferroicity. For example, in multiferroics which exhibit a certain conical spiral spin order, both ferromagnetic and ferroelectric order parameters can develop due to the magnetic order and their domains can be coupled with each other. In this presentation, we show selective observations, control, and understanding of coupled order parameters and domains which coexist in magnetoelectric multiferroics breaking both space inversion and time reversal symmetries. Examples of such multiferroic oxides are hexaferrites (e.g., Ba$_{1.3}$Sr$_{0.7}$CoZnFe$_{11}$AlO$_{22}$) showing the so-called alternating longitudinal conical structure and olivine-type manganese germanate Mn$_2$GeO$_4$ showing canted antiferromagnetic conical spin chains. For the observations, we adopted single-crystal measurements of scanning resonant x-ray microdiffraction for the hexaferrites or (un)polarized neutron scattering for the manganese germanate. These techniques clarify multiple magnetic order parameters and domain structures and their manipulations by external stimuli such as magnetic and electric fields in these peculiar multiferroics. This work has been done in collaboration with H. Ueda, R. Misawa, J. K. H. Fischer, K. Kimura, Y. Tanaka, Y. Wakabayashi, T. Honda, J. S. White, M. Kenzelmann, and A. B. Harris.

Stabilizing Emergent Ground States in Multifunctional BiFeO$_3$ Using Interfacial Electrostatic Engineering
Julia Mundy$^1$, Colin Heikes$^2$, Bastien F. Grosso$^3$, Dan Ferenc Segedin$^1$, William D. Ratcliffe$^2$, Nicola Spaldin$^3$, Ramamoorthy Ramesh$^4$ and Darrell G. Schlom$^5$; $^1$Harvard University, United States; $^2$National Institute of Standards and Technology, United States; $^3$ETH Zürich, Switzerland; $^4$University of California, Berkeley, United States; $^5$Cornell University, United States

Dielectric capacitors hold a tremendous advantage for energy storage due to their fast charge/discharge times and stability in comparison to batteries and supercapacitors. A key limitation to today's dielectric capacitors, however, is the low storage capacity of conventional dielectric materials. To mitigate this issue, antiferroelectric materials have been proposed, but relatively few families of antiferroelectric materials have been identified to date. Here, we propose a new design strategy for the construction of lead-free antiferroelectric materials using interfacial electrostatic engineering. We begin with a ferroelectric material with one of the highest known bulk polarizations, BiFeO$_3$. We show that by confining atomically-precise thin layers of BiFeO$_3$ in a dielectric matrix that we can induce a metastable antiferroelectric structure. Application of an electric field reversibly switches between this new phase and a ferroelectric state, in addition, tuning of the dielectric layer causes coexistence of the ferroelectric and antiferroelectric states. Precise engineering of the structure generates an antiferroelectric phase with energy storage comparable to that of the best lead-based materials. The use of electrostatic confinement provides a new pathway for the design of engineered antiferroelectric materials with large and potentially coupled responses.

Electrically Switchable Magnetism and Topological Hall Effect in SrRuO$_3$ Thin Films Jinxing Zhang; Beijing Normal University, China

Reversibly controlling topological orders is fundamentally important but challenging. Strongly correlated oxides with coexistence and competition of multiple d electron order parameters may provide a platform for robust and controllable topological phases. Here, high-spin state and topological Hall effect are achieved in ultrathin SrRuO$_3$thin filmson SrTiO$_3$substrates. Oxygen vacancies transferred from SrTiO$_3$to the ultrathin SrRuO$_3$reconstructs Ru-4d electronic structure and orbital occupancy, leading to an enhancement of magnetic moment and an ~370 meV energy gap opening. Therefore, symmetry broken and Dzyaloshinskii–Moriya interaction in this ultrathin oxide structure give rise to a topological order in spin state, where the topological Hall effect can be reversibly switched by an electric-field-rectifying oxygen ionic diode.

A Correlated Material by Hydrogenation—HCsBiNb$_2$O$_7$ Lifu Zhang and Jian Shi; Rensselaer Polytechnic Institute, United States

Correlated compounds serve as model systems to study interactions among lattice, spin, charge and orbital degree of
freedom. Understanding the correlation and phase transition mechanisms in these compounds is paramount for the innovation of next-generation ultrafast and high-efficiency electronic/photonic devices. However, the number of discovered correlated oxides by now is still quite limited. Here we apply hydrogenation to create a new phase of correlated material HCsBiNb2O7 (HCBNO). We first synthesize CsBiNb2O7 (CBNO), a layered in-plane ferroelectric perovskite, by molten salt method and then dope it via hydrogenation in 5% H2 of Ar/H2 gas. This doping process is reversible and can induce pronounced changes in its optical properties, accompanying with electronic modulations. To achieve sufficient hydrogenation of the CBNO, atomically dispersed Pt catalyst was used to promote hydrogen spillover under a temperature of 475 °C. Raman and XRD characterization indicate the hydrogen is reversibly absorbed into, and released from CBNO without destroying its lattice structure. Ultraviolet-visible spectrum shows a significant increase (~ 3 times) in absorption after hydrogenation and transport measurement shows a nearly 10 times increase in electric conductivity, comparing to the pure CBNO at room temperature. Resistance-temperature measurement and ultraviolet photoelectron spectrum further confirm the transition of electronic orbital configurations. Our finding suggests the possibility of reversible modulation in CBNO via hydrogenation and may give some enlightenment in exploring novel electronic and photonic devices with complex correlated oxides.

Antiferromagnetic Spin Engineering in LaFeO3—A Route towards Uniaxial Néel Vector Control
Kristoffer Kjærness1, Tianxian Nan2, Ingrid G. Hallsteinsen1,3, Ruofan Li2, Alireza Qaiumzadeh1, Jonathan Schad4, Magnus Moreau1,2, Sverre Magnus Selbach1, Alexander Grutter6, Elke Arenholz3, Arne Brataas1, Daniel C. Ralph2, Chang-Beom Eom7 and Thomas Tybell1; 1Norwegian University of Science and Technology, Norway; 2Cornell University, United States; 3Lawrence Berkeley National Laboratory, United States; 4University of Wisconsin—Madison, United States; 5Silicon Labs Norway, Norway; 6National Institute of Standards and Technology, United States

Spintronics based on antiferromagnetic (AF) materials are attractive for energy efficient device technology, offering robustness against magnetic perturbations and ultra-high frequency spin dynamics allowing for THz device technology. Currently, there is focus on developing methodologies to tailor the AF spin texture. Transition metal oxide-based systems are in this regard promising candidates, and here, we present how anisotropic strain engineering permits tailoring of the AF Neel vector in epitaxial single crystalline LaFeO3 thin films synthesized by pulsed laser deposition. LaFeO3 is a prototypical G-type antiferromagnet with high Néel temperature. To impose anisotropic strain, we rely on the (111) pseudocubic facet of orthorhombic scandate- and gallate-based oxide substrates. X-ray studies confirm a lowering of LaFeO3 symmetry, from orthorhombic in bulk to monoclinic or triclinic, depending on the choice of substrate and the magnitude of anisotropic strain, in thin films. This is in accordance with DFT calculations. Epitaxial engineering allows us to efficiently tune the magnetic anisotropy from bi-axial in bulk to uniaxial in our thin films, as inferred from soft x-ray spectroscopy. By increasing the LaFeO3 thickness transition of the uniaxial spin direction takes place, a change from an out-of-plane to an in-plane AF spin axis above 16 d111-layers. We will discuss the possibilities that anisotropic strain engineering offers to tune the interface AF spin texture between LaFeO3 and a ferromagnet in a deterministic fashion, as confirmed by soft x-ray spectroscopy and spin-polarized neutron reflectivity. Furthermore, we will present non-local spin transport studies to exemplify that the uniaxial Néel vector control allows engineering of anisotropic spin transport. The experimental data will be correlated to spin transport theory.

4:00 PM MQ03.04.06
Coherent Imaging of Antiferromagnetic Domain Dynamics
Sangiae Lee1, Juan Jiang1, Gilberto Fabbris2, Claudio Mazzoli2, Mark Dean2, Frederick J. Walker1 and Charles H. Ahn1; 1Yale University, United States; 2Brookhaven National Laboratory, United States

Understanding the dynamics and energetics of the antiferromagnetic (AF) domains is of general and timely interest for the application of these magnetic materials in spin-based electronics for computing and communications. A fundamental requirement to understand and control AF domains involves the ability to image them. X-ray photon correlation spectroscopy (XPCS) measurements via coherent x-ray scattering can be employed to image the AF order parameter in thin films and to access the information about their dynamics. Recent studies on NdNiO3 (NNO) have shown that its electronic and magnetic phase transitions can be tuned by confining the nickelate layers to reduced dimensions in heterostructures. We study the AF ground state for atomically layered (NdNiO3)m/(NdAlO3)n heterostructures.
heterostructures to demonstrate that dimensional confinement enhances the phase fluctuations at AF domain boundaries. We analyze the speckle patterns arising from coherent x-ray scattering to access the information on long- and short- ranged correlations for varying thickness of nickelate layers, m. We find that the dynamics of the AF domain boundaries are dramatically enhanced as the reduced dimensionality of the NNO layers approach the 2D limit. Our study demonstrates a path to characterize dimensional effects on long-range order and the ability to control AF domain configurations in oxide heterostructures.

Neutron Investigation of the Phase Transitions and Domain Dynamics of Multiferroic GaV₄S₈
Jeffrey W.
Lynn¹, William D. Ratcliff¹, Marcus Bleuel¹,², Rebecca L. Dally¹, Heung-Sik Kim³,⁴, Kristjan Haule¹, David
Vanderbilt¹, Lunyong Zhang¹ and Sang Wook Cheong⁵; ¹National Institute of Standards and Technology, United
States; ²University of Maryland, United States; ³Rutgers University, United States; ⁴Kangwon National University, Korea (the Republic of); ⁵Pohang University of Science and Technology, Korea (the Republic of); ⁶Rutgers, The State University of New Jersey, United States

We have carried out neutron diffraction and small angle neutron scattering measurements on a high quality single crystal of the cubic lacunar spinel GaV₄S₈ multiferroic as a function of magnetic field and temperature. The system undergoes a structural transition at 44 K to a non-centrosymmetric rhombohedral symmetry and becomes ferroelectric. The system then orders magnetically below ~13 K into an incommensurate cycloidal phase. Further reduction of temperature transforms the system below 7 K into a ferromagnetic ground state. The ferromagnetic order parameter appears to be continuous with an ordered moment of 0.9 μB at the lowest temperature. Measurements of the magnetic intensities using both polarized neutron diffraction measurements and unpolarized field-induced moment measurements in the temperature range between the magnetic and ferroelectric transitions demonstrate that the single electron spin is distributed across all four V ions of the V₄ molecular unit, and does not just reside on the single apical V ion. This is in reasonable agreement with DFT calculations which show a moment on all four V but with an enhanced occupancy on the apical V in the ferroelectric phase. In the vicinity and below the transition to long range magnetic order there is a clear coupling of the ferroelectric and magnetic order parameters, necessitating polarized neutron measurements to determine the magnetic form factor. Field-dependent SANS data exhibit the cycloidal and skyrmion phases, which have been investigated in detail as a function of temperature and applied magnetic field. The intensities depend strongly on both temperature and field, while the incommensurate wave vector is strongly temperature dependent but exhibits a very weak field dependence. Finally, the skyrmion dynamics have been investigated at long time scales using the neutron time-tagging technique with a periodic perturbative magnetic field complementing the steady-state applied field. Varying the amplitude and frequency of the perturbation has been used to reveal important details of the time dependence of the Néel-type skyrmions as well as other aspects of the magnetic order.

