density. The distribution of Ni and Mn at the octahedral sites plays a key role in the electrochemical performances such as capacity and cyclability, and it brings complexity in the material synthesis, thermal treatment and structure tuning. Thanks to its high sensitivity in detecting lithium ions and distinguishing transition metals, in-situ neutron scattering is used here to study the TM-mediated structure transition during the synthesis, as well as crystal structures in global and local scales, which is correlated with the electrochemical behaviors. In-situ neutron diffraction monitors the TM activities at elevated temperature, which are found to be significantly influenced by the atmosphere. In air, Ni and Mn reversibly exchange at the octahedral sites between 700~750 °C, mediating the “ordered” and “disordered” TM arrangement. The spinel-to-rocksalt structural transition occurs at higher temperatures, and it is reversible upon cooling. In contrast, in oxygen-deficient atmosphere it is found that the TM atoms not only exchange at the octahedral site but also migrate to the Li tetrahedral sites, resulting in the formation of a tetragonal spinel phase with the cubic spinel phase reserved. In-situ neutron diffraction reveals the kinetics of the TM migration, and the in-situ neutron pair distribution function evidences the TM valence change during the phase transition. The results will further guide and accelerate the novel material finding for high performance Li ion batteries.

Chitosan Based Gel Electrolytes for Zn-MnO2 Alkaline Rechargeable Batteries
Aswani Poosapati, Karla Negrete and Deepa Madan; University of Maryland, United States

Our study focuses on the use of Chitosan, a naturally available polysaccharide to form flexible films that act as gel electrolytes. Chitosan was chosen among various polysaccharides for testing due to natural abundance, renewability, biodegradability, cost-effectiveness, eco-friendly nature and a high degree of functionality, which is not available in most synthetic polymers. During initial testing, the ionic conductivity value obtained for pristine chitosan was approximately 10^{-6}S/cm, which is at least two orders of magnitude higher than the conventional synthetic polymers (PEO, PVP, etc.). This inherent advantage encouraged us to explore the possibility of their use as an electrolyte layer in batteries. It was noted that a semi-stable gel is formed when these biopolymers were vigorously mixed with minute amounts of acetic acid and dissolved in deionized water and allowed to sit for a while. It was also noted from the literature that chitosan films have an enormous surface area per unit volume (high aspect ratio), which makes us anticipate higher efficiencies. In our effort to make stable yet flexible organic films, various amounts of PVA (x=0.2, 0.4, 0.6, 0.8, 1) were added individually to Chitosan (CPx, CP=Chitosan: PVA), vortex mixed, cast into films, dried and then tested against SS blocking electrodes. Ionic conductivity studies on the various films provided a best average ionic conductivity value of 6.8mS/cm for CP0.2. This sample was then chosen and used for future experimentations due to enhanced conductivity and flexibility properties in comparison to pristine chitosan. To further enhance the ionic conductivities, varying amounts of KOH (y=0.1, 0.2, 0.3, 0.4, 0.5) were added individually to CP0.2 (CPKy, CPK=CP0.2: KOH) and cast into films and tested in a similar process as earlier. An average highest ionic conductivity of 105mS/cm was obtained for CPK0.3 (Chitosan: PVA: KOH= 1:0.2:0.3) sample. This sample CPK0.3 is then further analyzed for application in Zn-MnO2 batteries. Zn-MnO2 chemistries are chosen for testing the alkaline electrolyte due to their high-rate capabilities and mercury-free nature. Also, MnO2 is inexpensive, nontoxic and readily available. Prior to complete battery testing, the electrolyte is tested for electrochemical stability by conducting the linear scan voltammetry for SS/CPK0.3/Zn configuration. It was observed that the electrolyte was stable under 1.5V potential. This operating voltage window is a generic for Zn based systems. Then a cyclic voltammetry was performed between -0.5V and 1V, at a scan rate of 10mV/s for a Zn/CPK0.3/Zn configuration. It was observed that the electrolyte actually facilitates the oxidation and reduction at 0.5V and -0.35V potentials respectively. After these preliminary electrochemical studies, the prepared chitosan based gel electrolyte is then tested in a Zn-MnO2 system by using a Zn foil as anode and a MnO2 film prepared in-house after optimizing the ratios of MnO2, carbon and chitosan as cathode. Cyclic voltammetry and charge-discharge studies were then performed on this Zn/CPK0.3/MnO2 configuration battery. It was found that the cell stabilizes after the initial 3 cycles. A rapid galvanostatic charge-recharge study was also conducted at 50C rate for 15 cycles. The capacity attained was approximately 140 mAh/g and is relatively stable for the 15 cycles obtained. Further experiments with lower rates and more cycles need to be conducted and analyzed.

Structural Analysis of Li1+xAlxTi2-x(PO4)3 Thin Films for All-Solid-State Li-Ion Battery Applications
Marie
Francoise C. Millares1, Hunter Frost1, Matthew Chebuske1, Kevin Shah1, Yashashvini Andugula1, Spencer Flottman2,3, Seiichiro Higashiy4, Devendra K. Sadana4 and Harry Efstratiadis1; 1SUNY Polytechnic Institute College of Nanoscale Science and Engineering, United States; 2Oak Ridge National Laboratory, United States; 3Eonix, LCC, United States; 4IBM T.J. Watson Research Center, United States

Significant interest has arisen in all-solid-state lithium-ion batteries due to benefits in safety and cost. The electrolyte compounds used have many other benefits over traditional liquid electrolytes. One solid-state electrolyte of interest is the NASICON-like solid compound lithium aluminum titanium phosphate (Li1+xAlxTi2-x(PO4)3, LATP), due to its demonstrated high ionic conductivity of ~3x10^-3 S cm^-1. In this study, LATP thin films were successfully prepared through RF-magnetron sputtering of a 99.9% pure single LATP target onto a variety of substrates. LATP thin films (~100-150nm) were deposited at a range of temperatures varying from room temperature to 300°C, and annealed post-deposition at a variety of temperatures ranging from room temperature to 400°C. These alterations in process temperature have a significant impact on the resulting crystal structure of the thin films, as well as affecting both its ionically conductive and electrically resistive properties. The films' structural and compositional properties were characterized using x-ray diffraction (XRD), scanning electron microscopy (SEM) and secondary ion mass spectroscopy (SIMS). The resulting XRD spectra depict a primarily polycrystalline structure with peaks at 35° and 50°, which can be attributed to the presence of LiOTi and AlTi alloy, respectively. SEM analysis shows crack-free films with clear surface morphology, which is ideal for minimizing electrolyte-electrode interface resistance, and SIMS analysis shows films with uniform composition.

Xerion’s Disruptive Battery Technology for Electrical Vehicle and Consumer Electronics Chadd Kiggins and John Cook; Xerion Advanced Battery, United States

As the demand for Li-ion battery technologies increase, transformative battery materials are desperately required. Cost, performance, and safety are major driving forces that determine the mass adoption of new materials by industry and consumers alike. Xerion Advanced Battery Corporation (XABC) produces low cost, high performance Li-ion batteries with increased safety by using a revolutionizing electroplating method. Cathode chemistries such as LiCoO2 and anode chemistries such as silicon can be directly electroplated onto current collectors yielding binder and carbon free electrodes. This architecture leads to a drastic increase in battery safety as it can shut down conductive pathways during a hard short since active materials like LiCoO2 are much less electrically conductive than carbon. This electrodeposition method doesn’t use highly purified starting raw materials, which reduces the cost of a cell by up to 50%. The unique electrode architectures are directly adhered to the current collector thereby reducing interfacial resistance and enhancing the power and energy of a given battery chemistry. This poster will give an overview of what Xerion’s battery technology is currently capable of delivering. The technology will be discussed from a cost and performance perspective.

EN02.19.59
Analytical Microscopy Studies of SEI Formation on Model Si Electrodes Andrew G. Norman1, Caleb Stetson2,1, Yanli Yin1, Manuel Schnabel1,2, Sang-Don Han1, Chun-Sheng Jiang1, Mowafak Al-Jassim1 and Anthony Burrell1; 1National Renewable Energy Laboratory, United States; 2Colorado School of Mines, United States

Lithium ion batteries are becoming an increasingly important part of everyday life with diverse applications from low emission electric vehicles to consumer electronics. Si anodes offer the potential for approximately ten times higher capacity than the presently used graphite electrodes. However, Si anodes have several challenges that have so far prevented their commercial application on a large scale. These include high capacity fade, a poor shelf life, and the long-term stability of the electrode materials. Solid electrolyte interphase (SEI) formation and stability is poorly understood in Si anodes as compared to graphite anodes. Problems faced include the large volume expansion/contraction on lithiation/delithiation and extensive gas formation during cycling.

In this work, we report on analytical scanning transmission electron microscopy (STEM) studies of the lithiation behavior and SEI formation on various model Si electrode structures. These include bare wafer Si and wafer Si with different thickness native and thermally grown SiO2 layers. We report data on the structure and chemistry of the lithiated electrodes and SEI layers formed. The results are correlated with results obtained by other techniques on the same samples including electrochemical cycling data and scanning spreading resistance microscopy (SSRM).
measurements on SEI thickness and resistivity. We have observed that resistance changes of the SEI measured by SSRM correlate with compositional differences in the SEI as determined by STEM electron energy loss spectrometry (EELS) and energy dispersive x-ray spectrometry (EDS) measurements.1

EN02.19.60
Comparative Study of Sulfide Solid Electrolytes for All-Solid-State Lithium-Ion Batteries—Chemical and Thermal Stability, Conformity with Cathode Material Jae-Ho Park1,2, Jiwon Jeong1,2, Jun Tae Kim1, Hun-Gi Jung1,2, Hwa Young Lee1, Woo Young Yoon2 and Kyung Yoon Chung1,3; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Korea University, Korea (the Republic of); 3Korea University of Science and Technology, Korea (the Republic of)

Recent studies on lithium-ion batteries (LIBs) have focused on satisfying the electrochemical performance that required for their applications such as electric vehicles and energy storage systems. Along with this research trend, there is also growing interest in preventing the risk factors on present LIBs caused by excessive improvement. In this respect, all-solid-state lithium-ion batteries (ASLBs) are one of the attractive candidate for next generation batteries that can improved both performance and safety compared to conventional LIBs.

Among various types of solid electrolyte (SE) candidates, sulfide-based SEs are promising due to high ionic conductivity which is comparable to commercial liquid electrolytes (~10⁻² S cm⁻¹ at room temperature) and high-formability which enables favorable inter-particles contact on composite electrode for ASLBs. Despite the advantages of sulfide-based SEs, there are several problems that should be solved such as chemical and oxidation instability, diffusion of mutual elements on interface with cathode materials.

In this work, we synthesized Li₇P₃S₁₁ and Li₆PS₅Cl sulfide-based SEs which have been widely studied, and we have conducted a comparative study on their chemical and thermal stability. To compare them, we performed optical observation and advanced X-ray diagnostics. Further more, we also confirmed the conformity between sulfide-based SEs and commercialized cathode material. The details will be discussed at the conference.

EN02.19.61
Tin Nanoparticles Embedded in Carbon Buffer Layer as Preferential Nucleation Sites for Stable Sodium Metal Anodes Huan Wang, Edward Matios, Chuanlong Wang and Weiyang Li; Dartmouth College, United States

Sodium (Na) metal is one of the most appealing anode materials for grid-scale energy storage systems owing to the high earth abundance and low cost of Na resources. Nevertheless, the implementation of Na metal anode is hindered by two primary issues associated with Na dendrite growth and volume expansion, resulting in low Coulombic efficiency and poor cycle life. Herein we present a facile and scalable method to synthesize tin (Sn) nanoparticles (NPs) that are uniformly embedded within carbon network (denoted as Sn@C composite), which can address the two issues simultaneously. Specifically, Sn NPs can serve as preferential nucleation sites to guide Na nucleation and thereby lower the Na deposition overpotential, while the carbon network can act as buffer layer to effectively minimize the volume change and alleviate the exfoliation of Sn NPs over repeated cycles. Consequently, high-capacity Na anodes can be realized with long-term reversibility and stability. Moreover, a room-temperature Na-sulfur battery based on the Sn@C composite as anode coupled with commercial sodium sulfide as cathode was demonstrated with significantly improved electrochemical performance. We believe this work provides a new pathway in designing high-energy Na metal batteries.

EN02.19.62
Exploiting Lewis Basic Nature of Boron-Containing Polymers to Improve Ionic Conductivity in Solid-State Electrolytes Megan Van Vliet; Temple University, United States

To improve the safety of Lithium Ion Batteries (LIBs) more desirable, non-flammable, highly conductive solid-state electrolytes are needed for commercial use. One promising alternative is the synthesis of highly conductive and flexible polymer electrolytes. Current polymers often suffer from low ionic conductivities that cannot meet current
standards for operation in LIBs. In order to increase performance and longevity, materials that only admit the electrochemically active cation are desirable. For this reason, synthetic efforts toward single-ion conducting polymers are necessary. A promising synthetic pathway is with the exploitation of the Lewis basic nature of borane compounds. With matching salts with Lewis basic anions to Lewis acidic boron-containing polymers, the interaction of the anions with the boron-containing polymer backbone are likely to hinder anionic movement. Meanwhile this allows the cations to be the most likely ionic conductor and help improve overall ionic conductivity of the system. The preparation of step-growth or Ziegler-Natta catalyzed boron-containing electrolyte polymers will be synthesized and analyzed via thermal gravimetric analysis, differential scanning calorimetry and electrochemical impedance spectroscopy for preliminary characterization.

EN02.19.63
An Alternative Route to Single Ion Conductivity Using Multi-Ionic Salts Sumanth Chereddy; Temple University, United States

One of the major problems with the Li metal batteries is the safety issues associated with dendrite growth when using metallic Li0 anode. There has been extensive research on the prevention of dendritic growth, including mechanical inhibition and limiting concentration gradients that result in anion depletion near the anode. The latter can be achieved by the use of electrolytes with high ionic conductivities and low anion mobility, i.e. high Li+ ion transference numbers (tLi+). Concentration gradients are avoided in polymer single ion conductors (SICs) with tLi+ ~ 1. However, conductivities of polymer SICs have remained low (< 10^{-5} S cm^{-1}). One of the reasons for low conductivity in polymer SICs is extensive ion aggregation. In this work we proposed the use of multi-ionic polyhedral oligomeric silsesquioxane (POSS) with dissociative lithium salts [POSS-(LiNSO2CF3)$_8$] dissolved in tetruglyme (G$_4$), CH$_3$-O-(CH$_2$CH$_2$O)$_4$-CH$_3$, as electrolytes having both high ionic conductivity and high lithium ion transference numbers. [POSS-(LiNSO2CF3)$_8$] can be dissolved at very high loadings into G$_4$, where they can be considered solvent-in salt electrolytes. Two systems were investigated, neat [POSS-(LiNSO2CF3)$_8$] in G$_4$ and mixtures of [POSS-(LiNSO2CF3)$_8$] with LiPF$_6$ or lithium bis(trifluoromethanesulfonyl)-imide (LiTFSI). PFG-NMR indicates that Li can be un-dissociated, completely dissociated and surrounded by G$_4$ molecules, or as contact ion pairs (in which there are 3–4 ether oxygen contacts and one contact with the oxygen from the anion). Equilibria exist between the species of [POSS-(LiNSO2CF3)$_8$] and if there is rapid equilibration between the Li states and close enough proximity between the POSS-(LiNSO2CF3), then the Li$^+$ ions can migrate by a Grothuss-type coordinated hopping mechanism, as well as by a purely diffusive motion. Unlike polymer single ion conductors, where the backbone flexibility permits cluster/aggregate formation, which inhibits escape and mobility of the Li$^+$ ions, the rigid POSS cube and its colloidal structure in G$_4$ prevents formation of POSS-(NSO$_2$CF$_3$)$^-$ Li$^+$ (CF$_3$NSO$_2$) POSS triplets. Instead, the solvated Li$^+$ in POSS-(NSO$_2$CF$_3$)$^-$ Li$^+$ G$_4$ can be more easily removed to form conductive G$_4$ Li$^+$ G$_4$. Good ionic conductivities (< 10^{-4} S cm^{-1}) and lithium ion transference numbers of tPP = 0.65 can be achieved in these systems. Mixtures of 80 wt% LiTFSI and 20 wt% [POSS-(LiNSO2CF3)$_8$] in G$_4$ at an O/Li ratio of 20/1, yield both high conductivity (3.3 x 10^{-3} S cm$^{-1}$) and high (tPP = 0.65) transference number. Stable cycling at C/4 with high capacity retention was achieved using Li$^0$/[G$_4$/80 wt% LiTFSI/20 wt% [POSS-(LiNSO2CF3)$_8$]/LiFePO$_4$ half-cells.

Constructing Electrode/Electrolyte Interfaces with Low Resistance for All-Solid-State Batteries Nataly C. Rosero Navarro, Ryunosuke Kajiura, Akira Miura and Kiyoharu Tadanaga; Hokkaido University, Japan

All-solid-state lithium batteries based on oxide solid electrolytes are a practical proposal for large-scale energy storage applications because of chemical stability and ease to handle of oxide solid electrolytes (e.g. Li$_7$La$_3$Zr$_2$O$_{12}$, LLZ). The high interfacial resistance between electrode and electrolyte remains a major concern for their application. Here, an amorphous layer of lithium silicate is proposed as a suitable conductive material to construct a low interfacial resistance between garnet solid electrolyte and lithium metal. An adequate thickness of the lithium silicate layer allows obtaining an interfacial resistance as low as 50 Ω cm$^2$. Moreover, the symmetric cell of the Li$_2$SiO$_3$ modified garnet solid electrolyte and lithium metal shows a stable plating-stripping cycling behavior at a current density of 0.1 mA cm$^{-2}$ with a voltage response of less than 5 mV for up to 500 cycles.

EN02.19.65
Liquid-Phase Syntheses of Sulfide Electrolytes and Application in All-Solid-State Lithium Battery Nataly C. Rosero Navarro, Akira Miura and Kiyoharu Tadanaga; Hokkaido University, United States

Sulfide-based solid electrolytes are promising for all-solid-state batteries because of their high ionic conductivity and good mechanical properties that allow an intimate contact at the interface between electrode and electrolyte by using only room temperature pressing [1,2]. A sulfide-based solid electrolyte with high ionic conductivity and small particle size is desirable to improve the charge transfer and to obtain a large interfacial contact area between the electrolyte and active material.

The synthesis of sulfide solid electrolytes by a liquid-phase process using an organic solvent has been recently reported. Reaction times from 24 h to more than 3 days are required. Here, we report an efficient synthesis of sulfide solid electrolytes by a simple procedure involving a liquid phase process under ultrasonic irradiation, with the short reaction time of 30 min, and heat treatments at low temperatures [3]. Sulfide solid electrolytes, such as Li7P3S11 and argyrodite Li6PS5Cl, with high ionic conductivity up to 1 mS cm-1 can be prepared. The control of the morphology was found to be essential to achieve high ionic conductivity.

Ab Initio Investigation of the Diffusion Mechanism Lithium in Li4Ge1-xSnxS4 Hamidreza Seyf, Partha Mukherjee and Vilas G. Pol; Purdue University, United States

All-solid-state lithium-ion battery is regarded as the next generation battery to replace the current commercial lithium-ion battery. As one critical component in solid-state lithium-ion battery, solid-state electrolyte should possess superior operational safety and high ionic conductivity. Recently experimental studies have shown that substitution of Ge4+ by Sn4+ within Li4Ge1-xSnxS4 broaden the diffusion bottleneck, modify the lithium distribution, and enhance connectivity between the conduction channel, hence leading to an increase of the ionic conductivity for Li4SnS4. In this work, we have conducted an expensive ab initio molecular dynamics simulation to systematically study the diffusion mechanism of lithium ions in Li4Ge1-xSnxS4 at different Sn composition and temperature. Mean square displacements, pair correlation functions, diffusion coefficient, activation barrier, and pair correlation functions are calculated and their relation to the structural modification and transport properties are discussed.

EN02.19.67
A Theoretical Investigation of Enhanced Electrochemical Performance of Birnessite-Type MnOx Nanosheets Assembled on Reduced Graphene Oxide Template Yoon-Su Shim1, Segi Byun2, Jong Min Yuk1, Chan-Woo Lee2, Jungjoon Yoo2 and Jin Yu1; 1Korea Advanced Institute of Science and Technology, Korea (the Republic of); 2Korea Institute of Energy Research, Korea (the Republic of)

Graphene-based micro-supercapacitors have drawn valuable attention as a new class of micro-energy storage devices. However, due to their low volumetric energy densities, they have been limited for the use in micro-power sources. Here, we propose the densely packed manganese oxide/reduced graphene oxide hybrid film (MnOx/rGO) consisting of multi-valent Mn ions as the promising electrode material for high energy density. To study K ion storage behavior of MnOx/rGO nanosheet, density functional theory (DFT) calculations are employed. With the DFT calculation, we expect high thermodynamical stability of K-MnOx/rGO capacitor and its enhanced
We investigate the origin of the performance enhancement in terms of the charge gain from rGO and the increased electronic states near the Fermi level.

The charge gain is triggered by the formation of an interface between MnOx and rGO, which implies the changes of the oxidation state facilitating K-ion storage reaction. The enhancement of conductivity is also expected as a result of increased electronic states near the Fermi level. We believe that our finding will provide an invaluable insight on metal oxide/rGO composite for super capacitor.

**Nanoscale Morphology Evolution in Nanoporous Alloy-Type Lithium-Ion Anodes Elucidated by Transmission Electron Microscopy** John Corsi and Eric Detsi; University of Pennsylvania, United States

With the increasing adoption of solar and wind energy technologies, a large demand exists for energy storage with high energy density to accommodate the intermittency of these technologies. Although intercalation type battery lithium-ion electrodes have been highly successful due to their reliability, these chemistries have limited capacity. Alloy-type lithium-ion battery electrodes are an attractive alternative due to their large theoretical energy densities. However, these electrodes often experience poor cycle stability. This is due to the large volume changes (~300%) which occur during lithiation, causing the active material to crack during delithiation, and inducing delamination of this active material from the current collector.1 Previous work demonstrated that nanoporous electrode materials, consisting of an open three dimensional bicontinuous network of nanoscale ligaments and pores, have improved cycling performance compared to their bulk counterparts. Currently, it is hypothesized that this lithiation induced volume change is minimized due to a buffering mechanism in which the ligaments expand while the pores shrink, resulting in a smaller lithiation-induced net volume change.1 In an attempt to verify this hypothesis, synchrotron-based transmission X-ray microscopy (TXM) has been used to image these volume changes in nanoporous Sn (NP-Sn) and it was found that NP-Sn particles accommodate the lithiation-induced volume changes better than dense Sn.2 However, the TXM is only able to accurately probe the volume change in sub-micrometer sized Sn particles. My work seeks to build on this understanding by probing the structure at the nanoscale with transmission electron microscopy (TEM) using nanoporous gold (NP-Au) as a model material system for Li storage. The lithiation and delithiation of NP-Au electrodes were imaged *ex situ* using TEM at different stages of the process, to observe the structural evolution of the nanoporous ligament-pore structure. The next step will involve an *operando* study in which the NP-Au is imaged in real-time in the TEM. Through this methodology, this experiment will be able to address fundamental questions involving structural changes in nanoporous alloy-type lithium-ion battery anodes during (de)lithiation cycling. Although NP-Au was studied because it is considered a model nanoporous material, this methodology can be applied to earth-abundant candidate battery materials such as tin and aluminum.

**Intercalation-Conversion Hybrid Strategy Enabling Li-S Full-Cell Architectures with High Energy Density** Weijiang Xue; Massachusetts Institute of Technology, United States

A common practice in research of Li-S batteries is to use high electrode porosity and excessive electrolytes to boost sulfur-specific capacity. Here we propose a class of dense intercalation-conversion hybrid cathodes by combining intercalation-type Mo6S8 with conversion-type sulfur, to realize a Li-S full cell. The mechanically hard Mo6S8 with fast Li-ion transport ability, high electronic conductivity, active capacity contribution and high affinity for lithium polysulfides is shown to be an ideal backbone to immobilize the sulfur species and unlock their high gravimetric capacity. Cycling stability and rate capability are reported under realistic conditions of low carbon content, low electrolyte/active material ratio, low cathode porosity and high mass loading. A pouch cell assembled based on the hybrid cathode and 2× excess Li metal anode is able to simultaneously deliver a high gravimetric and volumetric energy densities.

**EN02.19.70**

**MXene-Based Nanomaterials as a Stable Matrix for High Performance Sodium Metal Anodes** Jianmin Luo
Sodium (Na) metal is a promising alternative to lithium metal as an anode material for the next-generation energy storage devices due to its high theoretical capacity, low cost, and natural abundance. However, dendritic/mossy Na growth caused by uncontrollable plating/stripping results in serious safety concerns and rapid electrode degradation. These studies present Sn²⁺ pillared Ti₃C₂ MXene/pillared MXene-derived porous nanocomposite serving as stable matrixes for high-performance dendrite-free Na metal anodes. 1) The intercalated Sn²⁺ between Ti₃C₂ layers not only induces Na to nucleate and grow within Ti₃C₂ interlayers, but also endows the Ti₃C₂ with larger interlayer space to accommodate the deposited Na by taking advantage of the “pillar effect” that leads to uniform Na deposition. 2) The obtained matrix facilitates Na nucleation and growth within interconnected nanopores promoted by the preferential chemical interaction between deposited Na and the matrix. As a result, the pillar-structured MXene-based Na metal anode exhibits superior electrochemical performance than that with host-less commercial Na. It is believed that the well-controlled MXene-based Na anode not only extends the application scope of MXene, but also provides guidance in designing high-performance and safe Na metal batteries.

EN02.19.71
Salt-Organic Cocrystals as Soft-Solid, Melt- and Press-Castable Solid Electrolytes for Lithium- and Sodium-Ion Batteries
Michael J. Zdilla¹, Stephanie Wunder¹, Birane Fall¹, Prabhat Prakash², Arun Venkatnathan² and Abdel Aziz Jalil¹; ¹Temple University, United States; ²IISER Pune, India

The cocrystalization of weakly-ligating organic molecules with lithium and sodium salts is a general phenomenon. Most of the time, these structures contain channels of weakly-bound cations that are highly mobile, giving conductivities as high as 5 x 10⁻⁴ S/cm, high for solid organic electrolytes. Preparation and characterization are described. Examples are given with high conductivity, good anode stability, and high cycle life. A unique feature of this class of electrolytes is an ionically conductive nanoliquid layer at the surface of the crystallites that facilitates grain binding and self-healing. This nanoliquid layer is additionally characterized by SEM, XRD, DSC, and its dynamical properties are described using molecular dynamics simulation.

EN02.19.72
Expanded Graphite Anodes Employing Atomic Metallic Pillars for High Capacity Sodium-Ion Batteries
Yoo Jin Kim and Won-Hee Ryu; Sookmyung Women's University, Korea (the Republic of)

Na-ion battery is a substitutional energy storage system for future large scale applications because of economic virtue and rich deposits of Na resource.[1, 3] However, low electrochemical performance (e.g. capacity, cycle life, and rate capability) of the electrode materials in Na-ion cell, originated from a large radius of the sodium ion, should be improved. Previous studies regarding anode materials for Na-ion batteries have further focused on improving affordable sites for Na ions and consequent reversible electrochemical reaction in Na accommodation layer. Improving anode materials is the important key to realize high capacity and stable cycle life of Na-ion batteries.

Graphite has been extensively used as an anode for commercialized lithium-ion batteries.[2] The graphite known as a long range and high crystalline carbon material can deliver a good capacity of ~350 mAh/g in Li-ion cells, yet poor capacity in terms of sluggish intercalation of large Na ion is shown in Na-ion cells.[3, 4] In this regard, non-graphitic hard carbon materials have been utilized as an alternative instead of the graphite due to high capacity around 300 mAh/g. However, their expensive material cost and low structural stability resulted from low crystallinity are a critical reason why we should seek better carbon alternatives.

Directly expanding interlayer of graphite is a preferred solution to develop carbon-based anode material for Na-ion batteries. Larger interlayer space and stable long-range order of the expanded graphite anodes enable excellent electrochemical performance.[5] Although there are many advantages of the expanded graphite anodes, side reactions easily occur between Na ions and a lot of oxygen contents in the carbon layers. The proper pillar components should be applied for developing high performance expanded graphite anodes.

In this work, we synthesized expanded graphite anode materials for Na-ion batteries using the functional introduction of atomic metallic pillars between graphene layers. We examined its morphology and structures of the
expanded graphite anode materials. Finally, we successfully achieved improved electrochemical properties of Na-ion batteries employing the expanded graphites, in comparison with reference samples due to the generation of sufficient Na-ion sites by functional pillar species.

A Solid-State Electrolyte Lithium Phosphorus Oxynitride Films Prepared from Li3PO4 Sintered Target for Li-Ion Batteries Prashanth Kumar Kodhamda1, Thulasi Raman K H2, Divya Bharathi M S1, Balasundaraprabhu R1, G Mohan Rao2 and Prasanna S1; 1PSG College of Technology, India; 2Indian Institute of Science, India

In the present work Lithium phosphorus oxynitride (LiPON) thin films which is used as solid electrolytes for Li-ion batteries, were deposited by reactive radio frequency (rf) magnetron sputtering technique using Li3PO4 sintered target under N2 atmosphere. It was observed that sintered target provides higher deposition rates, enhanced ionic conductivity, porous free thin films and could be used for more no of depositions using single target when compared to compact Li3PO4 powder targets. The non-porous nature of the film prevents the degradation of LiPON when exposed to moisture. Moreover, the deposited LiPON films exhibit good chemical stability for more no of charge/discharge cycles during full battery testing. It shows the superior interfacial compatibility with Li metal anode and it does not decompose when it comes into contact with Li, like other electrolytes. The electrochemical impedance spectroscopy of LiPON films showed an ionic Conductivity of $2.3 \times 10^{-6}$ Scm$^{-1}$ for sintered target thin films. Therefore we strongly believed that LiPON films deposited from sintered target are best suitable for solid state battery fabrication.

EN02.19.74
Printed Miniature Lithium-Ion Batteries for IoT Devices Anju Toor, Albert Wen and Ana Claudia Arias; University of California, Berkeley, United States

The rapid growth of the electronics industry has stimulated ever-increasing needs for both the amounts and types of portable electronics. Intensive efforts have been made to continuously develop miniaturized wireless devices, which can be used for smart medical implants, micro-electromechanical systems (MEMS). Such onboard autonomous devices need integrated power supplies or standby power sources to guarantee a stable current supply, and the size requirements for such kinds of power supplies are in a volume smaller than 10 mm$^3$.

Portable electronic devices evolved and incorporated several different types of rechargeable batteries, including lead-acid, Ni-Cd, Ni-MH, and Lithium-ion batteries. A Lithium-ion battery system is a preferred candidate for microscale power sources that can be integrated into autonomous on-chip electronic devices. They are not only able to provide relatively high power and energy density simultaneously, but also make the energy/power ratio and operation temperature adjustable by changing the electrode components and structures under the requested conditions.

Printed batteries incorporating additive manufacturing methods to achieve low-cost fabrication$^{[1-3]}$ and high throughput are excellent candidates for powering wireless electronic systems. Printing techniques such as stencil and screen printing offer the flexibility to customize battery active area as per the device layout and size requirements while also accommodating a wide range of substrate materials, ranging from flexible plastics to rigid substrates e.g. silicon. Although a significant amount of work has been performed on printed batteries for large-area applications, reports emphasizing on scaling battery size and power for typical IoT system requirements are limited$^{[4-6]}$.

In this contribution, a stencil-printed Lithium-ion battery with an electrode area scaled down to 1mm$^2$ is demonstrated. This work investigates the electrochemical limitations of Lithium-ion batteries as the active areas are
scaled-down. The battery consists of graphite and lithium cobalt oxide (LCO) as the respective anode and cathode layers printed on thin evaporated current collectors. For the fabrication of miniature batteries, a thin film configuration is adopted where single layers of anode, separator, and cathode are stacked together and sealed. A novel bonding strategy is developed to achieve a hermetic seal between (1) glass-glass and (2) silicon-glass substrates each having respective (cathode/anode) printed active layers. The batteries demonstrate an areal capacity of ~4 mAh/cm² and capacity retention of >95% under 100 charge/discharge cycles. Preliminary experiments show that a 5mmx5mm printed battery can easily power a micromote[7] that consumes a baseline current of 500-600μA. Further efforts to enhance the battery capacity at higher C-rates are currently in progress.

All-Solid-State Asymmetric Supercapacitors with Metal Selenides Electrodes and Ionic Conductive Composites Electrolytes Yongrui Yang, Tao Zhu, Lei Liu and Xiong Gong; The University of Akron, United States

All-solid-state flexible asymmetric supercapacitors (ASCs) are developed by utilization of the graphene nanoribbon (GNR)/Co0.85Se composites as the positive electrode, the GNR/Bi2Se3 composites as the negative electrode and the polymer-grafted-graphene oxide membranes as solid-state electrolytes. Both GNR/Co0.85Se and GNR/Bi2Se3 composites electrodes are developed by a facile one-step hydrothermal growth method from graphene oxide nanoribbons as the nucleation framework. The GNR/Co0.85Se composites electrode exhibits a specific capacity of 76.4 mAh/g at the current density of 1 A/g and the GNR/Bi2Se3 composites electrode exhibits a specific capacity of 100.2 mAh/g at the current density of 0.5 A/g. Moreover, the stretchable membrane solid-state electrolytes exhibit superior ionic conductivity of 108.7 mS/cm. As a result, the flexible ASCs demonstrate an operating voltage of 1.6 V, an energy density of 30.9 Wh/kg at the power density of 559 W/kg, and excellent cycling stability with 89% capacitance retention after 5000 cycles. All these results demonstrate that we provide a simple, scalable, and efficient approach to fabricate high performance flexible all-solid-state ASCs for energy storage.