Raman Spectroscopy as a Probe of Magnetic Phenomena in Layered Quantum Materials
Amber McCready¹, Jeffrey Simpson¹,², Thuc Mai¹,³, Rolando Valdes Aguilar¹ and Angela Hight Walker¹; ¹National Institute of Standards and Technology, United States; ²Towson University, United States; ³The Ohio State University, United States

Recent observations of long-ranged magnetic ordering in van der Waals bonded, layered magnetic materials down to the single layer limit has led to a plethora of research dedicated to the study of two-dimensional (2D) magnets, with plenty of opportunities to investigate fundamental physics and potential quantum applications. With these materials, the properties are typically strongly correlated to the number of layers, with new physics occurring in the few-layer (~few nm) regime. In this sense, common techniques used to measure magnetic behavior such as neutron scattering and SQUID are at a disadvantage due to sample size requirements. On the other hand, Raman spectroscopy, which has diffraction-limited spatial resolution, is a powerful, non-destructive optical method to probe magnetism in 2D layered materials through inelastic scattering. An amazing amount of information is quantified from the Raman spectra such as layer thickness, disorder, edge and grain boundaries, strain, etc. Raman also efficiently probes the evolution of the spin-phonon interactions and magnetic excitations, such as magnons, as a function of temperature, laser energy, polarization, and magnetic field. I will discuss how we used our unique magneto-Raman capabilities to study the magnetic properties of the metal phosphorus trisulfide family (MPS₃, where M = Fe, Mn, and Ni) which are layered antiferromagnetic semiconductors. While the three materials have the same crystal structure, their varying spin structures result in distinct behavior as a function of temperature and magnetic field, which will be
presented herein. In FePS$_3$, we investigated spin-phonon coupling as well as the emergence of new modes in the magnetically ordered state that were not present in MnPS$_3$. Through magneto-Raman spectroscopy, we will show that one of these modes is actually a Raman-active magnon, where the symmetry behavior of the magnon can be explained using the magnetic point group of FePS$_3$.

SESSION MQ03.05: Charge, Spin and Topological Orders in Unconventional Superconductivity
Session Chairs: Alex Frano and Mingda Li
Wednesday Morning, December 4, 2019
Hynes, Level 2, Room 203

8:00 AM *MQ03.05.01
Superconductivity in an Infinite-Layer Nickelate Danfeng Li$^{1,2}$, Kyo Hoon Lee$^{1,2}$, Baiyang Wang$^{1,2}$, Motoki Osada$^{1,2}$, Samuel Crossley$^{1,2}$, Hyo Young Lee$^{1,2}$, Ye Cui$^{1,2}$, Yasuyuki Hikita$^1$ and Harold Y. Hwang$^{1,2}$; $^1$SLAC National Accelerator Laboratory, United States; $^2$Stanford University, United States

Since the discovery of high-$T_c$ superconductivity in (La,Ba)$_2$CuO$_4$, superconductivity in nickel oxide compounds has been a target of interest for many years. We report the observation of superconductivity in an infinite-layer nickelate that is isostructural to the infinite-layer cuprates [1]. Using soft chemistry topotactic reduction, single crystal infinite-layer nickelate thin films are synthesized by reducing the perovskite precursor phase. Experiments on these films indicate a $T_c$ of ~9-15 K. This compound can be considered one member of a series of reduced layered nickelate crystal structures, suggesting the possibility of a family of nickelate superconductors. In this talk, I will describe the film synthesis, discuss the superconductivity measurements, and present the latest developments in this emerging field.

8:30 AM *MQ03.05.02
Recent Developments from X-Ray Scattering Studies on Charge Order in High-$T_c$ Superconducting Cuprates
Matteo Minola; Max Planck Institute for Solid State Research, Germany

Incommensurate charge order (CO) has been identified as the leading competitor of high-temperature superconductivity in all major families of layered copper oxides, but the perplexing variety of CO states in different cuprates has confounded investigations of its impact on the transport and thermodynamic properties. The three-dimensional (3D) CO observed in YBa$_2$Cu$_3$O$_{6+x}$ (YBCO) in high magnetic fields is of particular interest, because quantum transport measurements have revealed detailed information about the corresponding Fermi surface. Here, we report a high-resolution inelastic hard x-ray scattering study of the high-temperature superconductor YBa$_2$Cu$_3$O$_{6.67}$ under uniaxial stress and show that a 3D long-range-ordered charge density wave (CDW) state akin to that observed in field along the $b$-axis can be induced by pressure applied along the $a$-axis, in the absence of magnetic fields and after enhancing the planar 2D CDW [1]. The amplitude of the 3D CDW is strongly suppressed below the superconducting transition temperature, indicating strong thermodynamic competition with superconductivity. We also show that a strong softening of an optical phonon mode is associated with the transition. We also used resonant soft X-ray scattering (RXS) at the Cu $L_3$ edge to investigate the planar symmetry of the strain-induced enhancement of the 2D CDW as well as the energy- and temperature-dependence of the 3D CDW scattering peak in single crystals of YBCO [2] and we compare the results with RXS data on the 3D charge order discovered in YBCO films grown epitaxially on SrTiO$_3$ (STO) [3]. The findings offer fresh perspectives for experiments elucidating the influence of 3D CDW on the electronic properties of cuprates without the need to apply high magnetic fields.

Coupling between Dynamic Magnetic and Charge-Order Correlations in the Cuprates Measured by RIXS
Eduardo H. da Silva Neto; University of California Davis, United States

Charge order has now been observed in several cuprate high-temperature superconductors. We report a resonant inelastic x-ray scattering experiment on the electron-doped cuprate NCCO that demonstrates the existence of dynamic correlations at the charge-order wave vector. Upon cooling we observe a softening in the electronic response, which has been predicted to occur for a d-wave charge order in electron-doped cuprates. At low temperatures, the energy range of these excitations coincides with that of the dispersive magnetic modes known as paramagnons. Furthermore, measurements where the polarization of the scattered photon is resolved indicate that the dynamic response at the charge-order wave vector primarily involves spin-flip excitations. Overall, our findings indicate a coupling between dynamic magnetic and charge-order correlations in the cuprates.

Light Induced Non-Volatile Switching of Superconductivity in Single Layer FeSe on SrTiO$_3$ Heterostructures
Ming Yang, Chenhui Yan, Yanjun Ma, Lian Li and Cheng Cen; West Virginia University, United States

The capability of controlling superconductivity by light is highly desirable for active quantum device applications. Since superconductors rarely exhibit strong photoresponses, and optically sensitive materials are often not superconducting, the efficient coupling of these two characters in a single material can be very challenging. Here we show that, in FeSe/SrTiO$_3$ heterostructures, the superconducting transition temperature in FeSe monolayer can be effectively raised by the interband photoexcitations in the SrTiO$_3$ substrate. Attributed to a light induced metastable polar distortion uniquely enabled by the FeSe/SrTiO$_3$ interface, this effect only requires a less than 50 µW cm$^{-2}$ continuous-wave light field. The fast optical generation of superconducting zero resistance state is non-volatile but can be rapidly reversed by applying voltage pulses to the back of SrTiO$_3$ substrate. The capability of switching FeSe repeatedly and reliably between normal and superconducting states demonstrate the great potential of making energy-efficient quantum optoelectronics at designed correlated interfaces.

9:45 AM MQ03.05.05
In Situ Micromechanical Characterization of Iron-Based High Temperature Superconductors
Seok-Woo Lee, Gyuho Song, John T. Sypek and Shuyang Xiao; University of Connecticut, United States

High temperature Fe-based superconductors have recently drawn a strong attention due to their superconducting capability even in the presence of magnetic Fe, which has been regarded as a harmful element for superconductivity. Particularly, ThCr$_2$Si$_2$-structured Fe-based superconductors have been extensively studied due to their strong pressure sensitivity of structure and electronic/magnetic properties. Under hydrostatic pressure, they undergo the collapsed tetragonal (cT) phase transition through the formation of Si-Si type bonds. During this process, a magnetic state changes and superconductivity often disappears. Therefore, it is interesting to understand how mechanical deformation influences electronic structure, magnetism, and superconductivity.

For the last decade, nanomechanics community has reported numerous papers regarding the size-dependent strengthening and toughening at the nanometer scale; as the sample dimension decreases, a material can withstand the larger elastic deformation under uniaxial mechanical loading. For instance, silicon nanowire can be uniaxially stretched up to a strain above 15% before failure. This giant elastic deformability at the nano-scale can certainly open a new opportunity of “Strain-Engineering of Superconductors”. In this presentation, we will introduce our custom-built in-situ cryogenic micromechanical testing system that allows us to characterize mechanical behaviors of micron-sized iron-based high temperature superconductor under uniaxial mechanical loading. Micropillars of various ThCr$_2$Si$_2$-type iron-based superconductors were fabricated using focused ion beam milling, and uniaxial mechanical tests were performed along a [0 0 1] direction. Contrast to the conventional belief of easy brittle fracture under uniaxial loading, our results show the giant elastic strain over 10%, which is high enough to see the cT phase transition. This large elastic deformation is reversible, implying that it is possible to induce the forward and backward transitions continuously under the application of cyclic force. Thus, the giant elastic deformability at the
nano-scale is still hold for iron-based superconductors. Compared to hydrostatic pressure, uniaxial mechanical loading has a great advantage to apply a mechanical force along a chosen crystallographic orientation. In addition, our on-going development of liquid helium cooling capability will allow us to explore the effects of uniaxial deformation on superconductivity. We will share some of our preliminary results of in-situ cryogenic mechanical testing on high temperature superconductor, CaKFe4As4 at T=40~298 K. We strongly believe that the combination of nanomechanics and superconductivity will create a unique opportunity to explore the effects of unconventionally large elastic strain on the critical temperature of superconductivity, magnetism, and electronic structures of superconductors.

Pair-Density Waves and Gapless Spin Fluctuations in Cuprate Superconductors John M. Tranquada; Brookhaven National Laboratory, United States

An unusual form of two-dimensional (2D) superconductivity has been observed in bulk crystals of La2-xBaxCuO4 (LBCO) with x ~ 1/8. To explain the apparent frustration of interlayer Josephson coupling, the occurrence of pair-density-wave superconductivity has been proposed [1], which is compatible with the known existence of spin and charge stripe orders. To test this possibility further, we recently performed transport measurements in a c-axis magnetic field of up to 35 T. At a temperature of less than 1 K, evidence was found for a progression, with increasing field, from 3D order to reentrant 2D superconductivity to an unusual metallic state with very large resistance per plane but negligible Hall effect. To see whether such behavior is unique to LBCO, crystals of La2-xCa1+xCu2O6 have been grown. Annealing in high-pressure oxygen results in dilute intergrowths of La2CuO4 and La8Cu8O20; however, the apparent Ca-enrichment of the main phase results in a superconducting transition temperature $T_c$ as high as 55 K [3]. Transport measurements demonstrate a decoupling of the superconducting bilayers in modest magnetic field [4]. Time-of-flight neutron scattering measurements reveal low-energy spin fluctuations that do not develop a gap below $T_c$ [5]. This behavior is similar to that in LBCO, suggesting the importance of intertwined order.

Work at Brookhaven is supported by the Office of Basic Energy Sciences, Materials Sciences and Engineering Division, U.S. Department of Energy, through Contract No. DE-SC0012704.

11:00 AM MQ03.05.07

Growth of Single Crystals of Ni,ZrTe2 and Investigation of Superconducting Properties Lucas F. Correa, Frederico Santos and Antonio Machado; University of São Paulo, Brazil

This work is about the growth of high quality single crystals by the CVD method of dicalcogens that crystallize in the CdI2 prototype. Preliminary results shown in this plan strongly suggest that it is possible to grow high quality single crystals by this method represented by a member of the family which is Ni0.02ZrTe2. Band structure calculations, as well as some results reported in the literature, show that this type of prototype presents a non-trivial topology and, in this sense, the superconductivity that coming from this prototype can be a clear example of non-artificial topological superconductors. In addition to these aspects relevant to Condensed Matter Physics, the following plan intends to complement the formation of this candidate, in this effervescent area of the new Condensed Matter Physics

11:15 AM MQ03.05.08

Polyanions as Spacers to Create 2D Iron Materials Yohann Bréard; Crismat Laboratory, France

The properties of materials are determined by their dimensionality but also by the interatomic chemical bonding. It is then of interest to combine effort to control both aspects: chemical and dimensional. The low dimensional
transition metal oxides showing 2D magnetic sheets, are of great interest due to their strong magnetic and electronic anisotropies which usually lead to complex phenomena (as spin density waves, superconducting, or step magnetization reversibility to name a few). In addition to the fundamental interest, spintronic applications are also of great interest: 2D spin-valve compounds, or magnetic tunnel junction are currently heavily exploited for magnetic random access memory (MRAM) memories. The latter two-dimensional structure compounds consist mainly of alternately ferromagnetic and non-magnetic layers that are generally obtained by the thin-film deposition technique. It is of interest to obtain new solid 2D materials with an angstrom-scale alternation of magnetic / non-magnetic layers inherent to their atomic structure, through which analysing the spin-dependent transport. On the other hand, this would avoid the current synthesis by thin film deposition more complicated to implement.

The use of voluminous polyanions can leads to original 2D atomic structures - This has been amply demonstrated in cuprates superconductors (Sr2CuO2(CO3), La1.85Sr0.15Cu1-x(SO4)xO4)). Paradoxically, few studies have been conducted in mixed polyanion iron oxide systems. We can nevertheless quote the oxyphosphate compound SrFe3(PO4)O or the oxycarbonate Sr4Fe2O6(CO3), described by Yamaura and Bréard. The latter is an intergrowth between SrFeO3 perovskite layers and "rock-salt" SrO layers where FeO6 octahedra of the middle perovskite layer has been replaced by carbonate groups showing the possibility to create intergrowths between carbonates and a transition metal which is not a Jahn-Teller element. This substitution strategy has been recently extended to sulfate anions which are also divalent but even larger than carbonates and more electronegative than oxygen and carbonates; They have also a radically different geometry. All these differences lead to different magneto electric behaviors that will be highlighted in the presentation.

11:30 AM MQ03.05.09
Kauzmann Entropy Paradox, and the "Ideal Glass Transition" Viewed as a Self-Dual Critical Point at the Four-Dimensional Crystal/Glass Quantum Phase Transition Caroline S. Gorham and David E. Laughlin; Carnegie Mellon University, United States

Notwithstanding decades of work, the realization of a fundamental understanding of amorphous structures and their transport properties has remained a great challenge. In this research, we approach a description of amorphous structures by considering thermodynamic descriptions of the solidification of undercooled fluids upon the adoption of a quaternion orientational order parameter. Unlike the first-order transition of a liquid into a crystal, the glass transition is an entirely different phenomenon. In particular, as the temperature of an undercooled liquid decreases the difference in entropy between the liquid and solid phase decreases. At a certain point, known as the Kauzmann point that may be achieved in the limit of an infinitely slow cooling rate, the entropies of the liquid and crystal phase are equal. At the Kauzmann point, which occurs at a finite Kauzmann temperature, the liquid adopts a unique state of lowest energy such that its entropy approaches zero as temperature approaches zero. Herein, the "ideal glass transition" that occurs at the Kauzmann point is identified as a first order quantum phase transition between crystalline and non-crystalline solid states that are characterized by a four-dimensional quaternion orientational order parameter. In particular, there is a discrete change in the topology of the orientational order parameter manifold of the solid state at this critical point from a three-dimensional torus ($T^3$) to a three-dimensional sphere ($S^3$). Similarities between the finite temperature first-order crystal-to-glass transition and the superfluid-to-Mott insulator quantum phase transition are identified herein.

**Strain-Induced Enhanced Berry Curvature in Pyrochlore Iridate Thin Film**  
Tae Won Noh\(^1,2\), 1Center for Correlated Electron Systems, Institute for Basic Science, Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

Pyrochlore iridates have been predicted to exhibit many fascinating topologically non-trivial states due to strong spin-orbit coupling (SOC) and electron correlations [1]. Importantly, they have the all-in-all-out (AIAO) antiferromagnetic ordering that breaks time reversal symmetry (TRS). With broken TRS, it was predicted that a magnetic Weyl semimetal (WSM) phase could emerge in pyrochlore iridates. In addition, theoretical studies revealed the emergence of a new topological phase of which are hidden in the bulk and manifest only in thin films [3-5]. In spite of these exotic phenomena, most of the works were focused on the bulk single crystals or ex-situ grown relaxed films. The multi-phase boundary of iridium presents an extreme difficulty in the in-situ epitaxial growth of such thin film samples.

Here, we report a high quality Nd\(_2\)Ir\(_2\)O\(_7\) thin film grown on Yttrium stabilized ZrO\(_2\) (YSZ) substrates by pulsed laser deposition, using a special in-situ growth technique called “repeated rapid pulse annealing epitaxy”. A large anomalous Hall effect (AHE) signal was observed in Nd\(_2\)Ir\(_2\)O\(_7\) thin film where the size is ~ 10\(^6\) times larger than that of Nd\(_2\)Ir\(_2\)O\(_7\) bulk. The tight binding calculation provided that strain effect can produce large Berry curvatures in the system and responsible to give large anomalous Hall effect. Moreover, we have observed chiral anomaly from the transport measurement which considered to be related to its possible magnetic WSM states. Our finding highlights that strain effect in pyrochlore iridates can be the way to engineer Berry curvature. Moreover, it may open a door to investigate the Berry curvature engineered correlated topological states in the oxides.

**Synthesis of Barium Iridates with Unconventional Magnetic Ground States**  
Xiang Chen\(^1,2\), Dongsheng Yuan\(^1\), Siqi Wang\(^2\) and Robert Birgeneau\(^2,1\); 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States

Realization of new states of quantum matter is persistently desired in condensed matter physics and material science engineering. Some outstanding example systems include high transition temperature superconductors (high Tc SC), topological insulators (TI), quantum spin liquids (QSL), etc… A recently reported spin trimer chain compound Ba\(_4\)Ir\(_3\)O\(_10\), which crystallizes in a different lattice than conventional geometrically frustrated motifs such as in pyrochlore and Kagome lattice, might offer a new platform for engineering unusual quantum spin liquid states. The similar chain compound BaIrO\(_3\), however, exhibits magnetic order at much elevated temperature 183 K, concomitant with the onset of charge density order. Here we report the powder and single crystal growth of a plethora of Barium Iridium Oxides with contrasting unconventional magnetic ground states which share a great deal of structural similarities. Our current explorations indicate a potential playground for emerging quantum materials in Barium Iridates.

**Towards Building and Testing Quantum Structures Atom-by-Atom with Electron Beams**  
Stephen Jesse, Ondrej Dyck, Andrew Lupini and Sergei Kalinin; Oak Ridge National Laboratory, United States

Fabricating atomic scale structures remains as an ultimate goal of nanotechnology. Scanning Probe Microscopes and molecular self-assembly have demonstrated important successes towards achieving this goal. In this presentation, I discuss research activity towards the use of the atomically focused beam of a scanning transmission electron microscope (STEM) to control and direct matter on the atomic scale. Traditionally, STEM’s are perceived only as
imaging tools and the material modifications induced by their highly energetic (on the order of 100 kV) and highly focused (sub-angstrom) beams considered as undesirable beam damage. However, if these material changes can be directed through precise control over beam trajectory, the use of active feed-back, and control over temperature and environment, it is possible to use the STEM as a platform for not just imaging, but manufacturing at the atomic scale. We have demonstrated single defect formation, controlled individual dopant placement and migration, and drilling and milling in single layer 2D materials with the goal of building materials and devices for quantum application. I will introduce several examples of beam-induced fabrication on the atomic level, and demonstrate how beam control, rapid image analytics based on traditional and artificial intelligence techniques, better insight through modelling, and image- and spectroscopy-based feedback allows for controlling matter on atomic level and investigating emergent properties.

This material is based upon work supported by the U.S. Department of Energy, Office of Science, Division of Materials Science and Engineering, Basic Energy Sciences and was performed at the Oak Ridge National Laboratory’s Center for Nanophase Materials Sciences (CNMS), a U.S. Department of Energy, Office of Science User Facility.

The Many Faces of Spin—Orbit Coupling in Quantum Materials Alessandra Lanzara1,2; 1University of California Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States

Just when we thought the spin-orbit interaction in solids was finally explained, a plethora of new discoveries have appeared, challenging our understanding and imagination of what the implications and manifestation of this relativistic effect might be. Today the field of spin-orbit coupling is a vibrant one, ranging from the construction of revolutionary experimental tools for imaging spins of electrons in both momentum, energy and time domain, to the development of new theories and models aimed at predicting and explaining unexpected behaviors. In this talk I will present an overview on the state of the art experimental techniques to study such interaction in condensed matter physics, and I will discuss a couple of examples of how such interaction evolves from 2D transition metal dichalcogenides, to topological insulators and finally unconventional superconductors where such interaction gets coupled with strong correlation leading to novel behavior.

10:45 AM MQ03.07.06
A New Magnetic Topological Quantum Material Candidate by Design Xin Gui1, Ivo Pletikosic2,3, Huibo Cao4, Hung-Ju Tien1, Xitong Xu4, Ruidan Zhong4, Guangqiang Wang5, Tay-Rong Chang5, Shuang Jia6, Tonica Valla2, Weiwei Xie1 and Robert J. Cava1; 1Louisiana State University, United States; 2Brookhaven National Laboratory, United States; 3Princeton University, United States; 4Oak Ridge National Laboratory, United States; 5National Cheng Kung University, Taiwan; 6Peking University, China

Magnetism, when combined with an unconventional electronic band structure, can give rise to forefront electronic properties such as the quantum anomalous Hall effect, axion electrodynamics and Majorana fermions. Here we report the characterization of high-quality crystals of EuSn2P2, a new quantum material specifically designed to engender unconventional electronic states plus magnetism. EuSn2P2 has a layered, Bi2Te3-type structure. Ferromagnetic interactions dominate the Curie-Weiss susceptibility, but a transition to antiferromagnetic ordering occurs near 30 K. Neutron diffraction reveals that this is due to two-dimensional ferromagnetic spin alignment within individual Eu layers and antiferromagnetic alignment between layers - this magnetic state surrounds the Sn-P layers at low temperatures. The bulk electrical resistivity is sensitive to the magnetism. Electronic structure calculations reveal that EuSn2P2 might be a strong topological insulator, which can be a new magnetic topological quantum material (MTQM) candidate. The calculations show that surface states should be present, and they are indeed observed by ARPES measurements.

11:00 AM MQ03.07.07
Fermi Level Tuning and Quantum Coherent Transport in Bi-Doped Pb1-xSnxSe Jiashu Wang1, Xinyu Liu1, Seul-Ki Bac2, Sanghoon Lee2, Jacek K. Furdyna4 and Badih A. Assaf3; 1University of Notre Dame, United States; 2Korea University, Korea (the Republic of)
Pb$_{1-x}$Sn$_x$Se (x<0.4) is a narrow gap semiconductor and it can have topological phase transition to topological crystalline insulator (TCI) when the concentration of Sn increases. Its electronic properties are sensitive to electric and magnetic fields. It is thus worth considering in the fabrication of electronic devices. Here we investigated the MBE growth of Pb$_{1-x}$Sn$_x$Se (x=0.2-0.3) doped with Bi and characterized the sample using X-ray diffraction (XRD), and magneto-transport measurement. We showed that doping Bismuth into the sample can significantly lower the carrier density, even change its type from p=2.9×10$^{18}$ cm$^{-3}$ to n=1.1×10$^{19}$ cm$^{-3}$. We studied how quantum coherent transport depends on this tuning process. This tunability can be useful in the fabrication of quantum devices.

11:15 AM MQ03.07.08
Single Crystal Growth and Low-Temperature Characterization of Nonsymmorphic Ca$_2$Pt$_2$Ga Frederico Santos$^{1,2}$, Priscila Rosa$^1$, Joe Thompson$^1$, Eric Bauer$^1$, Filip Ronning$^1$ and Sean Thomas$^1$; $^1$Los Alamos National Laboratory, United States; $^2$Universidade de Sao Paulo, Brazil

Recently, about 25% of all known uncorrelated compounds have been predicted to host topological properties. According to these theoretical predictions, Ca$_2$Pt$_2$Ga is a filling-enforced topological semimetal candidate. Here we present a route for the synthesis of Ca$_2$Pt$_2$Ga single crystals, which are characterized by single crystal x-ray diffraction, energy dispersive spectroscopy, magnetic susceptibility, electrical resistivity, Hall effect and heat capacity at low temperatures. We will compare our experimental data with theoretical expectations.