Predicting the Open Circuit Potential Curve for a Class of Ni-Rich Cathode Materials Kevin W. Kimura1,2, Rebecca Wilhelm3,4, Soo Kim2, Munir Besli2,4, Camille Usubelli2,4, Joerg Ziegler4, Reinhardt Klein2, Jake Christenson2 and Yelena Gorlin2; 1Cornell University, United States; 2Robert Bosch LLC, United States; 3Technical University of Munich, Germany; 4Karlsruhe Institute of Technology, Germany; 6University of Strasbourg, France; 6Robert Bosch GmbH, Germany

From consumer products to the automotive industry, lithium ion batteries (LIB) are playing an ever-increasing role in the electrification of our society. In particular, the automotive industry has seen exciting growth in the demand for batteries to meet the needs of an expanding battery electric vehicles (BEVs) market. Li[Ni0.80Co0.15Al0.05]O2 (NCA) is a cathode composition, which is of significant interest to BEVs, due to its high energy density and suitable thermal stability. A significant drawback of this material, however, is that one of its constituents, Co, continues to be a substantial contributor to cost. As a result, the recent industry trend has been to raise Ni and lower Co content in NCA, to decrease the cost and further increase the energy density of the battery. Effective adoption of these emerging Ni-rich NCA cathode materials requires improved understanding of their electrochemical properties, such as the open circuit potential (OCP) curve. To address this point, we show how Ni stoichiometry influences the OCP curve and identify a methodology for predicting OCP curves for a class of Ni-rich cathode materials.
Dry Pressed, High Mass Loading Electrode Architectures Enabled by Holey Graphene Yi Lin\textsuperscript{1} and John W. Connell\textsuperscript{2}; \textsuperscript{1}National Institute of Aerospace, United States; \textsuperscript{2}NASA Langley Research Center, United States

For future electric aviation, advanced battery cell chemistry beyond lithium ion batteries are required to meet mission requirements. High energy density battery concepts such as lithium-sulfur (Li-S) and lithium-oxygen (Li-O\textsubscript{2}) chemistries are being intensively investigated to realize their extraordinary theoretical promise in terms of energy density. Most fabrication methods of cathodes for these novel battery chemistries followed a conventional approach. In this approach, the active material is mixed with a polymer binder and a conductive carbon in a high-boiling organic solvent to form a slurry, followed by casting onto a current collector and solvent evaporation. The process is usually lengthy and poses environmental hazards due to the use of organic solvents.

Graphene is known to be an advanced carbon additive in novel battery electrodes with good electrical conductivity, high surface area, and mechanical robustness to maximize the electrochemical function of the active materials. Holey graphene, a structural derivative of graphene with an array of through-the-thickness holes across the lateral surface of the nanosheet, allow more facile cross-plane ion and gas transport than intact graphene, making it an ideal electrode material for electrochemical energy storage.

In this presentation, we will discuss our recent progress based on a unique property of holey graphene in that it can be compression molded into robust articles or architectures under solvent-free conditions without the need for parasitic binders. This unique dry compressibility of holey graphene has enabled facile dry fabrication of high mass loading electrodes with both high density and high porosity and controlled architectures, which have found use in a variety of energy storage applications including, but not limited to, supercapacitors and Li-O\textsubscript{2}, Li-S, and lithium-selenium (Li-Se) battery systems.

Enhanced Electrochemical Stability of NCM811 Solid-State Batteries by Surface Altering Processes Qing Zhang\textsuperscript{1}, Peter Aurora\textsuperscript{1}, Joshua Gallaway\textsuperscript{2} and Alyssa Stavola\textsuperscript{1}; \textsuperscript{1}Kostas Research Institute at Northeastern University, United States; \textsuperscript{2}Northeastern University, United States

Solid-state electrolytes (SSEs) are nonflammable and have a wider operation temperature range, making them much safer than their liquid counterparts. An ideal all solid-state Li ion battery (ASSB) made with high-energy electrode materials and superionic Li ion conductors has the potential to meet the high-energy and safety requirements of existing and new battery applications. Among various categories of SSEs, the sulfide family demonstrates the highest Li ion conductivity because sulfur has small binding energy to Li ions and large atomic radius. However, the stability of the interface between sulfide electrolyte and oxide cathode materials such as LiCoO\textsubscript{2} (LCO) and LiNi\textsubscript{1-x-y}Co\textsubscript{x}Mn\textsubscript{y}O\textsubscript{2} (NCM) is poor due to the large reaction energy between sulfide electrolytes and transition metal oxide materials. Chemical reactions at the interface as well as the formation of a space-charge layer result in large interfacial resistance. The goal of our study is to build an ASSB with high-energy NCM811 material which has a theoretical capacity of \textasciitilde200 mAh\textpermg\textsuperscript{2} and Li\textsubscript{6}PS\textsubscript{5}Cl sulfide electrolyte which has an ionic conductivity of 1.6 mS\textpercm\textsuperscript{2} at room temperature. We employed various methods to coat NCM811 material with oxide protective coatings, which are stable with both sulfide electrolytes and NCM811. LiNbO\textsubscript{3} coating was prepared by a sol-gel method and TiO\textsubscript{2} coating was prepared by dry-mixing. Characterization results showed that both methods produced a uniform coating. By altering the surface chemistry of NCM811, the cyclic stability of the ASSB was significantly improved compared to bare NCM811.

Surface Modification of Copper Current Collector Using Graphene Oxide as a Buffer Layer to Impede Lithium Dendrites Growth in LMBs Zewdu T. Wondimkun\textsuperscript{1}, Wei-Nien Su\textsuperscript{1} and Bing-Joe Hwang\textsuperscript{1,2}; \textsuperscript{1}National Taiwan University of Science and Technology, Taiwan; \textsuperscript{2}National Synchrotron Radiation Research Center, Taiwan

Lithium (Li) metal anodes have attracted considerable interest due to their ultrahigh theoretical gravimetric energy density and very low redox potential. However, the issues of nonuniform lithium deposits (dendritic Li) during cycling are hindering the practical applications of Li metal batteries. Herein, we propose a surface modification of the copper current collector with ultra-thin spin-coated GO as buffer layer to regulate the movement of Li ions. The as-prepared GO coated film enables smooth, uniform, and dendrite-free lithium plating. Moreover, the cell with the
GO-coated electrode displays superior reversible plating/stripping efficiency, low plating/stripping polarization and stable voltage profile than the bare copper electrode. Thus, Li/Cu@GO exhibit a CE of ~ 98% and that of the Li/Cu half cells show ~75% within 1 M LiPF₆ (1:1 v/v) (EC/DEC) after 50 cycles. Our results demonstrate the GO-coated buffer layer can be a promising strategy to improve inhibiting the growth of Li dendrites and the performance of LMBs.

EN02.19.81
Next-Generation Zn-Ion Batteries with Enhanced Rechargeability and High-Rate Operation via 3D Nanostructured Electrodes and Mixed Salt Electrolytes
Maya Helms¹, Megan Sassin¹, Joseph Parker¹, Christopher Chervin¹, Jesse S. Ko², Debra R. Rolison¹ and Jeffrey W. Long¹; ¹U.S. Naval Research Laboratory, United States; ²SLAC National Accelerator Laboratory, United States

The low cost and safety advantages of primary Zn/MnO₂ batteries can be translated to next-generation “zinc-ion batteries” by replacing the alkaline electrolyte with a near neutral-pH Zn²⁺-based electrolyte. The functionality of such Zn-ion batteries can be extended to include rechargeability (100s of cycles) and high-rate operation (300 mAh g⁻¹ at 1C and 100 mAh g⁻¹ at 20C) by using a 3D nanoarchitectured MnOₓ@carbon nanofoam-paper (CNF) electrode and a mixed salt electrolyte (e.g., ZnSO₄ + Na₂SO₄). The MnOₓ stores charge via pseudocapacitance at potentials not associated with Zn²⁺-based redox reactions, while Zn₄(OH)₆SO₄.5H₂O precipitates during discharge and dissolves during recharge. This complex charge-storage reaction is reversible over hundreds of cycles, which is attributed to structural features of the 3D CNF electrode and the use of a mixed-salt electrolyte. Recently, we developed an in-place conversion to create nanocrystalline ZnMn₂O₄ spinel from the 10-nm–thick birnessite-like MnOₓ coating on the CNF and demonstrated that the ZnMn₂O₄@CNF electrode also undergoes precipitation/dissolution reaction when cycled in 1M ZnSO₄, but offers benefits in terms of discharge voltage and long-term cycling stability.

EN02.19.82
Activation of Asphaltene Using Melamine Sponge for Applications in High Performance Supercapacitors
Shayan Enayat¹, Mai K Tran¹, Devashish Salpekar¹, Mohamad Kabbani², Ganguli Babu¹, Fransisco Vargas¹ and Pulickel Ajayan¹; ¹Rice University, United States; ²Shell, United States

Asphaltene is the heaviest fraction of crude oil consisting of a mixture of organic compounds. During oil production, the asphaltene fraction can get destabilized due to the changes in pressure, temperature, and composition, allowing its precipitation out of the crude oil. These precipitated asphaltene aggregates can cause surface deposition within oilfield wellbores, leading to a significant reduction in the well productivity.

In this work we report a novel technique for converting crude oil asphaltene into an interconnected porous carbon network material using melamine sponge as template. Dispersed pristine asphaltene powder in toluene is mixed with aqueous KOH solution, then sonicated and homogenized. The melamine sponge is saturated with the homogenized emulsion and heated to burn off the melamine resulting in a porous activated asphaltene of BET specific area of 3868 m²/g as compared to that of 2466 m²/g for that of activated carbon obtained under the same conditions. Electrochemical measurements of activated asphaltene-based supercapacitors in a standard aqueous electrolyte gives a high-performance specific capacitance of 197.3 F/g. Moreover, the activated asphaltene electrodes with “water-in-salt” electrolyte showed potential for higher voltage operating up to 2.5 V, with an energy density up to 31Wh/kg.
in many technical parameters, beyond Li-ion chemistries (Na, K, or multi-valence ions like Zn and Mg etc.) were considered as alternative bypasses to higher energy densities. These efforts have encountered various challenges, with electrolytes being the most frequent obstacles. Replacing non-aqueous solvents with water could bring significant benefits in both safety and environmental friendliness, but nonetheless increasing some of the challenges for the efforts to increase energy densities. One such conspicuous challenges has been the electrochemical stability window of water. This talk will summarize our recent efforts in this direction, and the various high voltage aqueous beyond Li-ion chemistries thus enabled.

Designing Safer Electrode Materials Using Coupled High Throughput Ab Intio Calculations and Experimental Characterization Maxim Makeev1, Sourav Ghosh2, Vilas G. Pol2 and Nav Nidhi Rajput1; 1Tufts University, United States; 2Purdue University, United States

Developing sustainable and safe energy storage devices is inherently a materials problem, which requires design of optimal electrode and electrolyte materials, alike. The aspects of the problem related to design and development of novel materials for energy storage have been and remain to be of utmost importance. In the Materials Science domain, a serious consideration is given to potential application of organic materials in energy storage devices, including – but not limited to – batteries. Also, recently, sodium-ion batteries (SIB) have attracted much attention as a cheap alternative to their conventional lithium-based counterparts. For SIBs, various carbon-based anode materials have been under intense scrutiny, aimed at finding a solution with improved electrochemical performance and cycle life [1]. While significant benefits of such a paradigm shift is evident, a number of materials-related problems still remain to be solved. Thus, it is well realized by now that sodium-based batteries require a different set of materials to be used in battery architectures than their conventional counterparts, with organic materials being regarded as promising possible solution [2]. In this work, we focus on sodium terephthalate (Na2C8H2O4) as a material for electrodes, as it offers high flexibility in design and has been previously shown to be a good candidate for sodium-based batteries. It has also been noticed, however, that electron conductivity of the compound is below the desirable limit. Correspondingly, the purpose of the theoretical part of the present work is to understand the electronic properties of sodium terephthalate-based matrices and their response to intercalation of different types of ions. Within the framework, we restrict ourselves to three types of ions: sodium, lithium, and potassium. The comparative analysis of the structural and electronic properties of sodium terephthalate during sequential intercalation of ions of the three above types will be presented. The electronic structure calculations have been performed on both single molecule and unit cells of Na2C8H2O4 crystalline phase with periodic boundary conditions. All the computations, reported in this study, have been performed with high throughput screening paradigms; the method and its extensions developed for this work will be highlighted in the presentation [3]. The obtained theoretical results will be presented, discussed, and analyzed in the context of experimental data obtained on sodium terephthalate. This includes structural analysis performed using both XRD and SEM, and electrochemical characterization of lithium, sodium, and potassium ion batteries performance.

Humidity-Induced Degradation and Surface Reconstruction of Ni-Rich Layered Oxides Leiting Zhang1, Christoph Bolli1, Heino Sommer2, Petr Novák1 and Sigita Trabesinger1; 1Paul Scherrer Institut, Switzerland; 2BASF SE, Germany

There is a pressing need for improving the energy density and lowering the cost for next-generation Li-ion batteries. Ni-rich layered oxides, in a general term of Li(Ni\textsubscript{x}Co\textsubscript{y}Mn\textsubscript{1-x-y})O\textsubscript{2} (x > 0.5), are widely recognized as a competitive candidates. However, the high surface reactivity of the materials results in parasitic side reactions in contact with electrolyte and notable gas release when the cell is charged to higher potentials. Furthermore, the oxygen-loss leads to formation of a MO\textsubscript{x} spinel/rock-salt-like phase on the surface of the pristine material, accounting for significant internal resistance growth and, hence, quick capacity loss.
In this study, we embarked on a systematic investigation of the moisture-sensitivity of the LiNi_{0.85}Co_{0.1}Mn_{0.05}O_{2} material by aging it in a controlled environment with constant relative humidity (RH) of 63 % for different periods of time. Online electrochemical mass spectrometry (OEMS) was used as a main tool to investigate the gas release behavior of the aged samples. A thorough understanding of the interfacial degradation phenomena was gained by additional electrochemical and physiochemical characterization, such as experiments with isotopically-labelled electrolyte, surface carbonate titration, X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). A reaction scheme accounting for the origin of CO_{2} evolution will also be elucidated.

Enhancing the Structural and Li Transport Properties of Li_{4-2x}Fe_{x}SiO_{4} via Composition Engineering Yan Zeng¹, Karim Zaghib² and George P. Demopoulos¹; ¹McGill University, Canada; ²Hydro Québec, Canada

Compositional engineering can serve as an effective strategy to tune the electronic and crystal structures of intercalation compounds, hence enhancing their electrochemical properties. The recent development in advanced Li-rich layered oxides has shown the benefits of non-stoichiometry particularly in enhancing the energy density of Li-ion cathodes. We apply this strategy in improving another type of cathode material, Li_{2}FeSiO_{4}, which although possesses attractive properties in terms of safety and sustainability, has been suffering from low electronic and ionic conductivities and the difficulty in utilizing more than one Li-capacity per formula unit. We synthesized non-stoichiometric compounds Li_{4-2x}Fe_{x}SiO_{4}, in two directions– Li-rich and Fe-rich, via a hydrothermal method. X-ray diffraction with Rietveld refinements and elemental analyses reveal that there are solubility limitations to the extent of non-stoichiometry that can be sustained in Li_{2}FeSiO_{4} synthesized at 200°C. We demonstrate that Fe-rich Li_{2}FeSiO_{4} not only delivers higher capacity vis-à-vis the stoichiometric composition because of the higher Fe content but also shows promises in facilitating electronic and ionic transport. An evaluation integrating the experimental electrochemistry tests, including Cyclic Voltammetry (CV) and Galvanostatic Intermittent Titration Technique (GITT), with \textit{ab initio} DFT calculations suggests that the enhanced electrochemical performance is mainly attributed to the new Fe–O–Fe configurations and the pre-existing Li-vacancies.

Acknowledgments: This research is supported by a Hydro-Quebec/NSERC CRD grant and the McGill Sustainability Systems Initiative (MSSI).

Rational Design of Cathode Materials Operated by Anionic Redox Reactions for Advanced Sodium-Ion Batteries Duho Kim; Kyung Hee University, Korea (the Republic of)

In recent years, sodium-ion batteries (SIBs) have been identified as the most promising alternative to lithium-ion batteries (LIBs) owing to the low-cost and abundance of sodium resources. Therefore, numerous efforts have been invested in the development of SIBs for large-scale energy storage applications. Among various cathodes, Mn-based layered oxides have been considered to be promising materials to achieve high-energy-density cathodes owing to their low cost, abundance, and eco-friendliness. Considering the fact that the standard redox potential of Na/Na^{+} is lower than that of Li/Li^{+} (by ~0.3 V), many research groups have focused on the introduction of different transition metals (M) or non-M atoms with varying compositions in Mn-based layered oxides in order to gain high-redox-potential. Recently, anionic redox reactions have attracted great attention due to their potential to improve energy density of battery cathode materials for LIBs and SIBs. These anionic redox reactions have been considered to be a more crucial factor to overcome the limitation of energy density for SIBs than those for LIBs because the anion-based redox behavior induced by the pure lattice oxygen (O_{2}/O^{2-}) occur at a high-voltage of 4.2 V versus Na/Na^{+}. However, the only anion-based redox mechanism leads to structural instabilities resulting in severe phase separations and chemomechanical stresses, which reflect significant irreversibility in the first cycle, capacity and
voltage fading upon cycling. In this talk, we in detail present that Na[Li\textsubscript{1/3}Mn\textsubscript{2/3}]O\textsubscript{2} is rationally designed as an example of a new class of promising cathode materials through a fundamental understanding of the redox reaction mechanism in Li\textsubscript{3}MnO\textsubscript{3} exhibiting a high redox potential of ~4.2 V versus Na/Na\textsuperscript{+} with high charge capacity (190 mAh g\textsuperscript{-1}). In spite of the rigorously designed Na[Li\textsubscript{1/3}Mn\textsubscript{2/3}]O\textsubscript{2} utilizing the anionic redox of O 2p-electron of Na-O-Li configuration, two major challenges regarded as the phase separation and the chemomechanical stress remain to improve the electrochemical performance. Herein, we propose the rational use of anion-based redox reactions to mitigate the two drawbacks and attain high-energy-density cathodes with cyclic stability for SIBs, which enables the development of rechargeable sodium battery materials for high-energy-density.

Unsuitable Electrolytes Made Suitable for Li-O\textsubscript{2} Batteries with the Use of Redox Mediators Nuria Garcia-Araez, J. Padmanabhan Vivek, Tom Homewood, James Frith and John Owen; University of Southampton, United Kingdom

Redox mediators have demonstrated dramatic improvements in performance of Li-O\textsubscript{2} batteries. However, degradation reactions triggered by reactive intermediates in the oxygen reduction and evolution reactions (singlet oxygen, superoxide, etc.) are still the main cause of poor performance. This talk specifically addresses the development of redox mediators to prevent Li-O\textsubscript{2} battery degradation. The synergetic combination of redox mediators with water is shown to produce step change improvements in all performance metrics [1], which is attributed to an alteration of the reaction mechanism bypassing problematic reaction intermediates. In further work, a new type of inorganic redox mediator, polyoxometalates, is shown to exhibit high catalytic activity towards Li-O\textsubscript{2} battery reactions and unprecedented resistance against degradation [2]. In addition, redox mediators are also used to suppress the degradation of electrolytes in such a way that unsuitable electrolytes (e.g. prone to degradation by the attack of superoxide species) are transformed into suitable electrolyte candidates for Li-O\textsubscript{2} battery applications [3].

Is Nickel Hydroxide Charging Only Skin Deep? Joseph H. Hadden, D. Jason Riley and Mary P. Ryan; Imperial College London, United Kingdom

Renewable energy sources, which do not continuously produce power, rely on charge storage devices to hold excess energy when supply is high and provide energy when demand is high. Understanding the charging mechanism of energy storage materials is critical for further improving the performance of these devices. This work demonstrates a method of analysing the charging surface layer using time of flight secondary ion mass spectrometry in a model energy storage material, Ni(OH)\textsubscript{2}. Since Ni(OH)\textsubscript{2} exchanges protons with the electrolyte on charging and discharging in alkaline media, deuterated solvents were used to load the charging layer with deuterium, which could then be analysed using a depth profile. Electrodeposited Ni(OH)\textsubscript{2} was initially used, however the density was too low to provide a single flat surface for the reaction. Low melting point paraffin wax was used to fill all pores in the material, preventing electrolyte ingress. The surface was then ground down to allow electrolyte access to the top face of the electrodeposited Ni(OH)\textsubscript{2} only. Time of flight secondary ion mass spectrometry after potential cycling in deuterated aqueous alkaline electrolyte was performed on the samples before and after the wax deposition. It was found that despite an expected substantial deuterium background signal from the wax, a noticeable increase in deuterium was observed after cycling. This increase was proportional to the theoretical 50% exchange per cycle. Measuring the sputter crater depth using AFM allowed the decay with depth to be measured. It was found that the increase in deuterium only occurred over the first 20-30 nm, which agreed well with observations of a charging surface “skin”.

10:45 AM EN02.20.08
Electrostatically Tuned Microdomain Morphology and Phase-Dependent Ion Transport Anisotropy in Single-Ion Conducting Block Copolyelectrolytes

Chenxi Zhai¹, Huanhuan Zhou¹, Teng Gao², Lingling Zhao² and Shangchao Lin³; ¹Florida State University, United States; ²Southeast University, China; ³Shanghai Jiao Tong University, China

Block copolyelectrolytes are solid-state single-ion conductors which phase separate into ubiquitous microdomains to enable both high ion transference number and structural integrity. Ion transport in these charged block copolymers highly depends on the nanoscale microdomain morphology; however, the influence of electrostatic interactions on morphology and ion diffusion pathways in block copolyelectrolytes remains an obscure feature. In this paper, we systematically predict the phase diagram and morphology of diblock copolyelectrolytes using a modified dissipative particle dynamics simulation framework, considering both explicit electrostatic interactions and ion diffusion dynamics. Various experimentally controllable conditions are considered here, including block volume fraction, Flory–Huggins parameter, block charge fraction or ion concentration, and dielectric constant. Boundaries for microphase transitions are identified based on the computed structure factors, mimicking small-angle X-ray scattering patterns. Furthermore, we develop a novel “diffusivity tensor” approach to predict the degree of anisotropy in ion diffusivity along the principal microdomain orientations, which leads to hitherto missing mapping of phase-dependent ion transport properties. Inclusion of ions leads to a significant leftward and upward shift of the phase diagram due to ion-induced excluded volume, increased entropy of mixing, and reduced interfacial tension between dissimilar blocks. Interestingly, we discover that the inverse topology gyroid and cylindrical phases are ideal candidates for solid-state electrolytes in metal-ion batteries. These inverse phases exhibit an optimal combination of high ion conductivity, well-percolated diffusion pathways, and mechanical robustness. Finally, we find that higher dielectric constants can lead to higher ion diffusivity by reducing electrostatic cohesions between the charged block and counterions to facilitate ion diffusion across block microdomain interfaces. This work significantly expands the design space for emerging block copolyelectrolytes and motivates future efforts to explore inverse phases to avoid engineering hurdles of aligning microdomains or removing grain boundaries.

Point Defects in Lithium-Rich Layered Oxides for Energy Storage
William C. Chueh and Peter Csernica; Stanford University, United States

Layered LiₓMO₂₋ₓ (e.g., LiCoO₂) is a key component in lithium-ion batteries and is one of the most utilized nonstoichiometric oxides. The most studied point defect is the Li that occupies the van der Waals gap; its concentration is thoroughly studied as a function of lithium activity through coulometric titration. However, there are several additional point defects that are less investigated. They are: (1) Vₓ cation vacancies, (2) Liₓ/MₓLi antisites, and (3) Vₒ oxygen vacancies. In these oxides, metal vacancies can form by migrating a metal into the van der Waals gap. X-ray and neutron scattering measurements confirmed that introducing metal vacancies can substantially contract neighboring M-O bond length, transforming single bonds to double bonds (i.e., terminal metal oxo ligand). In select local configurations, even the peroxo species (O-O)²⁻ can form. These variations of oxygen bonding leads to dramatic modification of the Li and O redox potentials. Oxygen vacancies also exhibit coupling to other point defects, mainly through partial Schottky disorder. In this talk, I will discuss the characterization of these point defects for M = Ni, Mn, Co, Ru and Ir, their interactions amongst one another, and implications for engineering better lithium-ion batteries.

2:00 PM EN02.21.02
Achieving Superior Interfacial Stability from Well-Designed Artificial Lithium-Metal Interphase with Polymers of Intrinsic Microporosity
Hyun Jong Kim, Moon G. Hyeon, Dong Jae Chung, Hyun Dong Yoo, Hansu Kim and Yong Soo Kang; Hanyang University, Korea (the Republic of)
Li metal has been in the spotlight as the most promising anode material because it has the highest specific capacity and the lowest working potential. However, including fast capacity fading and dendrite formation derived from their high reactivity still remain challenges for practical application. In this work, we have investigated the artificial solid interphase with polymers of intrinsic microporosity which improving electrochemical performance and the associated morphological changes by various analytical techniques as well as electrochemical characterization techniques. As a result, we found a desolvation effect of electrolyte through the PIM-1 coating, thereby forming the uniform and stable lithium deposition during cycling. Adopting a highly stable artificial solid interphase with polymers of intrinsic microporosity can improve interfacial stability and electrochemical characteristics of lithium metal battery, encouraging the development of lithium metal-based rechargeable batteries.

2:15 PM EN02.21.03
Impact of Liquid Phase Formation on Microstructure and Conductivity of Li-Stabilized Na-β"'-Alumina Ceramics Marie-Claude Bay, Meike V. Heinz and Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Ceramic Na-β"'-alumina is a fast solid-state sodium-ion conductor deployed as electrolyte in commercial high-temperature NaNiCl and NaS batteries (0.2 S/cm at 300 °C). Furthermore, it is gaining attention as interesting candidate for all-solid-state batteries (1 mS/cm at room temperature). Processing of Na-β"'-alumina is, however, challenging and results in large variations in reported values for the ionic conductivity. We systematically reexamine the impact of sintering conditions on microstructure and sodium-ion conductivity of Na-β"'-alumina ceramics.[1] Depending on sintering temperature and sintering time, we measure conductivities between 0.04 and 0.37 S/cm at 300 °C on ceramics prepared from identical starting powders. During sintering, formation of a liquid phase is observed above 1500 °C, which promotes densification, but leads to abnormal grain growth for extended sintering times. While such conditions result in the highest conductivities measured for our sample series (0.37 S/cm at 300 °C), the corresponding microstructures are mechanically fragile. For mechanically robust, densely sintered samples, we identify the average grain size as the dominating factor controlling ion conductivity. For average grain sizes between 1 and 6 μm, we obtain conductivities between 0.17 and 0.27 S/cm at 300 °C. The influence of porosity in under-sintered, highly porous samples is well accounted for by Archie’s law and results in low ion conductivities down to 0.04 S/cm at 68% density. Our insights into microstructural factors controlling ionic conductivity such as grain size and density are instrumental for the successful integration of Na-β"'-alumina ceramic electrolytes into next-generation batteries.

2:30 PM EN02.21.04
Lithiated Lithiophilic (Li,Si) Layer Induced Li Host Materials for Next Generation High-Energy Li-Metal Batteries YoonKwang Lee and Jaephil Cho; UNIST, Korea (the Republic of)

Li-ion battery application has been simultaneously widened with the development of portable devices. In particular, high volumetric/gravimetric energy density LiB has attracted attention due to increasing demands for mass energy storage devices such as electric vehicles and Energy Storage System. Li metal has been reinspired as next generation preeminent promising anode materials because extensive researches of high-energy silicon anodes to commercialize it was insufficient to substitute graphite in terms of cycle stability. Li metal facilitates extremely high specific capacity (3860 mAh/g) and lowest electrochemical potential (~3.04 V) that it features its high power and energy density. However, the use LMB was hindered from severe safety issues related to volume expansion from non-uniform deposition, uncontrollable dendrite growth and crack induced repeated SEI formation. The above-mentioned reasons cause electrolyte consumption, low Coulombic efficiency, resulting in capacity deterioration and, more seriously internal short circuits and explosion. Regulating Li plating and suppression of Li dendrites should be realized to solve the problems.

In this study, we synthesized ion and electron conductive carbon structure, which contains sufficient space to accommodate Li during plating and striping. Li is intensely light metal denoting 0.534 g/cm³ density that the required dense lithium thickness is 14.6 μm for commercializable areal capacity (≥3 mAh/cm²). The interconnected porous structure containing 200 nm pore and showing 0.2 g/cm³ tap density takes merits in expanded potentious area
for Li deposition. To incorporate lithiophilic surface layer, thermal decomposed artificial interfacial Si nano-layer was deposited uniformly with 5 nm. The lithiophilic lithiated Si (LixSi) alleviated the polarization that it could induce planar Li nucleation and continuous Li accumulation at inner pore and outer surface region, followed by dense and smooth Li plating in electrode. The volume expansion of the electrode at lithiated state of 3 mAh/cm² was just 30% from 27 um to 35 um because of the adequate pore volume. And lithiophilic layer induced electrode exhibited prolonged lifespan and high power performances at high current density comparing to solely carbon frame.

2:45 PM EN02.21.05
Role of Solid Electrolyte Interphase in Sodium Electrodeposition Revealed through Liquid Cell Electron Microscopy Zhiyuan Zeng; City University of Hong Kong, Hong Kong

Solid-electrolyte interphase (SEI) plays a vital role in the performance of an electrochemical device, such as batteries and capacitors. Much progress has been made in the understanding of SEI formed on lithium metal, however little information is available on sodium SEI. Here, we report an in situ study of Na deposition with our development of electrochemical liquid cells, in which the electrodes within a cell are patterned in different configurations to produce a flat or sharp curvature. Real time observation using transmission electron microscopy (TEM) reveals an unprecedented level of detail on Na electrodeposition. The Na deposition shows granular growth. Variations in the SEI thickness on a Na nanograin introduce differences in the local growth rate and disparities in the morphology. The newly formed Na grains preferentially deposit at the base of existing grains close to the electrode. Such “base growth” behavior is more dramatic on the electrode with sharper curvature. Further studies using continuum-based computational modeling show the deposition behavior of an alkali metal is strongly influenced by the transport properties of SEI, thus the growth mode, either “tip growth” or “base growth”. Our direct observation of Na deposition in combination with the theoretical modeling provides critical insights for comprehensive understanding of SEI effects on the electrochemical deposition of an alkali metal.

Bioinspired Energy Storage Devices  Magdalena Titirici; Imperial College London, United Kingdom

Building a healthy and wealthy society fuelled by clean energy is the most important challenge of the 21st Century. New energy technologies rely heavily on materials, while materials production relies on energy. It is crucial we will address the fine balance between the development of emerging energy technologies and the materials we use to build them. Today, scarce metals are the most important components of energy storage and conversion systems. The current available supply for these metals cannot sustain the expansion of such technologies at a global scale. Sustainability means avoiding the depletion of natural resources to maintain an ecological balance. Sustainable development means meeting the needs of the present without compromising the well-being of future generations. Based on these definitions, the approaches we currently use to build renewable energy technologies are not sustainable, as we rely on materials choices that are limited and geographically constrained. We need to learn from past mistakes made with fossil fuels to build a future society based on clean energy. In this talk I will present new concept is making and manufacturing sustainable materials and their assembly into energy storage devices which are flexible, self-healing and compostable.

9:00 AM EN03.01.02
A Biomass-Derived Polyhydroxyalkanoate Biopolymer as Safe and Environmental-Friendly Skeleton in Highly Efficient Gel Electrolytes for Lithium Batteries Eliana Quartarone1, Piercarlo Mustarelli2, Davide Ravelli1 and Chiara Samorì3; 1University of Pavia, Italy; 2University of Milano-Bicocca, Italy; 3University of Bologna, Italy

The massive use of lithium batteries in industries, such as automotive and electrical network accumulation, requires the development of safer electrolytes, economic and possibly made from renewable resources using eco-friendly processes. In this work, we reported the synthesis and the physico-chemical and functional characterization of a polymer gel electrolyte (GPE) based on a skeleton of polyhydroxyalcanoate obtained from biomass by means of an easy and environmentally friendly chemical process. The GPE has an ionic conductivity of 0.8 mS cm\(^{-1}\) at room temperature, is thermally stable up to over 100°C and is not flammable. The electrochemical stability window is higher than 5V. The cell Li/GPE/LiFePO4 shows specific capacity of 100 mAhg\(^{-1}\) at 3C with 100% coulombic efficiency. These results demonstrate that the GPE based on polyhydroxyalcanoate is very promising for use in lithium batteries of high power density.

9:15 AM EN03.01.03
3D Architected Li\(_2\)S Composites Fabricated via Emulsion Stereolithography Max Saccone and Julia R. Greer; California Institute of Technology, United States

Additive manufacturing is a promising route towards the development of mechanically resilient 3D electrodes with complex architectures, high active material loadings, and large areal capacities relative to conventional 2D film electrodes. These types of processes for fabricating lithium-sulfur (Li-S) cathode materials are beginning to be explored; currently only extrusion methods have been reported, which are limited in resolution to >150 µm and offer limited control over the final morphology and microstructure of the printed material\(^1,2\).

We report an additive manufacturing process which enables fabrication of 3D architected lithium sulfide (Li\(_2\)S) carbon composite cathodes for Li-S batteries via digital light processing stereolithography and subsequent pyrolysis. The composites have feature sizes of ~50 µm and are comprised of a porous glassy carbon matrix containing crystalline Li\(_2\)S deposits within the pores. We 3D print porous polymer composites using water-in-oil emulsions of aqueous lithium sulfate dispersed in a UV-curable photopolymer resin. Pyrolysis converts the porous polymer matrix to glassy carbon and the lithium sulfate deposited within the pores to lithium sulfide via carothermal
reduction. We investigate the effects of surfactant concentration and emulsion composition on pore size, pore connectivity, and Li$_2$S morphology via SEM image analysis and show that pore size and Li$_2$S crystal size can vary from ~10 nm to ~5 µm and are related to the size of aqueous domains in the emulsion. We also report the effects of cathode architecture and microstructure on battery cycling performance and mechanical properties and discuss general design considerations for 3D structured electrodes.

**MXenes—From Active Material to Passive Components for Electrochemical Energy Storage** Xuehang Wang, Narendra Kurra and Yury Gogotsi; Drexel University, United States

MXenes are an emerging large family of two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides, that were discovered at Drexel in 2011 and have become versatile materials due to a combination of hydrophilicity and metallic conductivity. About 30 different MXenes have been experimentally synthesized already. Many more MXene compositions and their properties have been predicted computationally. Given their compositional diversity, tunable surface chemistry, existence of various ordered structures and solid solutions, MXenes may well be the largest family of 2D materials known to date. MXenes are usually produced by top-down synthesis, namely wet chemical extraction of ‘A’ atomic layers from the layered ternary carbide precursors, such as MAX phases. The resulting MXenes with surface terminations (-O, -F, -OH) impart negative surface charges, key for stable MXene dispersions in water and organic solvents which enable solution processing to ease the design of electrode architectures.

The available for intercalation 2D gallery spaces, accessible redox sites at the transition metal oxide-like surface, and metallic conductivity make MXenes promising as potential candidate materials for high rate capacitive energy storage applications. The ability of MXenes to intercalate a variety of cations while promoting fast charge transfer rates, expanding their widespread usage in a variety of electrochemical energy storage applications including hybrid metal-ion capacitors and battery applications. Besides the role of active charge storage matrix, MXenes have been explored as passive component in the form of current collectors and functional binders for designing degradable green electrochemical energy storage devices. Given the high electrical conductivity of titanium carbide MXene (beyond 10,000 S/cm), it was employed as current collector, replacing metal in fabrication of microsupercapacitors and hybrid energy storage devices. Functionalized surfaces of MXenes have shown the ability for binding carbon, silicon particles and organic systems, playing a role of conductive binder, replacing fluorinated polymers and improving the mechanical and electrochemical stability of the electrodes. Titanium carbide MXenes and also degradable in the environment, producing just titania and carbon dioxide and allowing development of green electrochemical energy storage devices.

10:30 AM *EN03.01.05*
**Coupling Energy Capture and Storage—Endeavoring to Make a Solar Battery** Deepa Khushalani; Tata Inst of Fundamental Research, India

Storage of solar radiation is currently accomplished by coupling two separate devices, one that captures and converts the energy into an electrical impulse (a photovoltaic cell) and another that stores this electrical output (a battery or a supercapacitor electrochemical cell). This configuration however has several challenges that stem from a complex coupled-device architecture and multiple interfaces through which charge transfer has to occur. As such presented here is a scheme whereby solar energy capture and storage have been coupled using a single bi-functional material. Two electroactive semiconductors BiVO$_4$ (n-type) and Co$_3$O$_4$ (p-type) have been separately evaluated exclusively for their energy storage capability in the presence and absence of visible radiation. Each of these have the capability to function as a light harvester and also they have faradaic capability. An unprecedented aspect has been observed in that upon photo-illumination of either of these semiconductors, *in situ* charge carriers being generated play a pivotal role in perturbing the electroactivity of the redox species such that the majority charge carriers, *viz.* electrons in BiVO$_4$ and holes in Co$_3$O$_4$, influence the redox response in a disproportionate manner. More importantly, there is an
enhancement of ca. 30% in the discharge capacity of BiVO₄ in the presence of light and this directly provides a unique route to augment charge storage during illumination.

10:45 AM EN03.01.06
Artificial Neuron Network Assisted On-Demand Device-Level Design of Graphene Membrane-Based Supercapacitors Longbing Qu, Dan Li and Zhe (Jefferson) Liu; The University of Melbourne, Australia

Supercapacitors, also called electrochemical double layer capacitors (EDLCs), store and deliver energy through ion adsorption/desorption at the electrical double layers. They have attracted intensive attention in the energy storage field in light of their fast charging capability, high power density, and long-life span. The low volumetric energy density (amount of energy stored per unit volume) is a crucial drawback index for impeding the broad application of EDLCs. The strategies used to increase EDLC energy density include developing new capacitive materials, applying high working voltage electrolytes, and designing asymmetric supercapacitors. The main task is thus to optimally match suitable positive and negative active materials with selected electrolyte. However, the optimal design of supercapacitors on device-level is still a tremendous challenge because of the high dimensional design space consisting of pore size (or packing density) and thickness of both electrodes, working voltage, and operation charging rate.

In this work, we will present that utilizing an artificial neuron network (ANN) can successfully establish the quantitative structure-property relation of supercapacitor electrodes and thus efficiently guide the supercapacitor device design. We adopted the tunable chemically converted graphene membrane (CCGM) as a suitable experimental platform with the standard KCl (1M) electrolyte. Using the capillary compression technique developed in our group, we tuned the pore size of CCGM from 1.7 down to 0.8 nm. The thickness of the electrodes was varied from 11 to 276 um. We did about 200 separated experiments to measure the capacitance of electrodes with different thickness and pore size under different charging rates. The obtained experimental database was used to train the ANN. Then, we apply the well-trained ANN model to predict the capacitance of positive and negative electrodes with various electrode structures, establishing a comprehensive and continuous quantitative relationship between CCGM structure and capacitance of both electrodes. After that, the numerical method was applied to explore the high dimensional design space modeled by ANN for the optimized matching of positive and negative electrodes on device-level. The results indicate that there are more than 1 million matching combinations for positive and negative electrodes that meet the general design rules. This result shows that it is an extremely complicated task for optimized supercapacitor design based on a conventional method. We then carried out experiments to successfully confirm the validity of our optimized supercapacitor device design. In the optimal device designs, the positive and negative electrode structures, including pore size and thickness, are hard to determine quantitatively from conventional trial-and-error experiments. Besides, the optimal designs depend on the charging rate. Our method provides a general solution to design CCGM based supercapacitor devices under different charging conditions. Our study indicates that the machine learning method offers computer models an ability to learn from the experiment database and make a reliable prediction of electrode capacitance, enabling the on-demand quantitative device-level supercapacitor design for practical applications.

11:00 AM EN03.01.07
Challenges and Opportunities for Thick Electrode Batteries and Supercapacitors Chaoji Chen and Liangbing Hu; University of Maryland College Park, United States

The fast growing demand of portable electronics and electric vehicles has driven the rapid development of rechargeable batteries and supercapacitors in the past forty years. Energy storage devices with higher energy density is desirable for a longer using time or driving range. In pursue of higher energy density, tremendous efforts have been made in the past few decades, mainly via the developing of novel battery chemistries and/or structural engineering. Battery structural engineering is able to improve the energy density of the energy storage devices via optimizing the configurations of electrode and/or battery architecture yet without changing the electrode chemistry, representing a promising direction towards high-energy battery and supercapacitor development. One most attractive battery structural engineering strategy is thick electrode design that is able to increase the ratio of active material and reduce the manufacturing cost by reducing the use of nonactive components in batteries (e.g., current collector, separator, binder, packaging material, electrolyte, etc.). Given the opportunities thick electrode design offered, intensive efforts from the energy storage community have been dedicated, and great progresses have been made recently. However, constructing thick electrode still faces several challenges, including the delamination of electrode slurry from metal current collector during the drying process, scalable manufacturing, and the sluggish
charge kinetics.

To address these challenges, Hu’s group has developed several strategies in constructing better thick electrodes for high-energy batteries and supercapacitors. One strategy is constructing three-dimensional (3D) conductive framework with low-tortuosity pores via direct carbonization of natural wood, where various active electrode materials (e.g., lithium iron phosphate, sulfur, manganese dioxide cathode, lithium metal, porous carbon anode) can be infiltrated or deposited with high active material mass loadings [1-3]. To maintain the mechanical robustness of wood, a new strategy was developed to convert natural wood into flexible wood electrode via partial delignification and multiple coating processes, where carbonization is avoided [4]. A cellulose based densified 3D electrode structure was also proposed via conformal coating of carbon black particles on each cellulose nanofiber to impart decoupled pathways for the fast transport of ions and electrons, followed by active material incorporation into the conductive framework and mechanical compression [5]. We will discuss these progresses in thick electrode development from our lab, challenges, and future research opportunities in this field.

Biomass Derived Hard Carbon as Sodium-Ion Battery Anode Arka Saha, Rosy Sharma, Malachi Noked and Gilbert D. Nessim; Bar Ilan University, Israel

In the last few years, sodium-ion batteries (SIBs) emerged as an economical, high energy alternative to lithium-ion batteries (LIBs) for large-scale energy storage applications. Nevertheless, even after a decade of research, the anode remains the biggest challenge towards its practical applications. Consequently, for acquiring higher energy density, superior power performances, and meaningfully prolonged stability from SIBs, we need a stable, efficient and cost-effective anode material.

Here, in our proposed research work, we utilized a variety of biomass waste like fruit peels, rice husk, etc. as a precursor to synthesize some new carbon- electrode materials for their application in SIB. The carbon materials were synthesis through H3PO4 acid treatment of the dried powdered biomass materials accompanied by washing and annealing at 900 °C at Ar atmosphere. The synthesized material exhibited a capacity as high as ~180 mAh/g. To further improve the electrochemical behavior of the material, we exploited different percentages of hetero-atom and found that if doping percentages are carefully optimized, they can, not only help in mitigating the material instability but also leads to significant improvement in rate performance. We further characterized the surface of the carbon material with high-resolution scanning electron microscopy, X-ray diffraction, and Raman spectroscopy before and after cycling to investigate the structural stability. We believe that the results presented herein opens a promising direction to exploit the bio-waste as precursors to fabricate carbon materials with promising electrochemical activity.

SiC Passivation Layer for Scalable One-Pot Hollow Nanostructured Si-Based Anodes Seungkyu Park and
Silicon has been considered as the most promising alternative for the conventional graphite anode in lithium-ion batteries, due to its high gravimetric capacity. There are tremendous approaches to alleviate the large volume change considered as the main reason of cycle degradation upon repeated alloying reaction. In particular, hollow nano-structure is one of feasible approach, in that free volume in hollow type of structure produces sufficient space to accommodate the large volume change stemming from alloying reaction. Nevertheless, fabrication procedure, involving toxic reagents and complicated reactions for removing sacrificial template hinders the commercial utilization. Here in, we develop technique enabling to synthesize silicon anodes with various morphologies such as sheet, tube and hollow typed-structure without any toxic reagents and complex reactions. In this technique, SiC$_x$ layer in which Si nanoparticles embedded in SiC passivation matrix acting as strong protection against oxidation, was coated on the carbonaceous templates (spherical, sheet and rod types) and etched via scalable one-pot thermal decomposition method using SiH$_4$, C$_2$H$_4$ and Air. Surprisingly, a few Si nanoparticles produced the silicon oxide even over 800°C owing to SiC passivation matrix. As a results, electrodes fabricated such anodes effectively alleviate large volume changes without pulverization during cycling with 100 cycle retention of 92%. In addition, it performs excellent initial coulombic efficiency compared with the previously reported Si hollow nanostructure. Specifically, SiC hollow nano-structure shows the high initial discharge capacity of 1862 mAh g$^{-1}$ with initial coulombic efficiency of 90.1%.

**SESSION EN03.02: Green Electrochemical Energy Storage Solutions—Materials, Processes and Devices II**

**3D Microsupercapacitors with High Areal Energy Density** Daniel Guay$^1$, Anais Ferris$^{1,2}$, David Bourrier$^2$, Sébastien Garbarino$^1$ and David Pech$^2$; $^1$INRS, Canada; $^2$LAAS-CNRS, France

The increasing need for onboard energy supply/storage in wearable electronics, wireless sensor networks, and the upcoming Internet of Things has pushed for the miniaturization of technologies, including energy harvesting and energy storage units that could be integrated directly onto microchips to achieve energy self-sufficiency. In this context, microsupercapacitors have attracted considerable attention for their use in various emerging micropower applications. A microsupercapacitor is a miniaturized supercapacitor that can be directly mounted on a chip to power integrated circuits. These small electrochemical energy storage devices are characterized by high power and excellent cyclability. However, they have moderate energy density because they rely on a charge storage mechanisms based on interfacial reactions. In order to improve their capacitance and energetic performances while maintaining reduced footprint, more active and accessible materials have to be loaded per unit area of the electrode. This can be obtained by designing 3D electrodes with high surface-to-volume ratio that achieves charge storage over an extended surface, thereby decoupling the direct relationship between power and energy density. Various strategies exist to fabricate these 3D nano-architected electrodes and they will be reviewed, with a special focus on disordered 3D architecture that has received increasing interest in recent years due to the impressive results obtained using this paradigm shift. These disordered 3D nano-architected electrodes rely on the deposition of pseudocapacitive materials, known for their large specific capacitance, onto a disordered 3D high-surface-area conductive support. The areal capacitance is improved from one to three orders of magnitude compared to the planar geometry.

**2:00 PM EN03.02.02**

**A 2 V Class Aqueous Sodium-Ion Battery with Low-Temperature Cycling Capabilities** David Reber$^{1,2}$, Ruben-Simon Kühl$^1$ and Corsin Battaglia$^1$; $^1$Empa, Swiss Federal Laboratories for Materials Science and Technology, Switzerland; $^2$École Polytechnique Fédérale de Lausanne, Switzerland

Rechargeable sodium-ion batteries based on non-flammable aqueous electrolytes are promising for large-scale energy storage for grid applications. Recently we reported a highly-concentrated 35 molal aqueous sodium
bis(fluorosulfonyl)imide (NaFSI) electrolyte with an extended stability window of 2.6 V on stainless steel current collectors.[1] However, such highly concentrated systems, often referred to as water-in-salt electrolytes, tend to crystallize already near room temperature, resulting in cell failure. Here, we report a ternary 25m NaFSI + 10m NaFTFSI electrolyte, which is kinetically robust against crystallization and allows long term cycling even at -10 °C. We show that the asymmetry of the FTFSI anion is crucial for efficiently suppressing crystallization in such supercooled electrolytes.[2] Taking into account the raw materials supply chain as an important challenge for scaling, we developed a 2 V class aqueous sodium-ion battery employing abundant raw materials, namely NaTi2(PO4)3 and Na3(VOPO4)2F on the anode and cathode side, respectively. With 64 Wh kg⁻¹, based on the masses of active materials of both electrodes, this battery displays an energy density that is almost twice as high as that of previously reported aqueous sodium-ion batteries. The cell displays excellent cycling stability at 30 °C with a capacity retention of 85% after 100 cycles at C/5 and 77% after 500 cycles at 1C. At -10 °C, we obtain a capacity retention of 74% after 500 cycles at C/5.

References:

In recent years, significant attention has been paid to the development of micro-devices as innovative energy storage solutions. For instance micro-sensor networks such as sensors actuators or implantable medical devices require power densities and cyclability that are several orders of magnitude higher than those of conventional Lithium-Ion batteries. For such applications, µSCs, a developing novel class of micro/nanoscale power source are rising alternatives, and their integration “on-chip” could allow significant innovations to emerge [1]. Therefore, a great deal of attention has been focused on µSCs, for which large series of nanostructured active materials have been developed.

In this work we focused to increasing the stability and the energy performance of the supercapacitors based on silicon nanostructures electrodes (nanowires and nanotrees) and in same time used safety and green electrolytes (aqueous) without lithium and ionic liquids. The nanostructures were grown by chemical vapor deposition (CVD) through a vapor-liquid-solid (VLS) process and take here advantage of a substantial increase of the developed surface of the electrode while structured at the nanoscale [2-4]. We realized a new nanocomposites electrodes based on silicon nanostructures/ protected nanometric layer/ electronic conducting polymer. This nanocomposite electrode is a real important lever for improving performance in terms of energy density and durability of devices that becomes possible via Atomic Layer Deposition (ALD) layers of Alumina [5]. We have demonstrated a clear gains of a layer of alumina of less than four nanometers which makes it possible to reach cyclability greater than 8 million cycles and retentions of capacities close to 100%. In addition, the first key steps in the process of producing flexible composite electrodes (Si nanowires / Al2O3 / conductive polymers) have recently been successfully completed. Thus a remarkably simple deposition of PEDOT-PSS by drop-casting of an aqueous solution of commercial polymer was used. Despite the poor control over the thickness of the deposit, the gravimetric performances proved to be excellent with a low capacity retention of 95% over 500 000 cycles for an initial gravimetric capacity 8.5 F. g⁻¹ and specific energies and powers of 8.2 mJ.cm⁻² and of 4.1 mW.cm⁻². Such cycling stability for a polymer-based nanocomposite in aqueous media combined with first-order electrochemical storage performance is unprecedented in the literature [6].
2:30 PM BREAK

Nanocellulose Enabled Green Electrochemical Energy Storage Solutions Liangbing Hu; University of Maryland, United States

I will start by giving an overview of our work on assembly and functionalization strategies of nanocellulose aimed at specific properties, with an eye toward high impact applications including energy, electronics, building materials and water treatment, including nanomanufacturing and light management in transparent nanopaper for optoelectronics (as a replacement of plastics); mechanical properties of densely packed nanocellulose for lightweight structural materials (replacement of steel, Nature 2018); artificial tree for high-performance water desalination and solar steam generations; and radiation cooling (Science, 2019).

I will then focus on our work on applying nanocellulose/wood as building blocks for advanced energy devices, including flexible, thick battery electrodes with nanocellulose binder, three-dimensional carbon derived from wood for advanced batteries (replacement of metal current collectors for beyond Li-ion batteries); nano-ionic membranes for thermoelectrics (Nature Materials, 2019).

3:30 PM EN03.02.05
Li-Ion Capacitors and Li-Ion Battery/Capacitor Hybrid Energy Storage Devices Jim P. Zheng; FAMU-FSU College of Engineering, United States

As a new generation of supercapacitor, the Li-ion capacitor (LIC) is an advanced energy storage device which consists of an electric double-layer capacitor (EDLC) cathode and a pre-lithiated anode [1,2], between which the ions shuttle during charge and discharge processes. The LIC cell not only retains all the advantages of EDLC such as high specific power >10 kW/kg and long cycle life >100,000 cycles, but also exhibits a higher specific energy of 15-25 Wh/kg and a higher maximum cell voltage than that of the EDLC [3]. Because of using pre-lithiated and low surface anode materials, the LIC can be charged to a maximum voltage as high as 4.0 V, which is much higher than of EDLCs and comparable to Li-ion batteries (LIBs); therefore, it allows the LIC and LIB to be assembled in one package as a LIB/LIC hybrid energy storage cell.

We have demonstrated a new hybrid energy storage cell that combines the advantages of both the LIB and the LIC [4], thereby avoiding their inherent defects, while bridging the gap between the high energy densities offered by batteries and the high power densities seen in EDLCs. The energy density and power density of the hybrid cell can be designed to meet the requirements by a reasonable distribution of the ratio between LIB and LIC electrode materials in the internal hybrid cell. For example, we show a hybrid LIC consisting of a Li nickel cobalt manganese oxide (NMC)/activated carbon (AC) composite cathode in combination with an ultra-thin Li film (u-Li) pre-loaded hard carbon anode. Additionally, we show that by utilizing three design approaches: dry composite electrode fabrication method, cathode to anode capacity ratio design, and pre-lithiation method using u-Li, we can demonstrate an energy storage device with excellent cycle life, and that can be tailored by composite ratios within the cathode to fit different applications. Shown here is an in-depth look at various composite material ratios, pre-lithiation calculations and hybrid Li-ion battery-capacitor energy storage device creation based on targeting essential energy-power performance characteristics.

References
Emergent green conductive materials are pivotal to reduce harmful and long-lasting electronic waste [1, 2]. At the same time, the electronics industry has demand to transform rigid devices into soft, wearable and conformable structures [2-3]. A first achievement towards flexible and sustainable electronics would be blending biomaterials and conductive nanoparticles to produce electronic components. Following such an approach, we have realized conformable resistors, capacitors and inductors using a fibrous structural protein extracted from bio-waste as a “polymer” matrix for graphene nanoplatelets (GnPs). Furthermore, we have obtained flexible conductors (sheet resistance ≈ 10 Ω/sq) by functionalizing cellulose with bio-based conductive inks made by mixing GnPs with biopolymers and/or natural proteins. These conductive biocomposites were exploited in foldable circuits, passive electrical components (such as filters), organic photovoltaic devices, electromagnetic interference shielding films, portable antennas and electrodiagnostic sensors [2, 4, 5]. The success of conformable and sustainable conductors will simplify the fabrication of easily disposable devices with a low environmental footprint and, simultaneously, support the transition towards flexible electronics.

Towards Electrochemical Synthesis of Cement—An Electrolyzer-Based Process for Decarbonating CaCO3 While Producing Useful Gas Streams Leah Ellis, Andres Badel, Mikki Chiang, Richard Park and Yet-Ming Chiang; Massachusetts Institute of Technology, United States

Cement production is currently the largest single industrial emitter of CO2, accounting for 8% (2.8 Gtons/year) of global CO2 emissions in 2015. Deep decarbonization of cement manufacturing will require remediation of both the CO2 emissions due to the decomposition of CaCO3 to CaO, and that due to combustion of fossil fuels (primarily coal) in the calcining (~900°C) and sintering (~1,450°C) processes. Here, we demonstrate an electrochemical process that uses neutral water electrolysis to produce a pH gradient in which CaCO3 is decarbonated at low pH and Ca(OH)2 is precipitated at neutral to high pH, concurrently producing a high purity O2/CO2 gas mixture (1:2 molar ratio at demonstrated stoichiometric operation) at the anode and H2 at the cathode. We show that the solid Ca(OH)2 product readily decomposes and reacts with SiO2 to form alite, the majority cementitious phase in Portland cement. Our electrochemical calcination approach produces concentrated gas streams from which the CO2 may be readily separated and sequestered, the H2 and/or O2 may be used to generate electric power via fuel cells or combustors, the O2 may be used as a component of oxyfuel in the cement kiln to further lower CO2 and NOx emissions, or the output gases may be used for other value-added processes including liquid fuel production. Analysis shows that in a scenario where the hydrogen produced by the reactor is combusted to heat the high temperature kiln, the electrochemical cement process can be powered solely by renewable electricity.

4:30 PM EN03.02.09
Architectural Design of Fully-Zwitterionic Copolymer Scaffolds for Nonvolatile Ionogel Electrolytes Morgan Taylor, Samuel Lounder, Ayse Asatekin and Matthew Panzer; Tufts University, United States

The strong interactions of zwitterionic polymers with ionic species and their self-assembly have been widely used for drug delivery, hydrogel materials, and membrane selective layer coatings, but little has been done to exploit their potential for electrochemical applications. Recent works within our group have focused on the development of polymer-supported ionogels containing one or more bio-inspired zwitterionic functional groups. By taking
advantage of the unique interactions between zwitterionic moieties and ionic liquid ions, we have developed a new class of ionogels with highly tunable properties that could provide several potential advantages for safer electrochemical devices. An important benefit to utilizing ionic liquids is that they can be recycled due to their nonvolatile nature, leading to the development of more environmentally friendly electrolytes. This presentation will describe the synthesis of fully-zwitterionic (co)polymer scaffolds for fabrication of ionogel electrolytes and reveal the importance of polymer selection and architecture on the observed gel properties. First, random zwitterionic copolymers were prepared in situ via free radical photopolymerization in 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (EMI TFSI). Spectroscopic characterization indicated different degrees of zwitterion/ion interactions and zwitterionic dipole—dipole physical cross-links depending on the zwitterion chemical identity. A wide range of ion transport and mechanical properties were obtained by tuning the copolymer ratio, which highlighted the benefits of combining more than one zwitterion chemistry.[1] Second, fully-zwitterionic ABA triblock copolymers were synthesized using sequential addition with a controlled radical polymerization method. While both polymeric subunits are zwitterionic, a difference in solubility drives copolymer self-assembly in various environments, including ionic liquids, which allows one to fabricate ionogels. Further tuning of the mechanical and ion transport properties of these ionogels can be achieved by changing the zwitterion identities of the polymeric subunits, or by adjusting the block lengths and molar ratio between the two functional groups. Incorporation of bio-inspired zwitterionic moieties in ionic liquid-based electrolytes is still relatively unexplored, and there is much room for additional investigation in order to build a deeper understanding of zwitterion behavior within ionic liquid environments. This work highlights some of the exciting possibilities of careful selection of zwitterion chemical identities and copolymer architectures towards the development of safer materials for electrochemical energy storage.

4:45 PM EN03.02.10
Electrochemistry, Solvation and Local Order in Mixed Cation Acetate-Based Water-in-Salt Electrolytes
Maria Lukatskaya1,2, Hans-Georg Steinrueck2, Christopher J. Takacs2 and Michael F. Toney2; 1ETH Zurich, Switzerland; 2SLAC National Accelerator Laboratory, United States

Electrolytes are an essential component of energy storage devices. Electrolyte composition has a significant impact on the safety, price and performance of the battery. Intrinsically nonflammable aqueous electrolytes can offer safer battery operation and decreased associated toxicity but suffer from a smaller electrochemical stability window (and hence energy density) compared to traditional organic electrolytes. To circumvent the small electrochemical stability window, highly concentrated “water-in-salt”, WIS, lithium organic imide systems which demonstrate significantly wider stability windows were recently proposed.1,2 However, the toxicity often associated with organic imides and high price make the practical implementation of current water-in-salt electrolyte chemistries into commercial energy storage devices challenging.

We address the challenge of developing new formulations of water-in-salt electrolytes caused by the lack of lithium salts having water solubility high enough to satisfy the water-in-salt condition. The proposed mixed cation strategy is whereby cheaper (by at least an order of magnitude) and more soluble salts featuring alkali cations beyond lithium, e.g. potassium acetate, are used to create the water-in-salt condition.3 We study co-dissolution of corresponding lithium and zinc acetate salts, we show that such highly concentrated electrolytes can provide the same benefits of the extended voltage window as imide-based electrolytes and, demonstrate compatibility with traditional Li-ion or Zn-ion battery electrode materials while being low-cost and environmentally benign. In addition, we demonstrate the strong effect of the solution concentration on the solvation structure of the cations and local order in the potassium acetate-based WIS systems and correlate it with the electrochemical response of different Zn-ion and Li-ion-based electrode systems.

SESSION EN03.03: Green Electrochemical Energy Storage Solutions—Materials, Processes and Devices III  
Session Chair: Hongli Zhu  
Tuesday Morning, December 3, 2019  
Sheraton, 2nd Floor, Republic A

8:00 AM *EN03.03.01  
Nanoscale Design for Lithium-Sulfur Batteries Yi Cui; Stanford University, United States

Lithium sulfur (Li-S) batteries have high theoretical specific energy for portable and stationary storage application. Sulfur is an earth abundant materials for potential green energy storage. However, Li-S batteries have many challenging issues at the materials level. Here I will present our recent progress on: 1) Nanoscale materials design for polysulfide binding, encapsulation and activation. 2) Discovery of liquid sulfur behavior at room temperature, leading to new guidance to materials design.

8:30 AM *EN03.03.02  
Sulfur Grafted Hollow Carbon Spheres for Potassium-Ion Battery Anodes David Mitlin; University of Texas at Austin, United States

Sulfur-rich carbons are minimally explored for potassium ion batteries (KIBs). Here, we chemically incorporate a large amount of S (38 wt. %) into a carbon host, creating Sulfur-grafted Hollow Carbon Spheres (SHCS) for KIB anodes. The SHCS architecture provides a combination of nanoscale (ca. 40 nm) diffusion distances and C-S chemical bonding to minimize cycling capacity decay and Coulombic efficiency (CE) loss. SHCS exhibits a reversible capacity of 581 mAh g⁻¹ (at 0.025 A g⁻¹), which is the highest reversible capacity reported for any carbon-based KIB anode. Electrochemical analysis of S-free carbon spheres baseline demonstrates that both the carbon matrix and the sulfur species are highly electrochemically active. SHCS also shows excellent rate capability, achieving 202, 160 and 110 mAh g⁻¹ at 1.5, 3 and 5 A g⁻¹, respectively. The electrode maintained 93% of the capacity from the 5th to 1000th cycle at 3 A g⁻¹, with steady-state CE being near 100%. Raman analysis indicates reversible breakage of C-S and S-S bonds upon potassiation to 0.01 V vs. K/K⁺. GITT analysis provides voltage-dependent K⁺ diffusion coefficients that range 10⁻¹⁰ to 10⁻¹² cm² s⁻¹ upon potassiation and depotassiation, with approximately five times higher coefficient for the former.

Assessing End-of-Life Options for Li-Ion Battery Cells and Materials—Materials Recycling and Second Use Duty Cycling Jay F. Whitacre¹, Rebecca Ciez² and Han Wang¹; ¹Carnegie Mellon Univ, United States; ²Princeton, United States

This presentation will compare and contrast various options in the quest for dealing with lithium ion batteries that have reached the end of their useful (first) lives. First, the economic and environmental impacts of recycling battery materials using multiple processing techniques will be examined and best practices will be suggested. We will then examine several different promising methods for direct recycling of cathode materials, as they have the most economic value and highest carbon footprint of the materials in most cells. Lastly, the durability of purposely aged second-use battery cells under several different application-specific duty cycles will be explored with the intention of understanding the likely benefits of using these aged cells in less taxing stationary applications such as intermittent renewable integration and for use in uninterruptible power supplies.

Improved Charge Storage Performance of Nanostructured Organic Electrodes Using Surface-Controlled Charge Storage Mechanisms Seung Woo Lee, Byeongyong Lee, Michael Lee, Shikai Jin and Yongmin Ko; Georgia Institute of Technology, United States

Redox-active organic compounds have been attracting extensive attention as active electrode materials to replace conventional transitional metal based inorganic electrodes for rechargeable batteries.¹,² Potential advantages of organic electrode materials include their environmental benignity, sustainability, and high theoretical energy density,
which can be ideal for large-scale energy storage applications.\textsuperscript{1,2} Despite these advantages, organic electrodes have suffered from poor cycling stability and rate performance, limiting their practical applications.\textsuperscript{1-3} A promising strategy to overcome these issues is to incorporate redox-active molecules onto 3D conductive substrates.\textsuperscript{1-3} In this presentation, we will discuss our recent progress in designing nanostructured organic electrodes for Li-/Na-ion storage. The assembled organic electrodes using carbon nanotube or graphene substrates have multiple redox reactions with Li-/Na-ions in high potential regions. Based on the redox reactions, these organic electrodes delivered high capacity at high potential regions with superior rate-performance and cycling stability, which can be promising cathodes for large-scale rechargeable batteries or hybrid capacitors. Next, we will introduce a new self-assembly technique using ligand exchange reactions on nanoparticles. This technique was used to convert the insulating paper or fabric to highly porous metallic current collectors. Using such metallic current collectors, we demonstrate flexible and wearable energy storage and conversion devices.

10:30 AM EN03.03.05
3D Printed Biomass-Derived Hierarchical Porous Carbon Aerogels for Supercapacitors at Ultralow Temperatures Bin Yao and Yat Li; University of California, Santa Cruz, United States

Supercapacitors (SCs) represents an emerging class of fast-charging and stable energy storage devices and have been extensively studied in recent years. However, most of the previous research are focused on SCs in aqueous and room temperature conditions. Improving the performance of SCs, especially at low-temperature environments, is significantly important for prolonged space exploration. This talk will report our new findings of using 3D printing method to fabricate biomass-derived carbon aerogels for supercapacitors at ultralow temperatures. The 3D printed biomass-derived carbon aerogel electrodes with periodic large pores have shown significantly improved electrochemical performance than the non-3D printed counterparts at low temperatures. More importantly, hierarchical pore structure with large periodic pores, macropores, mesopores and micropores in the 3D printed carbon aerogels enable the porous electrodes to achieve an excellent capacitance of around 150 F/g even under -70°C. The kinetic analysis further reveals the favorable ion diffusion property in the 3D printed hierarchical porous electrodes. Moreover, the effects of each type of pore structure on capacitance at low-temperature will also be explained. This talk will for the first time demonstrate the superiority of 3D printed porous electrodes for ultralow temperature energy storage, which might open a new door for the future work on high-performance fast-charging energy storage systems for space missions.

10:45 AM EN03.03.06
Energy Harvesting and Storage by Indoor Light Using Dye-Sensitized Solar Battery (DSSB) Myeong-Hee Lee, Byung-Man Kim, Tae-Hyuk Kwon and Hyun-kon Song; UNIST, Korea (the Republic of)

Photo-rechargeable batteries (PRBs) have been developed as all-in-one energy devices having a merit that both energy harvesting and storage are realized in a single device. A major portion of the PRBs are based on non-faradaic processes (capacitive PRBs) for their energy storage. On the other hand, several works have focused on using faradaic processes (faradaic PRBs) because the faradaic PRBs are much superior in terms of energy densities. However, for the spontaneous electron transfer between the photo-electrode and the storage-electrode, the energy levels of the two active materials should be matched well, so that there are not so many storage materials having faradaic reaction. In addition, dim-light performances of the faradaic PRBs have not been reported as far as we know. Herein, we present an external-power-free single-structured faradaic PRB, named dye-sensitized solar battery (DSSB), developed specifically for indoor light harvesting. The DSSB was designed to be photo-charged by the photo-anodic process of dye-sensitized solar cells (DSSCs) and the cathodic process of LiMn$_2$O$_4$ (LMO). Redox mediators in electrolyte of the compartment to the photo-electrode are oxidized to regenerate activated dye molecules. The
charged DSSB can be discharged by returning to their original state of the two redox active materials. The performances of DSSBs were strongly dependent on the thermodynamic and kinetic parameters of redox mediators. At one sun condition, the kinetics of mediator determined the light-to-charge energy efficiency ($\eta_{\text{overall}}$). A kinetically-fast but thermodynamically-unfavorable (can make smaller cell voltage) mediator (I-/I$_3^-$) showed the best results in terms of photo-charging current ($J_{\text{Ch}}$) and discharge capacity ($Q_{\text{dCh}}$). However, in dim-light condition (200 ~ 2000 lux), a thermodynamically-favorable (can make larger cell voltage) mediator (Cu$_{\text{II}}$/$\text{Cu}^{\text{III}}$(dmp)$_2$) delivered the highest photo-charging energy density ($E_{\text{DCh}}$) corresponding to $\eta_{\text{overall}}$ of 11.5 % because kinetic limitation becomes negligible. The successful demonstration of the DSSB to operate an IoT sensor node only by an indoor light (500 lux) opens the possibility of realizing indoor-light-harvesting PRBs.

11:00 AM EN03.03.07
Charge-Transfer Complexes for Organic Rechargeable Batteries with High Redox Potential and Power Density Sechan Lee$^1$, Jihyun Hong$^2$, Sung-Kyun Jung$^1$, Kyojin Ku$^1$, Giyun Kwon$^1$, Won Mo Seong$^1$, Hyungsub Kim$^1$, Gabin Yoon$^1$, Inyeong Kang$^2$, Kootak Hong$^1$, Ho Won Jang$^1$ and Kisuk Kang$^1$; $^1$Seoul National University, Korea (the Republic of); $^2$Korea Institute of Science and Technology, Korea (the Republic of); $^3$Korea Atomic Energy Research Institute, Korea (the Republic of); $^4$Institute for Basic Science, Korea (the Republic of)

Organic redox compounds are potential substitutes for transition-metal-oxide electrode materials in rechargeable batteries because of their low cost, minimal environmental footprint, and chemical diversity.[1] However, their electrochemical performances could not reach the level of currently used electrode materials due to the relatively low redox potential, low electrical conductivity and high solubility in organic solvents. Those drawbacks have not been simultaneously overcome with the single molecule-based tuning such as chemical modification and hybridization with conductive scaffolds.[2] Herein, we report the novel design paradigm of organic charge-transfer complexes for the new type of organic electrode material candidates which can solve the existing shortcomings of single-moiety-based organic electrode materials.[3] Organic charge-transfer complexes are an association of two or more types of organic molecules in which a fraction of electronic charge is transferred between the molecular entities. Well-ordered stacking of the molecular layers in charge-transfer complexes creates a charge-transport path which electrons can move freely, and the strong intermolecular interaction such as hydrogen bonding and -interaction result in high structural stability.

We first developed the donor components of organic charge-transfer complexes, 5,10-dihydro-5,10-dimethylphenazine (DMPZ)[4] and dibenzo-1,4-dioxin (DD)[5], which are ready-to-charge and have high redox potential. DMPZ and DD successfully show reversible redox reaction and high redox potential of 3.4 and 4.1 V vs. Li/Li$^+$, respectively. Following with these results, organic charge-transfer complexes, a novel class of electrode materials with intrinsically high electrical conductivity and low solubility that can potentially overcome the chronic drawbacks, are constructed with the developed ready-to-charge organic electrode material.[3] Combination of DD and 7,7,8,8-tetracyanoquinodimethane (TCNQ) via a room-temperature process leads to enhancement in the electrical conductivity for 5 order magnitudes and reduction in the dissolution resulting in the high power and cycle performances that far outperform those of each single-moiety counterpart. Moreover, full redox activation of donor and acceptor molecules is revealed with the practical energy density of 560 Wh kg$^{-1}$. By applying an investigation on the relationship between the redox potential and the charge carrying ions with DMPZ and terephthalate derivatives, it is confirmed that there is still a room for enhancing energy density with optimizing the cell configuration such as electrolyte and counter metal.[4, 6] These findings demonstrate the general applicability of the charge-transfer complex and opens up an uncharged pathway toward the development of high-performance organic electrode materials via the exploration of various combinations of donor-acceptor monomers with different stoichiometry.