11:30 AM MQ03.07.09
Electronic and Mechanical Property Characterization of Pure β-Tungsten Films Heun Tae Lee$^1$, Akira Nagakubo$^1$, Hitoshi Yamaoka$^2$, Hitoshi Sato$^1$, Yoshio Ueda$^1$ and Hirotsugu Ogi$^1$; $^1$Osaka University, Japan; $^2$RIKEN SPring-8 Center, Japan; $^3$Hiroshima Synchrotron Radiation Center, Hiroshima University, Japan

Thin film β-tungsten (β-W) is attracting extensive attention due to its giant spin Hall effect and promising application in spintronics as memory devices. Large spin currents have been used to set the magnetization of adjacent magnetic layers using the spin torque effect [1], and utilization of the large spin-Hall angle of β-W (0.3) [2] appears promising. However, the reason for the large magnitude of the spin Hall angle in β-W is presently not known. Clarifying whether the giant spin Hall effect arises from extrinsic or intrinsic properties is the first step towards engineering β-W based spin torque devices. Extrinsic effects arise from spin-dependent scattering with impurities or band structure peculiarities. To date, no work has experimentally examined the electronic density of states in pure β-W thin films. In this work, we present high-resolution valence band spectra near the Fermi level of pure β-W thin films measured by photoelectron spectroscopy using synchrotron radiation. Only fine difference in the double peak structure between -2 and -4 eV is observed between β-W and α-W. Such effects are qualitatively reproduced in calculations. However, the experimental spectra are complicated by the presence of oxygen surface contamination, and its presence is never reduced completely even after successive in-vacuo sputtering. Large spin Hall angles reported in other thin film materials generally arise due to spin-orbit interaction of impurities [3], or resonant/surface skew scattering effects with impurity sites [4]. Our results indicate that the role of oxygen impurities on β-W surfaces should be clarified in the reported large spin Hall angles of β-W layered systems. The mechanical and structural properties of thin films were characterized using a combination of novel picosecond ultrasonic measurements and standard X-ray diffraction. The calculated elastic constants using density functional theory agreed within 10% of the experimental values for both β-W and α-W.

Recent Work Involving Orbital-Free Density Functional Theory William C. Witt¹, Beatriz Gonzalez del Rio¹, Florian Libisch², Kaili Jiang¹ and Emily A. Carter¹; ¹Princeton University, United States; ²Vienna University of Technology, Austria

Simulations based on modern orbital-free density (OF) functional theory (DFT) can be orders of magnitude faster than those performed with conventional Kohn-Sham DFT, largely because OF-DFT does not require any wavefunction operations. However, while OF-DFT is sufficiently accurate for many materials of practical relevance, it cannot yet replace wavefunction-based KS-DFT entirely, a longstanding goal. We report recent progress towards this goal, beginning with advances in the construction of the local pseudopotentials (LPSs) that are commonly employed to account for the electron-ion (screened nucleus) interaction. In particular, we highlight a method for constructing LPSs appropriate for both solid and liquid phases, commenting on OF-DFT simulations that recently confirmed the existence of a second excitation mode in the collective dynamics of liquid Sn. We also discuss efforts to overcome the main obstacle to universally accurate OF-DFT, which is determining the (noninteracting) electron kinetic energy without recourse to wavefunctions. These efforts range from careful study of the local, gradient-based kinetic energy density of nearly free electrons, including the derivation of new response functions for this purpose, to hybrid techniques that incorporate localized atom-centered density matrices within the usual OF formalism. We conclude by outlining recent updates to our widely used OF-DFT code, PROFESS.

Has the Ubiquitous Use of Plane Wave DFT Codes Distorted the Perception of Functional Behavior and of the Need for +U? Daniel Koch¹ and Sergei Manzhos²; ¹National University of Singapore, Singapore; ²Institut National de la Recherche Scientifique, Canada

DFT-based computational materials science literature is dominated by the use of plane wave codes, with a single such code being most widely used. In the modeling of bulk materials and interfaces, GGA functionals remain most widely used. There is a well-established narrative according to which such functionals (e.g. the popular PBE functional) cannot reproduce localized states, resulting from e.g. doping of oxides with alkali and alkaline earth atoms, and cannot correctly reproduce the qualitative nature of the bandstructure, e.g. ordering of p and d bands in some oxides. This is typically remedied by the use of the Hubbard correction (DFT+U). Such correction, however, often distorts the geometry and worsens the issue of local minima in density optimization. The perceived need to employ the Hubbard correction for semiconductor but not for metallic phases is also an issue, as it may be impossible to correctly model different phases with a single computational setup; this in turn makes more difficult the modeling of phenomena involving phase transitions.
We show that it is possible to obtain qualitatively correct bandstructures and localization of states with the PBE functional without the Hubbard correction when using localized basis sets in cases where +U is necessary with plane waves. This was observed in different codes, using pseudopotentials or all-electron calculations. Correct band ordering can be obtained (such as O(p) dominated valence band maximum in NiO) and localized states and spin ladders due to interstitial n-doping can be obtained in oxides (titania and vanadia). Moreover, without +U, qualitatively correct bandstructures can be obtained with PBE for metallic and semiconductor phases of VO2 simultaneously, which we could not obtain in VASP without or with +U with commonly used U values. Formation energies computed in such systems without +U are in good agreement with experiments (as probed by insertion voltages with oxide cathodes in metal ion batteries).

We highlight the fact that with plane wave basis sets, expansion errors are higher for localized than for delocalized states, which could be contributing to artificial delocalization. To fully nivellate this issue, unrealistically high plane wave cutoffs could be required.

8:45 AM *MT01.01.03
Fast, Accurate and Scalable Large-Scale DFT Calculations Using DFT-FE Phani Motamarri, Sambit Das and Vikram Gavini; University of Michigan, United States

Large-scale DFT calculations are very crucial to improve the predictive capabilities of computation based design of new materials in a variety of application areas. For example, accurate determination of dislocation core properties in metals and semiconductors, understanding ion conduction mechanisms and computing diffusivities in solid-state electrolytes, and large-scale bio-molecular simulations, all require the ability to conduct accurate and computationally efficient DFT calculations involving many thousands of atoms on both metallic and insulating systems. However, the solution to governing equations in DFT demands significant computational resources, and accurate DFT calculations are routinely limited to materials systems with at most a few thousands of electrons restricting the system sizes to a few hundred atoms. This computational complexity is of even bigger concern in the context of ab-initio molecular dynamics with long time-scales, and geometry relaxation of large-scale systems needing large number of relaxation steps.

To overcome the above limitations, an open-source code DFT-FE [1] based on adaptive finite-element discretization of DFT has recently been developed. This talk will present the methodological and algorithmic advances incorporated into DFT-FE, which has enabled systematically convergent and computationally efficient large-scale DFT calculations on materials systems with tens of thousands of electrons for both metallic and insulating systems, on massively parallel computing architectures, while allowing for arbitrary boundary conditions and complex geometries. Key computational ideas involved in the development of DFT-FE will be discussed, which include: (i) a unified real-space formulation for DFT treating both pseudopotential and all-electron calculations in the same framework [2]; (ii) mesh adaption for efficient finite-element discretization [2]; (iii) adaptive higher-order spectral finite-element framework in conjunction with Chebyshev acceleration [3], spectrum splitting based Rayleigh procedure combined with mixed precision arithmetic; (iv) configurational force approach for geometry optimization [4]. The numerical investigations conducted with DFT-FE on representative benchmark examples will be presented alongside performance comparisons with other widely used DFT codes like Quantum Espresso and ABINIT.

Unraveling Exciton Dynamics in 2D van der Waals Heterostructures Junyi Liu, Xu Zhang and Gang Lu; California State University Northridge, United States
Two-dimensional (2D) van der Waals (vdW) heterostructures offer a fascinating platform to pursue fundamental science and novel device applications. Owing to quantum size confinement and reduced dielectric screening, electron-electron interaction and excitonic effect are prominent in 2D materials, which could dominate their electron and exciton dynamics. Recent experiments have revealed ultrafast charge (~100 fs) and energy (~1 ps) transfer dynamics in transition metal dichalcogenides (TMDs) heterostructures, which is surprising giving the strong electron-hole binding of the interlayer excitons. Most theoretical calculations to understand the experiments were performed based on local and semi-local exchange-correlation functionals, thus cannot capture the excitonic effect accurately. In this talk, I will introduce a first-principles method that combines non-adiabatic molecular dynamics (with the fewest switch surface hopping algorithm) and linear-response time-dependent density functional theory. Importantly, the method is formulated in the planewave bases and PAW pseudopotentials with range-separated hybrid functionals. As a result, the method can capture the excitonic effect accurately in extended 2D heterostructures. Using this method, we can shed light on the ultrafast charge transfer dynamics in TMD vdW heterostructures and elucidate the role of “hot” excitons in promoting ultrafast charge transfer despite the momentum mismatch in twisted heterostructures. We can also examine the properties of interlayer and intralayer excitons trapped by the moiré superlattices in the twisted heterostructures, and tune their properties and lifetimes by changing the twist angle, pressure and electric field.

Computational Raman Spectroscopy Based on Time-Dependent Density Functional Perturbation Theory Xu Zhang; California State University, Northridge, United States

Vibrational Raman spectroscopy is a widely used analytical tool in gas-phase and condensed-matter materials. Interpretation of the Raman spectra and detailed deduction of structures and/or conformations require theoretical simulations. However, the application of the present established computational Raman approaches to large-scale systems remains challenging, in a large part owing to their high computational demand. Here we propose a method that combine plane-wave pseudopotential method, time-dependent density functional perturbation theory and an elegant Lagrangian approach to circumvent key bottlenecks of Raman spectra simulations for large-scale systems. The method is validated for several molecular and solid systems, and exhibits excellent agreements with the experimental Raman spectra. We show that the method has a quadratic computational scaling with the number of electrons which can treat systems with more than 4000 electrons, opening doors for many large-scale Raman computations that are beyond the reach of previous approaches.

10:30 AM *MT01.01.06
High-Throughput Materials Discovery and Development—Breakthroughs and Challenges in the Mapping of the Materials Genome Marco Buongiorno Nardelli; University of North Texas, United States

High-Throughput Quantum-Mechanics computation of materials properties by ab initio methods has become the foundation of an effective approach to materials design, discovery and characterization. This data driven approach to materials science currently presents the most promising path to the development of advanced technological materials that could solve or mitigate important social and economic challenges of the 21st century. In particular, the rapid proliferation of computational data on materials properties presents the possibility to complement and extend materials property databases where the experimental data is lacking and difficult to obtain. The practical realization of these opportunities depends almost exclusively on the design of efficient algorithms for electronic structure simulations of realistic material systems beyond the limitations of the current standard theories. In this talk, I will review recent progress in theoretical and computational tools for data generation and advanced characterization, and in particular, discuss the development and validation of novel functionals within Density Functional Theory and of local basis representations for effective ab-initio tight-binding schemes.

Applications of these methods to a variety of systems (anomalous transport properties of 2D materials, topological insulators, minerals as novel thermoelectrics, etc.) will be showcased.

11:00 AM MT01.01.07
Accurate Ab Initio Tight Binding for Magnesium Richard Fogarty, Jana Smutna and Andrew P. Horsfield; Imperial College London, United Kingdom
Magnesium alloys are promising as lightweight structural materials, electrodes in Mg batteries, and for use in medical implants.\textsuperscript{1-3} As use of Mg is limited largely due to poor corrosion resistance a better understanding of these processes is required. Corrosion is an electrochemical process, involving transfer of electrons, thus a quantum mechanical theory is needed to model it. Density functional theory (DFT) has been used to study aspects of Mg corrosion, but its high cost limits the length and time scales which can be probed.\textsuperscript{4,5} Density functional tight binding (DFTB) represents a cheaper, though approximate, alternative to full DFT that maintains a fully quantum mechanical description. In this work we present a DFTB model for Mg which can describe the many properties of the metallic system at a level similar to DFT.

Compared to plane-wave DFT, our model introduces three approximations: we use the Harris-Foulkes functional up to first order (no self-consistency); we use a small (single-zeta) \textit{spd} basis set; we treat electron exchange and correlation in an approximate way using the McWeda method.\textsuperscript{6}

The validity of our DFTB model is demonstrated by comparison to plane-wave results for structural properties (e.g. volumes and bulk-moduli), electronic properties (density of states) and defect energies (self-interstitials and vacancies). Future work will focus on adding the necessary elements to investigate aqueous magnesium corrosion.

References
protocols, which often couple several specialised codes, make a quantitative description of error propagation and uncertainty quantification a critical issue.

To handle this high level of complexity we have developed the integrated development environment (IDE) pyiron – http://pyiron.org. The pyiron IDE combines a web based source code editor, a job management system for build automation, and a hierarchical data management solution. The core components of the pyiron IDE are pyiron objects based on an abstract class, which links application structures such as atomistic structures, projects, jobs, simulation protocols and computing resources with persistent storage and an interactive user environment. The simulation protocols within the pyiron IDE are constructed using the Python programming language.

In order to analyse the delicate interplay of uncertainties in our complex protocols, we introduce the concept of uncertainty phase diagrams. Based on this concept we model the convergence gradients of the contributing errors. It also provides a firm basis to automate the convergence process. Employing this approach we find that already the determination of the equilibrium lattice constant and bulk modulus require a careful analysis of the fitting of energy-volume curves, going beyond the consideration of standard convergence parameters like energy cutoff and k-points. Our investigations revealed that commonly used rules of the thumb for fitting ground state materials properties become invalid for high precision calculations, as the dominating sources of error change.