Green, Biodegradable and Implantable Energy Storage and Conversion Devices  
**Maher El-Kady** and Richard B. Kaner; University of California, Los Angeles, United States

As the world energy demand continues to rise and carbon dioxide emission reaching a dangerous level, many cities around the world have committed to replacing fossil energy with renewables. For this transition to take place, major improvements in current technology and investigation of new materials are essential. In this talk, I will discuss our efforts for the development of green energy storage and conversion devices including batteries, supercapacitors, and nanogenerators. We explore new materials and methods to store electricity using organic carbons and electrolytes to meet the growing demand for organic materials. The talk will be supported by several examples for green, biocompatible, biodegradable and metal-free energy storage devices. In addition, we have designed and tested supercapacitors that could make pacemakers and other implantable devices safer and more durable. On the other hand, nanogenerators have recently captured interest as an alternative for clean and sustainable energies. They could be used as a power source for self-charging batteries and supercapacitors. Here, we have developed an all-printable wearable device that can function as a stretchable energy harvester and a multifunctional sensor based on the principle of snow-electrification. These devices could potentially be integrated with solar panels to ensure continuous power supply in areas with frequent snowfall. In addition, we utilized this technology for fabricating self-powered, multifunctional electronic skin that is capable of detecting human physiological signals such as pressure, temperature, and humidity through an array of totally flat and lightweight sensors. When combined with a supercapacitor, this technology could potentially be used as a self-standing power source that is stretchable, breathable with excellent anti-bacterial properties, which is favorable for biomedical electronics.

Energy and Power Scaling between Coin and Prototype Devices—A Practical Study on Moving from Materials to Prototype Supercapacitors on Ragone Parameters  
**Alexander J. Roberts**; Coventry University, United Kingdom

With the increasing interest and research focus on energy storage devices such as batteries, hybrids and supercapacitors, more and more early stage materials and technologies are tested at small, usually coin cell, scale to screen materials and systems and assess their suitability for further scale-up. This small scale electrochemical testing is then often scaled through various factors and assumptions to inform likely behaviour at a larger commercial or prototype cell scale. This approach of testing and assessing at the small scale and applying the results to a larger device generally produces reasonable agreement with what follows in prototype devices in Li-ion battery systems, where many millions of cells are produced through standard processes and using standard materials each month. The wealth of knowledge and available data on such production and scaling has allowed models to be developed and parameterised, with extensive validation resulting. In EDLC supercapacitors, this is not the case. The vastly smaller scale of production of such devices, carried out almost exclusively in commercial entities rather than the wider academic community, has resulted in information on information on how to effectively scale from results in coin cells to larger devices being unavailable in the scientific literature. It is usually found that where a comparison is made between a coin cell (and materials properties) and how that would perform in a larger cell, parameters associated with batteries are used or parameters such as energy and power densities are quoted with no regard for the ‘parasitic’ but necessary cell components needed at a larger scale such as the mass and volume of current collectors, cans, electrolyte and the like.

In this study, the factors necessary to scale between material properties and those of prototype and commercial cells have been investigated. Commercial cells of various sizes between 100 and 3000F have been tested and characterised extensively before being disassembled into their component parts. The electrodes and separators have then been used to construct and fully characterise supercapacitor coin cells, with factors to scale between the coin
cell and the original commercial cells extracted. In addition, to investigate the effect changes in parameters such as electrode thickness would have on the scaling between cell sizes, prototype 100F pouch and cylindrical cells have been produced and extensively tested in parallel with their corresponding coin cells. Finally, through consideration of the Ragone plots generated at various sizes of cells, a realistic set of parameters to be applied to small scale tested materials is presented, along with insights into the effect of moving to larger cells on the expected lifetime of a material or system.

11:45 AM EN03.03.10
Stretchable Self-Charging Power Systems to Power Wearable Electronics Fang Yi; Sun Yat-sen University, China

Stretchable and wearable electronics have been an emerging class of electronics that enable a wide range of applications such as electronic skins, implantable devices, robotics, and prosthesis. Consequently, development of stretchable power sources for such devices is highly demanded with the possibility that it can harvest energy from the environment in which the device is deployed. Triboelectric nanogenerator (TENG), a biomechanical energy harvester, possesses the advantages of low cost, light weight, high efficiency, and eco-friendly feature. However, the electrical outputs generated by TENG are pulses and sometimes with irregular magnitudes owing to the uneven strength of the mechanical motion. To enable its ability to serve as a direct power source for most electronic devices that need a constant direct-current supply, it is necessary to integrate the TENG with energy storage devices. In addition, a self-protection from the external environment is preferable for stretchable power sources so as to adapt to real-world conditions.

Here, our recent studies on the flexible/stretchable self-charging power systems to power wearable electronics solely by harvesting biomechanical energy will be presented. The challenges, future directions and potential applications for wearable/stretchable electronics will also be discussed.

SESSION EN03.04: Green Electrochemical Energy Storage Solutions—Materials, Processes and Devices IV
Session Chair: Francesca Soavi
Tuesday Afternoon, December 3, 2019
Sheraton, 2nd Floor, Republic A

1:30 PM *EN03.04.01
Stretchable Rechargeable Lithium-Ion Batteries Soomin Park; Pohang University of Science and Technology, Korea (the Republic of)

Deformable, stretchable electronics are considered as next-generation devices; however, to realize highly flexible electronics, it is first necessary to develop a deformable energy device. Herein, a crumply and highly flexible lithium-ion battery is realized by using microfiber mat electrodes in which the microfibers are wound or webbed with conductive nanowires. This electrode architecture guarantees extraordinary mechanical durability without any increase in resistance after folding 1,000 times. Its areal energy density is easily controllable by the number of folded stacks of a piece of the electrode mat. Deformable lithium-ion batteries of lithium iron phosphate as cathode and lithium titanium oxide as anode at high areal capacity (3.2 mAh cm⁻²) are successfully operated without structural failure and performance loss, even after repeated crumpling and folding during charging and discharging.

As another deformable batteries, we demonstrate the fabrication of highly stretchable hybrid carbon/polymer (HCP) composite which was found to effectively retain its electrical conductivity, even when under high strain (~200%), due to the co-supporting network of hybrid nanofillers in its structure. We are the first to have developed a stretchable aqueous rechargeable lithium-ion battery (ARLB) that utilized this HCP composite as a stretchable current collector. The ARLB exhibited excellent rate capability (~90 mA h g⁻¹ at a rate of 20 C) and outstanding durability (capacity retention of 93% after 500 cycles).

2:00 PM EN03.04.02
Insights into Solid-State Electrochemistry of bi-Redox Organic Battery Materials Alae Eddine Lakraychi, Simon Kreijger, Deepak Gupta and Alexandru Vlad; Institute of Condensed Mater and Nanosciences, Belgium
The technological pressure on the present batteries, dominated by inorganic materials, has led to a sustainability dilemma, and therefore developing new battery chemistries has become of prime importance [1]. In this context, organic batteries are emerging as probably one of the most promising approaches to render the energy storage technology green and sustainable [2]. Presently, carbonyl-based electroactive materials are the most focused due to their potential to achieve simultaneously high energy/power density as well as extended cycling stability [3]. Within this framework, molecular engineering has played a big part in improving theirs electrochemical performances in terms of potential tuning [4] and preventing the unwanted dissolution [5]. However, these improvements usually partially penalize the gravimetric capacities and, in some cases, the exact origin of the operating potential shift as well as redox mechanism are still a matter of debates.

In this work, we will try to address both issues. Firstly, we will show how by using coordination chemistry, Ligand-Metal complexes with sustainable metals (Fe, Mn) as new multi-electron with bi-redox activity can be designed. These new materials can deliver capacities in excess of 200 mAh.g⁻¹ at an average working potential of 3 V vs. Li⁺/Li⁰. Secondly, we will detail on the electrochemistry of aromatic and heterocyclic dicarboxylate isomers. This study comprehends (i) the effect of N-heteroatom on the potential of the dicarboxylates, with a direct correlation between the operating potential and the ¹³C-chemical and vibration frequency shift of the carbonyl and (ii) the true redox mechanism that dictates the electrochemical activity in the case of bi-redox systems (pyrazine-dicarboxylate). This mechanistic investigation leads to the discovery of new nitrogen-related redox center that can be beneficially explored in the organic battery field.

“Water-in-Salt” Electrolyte Promises Green and Safe Al-Ion Based Electrochemical Energy Storage Systems
Zahid Ali Zafar¹,², Martin Silhavík¹, Ghulam Abbas² and Jiri Cervenka¹; ¹FZU-Institute of Physics of The Czech Academy of Sciences, Czechia; ²Faculty of Science, Charles University, Czechia

Electrochemical energy storage systems (EESS) with high energy density, safety, low cost, and low carbon footprint have become indispensable in the modern era of ubiquitous electronics, electric vehicles, and grid storage. Current EESS lack of these characteristics due to the utilization of critical materials which are precious, flammable and difficult to recycle. Whereas, aqueous electrolytes offer higher safety and lower costs. Nevertheless, their biggest bottleneck is the narrow electrochemical window (1.23V) that is preventing from attaining higher energy and power densities in most of the aqueous EESS. For instance, aqueous rechargeable aluminum ion batteries promise high energy density due to multivalent redox chemistry of aluminum ion (Al³⁺) but they exhibit much lower energy density in real experiments due to the limited electrochemical windows of the aqueous electrolytes. The water-in-salt based electrolytes (WiSE) can potentially eliminate this barrier by offering a larger electrochemical window by reducing the overall electrochemical activity of water on the electrodes. Here, we demonstrate a new concept using aluminum perchlorate based WiSE that is showing a stable and wide electrochemical window of nearly 3 V against Ag/AgCl. The electrochemistry tests of the electrolyte are performed using carbon-based redox-active electrode materials. We employ the new electrochemical system in aqueous rechargeable aluminum ion batteries and supercapacitors, revealing superior performance to standard aqueous electrolytes. Our findings provide new possibilities for widening the electrochemical window and enhancing the energy and power density in aqueous EESS.

References
The replacement of organic solvent-based electrode manufacturing by a water-based process offers an alternative processing route with regard to cost-reduction and more sustainability. However, the interaction of cathode materials with water changes their storage behavior and causes massive problems for electrode manufacturing and cell properties. Due to a Li⁺/H⁺ exchange reaction, the pH of the aqueous slurry is increased so that a corrosive attack of the aluminum foil takes place. The reduction of the pH value by the addition of an acid is one practical measure to prevent corrosion, but has also negative impact on slurry rheology, electrode conductivity or adhesion. These consequences are shown in an exemplary way for the addition of acetic acid. As especially the adhesion strength is influenced, this effect is investigated in detail for various acids. Best electrode properties are not found in the stable region of the aluminum foil, but at a higher pH of 9 to 10. Acetic acid treated cells show high capacities at their begin-of-life, but undergo stronger degradation than samples without acid addition.

Development of Conductive Organic Cathode Using Interface Charge-Transfer

Lithium ion batteries have become a mainstay as power storage devices with high energy densities. However, they contain heavy metal compounds such as LiCoO₂, which is constrained by limited resources and problems related to the processing of heavy metal waste. Moreover, the capacities of lithium ion battery cathodes are approaching their theoretical limit, since they rely on one-electron redox reactions of heavy transition metals. In order to increase the adoption of storage batteries in an environmentally friendly manner, the development of innovative electrode materials free of rare metals and having high output and high energy densities is necessary. In recent years, redox active organic compounds such as benzoquinone derivatives have attracted attention as candidate materials for battery electrodes. They exhibit excellent characteristics such as high capacities because of multi-electron redox reactions and their structures composed of light elements only. Moreover, their functional groups can be optimized by chemical modification. However, one of the problems in using an organic compound as cathode material is the insulating property of the organic molecule. The insulating property not only lowers the energy efficiency of the redox reaction but also requires the addition of a large amount of carbon material to ensure conductivity, which reduces the effective energy density.

In this study, we propose an organic cathode material based on a novel concept, the “Interface Charge-Transfer [1] (ICT)” phenomenon. In ICT, the electron transfer occurs at the interface between molecular solids that act as a donor and acceptor, respectively. Charge carriers are generated in the molecular solids, and electric conductivity is acquired. In order to realize an ICT “cathode,” we selected donor and acceptor molecules that are redox-active, that have a small molecular weight, so that both the donor and acceptor molecule can act as an active material, and that have a large theoretical capacity. Based on these criteria, we selected tetraphiafulvalene (donor) and 7,7,8,8-tetracyanoquinodimethane (acceptor). Powders of the molecules and polytetrafluoroethylene (PTFE) were mixed to form an electrode without adding any conductive filler such as carbon. The bulk resistivities were measured and it was revealed that the resistivity of the cathodes was very low (2-7 Ω cm). Then, we carried out charge-discharge cycle tests in a half cell system, and the batteries worked for at least 20 cycles while retaining more than 80% of the highest capacity value.

In summary, we succeeded in establishing a novel type of a cathode material, the “ICT cathode”, and examined its performance and characteristics. Since no additives are required to achieve electric conductivity, it is expected that this type of cathode has a high potential for future light-weight and environmentally friendly battery systems.

Reference:
We present the development of a zinc–polymer energy storage device where we employ redox–active polymers based on naphthalenetetracarboxylic diimides (NDIs) with large electron affinities as the cathode. We observe that electrodes made of the polymer can become reduced by zinc electrodes when both electrodes are immersed in aqueous electrolytes. To enable rapid charging in aqueous electrolytes, polar side chains are attached to the polymer backbone that facilitate fast cation transport from the electrolyte into the bulk of the polymer.[1] In addition, no additives or binders are required for the electrode to function in aqueous electrolytes which also enable to fabricate electrodes from solution. Due to the excellent charging properties of the polymers in aqueous electrolytes, we explore non–toxic aqueous electrolytes (salty water) and discuss pathways of how solid state electrolytes can be used in future devices. Finally, we will present how oxygen reduction reactions (ORRs) can be employed to develop a zinc–polymer–air energy storage devices where the redox-active polymer acts as the catalyst to reduce oxygen. We believe that our findings are of importance for the development of future zinc-air batteries, with the potential to use safe and environmentally friendly electrolytes.

It is known that the electrochemical performance of carbon-based supercapacitors depends on the porous structures of carbon-based materials. In this work, we prepare activated carbons (ACs) of different porous structures from xylose and use the prepared ACs as the electrode materials in coin-type supercapacitors with 1 mol/L Et4NBF4 solution in AN as electrolyte. The electrochemical performance of the coin-type supercapacitors is systematically studied. The largest specific capacitances obtained from the coin-type supercapacitors are 340 F/g at 0.5 A/g and 220 F/g at 50 A/g, which are much larger than the results reported for similar systems. The supercapacitors can maintain 86.8% of the capacitance after 10000 cycles at 50 A/g. The energy density is 48 Wh/kg at a power density of 13.6 kW/kg.

This work is supported by the NSF [CMMI-1634540].

One weakness of batteries is the rapid falloff in charge-storage capacity with increasing charge/discharge rate. Rate performance is related to the timescales associated with charge/ ionic motion in both electrode and electrolyte. However, no general fittable model exists to link capacity-rate data to electrode/electrolyte properties. Here we demonstrate an equation which can fit capacity versus rate data, outputting three parameters which fully describe rate performance. Most important is the characteristic time associated with charge/ discharge which can be linked by a second equation to physical electrode/electrolyte parameters via various rate-limiting processes. We fit these equations to ~200 data sets, deriving parameters such as diffusion coefficients or electrolyte conductivities. It is possible to show which rate-limiting processes are dominant in a given situation, facilitating rational design and cell optimisation. In addition, this model predicts the upper speed limit for lithium/ sodium ion batteries, yielding a value that is consistent with the fastest electrodes in the literature.

Self-Organization of Conducting Polymers on Nano-Scale Biopolymer Templates Dagmawi Belaineh1, Jens Wenzel Andreassen2, Justinas Palisaitis1, Sapiens Malti2, Karl Håkansson4, Aleksandar Mehandzhiyski2, Igor Zozoulenko1, Lars Wågberg3, Xavier Crispin1, Isak Engquist1 and Magnus Berggren1; 1Linköping University,
Renewable biomass-derived materials are the key to sustainable energy storage systems. Biopolymers derived from the forest have been blended with conducting polymers to produce green batteries and supercapacitors. In this work, we use cellulose, which is the most abundant biopolymer on earth, to study the critical intra-component interactions between the biopolymer and the seasoned conducting polymer poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS). We report a remarkable self-organization of PEDOT:PSS on cellulose nano-fibrils (CNF) which leads to a continuous, linear array of PEDOT:PSS nano-beads, with an average diameter of 13 nm, along the length of individual nano-fibrils. Atomic Force Microscopy (AFM) and Transmission Electron Microscopy (TEM) studies elucidate the self-aggregation of PEDO:PSS particles on cellulose. This self-organization leads to the enhancement of long-range electronic transport in the PEDOT which is confirmed by charge transport measurements. Furthermore, we utilize Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS) to pinpoint the face-on π-stacked crystallographic orientation of the PEDOT:PSS on top of the CNF. We conclude our investigations by confirming our experimental study by the theoretical modeling of the physicochemical processes that lead to the aggregation of PEDOT:PSS on cellulose using coarse-grained molecular dynamics simulations. Significantly, the simulations also predict nano-beads of PEDOT:PSS aligned along the CNF.

W-Co-Fe Metal Oxide as a Carbon-Free Catalyst for the Cathode of Li-O2 Batteries
Ruizhi Yang and Xuecheng Cao; Soochow University, China

The rechargeable aprotic Li-O2 batteries hold great promise for electric vehicles because of their high energy density and environmental friendliness. However, the carbon-based cathodes commonly used in Li-O2 batteries are not stable due to their reaction with discharge products (Li2O2, Li2O), which leads to the formation of insulating lithium carbonate and fades the batteries’ efficiency and cycling stability. In this work, a WCoFe@Ni cathode consisting of sub-stoichiometric tungsten oxide (W18O49), cobalt oxide and ferric oxide as a carbon-free cathode for Li-O2 batteries is presented for the first time. The resulting WCoFe@Ni cathode delivers a high specific capacity (5800 mAh g⁻¹ at 200 mA g⁻¹) and remarkable cycling stability (more than 400 cycles at a capacity of 1000 mAh g⁻¹ under 500 mA g⁻¹). The electronic structures of Co and Fe are modified upon the adding of W in the oxides. The amount of Fe³⁺ in CoFe (37 %) is higher than that in WCoFe (20.2 %), while the amount of Co²⁺ in WCoFe (66.8 %) is higher than that in CoFe (41.3 %). Furthermore, the Fe at the high-valence in WCoFe stabilizes the Co at the low-valence, which facilitates the formation of CoO-like species that is highly active for the decomposition of discharge products in the Li-O2 batteries. The synergistic interaction between W, Co and Fe in WCoFe@Ni cathode plays a critical role in promoting the performance of Li-O2 batteries. Moreover, the sub-stoichiometric tungsten oxide provides high electronic conductivity and the unique 3D nanowire network structure is beneficial for the storage of discharge products. The WCoFe@Ni is a promising carbon-free cathode for Li-O2 batteries.
lignin itself is electronically insulating. Polymer, partially reduced graphite or graphene oxide and graphene have been investigated for energy storage devices. However, these preparation procedures are complicated and difficult for scalable production. Herein, we report a facile process to combine graphite and the lignin derivative lignosulphonate (LS) with the help of simple mechanochemistry; graphite flakes and LS are co-ground in the solid state followed by treatment with water, resulting in a readily processable lignin: graphite paste that can be coated on substrates and directly applied in electrical energy storage devices.

The materials and electrodes are characterized by UV-vis spectroscopy, FTIR spectroscopy, Raman spectroscopy, XRD, dynamic light scattering (DLS), thermogravimetric analysis (TGA), SEM, cyclic voltammetry (CVs) and galvanostatic charge-discharge measurements. The hybrid electrodes with different stoichiometry give two symmetric redox waves defined at 0.67 V and 0.34V versus Ag/AgCl, which is ascribed to the redox reactions of Q groups in LS, a conductivity range from 70 to 290 S m⁻¹ and a charge capacity from 30 to 35 mAhg⁻¹. Moreover, considering the charge capacity from Q groups and mass of LS in the LS/graphite hybrid material electrodes, the charge capacity of the hybrid materials due to LS can be as much as 70 mAhg⁻¹. IR results and UV-vis results prove the LS/graphite pellets and supernatant contain a mixture of LS and graphite. The Raman spectra, TEM pictures and XRD results suggest the presence of fewer layers, more defects, more disorder and smaller crystallite size of graphite in the hybrid material electrodes than in the pristine graphite. The TGA results confirm the range of the stoichiometry of the LS/graphite pellets of 0.55-1.25. The SEM results illustrate that the ball milling process can reduce the grain size of graphite and LS, and create nanoscale geometries in the hybrid materials. Furthermore, the morphology of the LS/graphite hybrid material electrodes can be effected by the stoichiometry of LS and graphite in the ball milling process.

In summary, mechanical ball milling combined with aqueous process is a way to fabricate sustainable, environmental friendly, low cost and scalable LS/graphite hybrid materials with high conductivity and moderate charge capacity. The molecular interaction and charge transfer between LS and graphite in the electrodes make these electrodes candidates for energy storage.

EN03.05.02
In Situ Interface-Forming Technique of Poly(ionic liquid)s with Plastic Crystal and Lithium Salt in Electrodes for Solid Lithium Batteries Hideyuki Ogawa1, Akihiro Orita1, Katsunori Kojima1 and Hideharu Mori2; 1Hitachi Chemical Co. Ltd., Japan; 2Yamagata University, Japan

Recently, solid lithium batteries using solid electrolytes have attracted considerable attention due to their potentially high energy density and safety. However, some key issues remain unsolved. The good interface formation between the solid polymer electrolyte and the solid active material is needed. Specifically, an adhesive and flexible electrolyte are favorable to follow the volume change of an active material in an electrode upon charging and discharging. Actually, the addition of solid polymer electrolyte (in general, around 20wt-%) into an electrode to form the above good interface causes the degradation of an energy density, hindering their commercialization.

To solve these problems, we propose in-situ radical polymerization of diallyldimethyl ammonium bis(trifluoromethanesulfonyl)imide (DADMA-NTf₂) in the presence of lithium bis(trifluoromethanesulfonyl)imide (LiNTf₂) and 1-ethyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide (P12NTf₂) in an electrode with an active material. The ternary mixed solution (DADMA-NTf₂/LiNTf₂/P12NTf₂) is successfully permeated into pores of an electrode layer, and a solid-state ionogel is formed in the electrode after in-situ radical polymerization under air: without decreasing the ratio of the active material. In addition, there are no observable pores or defects by SEM and EDX measurements, suggesting that an ideal interface between the ionogel and the active material is formed. The ionic conductivity of such ionogel exceeds 1.0 x 10⁻³ S/cm at 50 °C, which is close to that of gel polymer electrolytes with ionic liquids as reported previously. The conversion of DADMA-NTf₂ during bulk polymerization decreases with increasing in the P12NTf₂ ratio in the feed, while the increase in P12NTf₂ leads to the improvement of the ionic conductivity. This result suggests that suitable content of the P12NTf₂ is crucial to obtain a solid-state ionogel with a high ionic conductivity. Batteries fabricated by simply stacking of a glass-fiber membrane between the positive and negative electrodes, all of which contain solvent-free in-situ formed ionogels, are successfully operated at a low current rate. Owing to no need of the volatile organic solvent and any special atmospheric control, this simple and environmentally-friendly procedure to prepare an electrode for solid batteries can help to ensure the wider practical use of solid lithium batteries.
EN03.05.03

Electrocatalytic Performance of Nitrogen and Oxygen Co-Doped Carbon Electrodes for Vanadium Redox Flow Battery

Doohwan Lee, Hyebin Lim and Seong-Cheol Kim; University of Seoul, Korea (the Republic of)

The electrocatalytic properties of graphite felt (GF) electrodes for vanadium redox flow battery (VRFB) are studied with N and O atomic dual doping on the GF surface by urea thermolysis. Simple impregnation of GF with urea and polyethylene glycol (PEG), followed by thermal treatment at elevated temperatures, results in significant N and O dual doping on the electrode with high surface uniformity and electrocatalytic activities. The correlation analysis on the electrocatalytic properties of the GF electrodes with respect to the configuration and elemental contents of the doped N and O functionalities suggests that the pyrrolic-N species on the carbon electrodes provide significant kinetic enhancement for vanadium redox reactions. The operando studies measuring the through-plane voltage losses in the VRFB single cell reveal that the N and O dual doping by urea thermolysis gives rise to approximately 3-fold improvement in the vanadium redox kinetics, particularly on the anode side, which greatly reduces the overall cell voltage loss. At practical charge–discharge condition, the N and O dual-doped GF electrode affords about 15 % increase in voltage efficiency and 2-fold increase in charge–discharge capacity of the VRFB over that obtained from the pristine-GF electrode. These results suggest the marked electrocatalytic effects of the N and O dual-doping on carbon electrodes for vanadium redox reactions, and the high effectiveness of urea thermolysis for the electrode functionalization for VRFB.

A Novel Ethanol/Water Binary Electrolyte Enabling Superior Cycle Stability of Na-Mn-O Cathode for Aqueous Rechargeable Sodium-Ion Batteries

Rodney Chua, Yi Cai, Sonal Kumar, Vivek Verma and Madhavi Srinivasan; Nanyang Technological University, Singapore

Aqueous rechargeable sodium-ions batteries (ARSIBs) have garnered extensive research interests due to its safety and abundant sodium resources towards sustainable large-scale energy storage applications. [1, 2] Among the various transition metal oxides employed in ARSIBs, Na0.44MnO2 (NMO) has been considered as an attractive cathode due to its unique tunnel structure that can facilitate fast transport of Na-ions during de/insertion processes.[3-6] However, the parasitic side reactions such as dissolution of active material, H2/O2 evolution reactions and water protons insertion into the NMO structure undermine the cycle life of NMO.[6] Therefore, the prevailing research challenge lies in maintaining the capacity over long cycles of NMO in an aqueous media.

Herein, for the first time, we propose a novel binary electrolyte for ARSIBs by using green and low-cost 1 m sodium acetate dissolved in the optimized ethanol/water cosolvents. Electrochemical behaviors are studied on NMO plates by using our binary electrolyte. Meanwhile, the NMO electrode was also tested in a single electrolyte (1 m sodium acetate dissolved in Di water) for comparison. The overlapping cyclic voltammetry curves of NMO cycled in binary electrolyte (NMO-Et/Di) indicate a highly reversible de/insertion processes of Na-ions. Furthermore, the NMO-Et/Di electrode exhibits a superior cycle stability, while the NMO-Di sample shows an obvious capacity fading after 1000 cycles. A combination of Fourier-transform infrared spectroscopy and nuclear magnetic resonance measurements carried at various cosolvents ratio coupled with ex-situ X-ray diffraction and scanning electron microscopy were conducted to further understand the dependence of the cathode/electrolyte interface, material stability and charge storage mechanism. It is noted that the intrinsic hydrogen-bonding interaction between ethanol and water protons in binary electrolyte is one of the main contributing factors towards a superior cycle stability of NMO. The results of the study provide insights into the electrode-electrolyte interactions and highlight the significance of electrolyte design and optimization in aqueous rechargeable batteries.

References
Typical fabrication methods, such as photolithography and rolling/stacking, that are commonly used in conventional electronics and energy storage systems respectively, have caused the devices to lack a variety of form factors and flexibility needed for countless new Internet-of-Things applications[1]. In the past decade, the development of digital printing technology in the field of printed electronics, has triggered an explosion of new ideas and alternative fabrication strategies that led to lean and cost-efficient manufacturing processes. In this work, the digital nature of inkjet printer was utilised to fabricate multifunctional energy storage sources in the form of casual letters in text. A new font style of the Latin alphabet was developed so that each character assembles a planar supercapacitor, able to be aesthetically and seamlessly connected, either in series or parallel configuration. A nanoparticle-based silver current collector, a nanoparticle-based nickel (II) oxide (NiO) active electrode material and a transparent ionic liquid/ultraviolet-cured triacrylate polymer-based solid-state electrolyte, were chosen as model materials to explore the feasibility of the proposed concept. The model letter-supercapacitors were able to deliver up to 27 mF cm\(^{-2}\) and handle scan rates up to 500 mV s\(^{-1}\) at a voltage window of 2.5 V. This approach underlines the exceptional applicability of the inkjet-printed letter-supercapacitors as a fabrication strategy towards multifunctional power sources with versatile form factors that lie far beyond what conventional fabrication technologies can achieve. The letter-supercapacitors can be used as energy storage units for electronic books, paper electronics and smart textiles with the potential of the proposed concept to be extended beyond interconnects and energy storage to seamless printed sensors and other electronic components.

Microporous Carbons from Different Lignin through Controlled Activation

Lu Yu\(^1\), David Harper\(^1\), Orlando Rios\(^2\), David Keffer\(^1\), David Alonso\(^3\), Kendhl Seabright\(^1\) and Valerie Garcia-Negrón\(^1\); \(^1\)University of Tennessee, United States; \(^2\)Oak Ridge National Laboratory, United States; \(^3\)University of Wisconsin–Madison, United States

With the awareness of sustainable development and solving the energy storage problem, convert woody biomass into carbon products for energy storage applications has attracted enormous attention. We extract high purity lignin from four different types of biomass materials, and then control the processing conditions to produce high-value carbon products. Chemical characterizations including TGA and DSC are conducted to get the thermal properties of the lignin, such as the glass transition temperature, average decomposition temperature, and char content. The lignin functionality and chemical composition were investigated by Fourier-transform infrared spectroscopy and nuclear magnetic resonance spectroscopy measurements. From this information, we optimized the carbonization conditions through control humidity, temperature and reducing environment needed for graphitization. Carbons after pyrolysis were activated to produce activated carbon foams. The physical and chemical activation were compared and explore the reactions during the activation. Brunauer–Emmett–Teller (BET) analysis was conducted to measure the surface area and pore size distributions (PSDs). The surface area and PSDs are significantly affected by the activation temperature and duration. Usually the higher temperature, the greater surface area and PSDs. In addition, various precursors also show different results under different activation duration. Changes in morphology were determined by SEM and TEM. Carbon morphology and composition were determined by x-ray diffraction and elemental analysis. Combined with these experiments results, the major reactions during the activation are clear and the way to control porosity through activation and produce microporous activated carbon are developed.

Dye-Sensitized Solar Cells Based on Tin and Zinc Oxide Composite Films Using Ionic Electrolytes

K.D.M.S.P.K. Kumaraasinghe\(^1\), G.R.A. Kumara\(^2\), Ajith DeSilva\(^2,3\), A.G.U. Perera\(^1\), Sunil Dehipawala\(^4\) and K. Tennakone\(^5\); \(^1\)National Institute of Fundamental Studies, Sri Lanka; \(^2\)University of West Georgia, United States; \(^3\)Georgia State University, United States; \(^4\)Queensborough Community College of CUNY, United States; 

Final Program 1/13/2020  503
After decades of research, long term stability of dye sensitized solar cells (DSCs) continue to remain a questionable issue. The observed instability is caused by dye and electrolytic degradation and gradual evaporative elimination of the volatile component of the electrolyte via unavoidable faults in the sealing. Degradation of the dye and the electrolyte is mainly due to photocatalytic reactions mediated by titanium dioxide. Of familiar high-band gap oxide materials, short wavelength (<300 nm) radiation initiated by photo-catalytic activity originating free radical generated by hole transfer to water molecules is strongest in titanium dioxide. Although DSCs made from less photo-catalytically active tin and zinc oxides are inefficient, composite tin-zinc oxide films yield efficiencies comparable to those fabricated out of titanium dioxide films. Studies conducted reveal that DSCs based tin-zinc oxide films are highly stable when moisture free high boiling point solvents are incorporated to solubilize the conventional iodide/tri-iodide redox system. Sensitized charge injection and transport in composite tin-zinc oxide films and the possible causes of enhanced stability will be discussed.

EN03.05.10
Controlled Phase Transformation of Ni-Co Layered Double Hydroxides and Their Effects on Electrochemical Performances for Wearable and Flexible Asymmetric Supercapacitors
Young-Min Jeong and Seong-Ho Baek;
DGIST, Korea (the Republic of)

Recently, due to the tremendous demand on wearable and flexible devices, there has been an urgent requirement for future energy sources that are compact, efficient, and implementable on small footprint. Supercapacitors (SCs) can supply higher capacity per unit area compared to traditional electrostatic or electric double layer capacitors (EDLCs) while they can provide faster power delivery and longer cycling ability than lithium ion batteries (LIBs). However, one of the biggest challenge of SCs is to find an efficient way to enhance energy density comparable to LIBs without sacrificing power density loss. To address these issues, much effort has been devoted on the improvement of electrode materials and novel structures in recent years. In this work, we demonstrate Ni and Co layered double hydroxides (NiCo–LDHs) on Ni–coated textile for wearable supercapacitor (SC) applications. LDHs are a group of two dimensional layered structures and have proven to be very promising due to high performance pseudocapacitive materials, high redox activity, and environmentally friendliness. In addition, we investigate that the crystal structure and electrochemical properties of NiCo-LDH can be controlled by adjusting the reaction time using hydrothermal method. We report on controllable phase transformation of NiCo-LDH and their morphology evolution from nanosheets to nanowires with increasing growth time. Lastly, an asymmetric pseudocapacitor is assembled with the graphitic carbon as negative electrode and the NiCo LDH as positive electrode. The best device result shows a high energy density of 55.8 Wh kg\(^{-1}\) at power density of 601 W kg\(^{-1}\) with a 1.2 V operating voltage.