SESSION MT01.02: Electronic Structure II

1:30 PM MT01.02.01
The Limits of Two-Center Tight Binding for Close-Packed Metals Jana Smutna, Richard Fogarty, Mark R. Wenman and Andrew P. Horsfield; Department of Materials, Imperial College London, United Kingdom

Tight binding models offer a compromise between the accuracy and transferability of DFT and the speed of empirical force field models. By explicitly computing the electronic structure of a given system, they can improve the understanding of the bonding in a given material. The use of a limited basis set of atom-centric orbitals and further approximations allow computationally expensive numerical integration to be replaced by a fast interpolation between pre-calculated values.

These models are promising when it comes to modeling corrosion or large scale defects (e.g. dislocation cores), where a good description of bonding plays a major role, but the system sizes needed are beyond the reach of conventional DFT. In particular, we would like to gain mechanistic insights about the effect of irradiation on the corrosion of zirconium alloy nuclear fuel cladding. To model the interaction of alloying and impurity elements with the damage resulting from neutron irradiation, a tight binding model capable of representing a range of impurity and alloying elements and atomic environments with good accuracy and transferability is needed. Here, we concentrate on the case of zirconium, however, the results can be generalised to most close-packed metals.

The majority of current methods for building tight binding models are heavily dependent on optimisation, making the addition of new elements challenging and the transferability limited [1,2].

In this work, we have followed a systematic, parameter-free method, starting from an appropriate choice of basis set and evaluating the effect of further approximations on the model. We have explored the two-centre approximation for both the pair potential and the components of the Hamiltonian matrix: crystal field terms and hopping integrals. While transferable and reasonably accurate corrections to the first two components are relatively straightforward, an equivalent correction for the hopping integrals is both theoretically and computationally challenging. We show that keeping the hopping integrals two-centre but adjusting their distance dependence causes significant transferability problems not only when describing other crystal structures, point defects or interstitial impurities, but also when simply considering one crystal structure in tension or compression.

The inclusion of three-centre integrals significantly improves the transferability of the model.

References
1. Schnell I, Jones MD, Rudin SP, Albers RC. Tight-binding calculations of the elastic constants and phonons of hcp
Understanding phonon-mediated heat transfer at the nanoscale remains an open and technologically-important challenge, with diverse applications across thermoelectrics, nanoelectronics, catalytic cells, and nanotheranostics. Such systems are often spatially inhomogeneous, necessitating theoretical descriptions with spatial resolution, and consist of non-crystalline disordered solids. Ab initio mathematical treatments developed for studies of lattice vibrations in perfectly ordered crystals, however, offer limited utility in investigations of disordered solids. These limitations include: (i) inseparability of diagonal (substitutional), off-diagonal, and ‘environmental’ disorder, and (ii) inconsistency in using perfect lattice states (i.e. phonons) as basis functions for the momentum representation of collective excitations. Numerical calculations, using lattice and molecular dynamics, on simulated disordered solids have corroborated the breakdown of phonons as well-defined excitations (i.e. with mean free paths much larger than their wavelength), and have suggested an alternate classification of ‘propagons’, ‘diffusons’, and ‘locons’.

While these advances have provided insight in spatially homogeneous (bulk) thermal transport in disordered solids, they depart from the intuitive ‘kinetic theory’ picture and as such offer limited use in atomistic-to-continuum modeling of spatially-resolved transport. We treat the medium as a continuum capable of supporting approximate plane-wave excitations, experiencing scattering due to the atomistic disorder, in much the same way external plane waves (e.g. x-rays) would. We compute these scattering rates, first proposed by Ziman and Morgan, from first principles using Fermi’s golden rule. In particular, the formalism requires access to the real-space harmonic and anharmonic interatomic force constants which, we will show in this talk, are extracted at finite temperature by sampling the canonical phase-space using Born-Oppenheimer ab initio molecular dynamics (BO AIMD). We demonstrate this formalism by computing the spatially-resolved thermal transport across crystalline/amorphous silicon (Si/α-Si) heterostructures with micron dimensions, length scales typically not accessible to (classical) molecular dynamics.

Polynomial Expansion and Purification Methods for Large Scale Electronic Structure Calculations Purnima Ghale and Harley T. Johnson; University of Illinois at Urbana-Champaign, United States

Computing the density matrix for a large Hamiltonian is the most expensive part of many electronic structure calculations. At zero temperature, the density matrix is a projection matrix constructed from the outer product of the lowest occupied eigenstates, satisfying idempotency and trace conditions. In this talk, we present a method combining two well-known algorithms – the Kernel Polynomial Expansion (KPE) method and Spectral Projection Purification – which allows us to obtain idempotent density matrices of large systems while relying only on sparse matrix-vector multiplication kernels. An implicit representation of the density matrix is obtained by combining the two aforementioned algorithms, which is then sampled using random vectors. This scheme allows us to compute the density matrix at linear computational cost in terms of floating-point operations. Additionally, the method is independent of the underlying basis set, and does not require the density matrix to be sparse. Within the context of density-functional based tight-binding (DFTB), we present results of self-consistent density matrix calculations of systems containing $10^7$ atoms. As an application of the method, we present results on time-dependent electron emission from dielectric surfaces under AC voltages in the kHz frequency range. The added challenge here is that...
while oscillations of the electronic system are in the THz or higher range, added perturbations due to AC voltage are in the kHz frequency range. As such, direct integration of the evolution of the electronic system requires long time-scales. We solve this challenge first using a semi-classical approximation in order to avoid temporal integration. Additionally, we show that a kernel polynomial expansion of the time-evolution operator can be used to allow direct integration of the quantum-mechanical evolution under an external AC voltage. This demonstration of KPE for both the electronic structure and the time integration of the system provides a computationally efficient framework for an inherently multiscale electronic structure problem, with implications for a variety of challenging problems.

2:15 PM MT01.02.04
Extreme Electric Fields in DFT Michael Ashton, Arpit Mishra, Christoph Freysoldt and Jörg Neugebauer; Max Planck Institute for Iron Research, Germany

Strong ($10^{10}$ V/m) electric fields can be used to trigger chemical processes with extreme precision by selectively stabilizing or weakening bonds to initiate reactions which are otherwise slow or do not proceed at all. The ability to manipulate electric fields to tailor and stimulate bond-breaking events is therefore a powerful experimental control knob, but one whose effects are difficult to predict due to a lack of suitable tools to probe its associated atomic-scale mechanisms. Atom Probe Tomography (APT) directly probes field-induced bond-breaking mechanisms, but its results must be interpreted through theoretical models, which are currently overly simplistic. Here we introduce a novel approach, which we term the Generalized Dipole Correction (GDC), that enables the direct study of ultra-high fields effecting bond-breaking and desorption at the level of single atoms using Density Functional Theory (DFT). As a prototype application, we consider field evaporation from a kinked W (110) surface. We reveal two qualitatively different competing mechanisms that can be switched by the applied field.

2:30 PM MT01.02.05
Atomic Scale Einstein-de Haas Effect Tomos Wells¹, Andrew P. Horsfield¹, Matthew Foulkes¹,² and Sergei Dudarev¹; ¹Imperial College London, United Kingdom; ²University of Illinois at Urbana-Champaign, United States

The Einstein-de Haas (EdH) effect, where the spin angular momentum of electrons is transferred to the mechanical angular momentum of atoms, was established experimentally in 1915. While a semi-classical explanation of the effect exists, modern electronic structure methods have not yet been applied to study this phenomenon. In this talk we investigate its microscopic origins by means of a non-collinear tight-binding model of an O₂ dimer as implemented in Ref. [1]. This includes the effects of spin-orbit coupling, coupling to an external magnetic field, and non-collinear Stoner exchange. By varying an external magnetic field in the presence of spin-orbit coupling, a torque can be generated on the dimer, validating the presence of the EdH effect. Avoided energy level crossings and the rate of change of magnetic field determine the evolution of the spin. We find also that the torque exerted on the nuclei by the electrons in a time-varying $B$ field is not only due to the EdH effect: other contributions arise from field-induced changes in the electronic orbital angular momentum and from the direct action of the Faraday electric field associated with the time-varying magnetic field.

2:45 PM MT01.02.06
Algorithms for the Generation of Generalized Monkhorst-Pack Grids Yunzhe Wang, Adarsh Balasubramanian, Pandu Wisesa and Tim Mueller; Johns Hopkins University, United States

Computational materials research has become increasingly vital in probing the properties of crystalline materials, especially in screening materials at a large scale to accelerate material discoveries for a wide range of applications.¹,² A routine operation for calculating the properties of crystalline materials is the evaluation of integrations over the Brillouin zone, which can be approximated by sampling the Brillouin zone at a set of points known as $k$-points. Many popular computational materials software packages generate $k$-points using the traditional Monkhorst-Pack (MP) scheme,³ which creates $k$-point grids that are regular and aligned with the reciprocal lattice vectors. We have previously demonstrated that much more efficient lattices can be generated if the Monkhorst Pack approach is generalized by relaxing the requirement that the grids be aligned with the reciprocal lattice vectors,⁴ which has since been confirmed by other researchers.⁵ This approach can roughly double the speed of well-converged calculations on crystalline materials, providing strong incentives to find an efficient algorithm for fast generation of
generalised Monkhorst-Pack grids.

Here, we present algorithms for rapidly generating generalized Monkhorst-Pack grids. To better serve the computational materials community, we provide three implementations of these algorithms in various languages and formats:
1. **K-Point Grid Server**: a ready-to-use online application with a pre-generated database for fast search.
2. **K-Point Grid Generator**: an open-source, stand-alone application for runtime environments that might not have an internet connection.
3. **kplib**: a lightweight open-source C++ library that does not make use of databases, for integration with computational materials software packages.

Benchmark results are provided to demonstrate the speed of these algorithms and the quality of generated grids.

**Simulating Material Dynamics on Near-Term Quantum Computers**
Lindsay Bassman¹, Aravind Krishnamoorthy¹, Kuang Liu¹, Yifan Geng¹, Daniel Shebib¹, Shogo Fukushima², Fuyuki Shimojo², Rajiv Kalia¹, Aiichiro Nakano¹ and Priya Vashishta¹; ¹University of Southern California, United States; ²Kumamoto University, Japan

High-accuracy quantum simulations of materials is becoming increasingly important for the development of new devices for electronic, thermoelectric, and energy applications. While these simulations tend to scale exponentially with the size of the system on classical computers, it has been shown that they can be made to scale polynomially on quantum computers. Performing dynamic simulations on quantum computers, therefore, can open new doors by allowing systems of larger (and more relevant) sizes to be simulated. In this work, we simulate photonic control of emergent magnetism in a two-dimensional material on Rigetti’s Aspen quantum processor. Results from the quantum computer are found to be in good qualitative agreement with theoretical ground-truth results, and in even better agreement with results from classically simulated noisy qubits. Furthermore, we map out the feasibility bounds of such dynamical simulations on state-of-the-art, near-term and near-future quantum computers.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607.

**Determining Nanoscale Structures from Experimental Data Using FANTASTX**
Eric Schwenker¹,², Venkata S Chaitanya Kolluru¹, Arun Kumar Mannodi Kanakkithodi¹, Spener Hills¹ and Maria K. Chan¹; ¹Argonne National Laboratory, United States; ²Northwestern University, United States

Determining the atomistic details of nanoscale structures is a fundamental problem. Although there are both experimental and computational methods to determine these nanoscale structures, they both possess limitations. We develop the FANTASTX code (Fully Automated Nanoscale To Atomistic Structure from Theory and eXperiment) to overcome the limitations of either by combining both experimental and computational data. We demonstrate the effectiveness of FANTASTX by determining the structures of nanoparticles and solid interfaces from x-ray and electron microscopy data combined with atomistic and first principles energies, using multi-objective optimization and a variety of canonical and grand canonical sampling algorithms.
The properties of molecules and materials are ultimately determined at the atomistic level. On the other side, their behavior at macroscopic scales is far more relevant to model for example chemical reactor processes and to determine promising changes to optimize catalysts, additives, and operating conditions in industrial processing plants. The multi-scale simulation platform ReaxPro aims to provide a customer-ready solution by combining several well-established tools and simulation programs such as the Amsterdam Modeling Suite, kinetic Monte Carlo methods, and computational fluid dynamics to bridge the many orders of magnitude in scale between atomistic quantum chemistry models and macroscopic chemical reactor design.

Such multi-scale simulations will not only significantly reduce experimentation costs but also allow for an in-silico high-throughput screening and predictions to guide experiments. In addition, valuable insights into the mechanisms at each scale can be gained in order to help researchers to improve reactor designs at different levels. The multi-scale material and process optimization of ReaxPro can also be applied in other fields of chemical industries such as the application-specific design of new polymers, photovoltaics, and batteries.

We have developed a module for calculating the mobility and conductivity of semiconducting materials based on the iterative method as proposed by Rode [1]. Various physical properties calculated through the density function theory (DFT) are used as inputs. We show the use of this module for Cadmium Sulfide (CdS) and Zinc Selenide (ZnSe). Since this strategy can take into consideration the inelastic scattering of the carriers due to the phonons, this module should serve a better objective than those based on the relaxation time approximation.

References

We introduce an orbital free electron density functional approximation based on alchemical perturbation theory[1]. Given convergent perturbations of a suitable reference system, the accuracy of popular self-consistent Kohn-Sham density functional estimates of properties of new molecules can be systematically surpassed - at negligible cost.

For example, using the CCSD solution for N₂, APDFT calculated properties of CO are more accurate than PBE already at 1st order (energies and dipole moments) and 2nd order (quadrupole-moments and forces).

The associated energy functional is an approximation to the integrated energy derivative, requiring only perturbed reference electron densities: No self-consistent field equations are necessary to estimate energies and electron densities. Instead, our approach relies on the electron density response w.r.t nuclear charges and treats changes of nuclear charges at any sites as perturbations to the system. We show that the resulting expansion in perturbation orders converges quickly by analytical proof for the hydrogenic atom and for any free atom. Numerical convergence is shown for alchemical perturbations of H₂, N₂, and benzene[1, 2].

APDFT based estimates of the electron density of a target molecule are obtained for the same perturbations. Estimated electronic ground state properties considered include covalent bonding potentials, atomic forces, as well as dipole and quadrupole moments.

We demonstrate the applicability of APDFT to scan a large chemical space by using 13 CCSD single point calculations to predict changes in energy and forces by BN-doping a C_{20} fullerene. This allows us to give total energy estimates for all 3.1 million uniquely BN-doped fullerenes.
APDFT is widely applicable to any level of theory that makes electron densities available and allows to assess a combinatorial number of molecules with one fixed set of calculations rather than calculating molecules one-by-one.

If the perturbation series converges and if the reference level of theory is of sufficient quality, APDFT represents a systematically improving DFT approximation of hierarchies of accuracy.

Machine Learning Exchange Correlation Functionals for Density Functional Theory David Clark¹, Blake Duschakto¹, Simon Batzner¹,², Jonathan Vandermause¹ and Boris Kozinsky¹; ¹Harvard University, United States; ²Massachusetts Institute of Technology, United States

Density Functional Theory (DFT) has become a ubiquitous and vital tool in a wide range of materials physics problems. It occupies an important space in the tradeoff between accuracy and computational cost - able to achieve high levels of accuracy and maintain computational feasibility. Within the DFT formulation this tradeoff is adjusted through the exchange-correlation energy functional. Advanced functionals can be substantially more accurate but can also be far more expensive computationally. Recent work has attempted to push back the optimal performance tradeoff curve through machine learned functionals trained on high level exchange-correlation energies, such as those from hybrid functionals or CCSD(T) [1,2]. A common theme among these is to assume a local model, where the exchange-correlation energy is a sum of local contributions.

While recent efforts have been primarily driven by neural network models to predict these contributions, we consider an alternative procedure wherein the electronic densities are projected onto a Gaussian basis to drastically reduce their dimensionality. An ordinary least squares problem is then solved to regress the exchange-correlation energy. In this context, we examine the limitations of a local model: we demonstrate that our model can accurately reproduce LDA functional data and explore effects on accuracy when trained on hybrid functionals. We further consider the implications of this model in its capacity to accurately and efficiently predict material properties.

Machine-Learning-Aided Development of Empirical Force-Fields Mathieu Bauchy; University of California, Los Angeles, United States

The development of reliable, yet computationally-efficient interatomic forcefields is key to ensure the accuracy of classical molecular dynamics simulations. However, parameterizing new forcefields is notoriously challenging, since the high number of parameters renders traditional optimization methods inefficient or subject to bias. Here, we present a new parametrization method based on machine learning, which combines ab initio molecular dynamics
simulations and Bayesian optimization. By taking the examples of silicate and chalcogenide glass, we show that our method yields new some empirical interatomic forcefields that offer an unprecedented level of agreement with ab initio simulations. This method offers a new route to efficiently parametrize new interatomic forcefields for disordered solids in a non-biased fashion.

Toward Efficient Methods for Generating Transferable Neural-Network Interatomic Potentials Talat S. Rahman; University of Central Florida, United States

Recent developments in neural network interatomic potentials have provided a pathway for reliable large-length and long-time scales atomistic simulations. However, their transferability is questionable because of incompleteness of the training dataset that relies on structure-energy (and/or forces) calculated using density functional theory (DFT), leading to inaccurate extrapolations or interpolations of the neural network. In this talk, we present two efficient methods for generating configurational spaces for training dataset: (1) molecular dynamics simulations with large time steps and (2) random walks on uniform grids. Both methods create chaotic displacements of atoms that move them far from equilibrium positions or trajectories, effectively enlarging the configurational space. We will demonstrate the effectiveness of the methods using examples of transferable neural network interatomic potential for: 1) the Si(001) surface and 2) defect-laden, two dimensional, hexagonal boron nitride (dh-BN). Both potentials are able to predict total energy within few meV of that obtained from DFT. Molecular dynamics simulations of the Si(001) surface for a wide range of temperature that show that the asymmetric, buckled structure of the surface dimer exists at all temperatures, but their increased flipping rate leads to a larger occurrence of the symmetric configuration, shedding light on the semiconducting-conducting transition of the surface. In the case of dh-BN the method allows simulations of grain-boundary structures consisting of thousands of atoms whose local configuration is not included in the training set. We compare our results with available data and discuss the pros and cons of the approach.

Neural Network Force Model for Large Scale Molecular Dynamics Simulation of Phase Change Materials Pankaj Rajak¹, Ken-ichi Nomura², Subodh C. Tiwari², Ye Luo¹, Aiichiro Nakano², Rajiv Kalia² and Priya Vashishta²; ¹Argonne National Laboratory, United States; ²University of Southern California, United States

High quality force field models are not available for many phase change materials such as Ge₂Sb₂Te₅, which has diverse applications in neuromorphic computing devices and non-volatile memory. Designing semi-empirical force fields for these systems is nontrivial and also doing ab-initio molecular dynamics (MD) simulations is not scalable for large systems, which is important to amorphization and recrystallization in these systems. We have developed a neural network (NN) based force field model for Ge₂Sb₂Te₅ which is trained using ab-initio MD simulations data to directly produce atomic forces at density functional theory (DFT) level accuracy. The neural-network architecture and input parameters of the feature vector for each atom type are optimized for training using Bayesian optimization so as to design a model with higher accuracy but with minimum complexity. Special care is taken to design radial and angular feature vectors that obey translational and permutational invariance and rotational covariance for forces. The accuracy of the NN force field model is validated by doing a MD simulation using NN force field model for up to 100,000 atoms and by computing various structural and dynamical properties such as radial distribution function, bond angle distribution, neutron structure factor and phonon density-of-states.

Learning Direct, Symmetry-Preserving and Efficient Force-Fields with Tensor-Field Neural Networks Simon L. Batzner¹,², Tess E. Smidt³ and Boris Kozinsky¹; ¹Harvard University, United States; ²Massachusetts Institute of
Deep Learning has emerged as a powerful tool for accelerating simulations of molecular and condensed matter by learning complex representations of the potential energy directly from atomic positions without the need for handcrafted descriptors. We present a deep learning approach aimed at molecular dynamics that directly predicts atomic forces instead of total energy. The proposed force-field is rotationally covariant, handles multiple species naturally, and bypasses the need for computing expensive derivatives of an energy-based model by predicting atomic forces directly from atomic position coordinates. The proposed algorithm achieves very high accuracy on a data set of organic molecules while outperforming energy-based models with respect to computational efficiency, both at time of training and inference. We show that our proposed method can accurately reproduce thermodynamic and kinetic materials properties from Molecular Dynamics simulations and benchmark the efficiency of the direct force prediction against energy-based models.

An Extendable Framework to Design Empirical Potential with Tuneable Accuracy Artur Tamm and Amit Samanta; Lawrence Livermore National Laboratory, United States

We present a general framework to generate machine learned interatomic potentials from ab initio density functional theory (DFT) databases. In our framework, atomic structure information residing in the configuration space is projected on to a space of descriptors that can systematically capture local many-body correlations. Specifically, we have included two-body, and a variety of three and four-body correlations. These correlations are realised using Chebyshev basis functions, but the framework is general and other basis functions can be used. To generate the inter-atomic potential, we have explored linear as well as non-linear regression techniques with different regularisations. The different correlation terms were grouped according to the number of atoms, and according to the bonds present in them. These variables control the dimensionality of the parameter set of the interatomic potential. We applied this framework to generate an interatomic potential for germanium using DFT (hybrid functional) database consisting of about 1.5 million atoms environments. This database includes structures with different crystal symmetries as well as liquid and amorphous structures. Different potential models were generated by using different types of correlation descriptors and the effect of different correlations were compared by analysing root mean square error as well as with histogram of errors between the model and DFT. In summary, we have developed a framework for building potentials with tuneable accuracy and shown its application to the case of germanium. The model is implemented as an extension to LAMMPS molecular dynamics code and can be used in large-scale simulations.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Molecular Dynamics Simulation Using Neural-Network Force Field Trained from Ab Initio Calculations Lin-Wang Wang; Lawrence Berkeley National Laboratory, United States

Neural-network force field (NN-FF) has become an intensly studied topic in recent years. In this talk, I will present our recent work in developing NN-FF and using it in molecular dynamics simulations. In our approach to train the NN-FF, not only we use the atomic forces from ab initio calculations, we also use decomposed atomic energies from density functional theory (DFT) calculations. This increases the number of data set, also makes the training process easier. We have developed Si and Na NN-FF in this approach. We also developed multiple element force fields like Al-H and Fe-H. We have used the NN-FF to study the crystal Si growth from melt Si. This NN-FF shows similar behavior as that of the direct DFT calculations, but it allows us to study much larger systems. I will also present our approaches to deal with long range Coulomb interactions for systems with ionic charges.

**Simultaneous Structure Exploration and Machine-Learned Potential Fitting**  
Noam Bernstein¹, Gabor Csanyi² and Volker Deringer²; ¹U S Naval Research Lab, United States; ²University of Cambridge, United Kingdom

Defining interatomic potentials as a high-dimensional fit of the reference (usually density functional theory) potential energy surface by taking advantage of regression methods from machine learning has recently become a powerful approach. However, because of their variational freedom, such potentials require large fitting datasets, which are typically developed using large amounts of manual selection and tuning of configurations by the researcher. To simplify this process, we present a highly automated iterative method where a preliminary Gaussian approximation potential (GAP) is used to carry out random-structure searches, and selected configurations from the searches are used to fit the next iteration's GAP. The resulting set of configurations constitutes an effective fitting database, spanning a wide range of geometries with a minimal number of reference energy evaluations. We test the method on several elemental and multi-component materials with different bonding types, from insulators to metals, including boron with its complex icosahedral $\alpha$-B$_{12}$ structure and the phase-change material GeTe. We show how the process converges in a few iterations, and how the resulting potentials reproduce the reference DFT values on a number of bulk and defect properties.

**Effect of Particle Geometry on T$_1$- and T$_2$-weighted Relaxivities for MRI Applications**  
Alexis G. Lavin and Bibek Thapa; Universidad de Puerto Rico, United States

MRI contrast agents based on iron oxide nanoparticles are advantageous alternatives to Gadolinium-based contrast agents in terms of toxicity, safety, and biocompatibility. However, it remains necessary to develop novel iron oxide nanoparticles able induce better T$_1$- and T$_2$-weighted relaxivities. Specifically, the manipulation of the iron oxide particle geometry should help increase the effective surface while provoking larger local disturbances in the magnetic field with a concomitant enhancement in relaxivities. Thereby, we synthesized spherical, cubic, hexagonal, and star-shaped iron oxide nanoparticles, characterized their structural and magnetic properties, and measured their T$_1$- and T$_2$-weighted relaxivities. The results show a significant relaxivity enhancement for the non-spherical particles, thus confirming the hypothesis that geometry has a large impact on the nanoparticles ability to locally disturb the random arrangement of the spins. We will discuss the nanoparticles property-function relationships and their potential as MRI dual T$_1$-T$_2$ contrast agents.