EN03.05.11
Investigations of Thermal Processing of Nasicon-Like Lithium-Ionic Conductors for All-Solid Li-Ion Batteries
Hunter Frost\(^1\), Marie Francoise C. Millares\(^1\), Kevin Shah\(^1\), Yashashvini Andugula\(^1\), Spencer Flottman\(^2,3\), Seiichiro Higashiya\(^1\), Devendra K. Sadana\(^4\) and Harry Efthathiadis\(^1\), \(^1\)SUNY Polytechnic Institute College of Nanoscale Science and Engineering, United States; \(^2\)Oak Ridge National Laboratory, United States; \(^3\)Eonix LLC, United States; \(^4\)IBM T.J. Watson Research Center, United States

For decades, solid electrolyte thin films have opened up new avenues for power storage, as well as offering alternative applications, such as neuromorphic computing, and have represented many benefits concerning safety, cost, and energy efficiency compared to their liquid electrolyte counterparts. The NASICON-like solid compound, lithium aluminum titanium phosphate \((\text{Li}_{1.4}\text{Al}_{6.6}\text{Ti}_{2.4}(\text{PO}_{4})_3)\), LATP has shown promise as a solid electrolyte, with a demonstrated ionic conductivity of \(\approx 3 \times 10^{-3} \text{ S cm}^{-1}\). Here, LATP thin films were deposited via RF-magnetron sputtering; this method is more suitable for large scale implementation and reproducibility, unlike the commonly utilized sol-gel method. This study focuses on the effect of thermal processing on electrical resistance for both micrascale batteries and unique MIM structures created with the sputtered LATP thin films. The two thermal processes studied here are the effects of both mid-deposition heating and post-deposition annealing on these devices. During the fabrication process, a range of mid-deposition heating temperatures and post-deposition annealing temperatures are examined to determine optimal processing conditions for maximizing electrical resistivity. It has been found that optimal electrical resistivity (~150 M\(\Omega\)) is achieved only through post-deposition annealing at >350\(^\circ\)C, with notable resistivity improvements arising from mid-deposition heating. Microscale half-cell batteries (~100 \(\mu\)m x 100 \(\mu\)m) created with the annealed LATP films show behavior typical of half-cell batteries, with minimal to no signs of leakage.
EN03.05.12
A Novel, Water-Stable 2D Sheet-Like Neutral Cu(i)-Sulfonate MOF Containing π-Acidic Naphthalenediimide (NDI) Ligand Dillip K. Panda; Clemson University, United States

In this study, we report the design, synthesis, and characterization of a novel, water-stable 2D sheet-like neutral Cu(I)-sulfonate metal-organic framework (MOF) having π-acidic naphthalenediimide (NDI) disulfonate as ligands. This NDI-based ligand has an ability to bind the guest lithium ions (Li+) with its carbonyl and sulfonate oxygen atoms, and whereas, the diffuse perchlorate anions (ClO4-) binds via anion−π and CH...anion interaction. The measured ionic conductivity of this MOF [Cu2(BPY)2(NDIDS)] has significantly enhanced to 10^6 times (2.3x10^{-4} S/m) by inserting LiClO4 dopant. This Lithium-ion conducting (MOFs) act as an ion permeable electrode separators and useful for rechargeable batteries. For the first time, such enhancement of lithium-ion conductivity is observed in a neutral, and solvent-free, not post-synthetically modified MOF. Moreover, the determined low activation energy (E_a =0.167 eV) and high Li-transference number (τ_{Li} =0.749), suggest that the newly developed ion-conducting disulfonate could be a potential solid-electrolyte for battery applications. To demonstrate further the influence of the Li^+ binding, the MOF was also treated with Bu4NClO4 salt which shows the poor electrical conductivity (4.55x10^{-10} S/m) similar to the pristine untreated MOF (4.65x10^{-10} S/m) at room temperature. The same conductivity properties could be attributed to the size exclusion and facile removal of large uncoordinated Bu4N^+ cations. The impact of ionic conductivities of this MOF upon doping with various cations such as (K^+, Na^+, Mg^{2+}) and anions (BF_4^-, I^-, PF_6^- TfO^-) with this [Cu2(BPY)2(NDIDS)] MOF are under investigation in our lab.

EN03.05.13
Value-Addition Recycling Process for Electric Vehicle Battery Cathode Materials Linsen Li, Guannan Qian, Zi-Feng Ma and Yushi He; Shanghai Jiao Tong University, China

The word is embracing a new electrification revolution sparked by the rapid development and mass deployment of lithium-ion batteries. LIBs based on lithium nickel manganese cobalt (NMC) or lithium nickel cobalt aluminum oxide (NCA) cathode materials are now dominant power sources for electric vehicles. Ni and Co are expensive heavy metals that are attractive for recycling. Currently, Ni and Co are recovered from the used batteries either by pyrometallurgy or hydrometallurgy method. Hydrometallurgy method is more widely used because it can be integrated into the production of hydroxide precursors for NMC or NCA. This is a profitable process thus goverment subsidies are no longer necessary. However, this recycling method consists of many steps (>10) and generates a large amount of heavy-metal containing acid-waste and base-waste. To better address the NMC battery recycling challenge, it is necessary to develop greener and more cost-effective methods. We have recently developed a convenient and scalable method based on advanced molten-salt chemistry to convert the structurally damaged and lithium deficient polycrystalline NMC materials in the used batteries into high-performance single-crystal NMC cathode materials. During the conversion, it is also possible to increase the Ni content in the cathode materials to further boost the energy density and increase the value. Cost analysis are performed to confirm that the new method is a value-addition process. This work reveals a promising new path toward better recycling used battery cathode materials at a large scale and with much less environmental impact.

SESSION EN03.06: Green Electrochemical Energy Storage Solutions—Materials, Processes and Devices V

8:30 AM *EN03.06.01
Structural Water Containing Materials for Aqueous Post-Lithium-Ion Batteries Jang Wook Choi; Seoul National University, Korea (the Republic of)

Although Li-ion batteries have been successful in various applications, their shortcomings with regard to high cost and global maldistribution of raw materials, as well as safety concerns have promoted alternative rechargeable batteries based on other carrier ions represented by sodium and magnesium ions, targeting grid-scale energy storage
systems (ESSs). However, many electrode materials in these emerging systems often suffer from sluggish kinetics due to the larger size or bivalency of carrier ions, limiting electrochemical performance particular in specific capacity and operation voltage. In this talk, I will introduce a new approach of engaging intercalated water in layered cathode materials. The intercalated water improves the performance of the given materials substantially by shielding electrostatic interactions or maintaining the crystal frameworks over repeated cycles. Detailed effects of intercalated water will also be described, along with promising potentials towards aqueous operations. Electron microscopy characterization for in-depth understanding of these materials will also be introduced.

9:00 AM *EN03.06.02
Facile-Processed Sulfur Cathodes for High Performance Sodium-Sulfur Batteries Weiyang Li; Dartmouth College, United States

Room-temperature (RT) sodium-sulfur (Na-S) batteries using all earth-abundant resources as electrode materials are considered to be the next-generation cost-effective energy storage devices. However, their practical applications are still plagued by the low reversible capacity of commercial S, low Coulombic efficiency, and poor cycling stability caused by sluggish kinetics of Na-S electrochemical reactions and severe shuttle effect of polysulfides. Here we present our most recent works on developing high-performance RT Na-S batteries using facile-processed S-based cathodes. A simple and scalable approach has been developed to synthesize hollow sodium sulfide nanospheres embedded in a highly hierarchical and spongy conductive carbon matrix, forming an intriguing architecture similar to the morphology of frogspawn coral, which has shown great potential as a cathode for high-rate performance RT Na-S batteries. The shortened Na-ion diffusion pathway benefits from the hollow structures together with the fast electron transfer from the carbon matrix contributes to high electrochemical reactivity, leading to superior electrochemical performance at various current rates. A Na-metal-free Na-S battery is demonstrated by pairing the hollow sodium sulfide cathode with tin-based anode. Besides using sodium sulfide as cathode, we also develop a highly stable RT Na-S battery using a facile-processed commercial S cathode and gel polymer electrolyte, which delivers a reversible capacity of >700 mAh g\(^{-1}\) with near 100% Coulombic efficiency and an ultrahigh capacity retention of 98.2% at 0.2C after 200 cycles.

10:00 AM *EN03.06.03
Materials and Processes for Sustainable Batteries Stefano Passerini; Karlsruhe Institute of Technology, Germany

Our society is presently facing the great challenge to switch from depleting energy sources like oil, coal, or gas, to renewables such as solar and wind. With regard to their inherent intermittency and commonly decentralized generation, however, efficient and sustainable energy storage is of utmost importance. Beside large-scale solutions like hydropower or compressed air, electrochemical energy storage, in particular secondary batteries, is currently considered to be the most suitable technology, particularly for relatively smaller applications like transportation or short- to mid-term stationary energy storage.[1–4] As a matter of fact, the number of electric vehicle (EV) sales is steadily increasing within the past years and the same trend is observed for the implementation of secondary batteries for buffering the intermittent energy supply by solar and wind.[1–4] Consequently, batteries play a vital role for moving towards a more sustainable “energy future”, raising, however, concerns about the impact that their production and disposal could have on the environment.[5] Renewable materials, environmentally-friendly processes and safer batteries are needed for the sustainable development of electrochemical energy storage [6].

The sustainable use of natural resources is indispensable for future energy storage. As a step towards the utilisation of biowaste, hard carbon produced from waste apples is demonstrated to be a high performance active material for Na-ion batteries [7].

The aqueous processing of lithium-ion battery (LIB) electrodes has the potential to notably decrease the battery processing costs and paves the way for the sustainable production (and recycling) of electrochemical energy storage devices. In this study, we show that the addition of small quantities of phosphoric acid into the cathodic slurry yields NMC electrodes with outstanding electrochemical performance in lithium-ion cells [8]. Another example is the excellent performance of graphite/LNMO cells with both electrodes made using water-soluble binder [9].

A Photochemical Artificial Photosynthesis of CO₂ Reduction into Syngas Production

Roksana Rashid¹, Mohammad Faqrul Alam Chowdhury¹ and Zetian Mi¹,²; ¹McGill University, Canada; ²University of Michigan–Ann Arbor, United States

In this study, we have demonstrated for the first-time, enable, efficient, unassisted photochemical reduction of carbon dioxide (CO₂) into syngas using wafer scale multiband InGaN/GaN nanowire structures without using any sacrificial reagent. The effective manipulation and control of charge carrier flow in nanostructured photocatalysts provides critical insight in achieving high efficiency artificial photosynthesis, which includes the efficient and selective reduction of CO₂ into solar fuels.

Supercapacitors within the Water-Energy Nexus

Francesca Soavi¹, Federico Poli¹, Francesca E. Spina¹, Alessandro Brilloni¹, Jacopo Seri¹, Mehrdad Mashkour¹,², Mohammad Said El Halimi¹,³, Maria L. Focarete¹, Clara Santato⁴, Carlo Santoro⁵, Bridget K. Mutuma⁶, Amanda Bubu⁶ and Ncholu Manyala⁶; ¹University of Bologna, Italy; Babol Noshirvani University of Technology, Iran (the Islamic Republic of); ³University Abdelmalek Essaadi, Morocco; ⁴Polytechnique Montréal, Canada; ⁵University of West of England, United Kingdom; ⁶University of Pretoria, South Africa

Supercapacitors (SC) are playing a key role within the so called Water-Energy Nexus. Indeed, SCs can improve the quality of electric energy harvested from intermittent renewable energy source and from microbial fuel cells (MFC) that are bio-electrochemical devices that convert the chemical energy of wastewater organic compounds directly into electrical energy.

In this scenario, lowering the price and minimizing the environmental and economic impact of disassembly and recycling of end-of-life SCs are is mandatory.

The use of water-processable electrode binders and new membrane production techniques like electrospinning are viable approaches to decrease cost and environmental footprint.

A study on the development of bio-inspired supercapacitors and their integration with MFCs is reported and discussed.

Specifically, a pullulan-based supercapacitor featuring carbon electrodes obtained by the pyrolysis of pepper seeds and working with ionic liquid electrolyte is hereby proposed. The use of a water soluble, biodegradable polymer as binder and separator along with a hydrophobic ionic liquid brings about a novel approach for device end-of-life management. The use of melamine as pseudocapacitive electrode material is also presented.

Acknowledgments

The research has been carried out under the Italy-South Africa joint Research Programme 2018-2020

Greener Process for Greener Batteries—Application of Use of Water Processable Binders in Aqueous Rechargeable Lithium-Ion Batteries

Steeve Rousselot, Lida Hadidi, Jacopo Profili, Erica Tomassi, Maxime Nicolas and Mickael Dollé; Université de Montreal, Canada

Sustainability for energy storage systems and environmental protection imply both the use of environmentally benign materials and the development of green processes. Rechargeable lithium ion battery (LIB) with organic electrolyte has found many applications. Its high energy density and long cycle life make it the best option compared to other secondary batteries. However, environmental impact throughout their fabrication and disposal, safety concerns during their use, and cost remain the main drawbacks for large-scale applications. Hence, interest in aqueous electrolyte rechargeable LIB (ARLB) has grown, particularly for safe and cost effective large scale devices.

To reduce the adverse environmental/human impact of LIB production, the electrode preparation process needs to be revisited. In this regard, replacing common binders (e.g. fluorene-containing polymers; polyvinylidene difluoride (PVDF)) and noxious organic solvents (e.g. N-methyl-2-pyrrolidone (NMP)) by non-toxic and aqueous processable binders is a must. Water soluble binders such as carboxymethyl cellulose (CMC) have gained considerable attention due to their natural abundance, water processability and lower cost.

Nevertheless, using water soluble binders in electrodes for aqueous batteries is challenging because of their solubility in aqueous electrolyte with low salt concentration. In our group, we successfully addressed this issue by developing a strategy to prepare electrode employing CMC usable in ARLB. A chemical modification of the electrodes prevents the loss of electronic percolation and allows the cycling over a prolonged number of cycles in low concentrated aqueous electrolytes.

In this presentation, the physiochemical properties and electrochemical performance of such electrodes were investigated and compared to that of electrodes prepared with typical binders in organic electrolytes.

11:30 AM EN03.06.08
Pillared and Hetero-Layered 2D Metal Carbides (MXenes) for Electrochemical Energy Storage

Armin VahidMohammadi1, Weiqian Tian2, Wentao Liang3, Mehrnaz Mojtabavi3, Meni Wanunu3, Mahiar M. Hamedi2 and Majid Beidaghi1; 1Auburn University, United States; 2KTH Royal Institute of Technology, Sweden; 3Northeastern University, United States

Two-dimensional (2D) materials have shown promising performances as electrode materials for electrochemical energy storage devices. Most individual 2D materials, however, suffer from certain limitations and therefore, cannot be individually considered as practical electrode materials for supercapacitors or batteries.[10] Controlled pillaring of 2D materials into multilayers and vertical stacking of different 2D layers into heterostructures have shown to be effective methods to avoid their self-restacking and overcome drawbacks of individual 2D materials. Such pillared 2D multilayers or superlattice heterostructures built by sequential stacking of single or multiple 2D layers can
display new and improved electrochemical responses and offer a combination of their building blocks’ best properties. 2D metal carbides (MXenes) have recently received huge attention for energy storage applications due to their diverse compositions, ability to intercalate a variety of cations, and high rate pseudocapacitive properties. Self-restacking of MXenes and their lower capacitances compared to other pseudocapacitive materials, however, have hindered their further development. Also, because of instability and rapid structural degradation of the delaminated form of various MXene compositions, most studies on MXenes have been limited only to Ti$_3$C$_2$Tx. Here in this presentation, we demonstrate new pillared and heterostructure MXene architectures fabricated by controlled self-assembly of individual MXene sheets. The fabricated pillared MXene multilayers and MXene heterostructures show stable and superior electrochemical performances in aqueous and organic electrolytes. For example, alkali-cation pillared multilayers of V$_2$CTx could deliver volumetric capacitances of over 1300 F cm$^{-3}$ and maintain ~78% of their initial capacitance after one million cycles at a rate of 100 A g$^{-1}$ in aqueous supercapacitors. In addition, all-solid-state supercapacitors based on pillared Ti$_3$C$_2$Tx electrodes fabricated by a precise layer-by-layer (LBL) self-assembly method delivered high energy and power densities of 3.0 Wh L$^{-1}$ and 4400 W L$^{-1}$, respectively. This is while Ti$_3$C$_2$Tx and V$_2$CTx MXene heterostructures showed new features in their cyclic voltammetry profiles and could deliver the highest volumetric capacitance of ~1470 F cm$^{-3}$ in 3M H$_2$SO$_4$ electrolyte. This study paves the way for the preparation of high-performance pillared and hetero-layered MXene structures for electrochemical energy storage applications and beyond.

NMC Cathode Materials with Outstanding Performance Generated by a Closed-Loop Recycling Process
Mengyuan Chen$^1$, Bin Chen$^1$, Xiaotu Ma$^1$, Zifei Meng$^1$, Dennis Bullen$^2$, Jun Wang$^2$, Zhangfeng Zheng$^3$, Eric Gratz$^3$ and Yan Wang$^1$; $^1$Worcester Polytechnic Institute, United States; $^2$A123 Systems, United States; $^3$Battery Resources, United States

Lithium-ion batteries (LIBs) is widely used in every aspect of our life due to its high energy density and long cycle life. However, the large demand of LIBs will also lead to a substantial end-of-life (EOL) batteries which requiring proper treatment. Recycling EOL LIBs not only mitigates the production of hazardous waste caused by improper disposal, it also can recover the value from strategic materials. A closed-loop recycling process developed in WPI has demonstrated its successful in synthesizing recycled NMC 111 with excellent electrochemical performance when compared with a commercially available cathode. Now, WPI moves forward to demonstrate its feasibility to synthesize high-nickel NMC cathode powder-NMC 622. Here, recycled NMC 622 shows better rate and cycle performance comparing to a commercially and chemically equivalent. In addition to that, NMC 622 cathode is coated with alumina oxide using two coating methods (dry coating and wet coating) and its cycle stability is improved.

Electrolyte Dictated Organic Electrode Materials Design for Energy Storage
Yan Yao; University of Houston, United States
The quest for cheaper, safer, higher-density, and more resource-abundant energy storage has driven significant battery innovations. Existing lithium-ion batteries (LIBs) use cobalt-heavy active electrode materials that are predicted to see supply constraints going down the path and can be too expensive to meet long-term capital cost goals for grid storage and electric vehicle systems ($100 kWh^{-1}$). On the other hand, the safety issues with commercial LIBs mainly originate from the flammable and volatile nonaqueous electrolytes. Safer systems with solid-state and aqueous electrolytes are being actively developed, but today’s active electrode materials are not optimized for these electrolytes in terms of chemical and electrochemical compatibility. In the course of overcoming the above limitations, considerable innovations are taking place in the development of active materials featuring sufficiently high energy, Earth-abundant elements, and unique electrolyte-dictated properties. A notable family of such materials is organic battery electrode materials (OBEMs), which comprise electrochemically redox-active organic compounds including molecules, polymers, and organometallics where the organic components contribute to redox activity. In this talk, I will compare OBEMs with dominating/competing inorganic materials through analyses of charge storage mechanism, working potential, specific capacity, resource availability. We show that from high-energy lithium batteries to aqueous, Mg-ion, and all-solid-state batteries, OBEMs can be designed to be sufficiently capable and offer unique feature sets unmatched by other materials.

How Protective Layer Forms in High-Concentrated Sodium Aqueous Electrolyte for High-Voltage Aqueous Rechargeable Battery

Myeong Hwan Lee, Sung Joo Kim and Kisuk Kang; Seoul National University, Korea (the Republic of)

In the non-aqueous based conventional Li-ion battery (LIB) system, solid-electrolyte interphase (SEI) layer have been successfully prevented the electrolyte decomposition on the electrode surface, which enables the representative reversible electrochemical reaction, while the aqueous electrolyte could not form a stable protective layer on the electrode. However, the recent invention of highly concentrated aqueous electrolytes has outperformed conventional electrolytes by producing the SEI layer with anion decomposition and suppressing water splitting. Nevertheless, the high-concentrated aqueous electrolyte systems give a widened stability window and cycle stability with a robust protective layer, it still has a significant economic issue for their commercialization regarding the use of high-cost imide based organic solutes. In this study, we focused on finding a new low-cost high-concentrated aqueous electrolyte and studying how SEI layer forms in this newly investigated aqueous electrolyte. For evaluating these issues, we revisited all the commonly used low-cost inorganic salts and demonstrate them for their use in high-concentrated aqueous electrolytes. The reinvestigated highly concentrated aqueous electrolyte offers a wide electrochemical stability window of up to 2.7 V with forming a stable protective layer without involving the reduction of salt anions. In addition, we proposed a new mechanism of the protective layer formation on the electrode surface involving the residual gas reduction in different from the model of the anion decomposition. It was noted that the relative stability of this protective layer in the high-concentration aqueous electrolyte assists the stability of the electrode in the cell, resulting to exhibit the extraordinary electrochemical storage stability of the full-cell for over 900 hours.

Highly Porous Anisotropic Wood Aerogels

Jonas P. Garemark, Yuanyuan Li, Xuan Yang and Lars Berglund; KTH Royal Institute of Technology, Sweden

Highly porous aerogels with anisotropic structural properties are highly demanded in many areas, ranging from thermal insulators in buildings to supercapacitors in electrical devices. Currently, aerogels are often made from synthetic polymers. With the depletion of fossil energy and increasing environmental concerns, the research focus has been shifted to biomass-based materials. In this work, a highly porous anisotropic wood aerogel is prepared from a top-down synthesize method. The preparation comprises removal of lignin followed by a cellulose dissolution/regeneration regime with DMAc/LiCl. The co-solvent partially dissolves the cell wall and the regeneration results in a porous cell wall with fibrillated networks inside the fibres lumen. The aerogels retain the structural anisotropy of natural wood, exhibits a high specific area of 247 m²/g, whilst remaining mechanically strong. As a demonstration, the aerogels are carbonized to yield electrodes towards supercapacitor applications. This top-down approach is found to be a novel preparation method for porous materials towards energy storage and harvesting.

Exploratory Studies of an Alkaline Polysulfide-Permanganate Redox Flow Battery

Jesse Hinricher and Fikile Brushett; Massachusetts Institute of Technology, United States

Energy storage has emerged as a key technology for improving the sustainability of electricity generation by improving the efficiency of existing fossil-fuel infrastructure through load-leveling, alleviating the intermittency of renewables, and providing high-value services (frequency regulation, voltage support, or back-up power) [1]. Redox flow batteries (RFBs) are promising devices for low-cost grid energy storage due to decoupled capacity and power scaling, long operational lifetime, easy thermal management, and reliable safety features. While a variety of redox chemistries have been investigated over the years, the all-vanadium RFB has been the most successful as it is based on four stable, water-soluble oxidation states of vanadium that enable both high cell potential and crossover tolerance. Despite these favorable attributes, the technology is considered too expensive for broad adoption, motivating efforts to advance new redox chemistries, separation strategies, and reactor formats which may offer pathways to lower-cost RFB systems.

In this presentation, I will describe an alkaline polysulfide-permanganate RFB whose cell voltage, solubility, and potentially-inexpensive constituent components make it a promising candidate redox chemistry [2, 3]. Cell performance and durability will be evaluated as a function of component material selection (electrodes, membranes), electrolyte composition, and operating conditions. In addition, failure mechanisms will be assessed and performance recovery strategies proposed.

Sustainable Free-Standing N-Containing Bubbled 3D Carbon Sponge for Supercapacitor Application

Arthi Gopalakrishnan and Sushmee Badhulika; Indian Institute of Technology Hyderabad, India

To overcome the increased demand in energy consumption and fossil fuel depletion, there’s a huge requirement for sustainable energy storage devices. Supercapacitors play a vital role compared to batteries and fuel cells in terms of high-power density, long cyclic stability and environment friendly. The simple, low-cost N-containing bubbled 3D carbon sponge was prepared by the carbonization of polyaniline nanofibers coated onto pre-carbonized carbon sponge as scaffold. In this material, the 3D carbon sponge derived from kitchen sponge acts as a base framework for polyaniline fibers growth by chemical synthesis. The further carbonization of fibers on carbon sponge results in bubble formation at the nodes of network with nitrogen doping that leads to increasing the specific surface area from 75 m² g⁻¹ for carbon sponge to 212 m² g⁻¹ for bubbled carbon sponge. The morphology and N-doping of the material was confirmed by scanning electron microscope and energy dispersive spectroscopy respectively. It was found that this free-standing 3D nitrogen doped carbon sponge in symmetric cell exhibits high specific capacitance of 273 F g⁻¹ at 0.5 A g⁻¹ of current density with excellent cyclic stability. This high specific capacitance of the material was due to the interconnected microporous structure of carbon framework with bubbled structure at nodes that provides pathway for the rapid electron transfer kinetics during electrochemical reaction, N-doping and its high electrical conductivity. The high electrochemical performance makes this free-standing 3D all carbon framework a material promising for developing nanocomposites coated with metal oxides, sulfides etc. for practical potential energy storage applications.

Charge Transport Properties of the Biopigment Sepia Melanin Towards Sustainable Electronics

Abdelaziz M. Gouda¹, Francesca Soavi¹ and Clara Santato¹; ¹Ecole Polytechnique Montreal, Egypt; ²Alma Mater Studiorum Università di Bologna, Italy

The intermittent nature of the most reliable energy source, the Sun, requires high performance energy storage technologies [1]. Organic electrode materials operating in aqueous electrolytes offer the opportunity to use
abundant, nontoxic, low cost materials, avoiding the use of critical elements. Unfortunately, organic materials often feature limited cyclability [2, 3].

Among organic materials, eumelanin is a bio-sourced, redox active, quinone-based macromolecule, ubiquitous in flora and fauna. Eumelanin originates from the oxidative polymerization of L-3-(3,4-dihydroxyphenyl)-alanine (L-dopa) via 5,6-dihydroxyindole (DHI) and 5,6-dihydroxyindole-2 carboxyl acid (DHICA) building blocks [4]. It has fascinating properties beyond the redox activity, such as strong broadband UV-visible absorption, metal binding affinity and radical quenching [5]. The redox activity of the building blocks and the capability to reversibly bind cations constitute the foundation for the use of eumelanin in energy storage [2, 6].

In this work, we report on the electrochemical energy storage performance of composites of N-doped and pristine Carbon Quantum Dots (CQDs) with eumelanin. The composites were prepared at different weight ratios (eumelanin building block:CQD 1:0, 1:0.4, 1:1, 1:2) through a solution-based process followed by in situ polymerization [7]. From the cyclic voltammetry, galvanic charge/discharge and electrochemical impedance spectroscopy characterizations of the composite electrodes in nearly neutral aqueous electrolyte solutions, it has been possible to deduce, with respect to bare melanin electrode, that the composite electrodes feature an increase of the areal capacitance from 0.02 mF/cm² to 0.84 mF/cm² and a decrease of the charge transfer resistance from 42 Ohms to 20 Ohms. Composite electrodes also feature a capacitance retention of ca. 99.5% and coulombic efficiency of ca. 100% during 4000 cycles.

4:30 PM EN03.07.07
Stable Thiophosphate-Based All-Solid-State Lithium Batteries through Conformally Interfacial Nano Coating Daxian Cao¹, Yubin Zhang², Adelaide M. Nolan¹, Yifei Mo³, Yan Wang² and Hongli Zhu¹; ¹Northeastern University, United States; ²Worcester Polytechnic Institute, United States; ³University of Maryland, United States

All-solid-state lithium batteries (ASLBs) are promising for next generation energy storage system with critical safety. Among various candidates, thiophosphate-based electrolytes have shown great promises because of their high ionic conductivity. However, the narrow operation voltage and poor compatibility with high voltage cathode materials impede their application in the development of high energy ASLBs. In this work, we studied the failure mechanism of Li₆PS₅Cl at high voltage through in situ Raman spectra and investigated the stability with high-voltage LiNi₁/₃Mn₁/₃Co₁/₃O₂ (NMC) cathode. With a facile wet chemical approach, we coated a thin layer of amorphous Li₀.₃₅La₀.₅Sr₀.₀₅TiO₃ (LLSTO) with 15-20 nm at the interface between NMC and Li₆PS₅Cl. We studied different coating parameters and optimized the coating thickness of the interface layers. Meanwhile, we studied the effect of NMC dimension to the ASLBs performance. We further conducted the first principles thermodynamic calculations to understand the electrochemical stability between Li₆PS₅Cl and carbon, NMC, LLSTO, NMC/LLSTO. Attributed to the high stability of Li₆PS₅Cl with NMC/LLSTO and outstanding ionic conductivity of the LLSTO and Li₆PS₅Cl, at room temperature, the ASLB exhibit outstanding capacity of 107 mAh g⁻¹ and keep stable for 850 cycles with a high capacity retention of 91.5 % at C/3 and voltage window 2.55-4.0 V (vs. Li-In).

4:45 PM EN03.07.08
Structural Influences on the Performance and Storage Mechanisms in Hard Carbons for Sodium-Ion Batteries Heather Au¹, Hande Alptekin¹, Anders Jensen², Alan Drew² and Magdalena Titirici¹; ¹Imperial College London, United Kingdom; ²Queen Mary University of London, United Kingdom
Sodium-ion batteries have shown potential as a cost-effective successor to lithium-ion batteries, but the performance is still limited by their low energy density and poor cycleability compared with lithium-ion analogues. The development of suitable electrode materials is crucial for the realisation of sodium-ion batteries as a feasible replacement. Disordered carbons, also known as ‘hard carbons’ (i.e. those with some degree of graphitisation but randomly oriented graphitic domains) are considered promising anode materials due to negligible volume change during the sodiation/desodiation cycles, essential for achieving a long cycle life.

A range of materials were prepared via hydrothermal carbonisation of various biomass precursors followed by further heat treatment; by tuning the carbon source, the nature and amount of dopant, the templating agent and the treatment temperature, carbon anodes with varying degrees of graphitisation and tailored pore size, wall thickness and heteroatom functionalities were obtained. The pore structure, particle size, nature of defects and degree of doping were found to have a significant effect on the storage capacity and cycleability of the batteries. The ability to tailor these hierarchical nanostructures therefore makes this process a promising route to achieving new electrode materials.

EN03.08.01

Carbon Nanomaterials with Dominant Micropore Texture Parameters for Capacitive De-Mineralization
Cecil King'ondu1, Enock T. Kibona2 and Steven L. Suib3; 1Botswana International University of Science and Technology, Botswana; 2University of Dar es Salaam, Tanzania, United Republic of; 3University of Connecticut, United States

With a growing number of studies providing credible evidence that the highest capacitance in carbon nanomaterials is attainable only when the pore size is 0.7 nm, the special attention in porosity engineering is strongly biased towards micropore. Microporous carbon materials are thus extremely promising in the development of high-performing capacitive devices compared to their meso and macroporous counterparts. In this study therefore, carbon materials with extremely high micropore content was derived from *parinari curatelifolia* (PC) waste seeds via pyrolysis and chemical activation. Characterization using SEM, EDAX, TEM, Raman, and XRD techniques show that the microstructure and composition of the as-prepared carbon materials are strongly dependent on the KOH to carbon mass ratio. High BET surface area of 1898 m² g⁻¹, type I isotherm, and 99% micropore content were obtained for the carbon materials. The electrodes made from these carbon materials showed high specific capacitances of 423 F g⁻¹ at 5 mV s⁻¹ and cyclic stability of 98% after 50000 cycles both of which are indicative of our carbon materials huge potential in making high performance capacitive demineralization devices. The high specific capacitance the PC carbon materials deliver is due to the enhancement of diffusion and charge storage stemming from the synergetic interplay of the aforementioned textural parameters.

EN03.08.02

Dehydrogenation Kinetics of Mg2FeH6 by In Situ Transmission Electron Microscopy
Juyoung Kim1,2, Julien Fadonougbo2, Jae-Hwan Bae2, Jaeyoung Hong2, Young Whan Cho2, Gyeung Ho Kim2, Jin Yoo Suh2 and Dongwon Chun2; 1Yonsei University, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of)

Hydrogen is considered as a promising alternative energy sources because it can potentially replace fossil fuel to clean energy due to its high energy density (142MJkg⁻¹) as well as no harmful gaseous by-products after combustion [1]. Nevertheless, the lack of efficient storage system hinders its widespread application. For the efficient hydrogen system, storage materials must readily take up hydrogen and subsequently release it again at a sufficiently high rate.
of hydrogenation / dehydrogenation process. Thus, understanding the kinetics of hydrogen storage materials during the process is indispensable.

Magnesium ternary hydrides Mg$_2$FeH$_6$ have been extensively studied as a candidate hydrogen storage materials due to its hydrogen gravimetric density (150 kg/m$^3$) as well as a good cycling ability (~1000 hydrogenation / dehydrogenation cycles) [2,3]. However, kinetics during hydrogenation / dehydrogenation process in Mg$_2$FeH$_6$ is unrevealed by the limitation of in-situ observation analytical method.

In this study, we investigated the dehydrogenation kinetics of Mg$_2$FeH$_6$ by in-situ transmission electron microscopy (TEM) holder system (Fusion, Protochips). We placed nanostructured Mg$_2$FeH$_6$ sample on the chip and heated up the temperature 300 °C for 30 minutes to trigger the hydrogen decomposition in Mg$_2$FeH$_6$. We acquired high-resolution images and diffraction patterns (25 frames every second) of Mg$_2$FeH$_6$ during dehydrogenation process by one-view camera (One-view, Gatan) attached on Titan (G2, FEI). In addition, EDS analysis was performed by super-EDS embedded TEM (Talos F200X, FEI) to investigate particle size of Fe and Mg after dehydrogenation.

As expected, Mg$_2$FeH$_6$ diffraction patterns were observed in as-prepared Mg$_2$FeH$_6$ sample. Upon heating, intensities of Mg$_2$FeH$_6$ diffraction patterns decrease and eventually disappeared due to the hydrogen desorption. On the other hands, new Mg and Fe diffraction patterns were produced in the beginning of dehydrogenation process due to the phase segregation of Mg and Fe from Mg$_2$FeH$_6$. In addition, oxide phases such as MgO and Fe$_2$O$_3$ were observed possibly due to the oxidation inside TEM column.

We estimated dehydrogenation speed from the diffraction patterns of Mg$_2$FeH$_6$ and it rapidly increases up to the process temperature of 300 °C. For example, diffraction patterns of Mg$_2$FeH$_6$ were disappeared within 120 sec at 260 °C and it was shorten to 12 sec. At the process temperature of 280 °C. Also, average particle size of Fe after the dehydrogenation process was investigated through EDS results because hydrogenation speed largely depends on its dimension. It was revealed that estimated average particle size after the process is ~ 10 nm at 260 °C and 15 nm at 280 °C.

Sulfur-Doped Biomass-Derived Graphene-Based Carbon for Supercapacitor with High Energy Density and Ultra-High Power Density SungHoon Jung, Yusik Myung and TaeYoung Kim; Gachon University, Korea (the Republic of)

Here, we report a facile method to produce sulfur-doped graphene based-carbon with three-dimensional (3D) open structure from a biomass. The 3D graphene-based carbons were produced via the transformation of glucose-derived polymers and organosulfur compounds with starting materials provide additional properties of the graphitic carbon such as sulfur doping and coral-like open structures. In-situ physical activation was performed on this method and the open structures contributed hierarchically porous and sulfur doped biomass-derived graphene-based carbon with Brunauer-Emmett-Teller theory specific surface area of 3,426 m$^2$/g, providing a defined-mesoporosity without additional chemical activation. On organic electrolyte system, this carbon showed a high specific capacitance of 143 F/g for its high surface area, unique and interconnected structure and a highly graphitization with sulfur doping. Furthermore, this carbon-based supercapacitor electrodes exhibited high energy density of 33 Wh/kg and ultra-high power density of 1,732 kW/kg derived from its specific capacitance of 133 F/g at the high current density of 256 A/g.