**Lattice Dynamics and Thermodynamics of Strongly Anharmonic Solids via Bayesian Learning and Convolutional Neural Networks**  
Taishan Zhu, Sheng Gong and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Strongly anharmonic solids have been widely sought, ranging from thermoelectrics to multiferroics and to shape-memory materials, but the effects of strong anharmonicity to their thermodynamic and transport properties are less understood. In this work, we extend our earlier crystal graph convolutional neural network framework, and explore an alternative Bayesian description for the vibrational modes and their transport in strongly anharmonic solids exhibiting soft modes. We demonstrate our theory on a one-dimensional toy lattice, including a probabilistic extension to the conventional phononic dispersion relationship, as well as its consequences to lattice conductivity, other thermal properties, and phase transition. This Bayesian framework also provides naturally an uncertainty quantifying scheme for these physical quantities, including those uncertainties inherent for meta-stable and partial-crystal-partial-glass solids. Our theory is then extended to two halide perovskites: all inorganic CsPbI$_3$, and hybrid inorganic-organic MAPbI$_3$, and our Bayesian predictions are compared with existing experiments of heat capacity and lattice conductivity. More interestingly, some anomalous phononics observed from experiments could be explained within this framework.

Machine Learning for the Construction of Lattice Based Models Mattias Ångqvist1, Fredrik Eriksson1, William Armando Muñoz1, Magnus Rahm1, Erik Fransson1, Céline Durniak2, Piotr Rozyczko2, Thomas Holm Rod2 and Paul Erhart1; 1Chalmers University of Technology, Sweden; 2European Spallation Source, Denmark

Modeling the thermodynamic and kinetic properties of materials commonly requires taking into account both vibrational and compositional degrees of freedom. While electronic structure calculations strictly speaking can provide the necessary information, they are computationally too demanding for many practical purposes. One therefore requires models that can reproduce the relevant parts of the potential energy landscape at a much smaller computational cost.

Here, we will present a set of software packages that we developed over the course of the last years that allow one to rapidly construct and sample models that map vibrational (hiPhive [1]) and/or compositional degrees of freedom (icet [2]).

These tools can be integrated in a homogeneous Python based workflow, which combines structure generation, electronic structure calculations, model construction, thermodynamic sampling, and subsequent analysis. Example applications include the prediction of alloy phase diagrams, temperature driven phase transitions, thermal conductivities, and ordering phenomena.

AGNI—A Machine Learning Platform for the Rapid Prediction of Atomistic Properties James E. Chapman, Rohit Batra, Huan D. Tran, Chiho Kim, Anand Chandrasekaran, Deepak Kamal, Christopher B. Kuenneth and Rampi Ramprasad; Georgia Institute of Technology, United States

Propelled partly by the Materials Genome Initiative, and partly by the algorithmic developments and the resounding successes of data-driven efforts in other domains, machine learning (ML) strategies are beginning to take shape within several subfields of materials science[1-4]. One area of enormous importance is atomic-level materials phenomena, which spans numerous fields from electronic structure theory to mechanical failure, and has been dominated by either quantum mechanics (QM) based methods [4-7]—which are time-intensive, but accurate and versatile—or semi-empirical/ classical methods[8,9]—which are fast but are significantly limited in veracity, versatility and transferability. ML methods have the potential to bridge the chasm between the two extremes and can combine the best of both worlds. We have created a platform for the rapid prediction of properties such as potential energy, atomic forces, stresses, charge density, and the electronic density of states. Our ML-models are trained on accurate QM reference data, and can reproduce the QM results with the same level of accuracy but several orders of magnitude faster [10-15]. The ML models can also be progressively improved in quality by periodically (or on-demand) exposing them to fresh QM data in regions of poor performance, a feature that currently is either impossible or daunting with modern empirical/classical methods. Our ML models may thus be used to perform large-scale and/or long-time simulations of important materials phenomena previously beyond the reaches of QM based methods. Here, we demonstrate the power and versatility of this new platform in correctly capturing electronic, thermodynamic, mechanical, and diffusive properties for a variety of systems, with the hope of ushering in a new era of atomic-level understanding of materials.

References:
Dislocations, which are line defects in solid, are a dominant factor of plastic deformation of solid. For advanced material design, it is very important to clarify the details of dislocation mechanics and dynamics. The energetics of dislocation mainly consists of the following two-part: atomic dislocation core and long-range elastic field. The dislocation core structure and behavior determine the mobility of individual dislocations and the condition of reactions between them. The elastic interaction determines the structure of mesoscopic aggregate of dislocations, such as dislocation cell walls. This structure is directly connected macroscopic mechanical behavior of crystals, such as work hardening.

To investigate the long-range elastic interaction, discrete dislocation dynamics (DD) modeling is a powerful tool, because it can treat micrometer scale in a realistic time scale. DD modeling is based on dislocation elastic theory. So, DD modeling requires the mobility and condition of the reaction of dislocations as input parameters. To investigate the dislocation core structure, the atomistic modeling is very suitable, because dislocation core structure and behavior are severely affected by the discreteness of atomic spacing. High accuracy density functional theory (DFT) calculations have established a leading position in atomistic modeling in decades. Due to the high-cost calculation of DFT, the number of atoms in DFT calculation is limited to a few hundreds, practically.

One solution to link the DD modeling and DFT atomic modeling is an atomic potential based on artificial neural network (ANN) framework [1]. By the universal approximation theorem, the ANN potential can compute any function. Therefore, with enough DFT training data, ANN potential becomes sophisticated replica potential of DFT calculation. In this work, we construct the atomic ANN potential for iron (Fe).

For DFT training data, we prepare the 5173 atomic structure of Fe calculated by Quantum ESPRESSO package [4]. For crystal structure data, we select the FCC, HCP, BCC and simple cubic structure. For defect data, we select the vacancy, divacancy, self-interstitial (T-site, O-site, [100], [110], [111]-dumbbell) and (100), (110), (111) and (112) surfaces model. To predict the exact dislocation core structure, we also prepare generalized stacking fault energy (GSF) surface on (110) and (112). The Chebyshev descriptor developed by Artrith et el. is used for the input descriptor of the atomic environment [2,3]. For neural network training, we use the aenet package by Artrith et el [3].

By using ANN potential, We investigate the a/2<111> screw dislocation core structure in BCC iron, where a is lattice constant. The screw dislocation core predicted by constructed ANN potential has nondegenerate compact structure. We also evaluate the Peierls barrier of a/2<111> screw dislocation by using the nudged elastic band (NEB) method. The Peierls barrier is estimated as 36.6 meV in units of length of Burgers vector. These results are a good agreement with previous DFT calculation [5].

Modeling Light Interstitials in Materials Ju Li; Massachusetts Institute of Technology, United States

Light interstitial atoms such as hydrogen, helium, oxygen, carbon and nitrogen are known to have profound effects on the material properties experimentally. Ab initio and atomistic methods are employed to address their equilibrium segregation, effect on thermally activated processes, as well as non-equilibrium effects. A conceptual framework based on Gibbs adsorption isotherm, but generalized to the saddle state, with activation strain-volume/entropy/excess, is developed to interpret the simulation and experimental results.

2:45 PM MT01.04.05
Improving the Accuracy of Coupled Spin and Lattice Simulations Julien Tranchida; Sandia National Laboratories (NM), United States

The approach consisting in coupling spin and molecular dynamics is an increasingly popular numerical method allowing to investigate the reciprocal influence of lattice vibrations and magnetization dynamics. Through the recently added SPIN package, LAMMPS now allows to perform such simulations at unprecedented accuracy and scale. A brief overview of this implementation and of some of its recent improvements will be first presented.

Although this implementation greatly improved the available algorithms for this methodology, the lack of magneto-elastic potentials remains a strong limitation to its development. Indeed, the most commonly used approach consists in overlaying the magnetic interactions on top of a purely mechanical potential (typically, a magnetic exchange interaction on top of an EAM potential), all those interactions being parametrized separately. As the magnetic interactions generates rather small forces compared to the mechanical potential, this approach proved to be sufficient to obtain numerous first order results.

However, it remains a rather crude approximation and cannot be used to recover fine experimental results. In this presentation, a new methodology based on high-fidelity machine-learned inter-atomic potential approaches and enabling to circumvent this difficulty will be presented.

Advancing Atomistic Capabilities for Heterogenous Systems Difan Zhang¹, Yuxiang Wang², Alexandre Fonseca³ and Susan B. Sinnott²; ¹Pacific Northwest National Laboratory, United States; ²The Pennsylvania State University, United States; ³Universidade Estadual de Campinas (UNICAMP), Brazil

Interactions between heterogeneous systems are challenging to model with high fidelity at the atomic scale across significant length scales. This presentation describes recent developments of third-generation charge optimized many-body (COMB3) potentials to enable metal-carbon interactions in classical molecular dynamics simulations. The potentials are applied to investigate the interaction of carbon materials, including metal-carbide-derived-carbons (CDCs) with titanium and aluminum, and the interactions of graphene and buckyballs with copper and aluminum surfaces. The results provide new insights into the bonding character at these interfaces and the role of defects, bond-angle, and temperature on interatomic interactions.

3:45 PM MT01.04.07
Absolute Free Energy Calculation for Liquid Metals and Alloys Michael Widom; Carnegie Mellon University, United States

First principles molecular dynamics efficiently calculates the internal energy of metals, both in liquid and solid form. We show that the liquid state correlation functions that are a byproduct of the simulation allow a similarly efficient calculation of absolute entropy based on a simple variant of the classical "S2" method. The method is quite accurate for nearly free electron metals, as demonstrated by comparison with experimental data for elemental liquid metals. For liquid alloys, hybrid Monte Carlo/molecular dynamics is utilized to enhance ensemble sampling. We combine the energy and entropy to calculate absolute free energies in liquid metals in order to explain the occurrence
of phase separation in liquid Li-Na compared with the eutectic in Na-K.

Fast and Accurate Machine Learning Models for Exhaustive Microstructure Sampling of Chemically Complex Materials
Hsin-An Chen¹, Ping-Han Tang¹, Guan-Jie Chen², Yen-Ching Wu², Sheng-Han Teng¹ and Chun-Wei Pao¹; ¹Academia Sinica, Taiwan; ²National Taiwan University, Taiwan

Chemically complex materials, namely materials comprised of multiple chemical components, are playing an increasingly important role in material applications including high entropy alloys (HEAs) for structural materials and complex mixed ion perovskite materials for solar cells as well as optoelectronic devices. The microstructures of these materials, for example, chemical short-range orders or phase segregations are critical for the material performance; however, characterization of microstructures of these chemically complex materials poses grand challenges to both experimentalists and theorists. From computer simulation perspective, exhaustive sampling of microstructures is computationally prohibitive for density functional theory (DFT) calculations owing to both system size and computation time limitations. Herein, we demonstrate that by utilizing neural network energy predictors trained from numerous images from DFT calculations, a 10⁵ computational speedup can be obtained by implementing the neural network predictor into the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS), while retaining high fidelity to DFT calculations. Hence, the neural network energy predictor allows us to perform exhaustive sampling of systems of thousands of atoms of CoCrFeNi HEAs and FAₓMA₁₋ₓPb₁Br₃₋y perovskite materials using Monte Carlo in combination with molecular dynamics simulations, thereby providing atomistic insights into microstructures and chemical short-range orders of these chemically complex materials with DFT accuracy.

Framework for Amorphous Polymer Synthesis to Study Dielectric Properties Using Polarizable Reactive Molecular Dynamics
Ankit Mishra¹, Ken-ichi Nomura¹, Subodh C. Tiwari¹, Aiichiro Nakano¹, Rajiv Kalia¹, Priya Vashishta¹, Rampi Ramprasad², Gregory A. Sotzing³ and Yang Cao³; ¹University of Southern California, United States; ²Georgia Institute of Technology, United States; ³University of Connecticut, United States

New dielectric polymer materials with high energy density while maintaining low loss at high applied electric fields are needed for increased energy and power density required in modern electronics. We propose a polarizable reactive molecular dynamics-based framework that offers near-quantum accuracy for estimating dielectric properties of various polymer systems within a small fraction of quantum-calculation time. We use this framework to demonstrate the essential role of morphological complexity that governs dielectric constant of industrially relevant model polymer systems. Our framework supports high dielectric performance of PDTC-HK511 and TDI-EDR148 polymer systems, which have been identified through rational co-design strategy based on advanced computational screening procedures. The proposed framework can augment screening procedures for identifying polymer dielectrics that are significantly better than the current state of the art.

4:30 PM MT01.04.10
Bayesian Active Learning of Gaussian Process Weight Force Fields—Application to Stability of 2D Materials
Yu Xie, Jonathan Vandermause, Lixin Sun, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Gaussian process regression was previously demonstrated to provide quantitative Bayesian estimates of prediction uncertainty, enabling on-the-fly active learning of force fields in molecular dynamics of rare events¹. However, the time complexity in this method of prediction grows linearly with the training data size. We build on earlier attempt to exploit the structure of the N-body kernel function, to decompose the prediction expression into contributions that can be interpolated in order to approximate atomic forces, without loss of accuracy compared to the full regression². Crucially, this approach no longer depends on training size and accelerates the Gaussian process prediction by several order of magnitudes. We present a method of mapping (1) force fields from the underlying kernel, and (2) predictive variance (uncertainty), combined with dimension reduction approaches. This method can be combined into an end-to-end on-the-fly Bayesian active learning workflow, accelerating prediction of both the force values and variances, with ab-initio accuracy and rigorous Bayesian uncertainty quantification. We demonstrate this workflow on large-scale molecular dynamics simulations of properties of 2D stanene and related structures, including adatom migration and melting transition.
Ability to compute reaction rates from free energy is the key to understand many chemical and physical biology problems, for example, surface catalytic reactions and protein folding. Enhanced sampling methods, such as metadynamics and umbrella sampling, can accelerate slow transitions and improve their statistical estimates by biasing molecular dynamics in a low-dimensional reaction coordinate / collective variable (CV) space. The choice of these CVs coordinates determines the efficiency and accuracy of sampling. However, choosing good CVs can be challenging, requiring chemical intuition, experience and many trial-and-error tests. Here, we proposed to use a machine learning dimensionality reduction approach to automate the design of collective variables. A multi-task machine learning algorithm is employed to learn collective variables from transition path ensembles. In this algorithm, one neural network is trained to map atomic configurations to a lower dimensional latent space, and two additional neural networks are trained to map the latent space to potential energies and metastable state labels. A specific training procedure optimizes the latent space to preserve the information of potential energies and the progression of reaction pathways. The resulting latent space can be used as CVs for metadynamics and umbrella sampling in a wide variety of reactive systems. This approach has been tested on model systems that have two metastable states with one reaction pathway, including a Muller-Brown potential model and alanine dipeptide.
Free Energy Minimization for the Prediction of Molecular Crystal Structures at Finite Temperatures
Hiroyuki Matsui1, Seiji Tsuzuki2, Yukihiro Shimoi2 and Tatsuo Hasegawa3; 1Yamagata University, Japan; 2National Institute of Advanced Industrial Science and Technology (AIST), Japan; 3The University of Tokyo, Japan

Most of the previous works on the prediction of molecular crystal structures have been based on the (static) lattice energy minimization (LEM), which neglects thermal and zero-point molecular vibrations. This leads to the neglection of thermal effects such as thermal expansion and phase transition. Another more serious drawback of LEM is that it results in too many polymorphs, which can be considered as a kind of artifacts, compared to experiments. Here we propose a new approach for the prediction of molecular crystal structures at finite temperatures by taking into account thermal and zero-point phonons. Our approach, free energy minimization (FEM), minimizes the Gibbs free energy which contains static lattice energy, phonon energy, and entropy-related term. Since the Gibbs free energy can be defined in equilibrium states only, the search space of FEM is not the whole set of the Cartesian product of lattice parameters and atom positions as in LEM but is its subset with constraints that all atoms are at equilibrium positions. In other words, only lattice parameters are regarded as independent variables, and atom positions are dependent variables determined by the constraints. As a proof of concept, we demonstrate the FEM simulation of crystal structures of solid argon. The lattice constants by LEM was found 1.6% smaller than the experimental value at 10 K. On the other hand, the lattice constants by FEM exhibited smaller mismatch, 0.5%, with experiments and also reproduced the thermal expansion quite well. In addition, FEM showed that the minimum point of the Gibbs free energy disappears above 87 K, which is consistent with the experimental boiling point of argon, 87.30 K. The reproduction of the unstability of argon crystal above the boiling point implies that FEM can properly eliminate polymorphs which are unstable at specified temperatures.

MT01.05.03
Determining the Structure of Rosette Nanotubes Using Multi-Scale Molecular Modeling—Ring Stack vs Helical Tube
Arthur A. Gonzales1,2, Hector Grande2, Takeshi Yamazaki2 and Hicham Fenniri2; 1University of the Philippines, Philippines; 2Northeastern University, United States

Rosette Nanotubes (RNTs) are tubular soft materials self-assembled from guanine-cytosine (GAC) hybrid molecules, which can be covalently functionalized for use in various applications. They have been shown to be effective assemblies in regenerative medicine, drug display and delivery, and catalysis.

Previous spectroscopic studies suggest they have a structure which is formed by hexameric rings, maintained by self-complementary hydrogen bonds, that are further stacked and supported by π-π interactions, which form the ring-stacked RNTs. While this mode of association maximizes the hydrogen bonding interactions and results in efficient π-π stacking, it is also possible to envision that the GAC modules assume a helical organization defining a tubular core. Imaging the nanotube using scanning tunneling microscopy (STM) proved inconclusive in differentiating the two configurations. Furthermore, comparing the calculated chemical shifts of the nitrogen atoms of the GAC monomers of both the stacked-tube (ST) and helical tube (HT) configurations showed no significant difference between them.

We further investigated this possibility by using the lysine-functionalized RNT (K1-RNT) and applying multi-scale molecular modeling methods, which include Monte-Carlo conformational search, molecular dynamics, and the statistical mechanical theory of molecular liquids, 3D-RISM theory. We considered three structures of the K1-RNT: ST, left-handed HT (LHT), and right-handed HT (RHT). Our results suggest that the formation of ST, LHT, and RHT K1-RNTs in water are favorable and are enthalpically driven. Moreover, 3D-RISM analysis suggests that the RHT conformation is more probable than the ST and LHT RNTs and this is due to a more favorable solute-solvent interaction energy. Using the 3D distribution of solvent sites around the RNTs (from 3D-RISM calculations), we were also able to determine the solvation structure and estimate the free energy of binding of each water molecule in the RNT channel. The results also corroborate the higher probability of the RHT conformation occurring. Studies are being done to verify these findings.

Comparison of Classical Molecular Dynamics and Ab Initio Molecular Dynamics Methods for Modeling Solvent - Lithium Salt Systems in Lithium Air Batteries
Emily J. Crabb1, Arthur France-Lanord1, Graham M. Leverick1, Ryan Stephens2, Yang Shao-Horn1 and Jeffrey C. Grossman1; 1Massachusetts Institute of Technology, United States; 2Shell International Exploration & Production Inc., United States
Lithium-air batteries are an active area of research because of their potential to have a much higher energy density than traditional lithium-ion batteries. However, they are not yet commercially viable due to poor efficiency, high charging voltages, and low cycle lifetimes. Experimental studies of Li-air batteries with aprotic solvents have shown that the O\textsubscript{2} reduction starts when superoxide (O\textsubscript{2}⁻) forms in solvent and reacts with Li⁺ to form lithium superoxide (Li⁺-O\textsubscript{2}⁻). Solid Li\textsubscript{2}O\textsubscript{2} then forms as the final discharge product on the cathode. Recent experimental work has suggested that the choice of solvent and the presence of any lithium salts in the system may have a large impact on how the discharge product forms at the cathode. We therefore modelled the clustering of lithium salt molecules in solvent systems without LiO\textsubscript{2} present by performing explicit solvent calculations using both classical molecular dynamics and \textit{ab initio} molecular dynamics simulations. Properties such as the vibrational density of states, coordination number, and structure factor were calculated for these simulations, and the results from the classical and \textit{ab initio} simulations were compared both with each other and with experimental data. Large differences in properties such as coordination number were observed for classical versus \textit{ab initio} simulations, which was not expected based on the widespread use of classical molecular dynamics for modeling solvent behavior. A summary of our results comparing and benchmarking computational approaches for properties such as vibrational density of states and coordination numbers for pure solvent and solvent-salt systems will be presented.

Uncovering Molecular Scale Driving Forces in Aggregation of Peptides for Silica Precipitation

Moke Mao, Janani Sampath, Jim Pfandtner and Gary Drobn; University of Washington, United States

Biomimeralization is a widespread process in living organisms through which hierarchical mineral assemblies are formed under moderate conditions of temperature and pH. To this end Silaffin, a naturally occurring protein known to mediate the silica biomimeralization process in diatoms, has been widely studied. In particular, R5 - the 19-residue segment of Silaffin, was found to precipitate silica in vitro, and has been extensively employed as a model peptide in many experiments and simulations to elucidate the driving forces of biomimeralization. For R5 to facilitate silica or titania precipitation in solution, there must be sufficient negative charge in the system to compensate for the relatively high positive charge on the peptide. In vitro, this has been accomplished with phosphate buffer to mimic post translational modification in the form of serine phosphorylation known to occur in vivo. Sprenger et al. used molecular dynamics (MD) to study the atomic mechanism underlying the phenomenon of protein-mediated biomimeralization, focusing on the role of pH and phosphorylation. The interaction of wild type R5, along with two mutants (local phosphorylation and global phosphorylation) to silica was investigated, and it was found that phosphorylation decreased the binding free energy at acidic and neutral pH. While the trends match experimental results of R5 binding on silica, peptide-surface binding is not the primary indicator of biomimeralization efficiency. The key role of phosphate suggests peptide-peptide interactions play an important role in the nascent phase of biomimeralization and in this work, we study R5 peptide dimerization, to shed light on inter-peptide interactions that enable the uniform templating of silica. To match closely to experimental systems, we study R5 dimers under five distinct conditions. These are (1) wild type R5 (2) R5 with phosphate ions (3) R5 with phosphorylation on Ser1 (4) R5 with phosphorylation on Ser14 (5) globally phosphorylated R5. Enhanced sampling using Parallel Bias Metadynamics with Partitioned Families (PBMetaD-PF) was employed to ensure convergence of the free energy profiles. Results indicate that R5 dimerizes in the presence of phosphorylated serine, or with phosphate ion in solution; and impacts of the number/location of phosphoserine in peptide is also observed. Dimer conformations are analyzed using K-means clustering algorithm. This work provides molecular insight on peptide aggregation in biomimeralization, and could potentially inform rational design of protein and nanomaterials.

Fracture in Nanoporous Gold—A Combined Simulation and Experimental Study

Nathan J. Beets, Joshua Stuckner, Diana Farkas and Mitsu Murayama; Virginia Polytechnic Institute and State University, United States

We present an experimental/simulation integrated study examining crack propagation in nanoporous gold. We utilized a simulation technique that combines continuum fracture mechanics with molecular dynamics. We applied this to a large atomistic digital sample of nanoporous gold to implement mode I crack propagation. Crack propagation tests were also conducted on an experimental sample, prepared via chemical dealloying and observed via in-situ TEM microscopy. We observed cracks in both samples propagating by the same mechanisms of sequential individual ligament failure. A series of nanowire computational deformation tests were also conducted to understand individual ligament behavior, and how this influences the overall sample fracture. This iterative direct
experiment/simulation comparison provides new insight into the failure response of nanoporous gold.

**Atomistic Studies of the Diffusion of H-Vacancy Complex in Cu**  
Junping Du1,2, W. T. Geng2,3, Kazuto Arakawa4,  
Ju Li5 and Shigenobu Ogata2,1; 1Kyoto University, Japan; 2Osaka University, Japan; 3University of Science and  
Technology Beijing, China; 4Shimane University, Japan; 5Massachusetts Institute of Technology, United States

Vacancy diffusion under hydrogen (H) environments is important to the mechanical performance of structural  
materials, such as in hydrogen embrittlement and hydrogen blistering. The vacancy diffusion is believed to  
be retarded by trapping H-atoms forming H-vacancy complexes. The diffusivity of the H-vacancy complex can be  
estimated using long-time molecular dynamics simulations or static energetics calculations provided that the  
thermodynamic equilibrium distribution of H-atoms around the vacancy has been achieved. From the static  
ergetics calculations based on the harmonic transition state theory, we found that the vacancy diffusion coefficient