EN03.08.04
2D Hexagonal Boron Nitride - Molybdenum Disulfide Nanocomposite Supercapacitor Electrodes Alptekin Aydinli$^{1,2}$ and Husnu E. Unalan$^{1,2}$; 1Middle East Technical University, Turkey; 2Energy Storage Materials and Devices Research Center (ENDAM), METU, Turkey

Two-dimensional (2D) materials are very promising as supercapacitor electrodes due to their high specific surface
area. In recent years, significant attention has been focused to environmentally friendly 2D hexagonal boron nitride (h-BN), since pristine 2D h-BN has many applications in high-temperature instruments and as a substrate for the growth of other 2D materials. However, its electrically insulating character in pristine form limits its utilization in electrochemistry and in electronic applications. Formation of nanocomposites with a conducting complementary materials offers a solution to this problem. In this study, we fabricated 2D h-BN/MoS$_2$ nanocomposite electrodes using solution phase synthesis routes and evaluated their electrochemical performance for supercapacitors. Prior to preparation of the electrodes both h-BN and MoS$_2$ were chemically exfoliated. Electrochemical properties such as specific capacity and capacity retention of the fabricated nanocomposite electrodes were examined through cyclic voltammetry, chronopotentiometry and electrochemical impedance spectroscopy in three electrode configuration. Obtained results were compared to that of the control sample fabricated from bare MoS$_2$ nanosheets. In order to determine the effect of electrolyte type on the electrochemical properties of the nanocomposite electrodes, various aqueous solutions, such as sodium sulfate (Na$_2$SO$_4$), hydrochloric acid (H$_2$SO$_4$) and potassium hydroxide (KOH) were investigated. Fabricated supercapacitor electrodes showed encouraging specific capacitance values exceeding 100 F/g. A comprehensive analysis on the electrochemical properties of the fabricated supercapacitor will be presented.

EN03.08.05
Green Electrodes Material, Electrolyte and Separator for High-Performance Supercapacitor
Mohammad Said El Halimi$^{1,2}$, Federico Poli$^1$, Mehrdad Mashkour$^1$, Alessandro Brillon$^1$, Nicola Mancuso$^1$, Alessandro Olivieri$^1$, Tarik Chafik$^3$ and Francesca Soavi$^1$; $^1$Alma Mater Studiorum University of Bologna, Italy; $^2$Abdelmalek Essaadi University, Morocco; $^3$Abdelmalek Essaadi University, Morocco

The global demand for clean energy and water combined with the rising market of supercapacitors requires materials, components, and systems to be developed with a green approach. Recently scientists making great efforts towards the development of sustainable materials for the future generation of supercapacitors, considering the environmental and economic impacts.

The present work investigates some green materials for supercapacitor such as: using Argan fruits shell (agriculture wastes) to obtain porous carbon electrodes material, ammonium acetate (salt in water electrolytes) and bacterial cellulose (biomaterial separator).

Carbon electrodes were obtained from the carbonization of Argan shells followed by activation using wet impregnation or dry physical mixing. The as-prepared samples have been subjected to textural investigations and comprehensive characterizations using SEM, XRD, Raman, FTIR, and BET. After selecting the sample with desired structural and textural proprieties, their electrochemical response was investigated ammonium acetate electrolyte with different concentration (from 1m up to 30m). Specifically, electrodes were obtained by using carbon-coated bacterial cellulose (BC) film as a current collector. The results of Electrochemical Impedance Spectroscopy (PESI), Cyclic voltammetry (CV) and Galvanostatic charge-discharge (GCPL) of the BC-electrodes and the BC-Supercapacitor making use of ammonium acetate solutions are here reported and discussed.

Acknowledgments
The research has been carried out under the support of the:
National Center for Scientific and Technical Research (CNRST), Morocco.

Hydrogenase-Assisted Catalysis on Titania Electrodes Xin Liu1, Patricia A. Carvalho2, Paul Hoff Backe3, Mingyi Yang3, Truls Norby1 and Athanasios Chatzitakis1; 1University of Oslo, Norway; 2SINTEF, Norway; 3Oslo University Hospital, Norway

The widespread use of fuel cells and water splitting devices for energy generation and storage is limited by the dependence on noble metal catalysts. There is thus a tremendous need for the development of efficient electrocatalysts based on Earth-abundant elements. Nature inspired hydrogenases (HydA) are metallo-enzymes that catalyze the reversible reaction of H2 to protons and electrons. Hydrogenases containing Fe at the active sites, known as [FeFe]-HydA, show activities comparable to that of Pt. This work addresses a new class of electrodes for [FeFe]-HydA attachment and bio-assisted catalysis based on TiO2 nanotubes. The conducting oxide material provides suitable electronic conduction and hydrophilicity, while the nanostructure ensures tunability (tube length, crystal orientation and pore diameter) and high surface area for HydA attachment. In this work, transmission electron microscopy and atomic force microscopy are used to characterize the bio-electrodes. Based on the experimental findings, density functional theory (DFT) calculations are used to probe the catalytic reaction sites on the HydA and address the interaction between enzymes and TiO2. The novel bioelectrode will be employed in a system of artificial photosynthesis and generation of solar fuels by simultaneous water splitting and CO2 capture and utilization.

Determination of Charge Carrier Transport Parameters in a Polymer Electrolyte Using Electrochemical Impedance Analysis T.M.W.J. Bandara1, Ajith DeSilva2, B.-E. Mellander1 and Sunil Dehipawala4; 1University of Peradeniya, Sri Lanka; 2University of West Georgia, United States; 3Chalmers University of Technology, Sweden; 4Queensborough Community College of CUNY, United States

Polymer electrolytes are key components in many electrochemical devices such as dye sensitized solar cells (DSC), fuel cells, batteries super-capacitors, sensors and biomedical applications. In order to characterize such electrolytes, we developed a method to determine the charge carrier density (n), mobility (µ), and diffusion coefficient (D) of ionic conductors with the help of dielectric analysis of electrolytes [1,2]. The method previously proposed by our group is further simplified making it possible to calculate these parameters by just using electrochemical impedance analysis (EIS). The method has been tested with gel polymer electrolyte based on polyacrylonitrile host polymer and alkaline iodide at deferent temperatures. The temperature dependence of n, µ, and D have also been studied. The results are in agreements with those available for the ionic electrolytes.

EN03.08.08
High Electrochemical Stability of Ag-Pt Core-Shell Nanowires in a Wide Potential Window Sensu Tunca1,
Silver nanowires (Ag NWs) are appealing candidates for supercapacitor electrodes due to their high conductivity in addition to their allowance for all active materials to be in close contact to facilitate charge transport. These are very important to attain maximum charge accumulation provided that Ag NWs are electrochemically stable within the utilized potential window. The potential window of bare Ag NWs was found as 0-0.5 V, where irreversible oxidation takes place at 0.6 V, limiting not only the potential window but also the power and energy density of supercapacitors in consequence. In this work, in order to extend the potential range, Ag NWs were coated with a thin platinum (Pt) shell layer using a simple solution based, green method. Fabricated core-shell nanowires were then deposited onto glass substrates in the form of networks via spray coating. Ag-Pt core-shell NW network electrodes were electrochemically tested and the potential window was found to be extended up to 1.2 V. The true potential of Ag-Pt core-shell nanowire network electrodes were further evaluated in coaxial nanocomposite form, which is simply achieved through cathodic electrodeposition of pseudocapacitive nickel hydroxide (Ni(OH)2) layers onto the networks [1]. Capacitive behavior of the coaxial nanocomposites was investigated through cyclic voltammetry, galvanostatic charge-discharge and impedance spectroscopy. Thorough analysis on the electrochemical stability and capacitive behavior of the fabricated nanocomposite electrodes will be presented in conjunction with different electrochemical coating parameters.

This work was supported by the Scientific and Technological Research Council of Turkey (TUBITAK) under grant no 117E539.

EN03.08.09
Rehydroxylation Methods on Mesoporous Silica with Impact on Fuctionalisation Tom F. O'Mahony; Trinity College Dublin, Ireland

Ordered mesoporous silica materials are used as supports for various applications from catalysts, chromatography and enzyme immobilisation. In this work, the impact of surface silane functionalisation was examined by various pre-treatment methods. The surface chemistry and physical properties were examined pre and post ‘cleaning’ of the supports.

The impact of these changes were then examined by functionalisation of the support with (3-aminopropyl)triethoxysilane with potentially increasing the efficiency of attachment and robustness of the end application.

SBA-15 was synthesised, calcined and characterised. The support was then rehydroxylated or ‘cleaned’ by various routes (H2O, H2SO4, H2O2/H2SO4 solution and UV/Ozonolysis) and then functionalised.

The results showed that using pre-treatment methods allowed for higher attachment of the silane.

Surface energy measurements were also determined showing the changes after pretreatment methods and after grafting with the silane.

EN03.08.10
Water-in-Salt Electrolytes for High-Voltage Aqueous Sodium-Ion Batteries David Reber1,2, Ruben-Simon Kühnel1 and Corsin Battaglia1; 1Empa, Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 2École Polytechnique Fédérale de Lausanne, Switzerland

The potential low cost and non-flammability of rechargeable batteries based on aqueous electrolytes make them a promising option for large-scale energy storage for grid applications. Using a highly-concentrated (35 molal) aqueous sodium bis(fluorosulfonyl)imide (NaFSI) electrolyte we recently reported a stability window of 2.6 V.[1] Using asymmetric FTFSI anions as solution to suppress the commonly encountered crystallization of highly concentrated aqueous electrolytes we further demonstrated that an electrolyte consisting of 25m NaFSI + 10m NaFTFSI is robust against crystallization at low temperatures and enables long-term cycling of 2 V class full cells even at -10 °C.[2]

Besides the electrochemical stability of an electrolyte, the chemical stability of its constituents is crucial for stable
Here, we explore the chemical stability and physicochemical properties of aqueous solutions of FSI salts as electrolytes for lithium-ion and sodium-ion batteries. We demonstrate that the rate of hydrolysis of this anion is strongly dependent on the salt concentration as well as the nature of the cation. We relate the stability of FSI to the interaction with the cation and the charge density of the latter, and show that also at elevated temperatures highly concentrated NaFSI electrolytes are significantly more stable than their lithium analogues. Yet, hydrolysis is still observed in the NaFSI electrolytes to some degree and we emphasize that major efforts are needed to develop new, highly soluble, stable salts in order to push the long-term performance of such aqueous systems towards competitive levels. [3]

Analysis of Crucial Parameters in the Solution Chemistry and Deposition Conditions Leading to the Synthesis of Pure Phase SnSb Electrodeposited From an Ethaline Solution
Jeffrey Ma and Amy L. Prieto;
Colorado State University, United States

Lithium-ion batteries are currently being used in majority of portable applications ranging from cell phones to electric vehicles. While the use of graphite as an anode has been successful for the last 30 years, there is currently a wide variety of research in new materials and architectures that can increase a lithium-ion battery’s overall energy density, cycle life, or rate capabilities. Intermetallic alloys have been promising due to their ability to improve the energy density when compared to graphite. Of these alloys, SnSb has been heavily studied and can be a potential candidate in replacing graphite.

We herein report on the synthesis of pure phase SnSb from ethaline solution. Previous reports on electrodeposition of SnSb resulted in the presence of a Sn rich product. While the synthesis may be described simply, specific parameters (in the solution composition as well as the method of deposition) must be achieved to form this material in the pure phase. An in depth analysis with multiple characterization techniques will be used to clarify what is occurring with changes to specific parameters in the synthesis. Lithium battery cycling studies will also be presented, showing the material’s performance compared to Sn-rich production seen in previous electrodeposition reports.

EN03.08.12
Preparation and Electrochemical Property Measurement of Monolithic Carbon Xerogel from Resorcinol-Formaldehyde-Graphene Oxide via One-Step, Template-Free and Catalyst-Free Hydrothermal Reaction
Minhu Huang, Jae-Suk Lee and Tae-Ho Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Monolithic carbon xerogel with co-continuous hierarchical porosity was prepared via one-step, template-free and catalyst-free hydrothermal polycondensation reaction with resorcinol(R), formaldehyde(F) and mildly oxidized graphene oxide. The gels were prepared in a pressurized Teflon mold at 100 °C for 6 h, followed by drying at 60 °C for 36 h and then 100 °C for 12 h, generating xerogels. The R/W ratio and loading of graphene oxide were varied to optimize pore size with co-continuous hierarchical pore structure. Next, the xerogels were subjected to pyrolysis at 900 °C for 2 h, followed by KOH infiltration and activation at 800 °C for 1h. The gels, before and after the activation, were subjected to N2 sorption study and also to electrochemical property measurement via cyclic voltammetry, while the samples for the latter were prepared via cutting the monolithic xerogels rwithout involving polymeric binder and solvent. In addition, XRD, Raman and SEM were also utilized for characterization.

EN03.08.14
Optimization of Nano Sized Silicon-Based Graphene Anodes for Lithium-Ion Batteries
Gunisha Jain, Sara Abouali, Vittorio Pellegrini and Fabio Di Fonso; Istituto Italiano di Tecnologia, Italy
Silicon graphene based composites can be very promising next generation lithium ion battery (LIB) anodes because of silicon having high capacity ($4200 \text{ mA h g}^{-1}$ and $2400 \text{ mA h cm}^{-3}$) and lower electrochemical potential with respect to Li ($< 0.35 \text{ V vs. Li/Li}^+)$.

Unfortunately, bulk silicon anode faces other problems, e.g. poor cycle stability and great volume expansion. However, reports have suggested that silicon nanoparticles can overcome these issues by relieving larger stress/strain and facilitated by the short Li$^+$/electron transfer length. Extensive research has been performed with nano silicon-based anodes and major complexities rely with the optimization of silicon particle size, degree of crystallinity, dispersion of silicon particles in graphene matrices, nano silicon percentage in the composite etc. In this report, optimization of oxidation and degree of crystallinity of silicon nanoparticles is studied for better battery performance. A simple and scalable plasma enhanced chemical vapor deposition technique is used to produce silicon nanoparticles with variable range of crystallinity. A detailed characterization is performed to investigate chemical, structural and morphological characteristics of these particles. Later, these particles are used as anode material in LIBs. Anodes are prepared with conductive few layers graphene and polyacrylic acid binder. These anodes showed excellent stability over 250 cycles with clear correlation between particle size, crystallinity and oxygen content. Results are very promising with these silicon NPs, with the capability of scalable production process.

EN03.08.15
Sulfurized Anodic TiO$_2$ Nanotube Layers for Energy and Catalytic Applications
Milos Krbal$^1$, Girish D. Salian$^2$, Siow Woon Ng$^3$, Ludek Hromadko$^{1,3}$, Hanna Sophie$^{1,3}$, Alexander T. Tesfaye$^2$, Jan Michalicka$^4$, Thierry Djenizian$^5$ and Jan M. Macak$^{1,3}$; $^1$University of Pardubice, Czechia; $^2$Center of Microelectronics in Provence, France; $^3$Brno University of Technology, Czechia

The self-organized TiO$_2$ nanotube (TNTs) layers have attracted considerable scientific and technological attention for the last two decades. Nowadays, they perform very well in a wide range of applications including photocatalysis, solar cells, hydrogen generation and energy storage [1]. The synthesis of 1D TNTs layers is carried out by a conventional electrochemical anodization of valve Ti metal sheet. The main drawback of TiO$_2$ is its applicability in the UV light (wavelengths < 390 nm). In order to obtain also visible light photoresponse, TiO$_2$ has to be doped or sensitized. For example, N [2] or C [3] were used as very effective TiO$_2$ dopants. Except the extension of the VIS light response, one of the major issues to extend the functional range of nanotubes is to coat homogenously the nanotube interiors by a secondary material. It has been shown that additional ultrathin surface coating of TNTs by secondary materials using Atomic Layer Deposition (ALD) significantly improves the functionality of the resulting hetero-structure for various applications [4]. Next to the ALD, sulphur treated 1D anodic TNT layers possess improved photo-electrochemical and catalytic properties and the energy storage compared to the blank TNT layers [5, 6]. This treatment was performed in the evacuated quartz ampoules in the temperature range from 250 to 450°C. An inspection of the sulfurized nanotube layers via scanning electron microscopy (SEM), X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) has disclosed a gradual crystal growth within nanotube walls, represented by TiS$_2$ or TiS$_3$ phases. It was found that each application requires a different optimum condition of sulfurization.

The presentation will focus on the sulfurization process of TNTs and their characterization. The potential applications in various fields (such as batteries, photocatalysis) of prepared TiS$_x$/TNTs heterostructures will be discussed.

Iron Layered Vanadate Nanocomposite with Fluorine Free-WIS Electrolyte for Low Cost and Green Energy
Supercapacitor Fitri Nur Indah Sari¹ and Jyh-Ming Ting¹,²; ¹National Cheng Kung University, Taiwan; ²Hierarchical Green-Energy Materials (Hi-GEM) Research Center, Taiwan

In this study, low-cost, environmental friendly “water in salt (WIS)” electrolyte was introduced to replace the expensive and toxic organic electrolyte of supercapacitor. Very recently, potassium acetate (CH₃CO₂K) electrolyte was found to be able to replace the LiTFSI in LiB. To our best knowledge, this new WIS electrolyte has not been demonstrated in aqueous supercapacitor. Moreover, CH₃CO₂K is safer and cheaper than LiTFSI-based WIS electrolytes. Therefore, in this study, we open up new opportunities of using acetate-based WIS electrolyte in the supercapacitor. We demonstrated that acetate-based WIS able to obtain wide potential window up to 2.5V. We investigated several acetate-based WIS, such as CH₃CO₂K, CH₃CO₂Na, CH₃CO₂Li, and its combination. The result shows that mixing two WIS leads to wider potential window up to 3V. We investigated the performance of CH₃CO₂K-CH₃CO₂Li WIS in iron layered vanadate nanocomposite. The synergistic effect of unique properties of iron layered vanadate nanocomposite and bi-WIS resulting high energy density of 53 Wh kg⁻¹ at power density of 672 W kg⁻¹. This environmental friendly electrolyte is very promising for next generation of supercapacitor.

EN03.08.17
Highly Conducting and Robust Laser Irradiated Graphene Film with Healed Defect for Integrated Metal-Free Energy Storage Devices Navpreet Kamboj and Ramendra S. Dey; Institute of Nano Science and Technology, Mohali, India

Small-scale energy resources become basic need for various widespread applications like implantable devices and portable electronics and internet of things (IOTs). Extensive development in supercapacitor technology aims to increase the electrical performance of electrode materials.¹ Interconnected porous graphene have gained a special attention to be use as supercapacitive material as well as current collector in developing metal-free interdigitated microsupercapacitor (IMSC) due to its superior conductivity and porosity.² Herein, Electrochemical followed by laser-irradiation (LI) method gives advancement in prototyping conductive graphene-based robust MSC device. Raman spectra proves that the laser irradiation method is capable of forming fused interconnected graphene sheets within healed structural defects, resulting high conductivity and improved crystallinity of LIG sample.³ An on-chip metal free microsupercapacitor using graphene as current collector as well as electrode material shows advantages of large working voltage of 1.2 V in aqueous solid electrolyte, providing high energy-density and long-term stability. The MSC, without any metal current collector, interestingly shows unique electrical-double layer behavior and unprecedented cycling stability with 100% retention of initial capacitance after 1,00,000 continuous cycle. A large cell voltage of 10.8 V was realized by modularizing the array of devices without much degrading the rectangular shapes of the voltammogram even at higher scan rates (100 V s⁻¹). Based on such high voltage MSCs, a hybrid structure of commercial solar cell and metal free supercapacitor was designed to make a self-charging power system. This study provides an effective strategy to build up metal-free supercapacitor with exceptional life cycle, highly durable and high-voltage flexible MSCs to facilitate progress toward a self-sustainable energy future.

Laser Ablation Synthesis in Solution (LASiS) as an Efficient Route for the Rational Design of Hybrid Carbon-Based Nanocomposites for Enhancements in Electrochemical Storage Erick L. Ribeiro, Bamin Khomami and Dibyendu Mukherjee; University of Tennessee, Knoxville, United States

The increasing global demand for clean and sustainable energy sources has given rise to the significant interest in the rational synthesis and design of low-cost and efficient functional nanocomposites and nanomaterials as supercapacitors in advanced electrochemical energy storage systems. Nonetheless, the design of such nanomaterials with tailored interfacial functionality and charge transport properties relies on the systematic and fundamental understanding of the processing-structure-property relations for precise tailoring of architectures and compositions of the active nanomaterials without using any undesired chemicals/surfactants/ligands that can compromise their electrochemical performance and interfacial activities. Herein, we present our most recent findings in using Laser
Ablation Synthesis in Solution (LASiS) as a strategy and pathway for the facile and environment-friendly, yet efficient, synthesis of new classes of carbon-based hybrid nanocomposites (HNCs) decorated with metal-oxide nanoparticles (NPs) that exhibit unique supercapacitive properties. Initially, we report the use of LASiS coupled with two-post treatments for the fabrication of (1) Co3O4 NPs/reduced graphene oxide (rGO), (2) Co3O4 nanorods (NR)/rGO, and (3) Co3O4 NPs/nitrogen-doped graphene oxide (NGO). This methodology allows us to tune the selective functionalities of the HNC by adjusting their structure-property relationships. The Nitrogen doping in the NR/rGO HNCs, for instance, promotes a higher electron conductivity while enhancing the electrochemical activity and preventing the aggregation between NPs. These interfacial energetics and arrangements coupled to the presence of a network of interconnecting 1D nanostructures have indicated to yield an effective charge transport and electrolyte diffusion at the electrode-electrolyte interfaces, resulting in the enhancement of the supercapacitive properties. Secondly, we will present the screening for other potential metal oxides with supercapacitive properties and the use of the same technique for the design of their HNCs for electrical chemical storage systems. Finally, we will present our advances on the development of functional conductive inks with fluidic properties containing the aforementioned HNCs for the fabrication of all-printed solid-state supercapacitors using drop-on-demand (DoD) inkjet printing; our results have shown that by tailoring the ratio of solvent, binder, and HNCs we can obtain an ink with the viscoelastic properties required for an efficient printing, while preserving the electrochemical efficiency of the composites.

EN03.08.19
Catalytic Origin and Universal Descriptors of Heteroatom-Doped Semiconductor Photocatalysts for Solar Fuel Production
Yonghao Zhu1, Lele Gong1, Detao Zheng1, Xiaowei Wang2, Jing Zhang3, Lipeng Zhang1, Liming Dai4 and Zhenhai Xia2; 1Beijing University of Chemical Technology, China; 2Univ of North Texas, United States; 3Northwestern Polytechnical University, China; 4Case Western Reserve University, United States

Solar fuels produced from sunlight via photocatalytic water splitting and artificial photosynthesis represent one of the most promising clean energy sources. Various semiconductors, including graphitic carbon nitride (g-C3N4) and transition metal oxides, have been considered as photocatalysts for the fuel production, but there lacks of the design principles for rapid screening of the best photocatalysts from numerous candidate materials. Here, we demonstrate, for the first time, a universal guiding principle that governs the photocatalytic activities of p-orbital element-doped C3N4-based photocatalysts for photocatalytic water splitting, which is also applicable to other doped semiconductors including ZnO and TiO2. An activity indicator is introduced to determine the efficiency of non-metal-doped semiconductor photocatalysts for the solar fuel production. These predictions are supported by experimental results. This generalized principle could guide a broad photochemical production of solar fuels including hydrogen, hydrocarbon, and other green chemicals.

EN03.08.20
Laser-Induced Graphene Microsupercapacitors from Biomass-Derived Poly(Furfuryl Alcohol) through Salt and Graphene Oxide Doping
Gillian Hawes1, Bruno Noremberg2, Dilara Yilman1, Priyanka Verma1 and Michael Pope1; 1University of Waterloo, Canada; 2Federal University of Pelotas, Brazil

Graphene has been widely investigated for applications in supercapacitors, due to its extremely high theoretical specific surface area, excellent electrical conductivity and lightweight nature. However, most synthesis routes for graphene-based supercapacitors are highly energy-intensive and costly, utilizing harsh chemicals, multiple synthesis steps, high temperatures, and/or specialized instrumentation. In 2014, the Tour group introduced a simple method to prepare high surface area, conductive and porous graphene through the laser-induced carbonization of specific polymers such as polyimide. This one-step approach is rapid, scalable, and cost-effective, utilizing commercial CO2 infrared laser systems commonly employed for laser cutting to combine graphene production and device fabrication in a single step. This approach has been utilized to fabricate polyimide-based laser-induced graphene microsupercapacitors with specific areal capacitances of ~ 9 mF/cm2. However, thus far this approach has been limited to costly synthetic polymers prepared from coal or petroleum-based products. Methods to extend this approach to other green materials such as lignin, paper, and wood employ more costly visible or UV lasers, fabrication in inert atmospheres, or pre-treatment of the substrate materials, limiting the ease and scalability of this approach. In this work, we demonstrate for the first time the laser-induced carbonization of poly(furfuryl alcohol), a green polymer easily prepared from the one-step polymerization of furfuryl alcohol, which is a biomass waste derivative obtained from corn cobs, rice hulls, bagasse, and wood. Notably, we explore the use of graphene oxide as a carbonization catalyst, demonstrating that loadings as low as 1 wt.% facilitate the laser-induced carbonization of
PFA utilizing an inexpensive CO2 laser under ambient conditions. Furthermore, we demonstrate that composites of PFA microspheres and graphene oxide can achieve specific areal capacitances as high as 16.0 mF/cm2 at 0.05 mA/cm2, which both outperforms the most commonly utilized polyimide films, and is among the highest specific capacitances achieved for supercapacitors prepared from this method. We further demonstrate that these devices cycle for over 10,000 cycles with over 97% capacitance retention. Finally, we introduce a novel method to utilize inexpensive and widely abundant salts, such as sodium chloride, as catalysts for the laser-induced carbonization of PFA. We demonstrate that these salts can enable the carbonization of the PFA into a porous, conductive carbon material and present results on the performance of supercapacitors prepared from these eco-friendly composites. Supercapacitors prepared from laser irradiation of PFA/GO and PFA/salt composites indicate the potential of uniting green materials and energy-efficient laser-induced fabrication for high-performance and sustainable next-generation supercapacitors.

Synthesis of Stable Bio-Based Aqueous Rechargeable Lithiu-Ion Batteries by Atmospheric Plasma Process
Jacopo Profili, Steeve Rousselot, Lida Hadidi, Maxime Nicolas, Luc Stafford and Mickael Dollé; Université de Montréal, Canada

In the last decade, many efforts have been made to develop new thin films by using atmospheric pressure plasma process. In this sense, many authors have developed complex materials such as nanocomposite thin films [1,2], biodegradable coatings [3] and advanced chemical treatments on complex surfaces [4]. In parallel, the use of plasma process has also been recently proposed to improve the electro-chemical characteristic of rechargeable lithium ion batteries (LIB) [5]. In this context, atmospheric pressure dielectric barrier discharges (DBDs) could offer the possibility to strongly improve the material’s surface properties with a limited cost and a little environmental impact in the manufacturing process. Moreover, today these systems can be easily modified to scale up the process in a production line.

Through this work, we aim to present our recent results on plasma-enhance modified composite electrodes employing water soluble Carboxymethylcellulose (CMC) as a binder that are usable in aqueous electrolyte rechargeable LIB (ARLB).

Plasma-deposited coatings were then characterized by SEM-EDX, FTIR and XPS. The electrical analysis of the process shows that the discharge remains stable and homogeneous during the process. This suggests that the substrate slightly affect the physical regime of the discharge. The SEM analysis obtained on the final electro-active material, shows a homogeneous surface and the creation of a specific morphology for the coating. From the FTIR analysis, different chemical groups were observed on the surface depending on the distance from the entrance of the discharge. Finally, the physico chemical properties and electrochemical performance of such electrodes were also investigated.

EN03.08.22
Dopamine-Assisted Au-Coated Polypropylene Micromembrane as a Flexible Porous Electrode
Shih-Cheng Chou, Bo-Han Huang, Tzu-Ling Fan, Wei-An Chung and Pu-Wei Wu; National Chiao Tung University, Taiwan

Porous electrodes exhibit impressive advantages including large surface area and fast electrolyte permeability. In the literatures, noble metals such as Au and Pt are known for electrochemical stability against different reactions and electrolytes, and therefore they are often used as the electrode materials. Unfortunately, due to their excessive cost, it is necessary to reduce their utilization. In this work, we adopt a polymeric membrane which provides a flexible and inexpensive porous substrate on which dopamine is deposited to render it hydrophilic so electroless Au deposition
could be proceeded successfully to fabricate a three-dimensional microporous flexible Au conductive electrode. SEM and EDS analysis are used to characterize the surface structure and composition distribution. Electrochemical and impedance analysis are carried out to identify the electrochemical surface area (ECSA) of Au film and solid-liquid interface resistance. In addition, we measure the resistance after multiple cycles of the bending test to determine the mechanical strength. We envision this Au-coated flexible porous electrode will become rather useful in flexible electronics.

**Binder-Free Phosphide-Based Nanostructures for High Performance Asymmetric Supercapacitor Devices**

Amina Saleh; The American University in Cairo, Egypt

A simple one-step method was demonstrated for the electrodeposition of phosphide-based nanostructures on nickel foam substrates. The electrodeposited materials were characterized using field-emission scanning electron microscopy (FESEM), X-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDS), and X-ray photoelectron spectroscopy (XPS) techniques. The materials were used as supercapacitor electrodes and showed exceptional high specific capacitance and rate capability. Upon using them to fabricate asymmetric supercapacitor device, high power density and energy density were obtained, indicating the high potential of the fabricated materials for practical energy storage devices.

**Melting Point Depression—A Simple Tool for Solubility Prediction of Phenothiazine Blends as High-Concentration Redox-Active Materials**

Giorgio Baggi, Darius A. Shariaty, Aman Preet Kaur and Susan A. Odom; University of Kentucky, United States

Non-aqueous redox flow batteries have shown great promise for grid energy storage, due to their independent scaling of power and energy, long operational lifetimes, simple manufacturing, and, when compared to their aqueous counterparts, a wider voltage window and a broader choice of electrochemical couples. Nevertheless, non-aqueous redox flow batteries must operate with high active material concentrations to exhibit high energy densities and simultaneously remain financially viable. In our previous work, we demonstrated that phenothiazine derivatives are valid candidates as posolytes for non-aqueous redox flow batteries, due to the high stability of their radical cations. The systematic chemical modification of the phenothiazine core allowed us to access an array of compounds with varying solubilities, both in neutral and radical cation state. Despite our effort to adopt simple and high-yielding synthetic routes, designing and synthesizing new redox active compounds with improved solubilities is time-demanding, often involving a trial-and-error approach. To overcome the burden of such discovery process, we proposed the study of binary and ternary mixtures of phenothiazines chosen from the active materials library developed in our group as higher-solubility alternatives to the pure constituents of such mixtures. Mixtures of solids are known to undergo the phenomenon of melting point depression – an “impure” solid exhibits a lower melting point than its pure form –, which, in turn, is associated to an overall increase in solubility of the mixture. In light of this, we first screened blends of phenothiazines to identify the ratios where a decrease in melting point is observed by thermal analysis. Subsequently, we determined the solubility of these mixtures in both states of charge – neutral and radical cation – in acetonitrile, with or without a supporting electrolyte, to correlate the extent of melting point depression to the increase in solubility. Preliminary results show significantly enhanced solubility for poorly soluble phenothiazines when present in mixtures. Also, an increase to up to three-fold has been observed for the total achievable concentration of mixtures of radical cation species. The results we report herein introduce an alternative, simpler method to achieve high concentrations of redox active materials and pave the way for a new approach to high-capacity non-aqueous redox flow batteries.

**EN03.08.25**

**Drop-on-Demand 3D Printed Lithium-Ion Batteries**

Ido Ben-Barak, Dan Schneier, Yosef Kamir, Meital Goor, Inna Shekhtman, Diana Golodnitsky and Emanuel Peled; Tel Aviv University, Israel

Innovation in rechargeable energy storage devices has a pivotal role in the green and sustainable energy cycle and in the portable device market. The recent trend of miniaturization of electronic devices in many fields, including remote sensors, personal electronics and medical implants, increased the demand for highly customizable, high energy-density batteries. These new demands provide opportunity for development of novel microbatteries and manufacturing processes that facilitate design of miniaturized electronic devices while maintaining a minimal
ecological footprint and waste production. Such devices have the potential to be designed to be lighter, smaller and more customizable, and use more sustainable chemistries than those of current commercial batteries.

To facilitate production of microbatteries of this type, we use drop-on-demand dispensing, a highly robust printing method already in use for various types of functional materials. This method, based on piezoelectrically actuated mechanical droplet formation, enables high accuracy and repeatability in the printing of active-material inks with different properties and rheological parameters. For a sustainable production process, we use aqueous inks, avoiding the use of organic solvents for the battery printing process, thus eliminating formation of organic fumes and waste. We have used this method to print various types of active materials for lithium-ion batteries, including cathode (lithium iron phosphate, LFP) and anode (silicon-nickel-based nanoparticles). Both yielded repeatable printability at a resolution better than 200µm, which allows customization of the printing process to produce various geometries, including 3D construction of upright electrodes for increased space efficiency and enhanced design possibilities. We found that the electrochemical performance of the printed active materials is highly competitive with traditional manufacturing methods. Cathodes show very high specific capacity, up to 160mAHr/g_{LFP}, close to its theoretical capacity, and good cycleability. Electrochemical impedance spectroscopy of cathodes shows that cathode chemistry and performance are unaffected by the printing process. Hence, direct implementation of well-established equivalent-circuit models is enabled for data analysis.

Anodes also show high capacity – up to 1200mAHr/g_{anode} and their electrochemical behavior is similar to that of anodes prepared by traditional methods. We studied the adhesion of printed anodes to several current collectors and present methods of improving it, both by modification of the current collector and the anode ink itself. The anodes with improved adhesion gave longer cycle life and better performance of microbatteries printed in nonconventional geometries.

As a substitute for typical battery separators, we have developed a self-pore-forming ink to be printed between electrodes. The ink is based on binders similar to those of the cathode and anode, which enable improved adhesion, high uptake of liquid electrolyte, and good mechanical and electrochemical properties.

Our results inspire further studies, development of manufacturing protocols, and designs for highly customizable batteries. Such development is of particular importance for small-scale and flexible production in many fields of applications, such as in-situ 3D printing of embedded batteries during the assembly process of electronic devices.

EN03.08.27
Electrocatalytic CO₂ Hydrogenation to Pure Formic Acid Vapour Using All-Solid-State Devices Lei Fan; Rice University, United States

Liquid electrolyte is inevitable to electrocatalytic transform CO₂ to liquid fuels, which will cause safety issues and energy-consumed downstream separations for pure products. Here we report an all-solid-state electrochemical CO₂ hydrogenation system, which can continuous produce pure formic acid (HCOOH) vapour without the employ of any liquid electrolyte in the full device. CO₂ and H₂ streams were separated into the cathode and anode by solid-state electrolyte (SSE), where generated HCOO⁻ and H⁺ were recombined to produce pure HCOOH vapour. Coupling with high activity (formate partial current densities > 440 mA cm⁻²) and selectivity (Faradaic efficiencies > 97%) grain boundary-enriched bismuth catalyst, we present a record high pure HCOOH vapour (ca. 100 wt.%). A wide range concentrations of pure HCOOH solutions without mixing with other ions were obtained by tuning the flow species (N₂ or water) and flow rates in the SSE layer. A 100-hour constant production of pure HCOOH with negligible degradation in selectivity and activity was demonstrated to verify the operational stability of our all-solid-state electrochemical CO₂ hydrogenation system.

EN03.08.28
Novel Binder-Free MXene/Transition Metal Oxide Hybrid Electrode Material with High Capacitance and Ultra-Long Lifetime Madhu S. Gaire, Kun Liang, Michael Naguib and Douglas B. Chrisey; Tulane University, United States

Transition metal oxide based pseudocapacitors have received significant attention as energy storage devices because of their excellent characteristics such as high power and energy density, long cycling stability etc. Among metal oxides, cobalt oxide (CoOx) is widely used; however, its low energy density compared to batteries, low conductivity along with larger volume change during the redox processes are still the limiting factors for utilizing it. A novel strategy to address these issues is to hybridize cobalt oxides with highly conductive and structurally robust materials that can improve the conductivity and the structural stability of the electrodes. In this regard, MXenes, a family of two-dimensional transition metal carbides and nitrides, are excellent candidates for the fabrication of the
nanocomposite with cobalt oxides due to their high conductivity, high surface area, hydrophilic surfaces and excellent electrochemical properties. As the size and surface morphology of the metal oxides play a crucial role in the electrode’s performance because the pseudocapacitance originates from the surface-based redox reactions, we have successfully synthesized a highly porous MXene-cobalt composite nanostucture, which facilitates the movement of ions/electrons and offers extremely high electrolyte-accessible surface areas, leading to a significant improvement in the electrochemical performance. Firstly, we have spray-coated the composite thin film on a Pt-Si substrate using an air spray. Secondly, we have synthesized the MXene-cobalt oxide composite electrode by using a novel PulseForge photonic curing technique in several seconds as opposed to the traditional methods such as, hydrothermal growth, chemical vapor deposition, chemical reduction etc. which take from minutes to hours for processing. To our knowledge, the processing we are reporting is the easiest, quickest and roll-to-roll amenable, making it a high-throughput and low-cost processing method. Furthermore, because of the extremely short photonic processing time, flexible and inexpensive substrates can also be used, signifying their potential application in modern wearable, flexible and portable electronics.

Through varying processing parameters such as the number of pulses, applied voltage, pulse length etc., we have shown we can easily control the resulting nanostructure of the electrode. The as-synthesized composite electrode exhibits initial specific capacitance of 26 mF/cm² and shows excellent improvements in electrochemical performance over the cobalt oxide electrode by retaining more than 60 % of initial specific capacitance whereas cobalt oxide electrode retains 30 % of initial specific capacitance after 15000 continuous charge-discharge cycles at 0.25 mA/cm² areal current density. These results could be attributed to the excellent electrochemical behavior of MXene along with its synergistic effect with the cobalt oxide material. Moreover, the nanostructures are grown directly on the highly conductive substrate, which improves the conductivity of the electrode and eliminates the need for a binder.

Organic Molecules as Charge-Storing Materials for Redox Flow Batteries  Susan A. Odom; University of Kentucky, United States

The development of charge-storage materials for use in redox flow batteries (RFBs) requires possession of a diverse property set that will lead to high capacities, voltages, and lifetimes for large-scale stationary storage application. High capacities require high solubilities in all states of charge. High voltages stem from large differences in redox potentials. Long lifetimes require stability far greater than the timescales at which many chemists are used to operating, who rarely have the need to isolate a charged species at high concentration in diverse environments for a decade or more. None of these properties may be compromised in realizing a commercial battery, on top of which low cost and scalability are paramount. Given the demands in materials design, cost, and scale, it’s a small wonder that the variety of redox couples utilized in commercial redox flow batteries are few. While the challenge of meeting these requirements may at first seem daunting, to the right organic chemist, an opportunity is presented. The flexibility in design and tunability of properties of organic materials presents a cornucopia of choices to evaluate as electrolyte candidates. In this presentation, I will focus on the design and characterization of organic molecules as candidates for charge-storage species in non-redox flow batteries with nonaqueous electrolytes.

9:00 AM EN03.09.02
Insertion Mechanisms of the PF6-, TFSI- and FSI- Anions in Carbonaceous Cathodes for All-Carbon Dual-Ion Batteries  Antonia Kotronia, Habtom Desta, Asfaw, Daniel Brandell and Kristina Edström; Uppsala University, Sweden

The possibility to intercalate anions into graphite is a well-known phenomenon, which was initially observed in 1983. However, studies of such compounds in the context of electrochemical energy storage were first reported in 2012, in connection with the coining of the term dual-ion battery (DIB). Dual-ion batteries operate through
simultaneous cation and anion intercalation in the anode and cathode and they could constitute a breakthrough for large-scale, grid energy storage applications. The main benefit of all-carbon DIBs compared to other battery chemistries is their completely metal-oxide free nature. This key characteristic of DIBs would result in cheaper, environment friendly, naturally abundant and more sustainable batteries. Furthermore, the replacement of oxygen-rich cathodes with graphite would be a big leap towards increased operational safety, since electrode decomposition and evolution of flammable gases would become minimized.

The main challenge faced by all-carbon DIBs at the moment is the capacity fading related to the structural changes of the graphite upon anion intercalation; since the anion together with its solvation shell occupies a substantial volume. This will eventually lead to exfoliation of the graphitic sheets and effectively loss of active material and capacity. However, recent research as well as the preliminary results of this study indicate that the exfoliation issue can be partially supressed through careful design of both the electrolyte and carbon host material.

In this study, several carbonaceous materials with different crystallographic and morphological features are explored as potential hosts: (1) a monolithic, graphitic carbon foam which is partially turbostratically disordered (2) a flexible, expanded graphite foil and (3) a composite electrode comprised mostly of highly graphitized KS6 graphite. Additionally, the intercalated anions are varied, with the main focus being on the PF₆⁻, TFSI⁻ and FSI⁻ species, which are inserted from both conventional organic solvents and from more "exotic" alternatives such as ionic liquids. The electronic and structural changes which occur in the graphite as a consequence of the cell cycling are followed through the aid of in-operando Raman spectroscopy and ex-situ X-ray diffraction. These results are thereafter coupled to the electrochemical behavior of the different carbon-salt systems in order to gain a thorough understanding of the related intercalation mechanisms.

9:15 AM EN03.09.03
Visualizing Electron Transfer at the Nanoscale in Printable Conductive Polymer Electrodes for Energy Storage
Zhiting Chen¹, Enrico Daviddi², Brooke Massani¹, Cameron Bentley², Patrick Unwin² and Erin L. Ratcliff¹;
¹University of Arizona, United States; ²University of Warwick, United Kingdom

Green or bio-sourced carbon-based materials offer sustainability in electrochemical energy storage applications. Electron transfer is a fundamental process and as such, understanding the underlying structure-function properties is critical to new technological development. In many cases, polymeric materials are blended together to create an ensemble of collective properties, such as combining redox activity with mechanical or optical properties. This blending results in spatial heterogeneity of electrochemical properties. Inspired by the ability to tune the opto-electronic properties of conductive polymers and the prospect of highly controlled photoelectrochemical processes, this work undertakes a proof-of-principle study to evaluate the charge transport-charge transfer mechanism in conductive polymer/electrolyte interfaces at the micron to nanometer length scale. Both charge transport and charge transfer will follow paths of least resistance, hypothesized to be due to local percolation pathways and intermolecular spacings. The vision to develop a collective characterization tool suite that allows for imaging of distributions in nanoscale properties, which will enable identification of key structure-function relationships leading to higher performance, and finally, leveraging these known nanoscale properties to increase photon-to-electron-to-molecule conversions.

As a model system, amorphous insulating polymethylmethacrylate (PMMA) was blended with conductive poly(3-hexylthiophene) (P3HT). The enthalpy and entropy of mixing are such that the materials phase segregate, creating an ideal spatial heterogeneity to investigate connections between macroscale and nanoscale electrochemistry approaches. Using scanning electrochemical cell microscopy, the spatially-dependent electron-transfer kinetics associated with a rapid outer-sphere electron transfer process (ferrocenedimethanol oxidation) is mapped at the nanoscale. We combine the kinetic insight with complementary conductive AFM to understand the underlying electrical charge transport properties. A new technique - synchrotron infrared nanoscale spectroscopy (SINS) - is used to image local chemical structure and evaluate composition of buried interfaces. Finally, using finite analysis, we demonstrate the limitations of macroscale electrochemical approaches to assess rate constants due to uncompensated resistances.

Study on Organic Compounds as Electrode Materials for Na Beta-Alumina Battery  Guosheng Li; Pacific Northwest National Laboratory, United States

Due to its high natural abundance and low material cost, sodium (Na) based battery technology faces tremendous opportunities for electric vehicle and grid scale energy storage applications. Traditional Na Beta-alumina batteries (NBBs), such as Na-S and ZEBRA batteries, have been commercialized to demonstrate a variety of grid services, including power shift, renewable integration, frequency regulation, and standby power, etc. However, it is quite difficult for traditional NBBs to penetrate into larger application market due to its inevitable “barrier”-high operating temperatures (> 300°C). In the past few years, we have been developing intermediate temperature (~190°C) Na-metal halide (Na-MH) batteries, which present several advantages, including simple battery architecture, improved thermal management, lower operating temperature, and lower manufacturing cost over traditional NBBs. Recently, we found that the use of organic compounds as electrode materials in NBBs can provide a new pathway to further reduce the battery operating temperature to near or below 100°C. Here, we will present the preliminary results on investigating the possible application of organic candidates for NBBs applications.

10:30 AM EN03.09.05

Green, Transparent and Flexible Batteries, Supercapacitors and Photovoltaics Based on Multicomponent Thin Films  Aldo J. Zarbin, Samantha Husmann and Lucimara Roman; Federal Univ of Parana, Brazil

Carbon nanostructures (graphene, nanotubes)-based nanocomposite thin films applied in the field of both energy storage devices (batteries and supercapacitors) and renewable energy (photovoltaics) will be presented in this work. We developed a novel and versatile way to prepare thin, transparent and homogeneous films of advanced and multi-component materials, based on immiscible liquid/liquid interfaces (for example, Zarbin et al., Adv. Funct. Mater. 2013; Electrochim. Acta 2016; Sci. Reports 2016; Sci. Reports 2017; J. Power Sources 2017; Electrochim. Acta 2018). Due to the specific preparation route (unique for some classes of materials as the ones discussed here), the films can be deposited over any kind of substrates, plastics included, allowing the preparation of flexible devices. Also, evident material economy is observed in the final process.

We will demonstrate the application of some of those films in green energy. First, carbon nanotubes/Prussian blue analogues developed according a methodology developed by us (Zarbin et al. J. Mater. Chem. 2012; J. Phys. Chem. C 2014; Chem. Eur. J. 2016), were applied as cathodes in ion-based batteries totally operating in aqueous electrolytes. Aqueous electrolytes are safer, cheaper, environmentally friendly and more conductive than organic ones. Results showed huge performances in K- and Na-ions batteries (cheaper than Li-ions ones), achieving impressive high discharge rates (up to 44.4 A g⁻¹), capacities up to 150 mAh g⁻¹ at 0.67 A g⁻¹ rate, and retention of 90% after 2000 cycles. A transparent and flexible device was built using those thin films deposited over plastics as cathode, a C/Co₃O₄ nanocomposite as anode and an aqueous NaCl solution as electrolyte, showing capacity of 85 mA h g⁻¹, energy density of 53.3 Wh kg⁻¹ and retention higher than 90% after 2000 cycles. Flexible and transparent batteries correspond to emerging technology with direct impact on modern flexible and transparent devices. The device operation will be demonstrated showing four charged 1x1 cm devices connected in series and lightening a white LED. Also, flexible and transparent alkaline-batteries based on carbon nanotubes/nickel hydroxide thin films, as well as symmetric supercapacitors based on carbon nanostructures/polyaniline thin films will be demonstrated. Prussian blue was also utilized as an innovative sensitizer in a photoanode for dye-sensitized solar cells – DSSC. An innovative tri-component nanocomposite thin films of carbon nanotubes/TiO₂/Prussian blue was prepared through the liquid/liquid route. In this configuration in a single film we have the sensitizer (Prussian blue, used by the first time for this application), the semiconductor (TiO₂ nanoparticles) and the carbon nanotubes as the anchoring point for both the sensitizer and the semiconductor, as well as an efficient charge-transport material. The photoresponse evaluated in a total aqueous electrolyte was of impressive 600 µA cm⁻².

Summarizing, this work presents the preparation of complexes and multi-component materials, their innovative deposition as thin films using an unique methodology and their application as active components in environmentally friendly batteries and photovoltaics, fully operating in water. Materials and processes for green energy.

PEDOT: PSS-Cellulose Nanocomposite Supercapacitors by Spray Coating and Printing  Mehmet G. Say¹, Calvin J. Brett²,³, Stephan V. Roth³,², L. D. Söderberg²,³, Isak Engqvist¹,² and Magnus Berggren¹,³; ¹Linköping University, Sweden; ²KTH Royal Institute of Technology, Sweden; ³Deutsches Elektronen-Synchrotron (DESY),

Final Program 1/13/2020  527
Conductive polymers have been extensively investigated as part of next-generation green electrochemical energy storage solutions. Organic electrochemical capacitors/supercapacitors are great candidates for flexible, portable power supply due to quick charge delivery and environmentally friendly materials and production. The combination of conductive polymer Poly (3,4-ethylenedioxythiophene): polystyrene sulfonate (PEDOT: PSS) and bio-sourced cellulose nanofibrils (CNF) provides a mechanically robust, ionically and electronically conductive nanonetwork for high energy and power density paper electrodes that can be solution-processed into supercapacitor systems. Spray coating allows large area, roll-to-roll compatible fabrication of nanometer thin up to, macroscopically thick, free-standing electrodes from functional inks. In this work, up to 30 µm thick conductive nanocomposite electrodes made from CNF and PEDOT: PSS were achieved by industrial spray deposition and then combined into supercapacitors. The crystalline structure of these spray coated nanocomposite films with certain additives and different thicknesses was evaluated by grazing incidence wide-angle x-ray scattering (GIWAXS).

The manufacturing strategies introduced in this study are to realize customized supercapacitor architectures for portable printed electronics by combining spray-coated electroactive paper electrodes with stencil printing of gel electrolyte and screen-printed cell components. Excellent electrochemical performance with 1.2 µWh/cm² energy and 20 mW/cm² power densities at 0.1 mA/cm² was demonstrated, and all-printed devices survived extreme bending tests and cycle life up to 3000 charge-discharge cycles. The proposed fabrication methods and architectures enable the integration of thin and flexible energy storage devices with printed solar cells, exemplified in a wristband for applications in low power wearable electronics.

Water-Transferable, Inkjet-Printed Supercapacitors towards Conformed Three-Dimensional and Epidermal Energy Storage Pavlos Giannakou, Mehmet Tas, Brice L. Borgne and Maxim Shkunov; University of Surrey, United Kingdom

The rapid development of Internet-of-Things (IoT) requires the use of embedded electronics into physical components and daily objects which stimulates a tremendous and rapidly grown interest for electronic devices and energy storage systems that are flexible, wearable and conformal. Typical fabrication methods, such as photolithography and winding or stacking, that are commonly used in conventional electronics and energy storage systems respectively, are difficult to be applied as fabrication strategies towards devices with advanced form factors (e.g. three-dimensional (3D), stretchable, conformal). In this study, we demonstrate the fabrication of supercapacitors on 3D objects through inkjet and water-transfer printing. To the best of our knowledge, this is the first reported study on water-transfer printing of an active functional device such as energy storage. Planar supercapacitors constituted from nanoparticle-based silver current collector, nanoparticle-based nickel (II) oxide (NiO) active electrode material and an ionic liquid or surfactant-based saturated magnesium perchlorate/ultraviolet-cured triacrylate polymer-based solid-state electrolyte, were chosen as model materials to explore the feasibility of the proposed concept. To further explore the practical potential of the inkjet-printed supercapacitors with a particular focus on wearable applications, we fabricated an epidermal (or tattoo) printable supercapacitor, that was water-transferred on the skin of a human subject, to potentially serve as the power source for wearable health systems. The 3D and epidermal devices showed areal specific capacitances of up to 52 mF cm⁻² and 27 mF cm⁻² respectively. This new class of water transferable, inkjet-printed, all-solid-state supercapacitors with advanced conformality, offer new alternative approach towards monolithically-integrated/object-tailed power sources that are needed for complex-shaped devices for IoT and flexible/wearable electronic applications.

11:15 AM EN03.09.08
New Chemistries and Structural Principles for Li-Containing, Air-Stable and High Voltage Organic Battery Chemistries Louis Sieuw¹, Jiande Wang¹, Philippe Poizot² and Alexandru Vlad¹; ¹Univ Catholique-Louvain, Belgium; ²Universite de Nantes, France

The redox chemistry of organic molecules is increasingly attracting interest as it has the potential to provide battery electrode material candidates combining high capacities, practical redox potentials and allow for transition metal-free chemistries. While many redox chemistries have been extensively explored, achieving high redox potentials has long remained a challenge. What is more important, lithiated organic redox chemistries (akin Li-ion inorganic cathodes) are severely lacking which makes difficult thus far practical implementation of an organic Li-ion battery technology.
This contribution aims at reporting some of our recent advances for the development of true organic Li-ion cathode materials. Design principles for new organic redox chemistries with limited solubility [1], high voltage via structural electrostatic interactions [2], as well as a new organic redox chemistry with intrinsic high voltage and ambient air stability will be detailed [3]. We hope that such findings can pave the way for designing high voltage organic Li-ion batteries in a near future.

11:30 AM EN03.09.09
Surface Modification of Lithium Iron Phosphate Electrode for an Innovative and Efficient Mining of Oceanic Lithium Po-Wei Huang and Nian Liu; Georgia Tech, United States

Clean and renewable energy has become a focal point due to its multiple impacts on our global sustainability. Lithium-ion batteries (LIBs), owing to its unique properties, have dominated the consumer electronics, automotive, medical, and industrial markets since the 1990s. Recently, the rapid development of portable electronic devices and electric vehicles (EVs) has led to an unprecedented demand for LIBs. Therefore, lithium, “the new gold,” become a strategically important commodity and is one of the most valuable resources in the foreseeable future. However, the current lithium production can’t satisfy the spiking demand for lithium and has been reported to cause negative impacts on the environment. Therefore, seeking new lithium sources and developing new lithium mining methods are the overarching issues to reach a sustainable future.

To address this challenge, we proposed to use an electrochemical method to extract lithium from the ocean. Inspired by lithium-ion rechargeable batteries, we applied lithium iron phosphate (LFP) to extract lithium from seawater due to its innate properties of lithium-ion selectivity, appropriate working potential, and fast cycling life. The ocean has been reported as the most potential source of lithium. While lithium is abundant in seawater, its low concentration hinders its practical application. Furthermore, the high concentration of sodium-ions that coexist in the seawater further increase the difficulty of the extracting process. From our experimental result, it showed that the lithium-recovery ability, the number of lithium-ions that can be released back into recovery solution, of LFP decrease 54% after one cycle in artificial seawater (0.1M LiCl + 0.5M NaCl) comparing to pure lithium solution (0.1M LiCl). Consequently, designing an electrode that can selectively extract lithium-ions, meanwhile, hinder the negative impacts causing by sodium-ions is the main challenge when developing electrochemical mining of oceanic lithium. From the electrochemical performance (galvanostatic charge-discharge measurement) of LFP in artificial seawater, we, the first, observed the second platform occurring in the discharge curve, corresponding to sodium-ion co-intercalation. The sodium-ion co-intercalation have been reported to cause phase transformation from LFP (olivine structure) to sodium iron phosphate (maricite structure), which not only cause capacity decay but also lower the reversibility. Surface modification has been used in our work to alleviate the co-intercalation reaction. We design a polymer, containing lithium ionophore, acting as a customized tunnel for lithium-ion to diffuse, but block sodium-ion, to enhance the selectivity. The second platform occurring in the discharge curve can be inhibited by applying our method; besides enhancing the concentration by a factor of 10.77 (Li/Na molar ratio of initial solution = 0.2 and Li/Na molar ratio of recovery solution = 2.15), we improve the selectivity of the LFP electrode by a factor of 3.15, and increase 19% of the “recovery efficiency” (amount of lithium-ions that can be released back into recovery solution/ amount of lithium-ions that have been extracted from the artificial seawater) after 25 cycles.

By utilizing the surface modification, we can greatly block the co-intercalation of sodium-ions, prevent the phase transformation of LFP, and enhance the cycling ability. By applying the electrochemical lithium mining method, we can shorten the manufacturing cycle from years to days and provide new opportunities to harvest the ocean’s resources, and accelerate progress toward a sustainable future.

11:45 AM EN03.09.10
Self-Assembly of 1D Particles and 2D MXenes for Nanocomposite Energy Storage Devices Mahiar M. Hamedi1, Weiqian Tian1, Zhen Wang1, Liangqi Ouyang1, Armin VahidMohammadi2, Majid Beidaghi2 and Lars Wågberg1; 1KTH, Sweden; 2Auburn University, United States

We report two different strategies to achieves nanocomposites with very high precision at the nanoscale:
i) Layer-by-layer (LbL) self-assembly of a small molecule, tris(2-aminoethyl) amine (TAEA), in combination with a colloidal dispersion of the 2D material, Ti3C2Tx MXene, to form self-assembled multilayers. This LbL assembly of MXenes with small molecules is fundamentally different from assembly with polymers and results in highly ordered pillared (MXene/TAEA)n multilayer where the TAEA expands the interlayer spacing of MXene layers by only around 1 Å and reinforces the interconnection between MXene flakes. The TAEA-pillared MXene multilayers show higher electronic conductivity of $7.3 \times 10^4$ S m$^{-1}$ to other MXene multilayers fabricated by LbL self-assembly. These multilayers are also resistant to mechanical deformation. Importantly, the MXene/TAEA multilayers could be used as electrodes for flexible all-solid-state supercapacitors delivering a high volumetric capacitance of 583 F cm$^{-3}$ and an integrated high energy density of 3.0 Wh L$^{-1}$ corresponding to a power density of 4400 W L$^{-1}$. This strategy enables large-scale fabrication of highly conductive pillared MXene multilayers, and potentially fabrication of other types of 2D heterostructures on various substrates.

ii) Aqueous self-assembly of a multifunctional nanocomposite using the combination of a one-dimensional (1D) abundant biomaterial (cellulose nanofibrils, CNFs) with Ti3C2TxMXene. This nanocomposite has one of the best multifunctional integration of strength (341 MPa), conductance (295 S cm$^{-1}$), and capacitance (298 F g$^{-1}$) than any previously reported composite. We rigorously studied and optimized these nanocomposites and concluded that the geometrical match between the 1D and 2D particles are crucial as they define the strength as well as the conductivity of the composite, and that the 1D and 2D phase must have a strong interaction at short range to overcome the colloidal repulsion and lock into a strong composite

Towards Rechargeable Batteries Made of Abundant Chemical Elements Philippe Poizot1, Alia Jouhara1, Vincent Cadiou1, Thibault Gutel2, Nicolas Dupré1, Eric Quarez1, Michel Armand1 and Franck Dolhem4; 1University of Nantes, France; 2CEA, LITEN, DEHT, STB, France; 3CIC Energigune, Miñano, Spain; 4University of Picardy Jules Verne, France

Routine access to power sources is an essential factor towards the continuing progress of our technology-oriented society, and toward ensuring a better quality of life. In this context, due to the ever-increasing implementation of renewable energy sources, electrical energy storage systems are set to play a central and potentially critical role in the next-generation energy infrastructure. The use of rechargeable (or secondary) batteries, which are already widely used for powering electric vehicles and electronic devices of all kinds, also seems to be particularly relevant with respect to this future scenario [1]. However, being faced with such a high global battery demand, issues concerning the resource availability or the recyclability also have to be further addressed together with the technical requirements in terms of capacity, energy density, cyclability, safety or cost. In this regard, and in parallel to research activities on regular inorganic-based electrode materials, the past decade has seen significant progress with respect to redox-active organic compounds, attracting much interest from the energy storage community. This is evidenced by the rapid increase in the number of studies and recent reviews on the topic [2], although this approach is still in its infancy. Based on the tailoring of naturally abundant chemical elements (C, H, N, O, and S in particular), organic chemistry also provides great opportunities for the discovery of innovative electrode materials able to operate both in aqueous and non-aqueous electrolytes. Additionally, it must be pointed out that two types of electrochemical mechanisms can be used in practice: n-type structures involving a charge transfer between the negatively charged state and the neutral state of the organic moieties (with cation release/uptake) and p-type
structures involving a charge transfer between the neutral state and the positively charged state of the organic moieties (with anion uptake/release). In this communication, we will present our past and recent advances for developing efficient and sustainable organic electrode materials. In particular, we will report on several types of terephthalate derivatives [3] able to reversibly host both cations or anions by electrochemical reactions making different cell configurations possible including anionic “rocking-chair” batteries for which few examples are reported in the literature.

Converting Eggs to Flexible, All-Solid Supercapacitors Yunya Zhang and Xiaodong Li; University of Virginia, United States

The rapid expansion of electrochemical energy storage markets has imposed an impending need for low-cost, sustainable materials for high-performance electrodes, separators, and electrolytes. A rational strategy is to derive the electrochemical materials from renewable biomass. Here, we report a feasible approach to fabricate flexible, all-solid supercapacitors from eggs. Egg white/yolk and eggshell acted as the carbon source and sacrificial templates for porous activated carbon, respectively. The egg-derived 2D graphene-like carbon sheets with a thickness of 1.25 nm exhibited an outstanding combination of energy density and power density when being used in supercapacitor electrodes due to their high specific surface area (1527.2 m²/g) and naturally doped functional groups. Egg white/yolk also reacted with KOH, forming gel-like solid electrolyte with competitive ionic conductivity and water preservation. With eggshell membrane as a superb separator, flexible, all-solid supercapacitors were assembled which exhibited superlative electrochemical performance and mechanical flexibility. The proof-of-concept study provides inspirations of comprehensive utilization of biomass materials for energy storage. The egg-derived 2D graphene-like carbon and solid-state electrolytes should find more applications in different fields.

Solar Light Enhances Melanin Electrochemical Energy Storage Performance Abdelaziz M. Gouda¹, Francesca Soavi² and Clara Santato¹; ¹Ecole Polytechnique Montreal, Egypt; ²University of Bologna, Italy

We explored the possibility to integrate the conversion and storage functions within the same multi-functional bio-sourced material. We identified the redox-active, quinone-based, melanin pigment, featuring a broad band absorption in the UV-Vis region, as the ideal candidate for such an exploration. Electrodes of melanin on carbon paper were investigated for their morphological, optical and voltammetric characteristics prior being assembled into symmetric supercapacitors operating in aqueous electrolytes. We observed that, under solar light, the capacity and the capacitance of the melanin electrodes significantly increase with respect to the dark conditions (by 22% and 39%, respectively). Once in supercapacitor configuration, besides featuring a Coulombic efficiency close to 100% after 5,000 cycles, the capacitance and capacity of the electrodes, rated by the initial values, improve after prolonged illumination, as it is the case for the energy and power density.

3:00 PM *EN03.10.04
A Facile Approach to Identify Lithium Content in Spent Battery Cathode Materials Chunmei Ban; Virginia Tech, United States

Electrochemical or chemical relithiation of end-of-life cathodes has been used to compensate the loss of lithium ion in the lithium-ion battery cathodes and recover their electrochemical reversibility. This method opens a new venue to directly recycle the spent cathode materials in a fast, energy-efficient and nondestructive way, without destroying the original structures happened in the traditional pyrometallurgy and hydrometallurgy processes. However, the
direct relithiation method can effectively restore the electrochemical properties of the spent materials, only if the loss of lithium ion is the primary aging mechanism for the cathodes. The lack of efficiently identifying the degradation mechanism and determination of lithium ion content in the spent cathode materials makes it difficult to sort spent cathode materials suitable for direct relithiation in the battery recycling process. The determination of lithium ion content in the cathode materials, which is currently performed by coupled plasma-mass spectrometry (ICP-MS), involves tedious procedure and error-prone preparation. In this work, a new method has been developed to quickly sort the spent cathode materials—herein, Li(Mn0.35Ni0.4Co0.23)O2—for relithiation recycling. Furthermore, we introduce a new methodology to fast determine the lithium content in spent cathode materials without using ICP-MS. Finally, we have applied these methods developed in this work, to investigate the effectiveness of direct electrochemical-relithiation on recycling the spent cathodes and provide the insights in the future development of direct battery materials recycling.

3:30 PM EN03.10.05
Flexible Fiber-Shaped High Performance Energy Storage Devices Bin Wang; China Academy of Engineering Physics, China

With the development of flexible wearable electronics, fiber-shaped energy storage devices (FSESSs) have attracted considerable interest in recent years. Owing to their large geometric dimension and solid inner structure, the specific surface area and the utilization of the electrodes are limited, which results in low capacities and energy densities of FSESSs. To further improve the energy densities of the FSCs, the nanostructure of the one-dimensional electrodes should be designed to promote the utilization and increase the accessible area for electrolyte and thus improving their specific capacities and energy density.

In this study, polymer or carbon-based fiber electrodes with hierarchical porous structures have been fabricated as electrodes of FSESSs. As electrodes of the all solid-state or quasi-solid-state FSESSs, the fiber electrodes exhibit high flexibility and remarkable electrochemical performances with a high energy density.

3:45 PM EN03.10.06
Stable Cycling of High-Voltage Lithium-Ion Batteries Enabled by Localized High-Concentration Electrolytes Xianhui Zhang1,2, Xia Cao1, Xiaodi Ren1, Haiping Wu1, Ji-Guang Zhang1 and Wu Xu1; 1Pacific Northwest National Laboratory, United States; 2Chinese Academy of Sciences, China

Nickel-rich layered oxide materials (LiNi0.5Mn0.35Co0.15O2, NMC), such as NMC622 and NMC811, have attracted great interest for application as high energy-density cathode materials in lithium-ion batteries (LIBs) because of their high specific capacities at high voltages compared with other commercial cathodes. Pushing cathode materials towards high-voltage operation is an effective way to further increase the energy density of the batteries. However, it is still a big challenge to operate Ni-rich NMC in LIBs under high voltage conditions (e.g. 4.4 V and above) due to the severe capacity fading. This fading is directly related to the instability of the cathode/electrolyte interface, induced by the ongoing chemical and electrochemical decompositions of electrolyte, the structural degradation of the cathode material and the dissolution of transition metals from the cathode; therefore, the commercial application of the Ni-rich NMC is limited so far. Besides the approaches of doping and coating the Ni-rich NMC materials to improve the long-term cycling stability of the batteries, developing new electrolytes is also an effective way to improve the practical application of Ni-rich NMC materials in LIBs. Here, we report new localized high-concentration electrolytes (LHCEs) that can greatly enhance the stability of Ni-rich NMC cathode and full cells with graphite (Gr) anode under 4.4 V comparing to the conventional carbonate electrolyte. This effect, in combination with the superior stability of Gr in these LHCEs, achieves dramatically improved long-term cycling performances of Gr/NMC cells in wide temperature range from -30 to 60 °C. The findings in this work shed light a very promising strategy to develop new electrolytes for practical high-energy LIBs with Ni-rich NMC cathodes.

4:00 PM EN03.10.07
Porous Carbon Fibers for Energy Storage Zhengping Zhou1,2; 1North Dakota State University, United States; 2Virginia Tech, United States

Porous carbon fibers with a high surface area and rich functionality are attracted as electrode materials for electrochemical energy storage devices (for example, supercapacitors and rechargeable batteries). Their widespread use is limited by their low porosity and ion-accessible surface area, and relatively sluggish electron/ion transport.
Here, we present a new strategy of utilizing the microphase separation of block copolymers associated with electrospinning, pyrolysis and chemical activation to synthesize a porous carbon fiber with a well-controlled improved porosity, a highly effective ion-accessible surface area, and a fast electron/ion transport. Two-electrode supercapacitors fabricated from the prepared porous carbon fibers yielded high capacitance values in ionic liquid electrolyte. In addition, this approach is readily scalable to produce porous carbon fibers on industrial levels.

4:15 PM EN03.10.08
Active Materials of Mixed-Phase MnO2/Nitrogen-Containing Graphene for Flexible Asymmetric Solid-State Supercapacitors Hsin-Ya Chiu and Chun-Pei Cho; National Chi Nan University, Taiwan

The MnO2/nitrogen-containing graphene (x-NGM) composites with various Mn contents hydrothermally fabricated were used as electrode active materials for flexible asymmetric solid-state supercapacitors (ASSCs). By SEM, TEM, EDS mappings, XPS, and Raman spectra, the presence of nitrogen-containing graphene (NG) and MnO2 was confirmed. TEM results manifested that the MnO2 in the composites was a two-phase mixture of γ- and α-MnO2. The co-existence of NG and MnO2 enhanced not only the reversible Faraday reactions on the surface but also the charge transfer capability. However, excess MnO2 caused reduced conductivity and a smaller slope of Nyquist plot in the low-frequency region unfavorable for ion diffusion and charge transfer. Better charge transfer efficiency was achieved only when the optimum MnO2 content was contained. Overloaded mass of active materials on the flexible electrode was detrimental to improved conductivity. Thus, both the mass loading of active materials and the MnO2 content were crucial to capacitor performance. The x-NGM composites and graphene (G) were used as the active materials for cathodes and anode, respectively, so the ASSCs were operated simultaneously by two charge storage mechanisms. The synergistic effect enabled better charge storage purposes. Among the supercapacitors, the 3-NGM1/G1 capacitor showed the highest conductivity, more efficient charge transfer, and thereby best capacitive properties. It exhibited a high specific capacitance of 579 F/g, giving rise to the high energy density and power density of 1223.3 Wh/kg and 73153.6 W/kg, respectively. The high retention rate (86.7 %) of specific capacitance after 2000 bending cycles demonstrated good cycle stability of the flexible ASSCs using the x-NGM composites. The best capacitor performance achieved in this work was superior to most literature results, implying that x-NGM composites are indeed promising electrode active materials for flexible ASSCs.

4:30 PM EN03.10.09
Energy Materials from Waste Maria Crespo Ribadeneyra1, Heather Au1, Hande Alptekin1 and Magdalena Titirici1,2; 1Imperial College London, United Kingdom; 2Queen Mary University of London, United Kingdom

Emerging energy technologies rely on materials, at the same time that the production of these materials relies on an energy supply. To keep a balance between the production of new materials we need to minimise the energy we employ to produce them, starting from which precursors we chose for their synthesis. In this context, we want to unlock part of the technological challenge of upgrading compounds generated from anthropogenic pollution, biomass and industrial by-products. We propose to produce highly efficient and low-cost energy components through the catalytic conversion of waste into non-geopolitically compromised rechargeable Na-ion battery electrodes as a sustainable solution to keep such energy/materials balance.

We present preliminary data on the hydrothermal carbonisation and microwave treatment of different biomass/plastic waste precursors in the presence of environmentally friendly catalysts. We study the relationship of carbonisation treatment with the final microstructure and relate this to the Na-ion absorption mechanism during electrochemical charge-discharge cycles between 2.5 and 0 V.

4:45 PM EN03.10.10
Direct Electrosynthesis of Pure Aqueous H2O2 Solutions Up to 20% by Weight Using a Solid Electrolyte Chuan Xia; Rice University, United States

Hydrogen peroxide (H2O2) synthesis generally requires substantial post-reaction purification. Here I will introduce a direct electrosynthesis strategy that delivers separate H2 and O2 streams to an anode and cathode separated by a porous solid electrolyte, wherein the electrochemically generated H+ and HO2- recombine to form pure aqueous H2O2 solutions. By optimizing a functionalized carbon black catalyst for 2-electron oxygen reduction, we achieved >90% selectivity for pure H2O2 at current densities up to 200 mA cm⁻², which represents a H2O2 productivity of 3.4
mmol cm^{-2} \text{h}^{-1} (3660 \text{ mol kg}^{-1} \text{cat} \text{h}^{-1}). A wide range of concentrations of pure H_2O_2 solutions up to 20 wt.% could be obtained by tuning the water flow through the solid electrolyte, and the catalyst retained activity and selectivity for 100 hours. As one representative practice, our device demonstrated a continuous treatment of total organic carbon in Houston rainwater with a processing rate up to 2180 L m^{-2} \text{electrode} \text{h}^{-1} to meet drinking water standards.

**Ion-Conducting Membranes for Large-Scale Energy Storage**  
Michael Hickner; The Pennsylvania State University, United States

New polymer membranes are needed to advance energy storage and conversion technologies for distributed and grid-scale applications. We have recently demonstrated new ion-conducting polymer membranes that have achieved excellent performance and long-lifetime stability in vanadium redox flow batteries, a leading technology candidate for deployment in renewable power networks and grid-scale energy storage systems with sizes ranging from 10s to 100s of megawatts. By tuning the nanoscopic self-assembly of the ionic domains in the polymers, we are able to increase the cycle life of the device by impeding vanadium ion transport through the membrane while facilitating high conductivity in the electrolyte to maintain the battery current density. For instance, by decreasing the vanadium permeability of the membrane by a factor of two, we have been able to double the lifetime of the device, which provides significant life-cycle cost savings. We have also demonstrated membranes with nearly zero vanadium permeability that show 100% coulombic efficiency in flow battery charge-discharge cycling tests. Currently, we are working on demonstrating these membranes over 100s of charge-discharge cycles. Anion exchange membranes have the potential to rid fuel cell technology of expensive precious-metal catalysts. Acidic fuel cells with NAFION® membranes require platinum, but anionic membranes that operate at high pH open the door for the use of silver and nickel fuel cell catalysts which would greatly decrease the cost of polymer fuel cell technology. We have developed new anion exchange membrane polymer structures that show exceptional stability under fuel cell conditions and have helped to increase the performance and lifetime of anion exchange membrane fuel cells. This talk will show how polymers with new chemical structures can be applied to many different types of batteries and other electrochemical devices. Common design principles and considerations for fabricating new ion exchange membranes for energy processes will be discussed.
9:00 AM EN04.01.02
Electrochemical Properties of Various Oxide Ion Conducting Membranes for Solid Oxide Membrane (SOM) Electrolysis Kuk Jin Hwang1,2, Miyoung Shin1, Myung-Hyun Lee1 and Tae Ho Shin1; 1Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); 2Pusan National University, Korea (the Republic of)

The solid oxide membrane (SOM) process is an environmentally friendly and innovative technology that can produce valuable metals directly from their oxides by high temperature solid oxide electrolysis. For direct metal-reduction high ionic conductors such as doped zirconia could use as the anode to remove oxide ion in the SOM electrolysis system. Particularly, yttria-stabilized zirconia (YSZ) tube is normally employed as the anode; it is immersed the molten salt containing dissolved metal oxides and oxygen anions that move to the tube where they are reduced without any emission. However, the SOM process for metal production via oxide reduction is limited because of several challenging issues, such as high oxide ion conductivity, YSZ phase stability and yttrium dissolution by the reaction at high temperature electrolysis condition in the harsh corrosive molten salt flux.

In this study, we introduce the layered configuration to improve stability and performance; the thin YSZ dense layer coated on porous Ni-YSZ cermet tube to reduce ohmic resistance of long oxide ion conducting path way in thick membrane, the protection layer coated on YSZ to enhance phase stability of the anode tube, and mixed ionic and electronic conduction (MIEC) materials were employed to reduce polarization of oxygen evolution reaction. When the electrical potential applied between the cathode and anode, it is expected that the ohmic resistance is reduced more than the conventional YSZ tube. It will be discussed that the effect of the functional layered SOM tubes for a current efficiency and the amount of metal reduction.

A Crosslinked Polyelectrolyte with Pendant Carbonate Group Demonstrating High Conductivity and Chemical Stability for Lithium Battery Yubin He, Yamin Zhang, Paul Kohl and Nian Liu; Georgia Institute of Technology, United States

Lithium ion batteries (LIBs) are the state of art power source in mobile devices like cellphones and electric vehicles. However, there are huge safety hazard due to the volatility and flammability of conventional liquid electrolytes. In the pursuing of high performance solid polyelectrolytes (sPE), polycarbonate (PC) has emerged as the most promising category due to its distinct advantages like extended electro-chemical stability window, decreased crystallinity and higher Li+ transference number.

Previously, several advanced PC-sPEs have been developed either by adding plasticizer or adopting the “polymer in salt” strategy. Although good conductivity ranging from 0.1 to 0.4 mS/cm was achieved, these method inevitable led to non-free-standing membranes due to weakened mechanical strength. Another problem of PC-sPE remains unsolved is its instability with lithium metal. The hydroxyl terminations of PC chains is readily reactive towards Li metal, leads to “unzipping” degradation.

To address the aforementioned problems of PC-sPE, an ultimate solution is developed to access free standing sPE with simultaneously achieved Li metal stability and high ionic conductivity. Firstly, an acrylate monomer with pendant propylene carbonate (DB-PC) is synthesized. Upon UV irradiation, this monomer is shown to polymerize within several minutes. Unlike the conventional PC-sPE, the UV cured sPE (UVPC-sPE) adopts polyethylene as mainchain and cyclic propylene carbonate as pendant group, thus avoiding thermal triggered main chain random scission and terminal –OH group triggered “unzipping” degradation respectively.

Besides, the abstraction of hydrogen attached to carbonate ring lead to enhanced chain transfer reaction and efficient crosslinking process. As a result, the free standing UVPC-sPE exhibits high room temperature conductivity up to 1 mS/cm, which is a significant upgrade to the conventional PC-sPE. In addition, the assembled Li/UVPC-sPE/LFP full battery shows excellent cycling performance at 0.5 C (25 °C) and 1C (65 °C), demonstrating its promising potential in Li ion battery applications.

9:30 AM EN04.01.04
Discovery of a New Class of Potential Superprotonic Conductors by High-Throughput Computing Pandu Wisesa, Chenyang Li and Tim Mueller; Johns Hopkins University, United States

The development of new proton conducting materials would be beneficial for a variety of applications, including hydrogen separation membranes and fuel cell electrolytes. Much of the work on proton-conducting inorganic
materials has been limited to a few well-known structure types, and many classes of materials remain relatively unexplored for their ability to conduct protons. We present the results of a high-throughput computational search for new classes of proton-conducting oxides. As the use of density functional theory (DFT) to directly screen for proton mobility would be prohibitively expensive, we have developed a potential energy model for rapidly screening candidate materials to identify classes of materials that are most likely to exhibit high proton mobility. We will present the results of our model on thousands of candidate materials, including both well-known proton-conducting oxides and a new class of stable oxide materials that are predicted by both our model and DFT to have exceptionally low activation energies for proton conduction.

9:45 AM EN04.01.05
Structural Designs of Alkaline Durable Imidazolium-Containing Anion Conducting Membranes Prepared by Radiation-Induced Grafting for Pt-Free Fuel Cells Kimio Yoshimura1, Yue Zhao1, Ahmed Mahmoud1, Akihiro Hiroki1, Hideyuki Shishitani2, Susumu Yamaguchi2, Hirohisa Tanaka3 and Yasunari Maekawa1; 1National Institutes for Quantum and Radiological Science and Technology, Japan; 2Daihatsu Motor Co., Ltd., Japan; 3Kwansei Gakuin University, Japan

We have been developing alkaline-durable anion conducting electrolyte membranes (AEMs) for liquid fuel (hydrated hydrazine) type fuel cell (FC) vehicles. Even though the AEM-FC system has been significantly attractive because of non-precious metals used as active catalysts, there is no commercially available AEMs due to the severe damage of the membranes in alkaline operating conditions [1]. Thus, we applied the radiation-induced grafting technique to introduce various anion conducting graft-polymers into a thermally and mechanically tough poly(ethylene-co-tetrafluoroethylene) (ETFE) film to develop new AEMs.

Recently, we investigated a series of imidazolium-type AEMs because of the low basicity of imidazolium hydroxide as an Arrhenius base [2]. Most of the imidazolium-type AEMs exhibited lower water uptake and higher thermal stability than those of the corresponding AEMs containing trimethylammonium hydroxide. Furthermore, AEMs containing weak base imidazolium groups suffered less damage of polymer backbones via self-base catalyzed degradation. Even though N-vinylimidazolium graft-type AEMs are subjected to $\beta$-elimination and hydrolytic ring opening degradation to reduce the anionic conductivity in an alkaline solution at elevated temperature (1M KOH, 80°C), we introduced the graft-copolymers of vinylimidazolium with styrene because the adjacent vinylimazolium cations led very fast elimination due to the double $\beta$-positioned hydrogen. Furthermore, for suppressing hydrolysis, the protecting group is introduced at 2-posion of imidazolium rings, which are subject to hydroxide attack. The alkaline durability of the AEMs having the abovementioned molecular designs showed drastically improved alkaline durability. Namely, a poly(2-methyl-N-vinylimidazolium hydroxide-co-styrene)-grafted ETFE (MIm/St-AEM, MIm/St ratio of 60/40) retained 26% of the initial conductivity (>14 mS cm$^{-1}$) after 1300 h in the actual fuel of 5% hydrated hydrazine in 1 M KOH at 80 °C. The membrane-electrode-assembly (MEA) consisting of MIm/St-AEM with the anion conducting ionomer having a similar polymer structure to the grafts, showed a maximum power density of 230 mW cm$^{-2}$ in a direct hydrazine hydrate FC [3].

Since the electrolyte properties, durabilities, and fuel cell performance of the graft-type AEMs could not be elucidated only by these chemical structures of the graft-type AEMs, we performed the hierarchical structure analysis of the synthesized AEMs. Contrary to the above mentioned MIm/St-AEM, the AEM with higher styrene ratios (MIm/St = 40/60 and 20/80) showed less durability in the alkaline solution. By a SANS contrast variation method, only the AEMs with MIm/St = 40/60 and 20/80 showed water puddle sphere with a diameter of 3-4 nm. Thus, we concluded that the imidazolium groups around the water puddle are subjected to the hydrolytic attack to lead the degradation of the AEMs [4]. We find out that the elucidation of hierarchical structures of the AEMs takes important role to develop alkaline durable AEMs.

An Overview of Composite Polymer Electrolyte Systems Bamdad Bahar; Xergy Incorporated, United States

Among all choices of electrolytes, polymer-based systems have attracted widespread attention due to their utility in cell design and excellent processability. Polymer electrolytes have an intrinsic feature: they lose mechanical properties with increase in ionic conductivity. Thus, in order to make high performance media, they must be mechanically supported (composited). This paper will provide a review on how this problem has been historically addressed including a survey of different composite media including fabrics, microporous media and discrete fibers and fillers and their impact on polymer electrolytes from an industrial point of view, leading to the current state of the art. The paper will discuss other critical features in polymer electrolytes where compositing can make a critical contribution to overall system performance – such as improved processability, cell separation, reduced reactant cross-over, reduced volume of electrolyte use, incorporation of crucial additives within support matrix, improvement of ionic continuity, ionic modification, and improved designs. Each aspect is discussed in detail. Specific polymer electrolyte composite strategies for different applications such as industrial electrolysis (Chlor-alkali), fuel cells, pervaporation and others are reviewed. In-situ measurements and specific features and benefits are discussed.

Mechanically Robust Polymer Membranes for Non-Aqueous Flow Battery Michelle Lehmann¹,², Guang Yang², Pengfei Cao², Ethan C. Self², Alexei Sokolov²,¹, Frank Delnick², Jagjit Nanda²,¹ and Tomonori Saito²,¹; ¹The University of Tennessee, Knoxville, United States; ²Oak Ridge National Laboratory, United States

Large scale grid storage is imperative for an efficient use of renewable energies. While aqueous redox flow batteries (RFBs) such as vanadium-based aqueous RFB are relatively mature technologies for a grid storage, non-aqueous RFBs present an attractive alternative strategy for potentially providing much higher energy density. One of the key enablers for non-aqueous RFBs is mechanically robust and highly ion-conductive membranes. In aqueous RFBs, membranes can achieve high proton or anion conductivity due to water mediating their ion conduction, thus there are various high performance membranes for aqueous RFBs. On the other hand, for membranes in non-aqueous RFBs, achieving high ion conductivity while maintaining mechanical and chemical stability is a major challenge. The design principle for such membranes is poorly understood due to the complexity of the system. Our membranes are developed for a non-aqueous RFB with an alkali alloy anode technology that has the potential to achieve high energy density, high safety, low cost and long cycle life. This presentation will discuss the fundamental design principle in polymer membranes for non-aqueous RFBs and our recent efforts on the development of novel plasticized polymer membranes that simultaneously provide high conductivity and tailored mechanical modulus. In one system, mechanically robust crosslinked poly(ethylene oxide) membranes were synthesized and doped with sodium triflate and tetraglyme. The relationships between ion conductivity (reached up to 10⁻⁴-10⁻³ S/cm at r.t.), salt/gel content, glass transition temperature (Tg) and mechanical properties are investigated. The synthesized membranes are mechanically robust with storage modulus maintaining at ~1 MPa from -20 °C to 180 °C even saturated with tetraglyme. In another system, mechanically tailored novel single-ion conducting polymer electrolytes (SICPEs); trifluoromethane sulfonimide (TFSI) functionalized block and graft copolymers are synthesized and investigated. The SICPEs with covalently attaching TFSI moieties to the polymer backbones only allows specific cations, such as lithium (Li) or sodium (Na) ions, to move freely and provide ionic conductivity (i.e. the transference number is close to 1), which is imperative for RFBs. The Li and Na ion conductivity and the mechanical properties with the presence of a plasticizer (non-aqueous solute in RFB) are investigated. RFB performance such as a cross-over behavior is evaluated.

Characterization of Mechanical Behavior and Stability of Membranes for Energy Conversion Devices
Claire Arthurs\textsuperscript{1,2}, Douglas Kushner\textsuperscript{2} and Ahmet Kusoglu\textsuperscript{2}; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Lab, United States

Ion-conductive membranes are the core components of electrochemical energy conversion devices (including fuel cells, electrolyzers and flow batteries) which offer a tremendous potential to reshape clean and renewable energy technologies for stationary and transport applications. Key to the sustainable performance of these devices is the concerted improvement in membrane transport and stability, which can be related to their functionality as the polymer solid-electrolyte and separator. Nevertheless, material parameters and operational environment that are optimized for membrane functionality and performance (e.g., ion-exchange capacity and hydration) could undermine mechanical stability. Understanding the interrelation of transport and stability, and how it is affected by structure and environment, is challenging for ion-containing polymers due to the complex polymer-ion-water interactions in a chemically-heterogeneous morphology. While such interactions have been studied for proton-exchange membranes (PEMs) for fuel cells, there is need to extend these investigations to membranes exchanged with various cations and anion-exchanged membranes (AEMs) employed in fuel-cells and electrolyzers. In this talk, the role of structure and hydration in mechanical properties of various ion-containing polymers will be explored to investigate environmental and structural factors governing the membrane’s transport-stability relationship. First, impact of environment on structure-mechanics relationship of cation-exchanged and composite perfluorinated sulfonic acid (PFSA) membrane will be presented, with a focus on the interplay between their mechanical response and hydration behavior. The results will be discussed to elucidate how a membrane’s mechanical properties change due to chemical structure and water-ion interactions. Then, these investigations will be extended to selected AEMs to present a broader picture on ion effects. Lastly, various mechanical properties will be compared and discussed to provide insight into mechanical testing techniques that could best characterize membrane stability relevant to the operation environment in energy conversion devices.

Preparation of Anion Exchange Membranes by Friedel-Crafts Bromoalkylation and Crosslinking of Polystyrene Block Copolymers Jong Yeob Jeon and Chulsung Bae; Rensselaer Polytechnic Institute, United States

Anion exchange membrane (AEM) fuel cells have gained significant attention due to the possible use of non-precious metal electrocatalysts which reduce the cost of fuel cells. However, there has been a lack of AEMs simultaneously satisfying high chemical stability, robust mechanical properties and high anion conductivity, under high pH operating conditions. Herein, we suggest a convenient method for the preparation of AEMs by Brønsted acid catalyzed Friedel-Crafts alklylation of aromatic polymers using bromoalkylated tertiary alcohols, followed by amination with trimethylamine. This simple one-step “bromoalkylation” allowed convenient control of both the degree of functionalization and cation tether length, by changing the molar ratio and the structure of the bromoalkylated tertiary alcohol. A series of elastomeric polystyrene-\text{-}b\text{-}poly(ethylene-co-butylene)-b-polystyrene (SEBS) based AEMs with different ion exchange capacities (IEC) and ionic tether lengths were systematically investigated by comparing water uptake and anion conductivity. Since the backbone of the SEBS AEMs are composed of all carbon-carbon bonds, they showed good alkaline stability under 1 M NaOH aq. solution at 80 °C. To enhance the mechanical properties of the AEMs, the hard segment PS units were crosslinked by 1,6-hexanediamine. The crosslinking of SEBS AEMs significantly reduced their water uptake (e.g., 155\% vs. 28\%) preserving IEC and ionic conductivity. Alkaline membrane fuel cell performance was evaluated with the crosslinked SEBS AEM, and a peak power density of 520 mW/cm\textsuperscript{2} was achieved at 60 °C under H\textsubscript{2}/O\textsubscript{2} conditions.
As a promising alternative to proton exchange membrane fuel cells (PEMFCs), anion exchange membrane fuel cells (AEMFCs) based on hydroxide conducting polymers have received great attention in recent years. The high pH operating condition of AEMFCs allows use of non-precious metal catalysts and less expensive metal hardware. Recently, a power density over 1.0 W cm\(^{-2}\) has been achieved for AEMFC approaching close to that of PEMFCs.

One of key requirements for high performance of AEMFCs is anion exchange membranes (AEMs) with high ion conductivity, good chemical stability and mechanical durability. New materials development using novel polymer backbones and side chain ionic functional groups have been extensively investigated over the past decade.

In this presentation, we will present the effects of different structures of polymer backbones and the location of ionic side chains on the membrane properties of AEMs and their device performance in fuel cell and electrolysis. Polymeric made of soft backbone, such as polystyrene-b-poly(ethylene-co-butylene)-b-polystyrene (SEBS), and rigid backbones, such as polyarylenes containing biphenyl and terphenyl core groups (namely BPN and TPN series), have been evolved from my group at RPI over the past years. Because the backbone of those polymers are made of all carbon-carbon bonds, they showed excellent chemical stability under alkaline conditions. The high molecular weights (>100,000 g/mol) of those functionalized polymers also afforded good mechanical strength and high strain when made into film. A perspective of quatern ammonium-functionalized polymers that have been developed from RPI will be presented with emphasis on synthetic strategy and materials performance in AEMFC test condition.

Decoupling Mechanical Properties and Ion Conductivity in Supramolecular Stretchable Battery Materials
David Mackanic, Xuzhou Yan, Yi Cui and Zhenan Bao; Stanford University, United States

As soft electronic devices increasingly require stretchable, conformable batteries, safety concerns regarding the use of liquid electrolytes in lithium ion batteries (LIBs) arise. Unfortunately, the canonical tradeoff between mechanical strength and ionic conductivity in polymer electrolytes has forced most reported stretchable batteries to incorporate mechanically weak electrolytes containing flammable liquids within strain engineered structures. Herein, we introduce a supramolecular design as a novel strategy to decouple ionic conductivity from mechanical strength in polymer electrolytes. The supramolecular lithium ion conductor (SLIC) is a block copolymer that includes a hydrogen-bonding domain based on 2-ureido-4-pyrimidone (UPy) and an ion conducting domain based on poly(propylene glycol)-poly(ethylene glycol)-poly(propylene glycol) (PPG-PEG-PPG). By systematically tuning the amount of UPy in the polymer backbone of SLIC, we demonstrate that the UPy domains and the PPG-PEG-PPG domains are orthogonally functional, and that varying the amount of UPy in the backbone has little effect on the ionic conductivity of the polymer. The resulting SLIC polymer containing 23 mol.% UPy in the backbone yields a polymer electrolyte with high resilience (4.9 MJ m\(^{-3}\)) and high ionic conductivity (1.2\times10^{-4} S cm\(^{-1}\) at 25\(^\circ\) C). Implementation of SLIC as a binder material allows for the creation of stretchable Li-ion battery electrodes with strain capability of over 900\% via a conventional slurry process. Impressively, strain capability of 100\% is maintained when the loading of polymer in the electrode film is as low as 20 wt.\%. The supramolecular structure of SLIC allows for intimate bonding at the electrode-electrolyte interface. Good adhesion between the stretchable battery components enables the fabrication of the first intrinsically stretchable LIB. The SLIC battery has a capacity of 1.1 mAh cm\(^{-2}\), an operating voltage of 1.8 V, and functions even when stretched to 70\% of its original length. The method reported here of decoupling ionic conductivity from mechanical properties opens a new route to create highly resilient ion transport materials for energy storage applications.

Gel Composite Electrolyte Membrane for Lithium-Metal Batteries
Xi C. Chen\(^{1}\), Yiman Zhang\(^{1}\), Laura C. Merrill\(^{2}\), Michelle Lehmann\(^{3}\), Tomonori Saito\(^{1}\), Jennifer L. Schaefer\(^{2}\), Frank Delnick\(^{1}\) and Nancy J. Dudney\(^{1}\); \(^{1}\)Oak Ridge National Laboratory, United States; \(^{2}\)University of Notre Dame, United States; \(^{3}\)The University of Tennessee, Knoxville, United States

Gel polymer electrolytes consisting of a crosslinked polymer electrolyte swelled with a plasticizer overcome the weakness of low ionic conductivity of typical dry polymer electrolytes. With a large amount of plasticizer, however, the mechanical strength of gel polymer electrolytes is weakened. The poor mechanical properties may render gel polymer electrolytes prone to lithium dendrite growth.
In this work, we fabricate gel composite electrolyte membranes by incorporating lithium-ion-conducting ceramic particles into the gel polymer matrix. The purpose of this work is to test the hypothesis that the high modulus of the ceramic particles helps preventing Li dendrite growth. Our results show that the room temperature ionic conductivity of the gel composite electrolyte is $1 \times 10^{-4}$ S/cm, the same as the gel polymer electrolyte without ceramic. The handleability of the gel composite membrane is significantly improved. Li symmetrical cell cycling performance is evaluated with different ceramic loadings. We also compare the ionic conductivity and Li symmetrical cell cycling performance of gel composite membranes with a single-ion-conducting gel polymer host.

Engineering Scale Simulation of Non-Equilibrium Diblock Copolymer Materials for Battery Electrolytes
Ludwig Schneider and Marcus Müller; Georg-August University, Germany

Diblock copolymer materials exhibit a rich equilibrium phase diagram, qualifying them for applications in fuel cells, filters, and battery materials. Self-assembly of these materials rarely results in the equilibrium structures. Instead, configurations are trapped in long-lived meta-stable states and can be stabilized via cross-linking or cooling below the glass transition temperature of one component. The properties of these structures, such as ion-conductivity and mechanical stability, can deviate from those of the corresponding equilibrium phases.

SOMA, our massively-parallel implementation of the Single-Chain-in-Mean-Field (SCMF) algorithm, enables us to study systems with billions of particles and predict their structure formation, thus unraveling the transport properties of self-assembled diblock-copolymers as a function of volume fraction, $f$. Our investigations show that non-equilibrium morphologies exhibit a large scale fractal-like domain structure that influences the transport properties. The length scale of these structures highlight the necessity of the simulation large system sizes with micrometer scale to obtain bulk properties. We quantify the transport via the tortuosity and the diffusion inside the network phase and show that equilibrium phases overestimate the transport capabilities of random networks.

Tuning Self-Assembly and Macromolecular Properties in Ion-Conducting Block Copolymer Systems by Controlling Monomer Segment Distribution
Thomas Epps; University of Delaware, United States

The self-assembly of block polymers (BPs) presents unique opportunities to design materials with attractive chemical and mechanical properties based on the ability of BPs to form periodic structures with nanoscale domain spacings. One area of recent progress in our group focuses on the behavior of tapered BPs in which the segment distribution at the interface between blocks is synthetically varied to tune morphology, domain density profiles, thermal transitions as well as mechanical and transport properties. Two application targets for these materials are lithium-ion conducting membranes for batteries and nanostructured thin films for nanotemplates and barrier membranes. In the first target area, we found that the taper volume fraction and composition allow us to manipulate the self-assembly of salt-doped BPs in a well-defined manner that permits optimization of morphology and ion-content. Additionally, we found that the tapered interfaces influence the glass-transition behavior of the ion-conducting block leading to significant changes in lithium-ion transport (ion conductivity). In the second target area, we found the taper content alters the rate of self-assembly as well as the rate of island/hole formation (and ultimate island/hole size) upon thermal annealing. Additionally, using reflectivity techniques, we probed the domain density profiles as a function of taper composition and linked these profiles to changes in domain spacing and glass transition temperature. Overall, these studies show the versatility of tapering to provide a unique handle for simultaneously optimizing multiple materials properties.
Solid polymer electrolytes (SPEs) have received sustained interest as a potential replacement for liquid electrolytes in lithium ion batteries because they are intrinsically nonflammable, processable, and mechanically robust. In the past decade, polymer networks with dynamic bonds that can undergo associative exchange processes, also known as vitrimers, have been investigated as recyclable and self-healing materials. It is an open question if a dynamic network can provide not only mechanical integrity to suppress dendrites, but also substantial conductivity. Here, we develop a vitrimer for Li ion conduction consisting of triethylene glycol, boric acid, and a lithium salt (LiTFSI). These networks were studied over a range of Li/ethylene oxide ratios and exhibit storage moduli > 1 MPa at room temperature but the ability to flow upon heating. Conductivities up to $10^{-4}$ S/cm were measured in the absence of solvent at 90 °C. The vitrimers also show an interesting phenomena where the network is no longer formed at high LiTFSI concentrations, likely due to anion interactions with boron. We report on conductivity and modulus trends as a function of molecular structure to demonstrate that vitrimer electrolytes are a promising platform for SPEs.

The performance of proton-conducting ionomer membranes is complicated by an intricate interplay between chemistry and morphology that is challenging to characterize and control. Here, we report on a class of perfluoro ionene chain extended (PFICE) ionomers that contain either one (PFICE-2) or two (PFICE-3) bis(sulfonyl)imide groups on the side-chain in addition to a terminal sulfonic acid group. PFICE ionomers are promising new materials, exhibiting greater water uptake and conductivity over a range of relative humidity values compared to prototypical perfluorinated sulfonic acid (PFSA) ionomers. Advanced in situ synchrotron characterization combined with simulations reveals insights into the connections between molecular structure and morphology that dictate performance. Energy-tunable X-rays with sensitivity to sulfur can decipher the unique bonding environment of different protogenic groups on the polymer side-chain. Guided by simulations, X-ray absorption spectroscopy can be sensitive to hydration level and configuration that dictates proton dissociation. In situ resonant X-ray scattering reveals that PFICE ionomers have a phase-separated morphology with enhanced short-range order that persists in both the dry and hydrated state, allowing for improved transport pathways across hydration levels. Furthermore, side-chain chemistry and length can be used as a molecular design parameter to predict phase-separated domain spacing. The enhanced conductivity of PFICE ionomers is attributed to a unique side-chain chemistry and structure promoting hydrogen bonding configurations that facilitate proton dissociation at low water content in combination with a well-ordered morphology that forms transport pathways. Our findings also show how energy-tunable X-rays can reveal additional details on the disordered morphology of well-studied PFSAs. Overall, these results provide guidelines to design new ionomers with improved transport properties and demonstrate the value of in situ characterization methods such as resonant X-ray scattering and spectroscopy for unraveling the structural features in chemically-heterogeneous polymer membranes.

Order-disorder and order-order morphological transitions of block copolymers are important phenomena to consider in mechanical properties and ion transports for various electrochemical devices. Among others, the transitions can often be caused by the addition of ionic liquids (room-temperature “molten” salt), but understanding the role of molecular interactions in the phase stability of the mixture of a block copolymer and an ionic liquid is still limited. To provide a better guiding principle to control phase behaviors, we developed a mean-field theory that accounts for the electrostatic interactions, excluded volume effect, and dielectric response between the species. Our theory compares favorably with observed transitions between the ordered microstructures corresponding to lamellae, hexagonally close-packed cylinders, body-centered cubic lattices, and double-gyroid phases, but it still poses a question about the stability of the gyroid phases. We will also discuss the effect of the dielectric contrast between the species on morphological transitions.
Using Chemical Functionalization to Control the Ion Permeability of 2D Material Based Laminar Membranes
Mark A. Bissett, Wisit Hirunpinyopas, Pawin Iamprasertkun, Jonathan Aze and Robert Dryfe;
University of Manchester, United Kingdom

The popularity of two-dimensional (2D) materials such as graphene and molybdenum disulfide (MoS2) have provided renewed interest in the development of laminar membrane technology. These membranes can be used for a variety of applications including water filtration, desalination, ion exchange, electrodialysis, reverse osmosis, and electrodeionization (EDI). Laminar membranes of two-dimensional materials are excellent candidates for applications in water filtration due to the formation of nanocapillaries that can exhibit a size and charge sieving effect, while allowing high water flux.

Previously we have demonstrated that laminar membranes of MoS2 show outstanding potential for practical applications in energy conversion/storage, sensing, and as nanofluidic devices by tuning their ion permeability by chemical functionalization.1 Chemical modification of these MoS2 membranes has been shown to improve their ionic rejection, however the mechanism behind this improvement is not well understood and further work is needed. To elucidate this mechanism we report the potential dependent ion transport through these functionalized MoS2 membranes.2 The effect of pH, solute concentration, and ionic size/charge on the ionic selectivity of the functionalized MoS2 membranes is also reported. Similarly graphene membranes are produced by simple liquid phase exfoliation possessing a low oxygen content, unlike the GO/rGO material commonly used, and their effectiveness in potential dependent ion sieving applications demonstrated.3 We observe a strong dependence on flake morphology, with decreasing flake size leading to an increase in the number and tortuosity of the nanochannels, resulting in a significant reduction of ion transport. By controlling the number of edge sites and hence surface functional groups this again demonstrates that the surface chemistry of these 2D materials can be used to carefully tune the ion permeability when used to form laminar membranes.

various treatment procedures that lead to an optimized activated product. $^{29}$Si magic-angle spinning nuclear magnetic resonance (MAS NMR) is useful to analyze the local silicate structure (the Q-distribution) in order to monitor the activation process. The Q-distribution is specified by the fraction of resolved Q$n$ resonances where “n” is the number of bridging oxygens (from one to four) in a silicate unit. The silicate composition, deduced from these experiments, provides information about the evolution of HTS’ silicate environment under various activation treatments.

**EN04.03.02**
Removal of Hazardous Dyes from Simulated Wastewater Using Nitro-Oxidized Carboxycellulose Nanofibers Extracted from Coconut Fibers

William Borges$^{1,2}$, Priyanka Sharma$^3$ and Benjamin S. Hsiao$^3$; $^1$Roslyn High School, United States; $^2$Independent High School Research Student, Stony Brook University, The State University of New York, United States; $^3$Stony Brook University, The State University of New York, United States

Harmful dye compounds found in dyeing industry wastes can have deleterious effects on human health and the environment, especially in developing regions. Also, the accumulation of coconut waste in developing areas poses a need for novel methods for coconut waste utilization. This study transformed waste coconut biomass into a negatively-charged Nitro-Oxidized Carboxycellulose Nanofiber (NOCNF) adsorbent for cationic dye removal in water by using the nitro-oxidation method. Nitro-oxidation has been noted as a simpler and more cost-effective method to extract CNF from raw biomasses compared to conventional methods, such as carboxymethylation and TEMPO Oxidation. In another step, positively-charged NOCNF was synthesized by modification with glycidyltrimethylammonium chloride (GTMAC) for the remediation of anionic dyes. Both the anionic and cationic NOCNF were characterized using FTIR, $^{13}$C CPMAS NMR, WXRD, TEM and SEM. Anionic NOCNF was found to possess carboxylate groups in the range of 0.777 mmol/gram. Moreover, the cationic NOCNF demonstrated 6% nitrogen content, indicating that the cationic charge existed in the form of NH$_3^+$ charge. Adsorption studies were conducted for Basic Red 5 (BR 5) and Malachite green (MG) dyes with anionic NOCNF and cationic NOCNF, respectively. Interestingly, both substrates showed significant removal of their respective dye in the range of 40-75 ppm with a removal efficiency of ~90-75% and ~92-70%. Anionic NOCNF exhibited maximum removal efficiency of BR5 with 100% at pH=4. Moreover, cationic NOCNF presented maximum removal efficiency of Acid Orange (AO) with ~100% at pH=8. The above studies show that coconut waste material is excellent for dye removal after using the simple nitro-oxidation method. Furthermore, this novel approach could be applied to solve the problem of overabundance of coconut waste in developing regions.

The Use of Sacrificial Graphene Oxide Layer for Inorganic Hollow Fiber Membranes with Superior Permeability

Young Hoon Cho$^1$, Hosik Park$^1$, Ho Bum Park$^2$, Seung-Eun Nam$^1$ and You-In Park$^1$; $^1$Korea Research Institute of Chemical Technology, Korea (the Republic of); $^2$Hanyang University, Korea (the Republic of)

Recently, the ceramic and inorganic membrane materials draw attentions in both conventional and emerging molecular separation applications due to their outstanding mechanical, chemical and thermal stability in various liquid, gas and vapor environment. However, there are several hurdles to compete with conventional polymeric membranes in the market such as high production cost, difficult scale-up, low packing density and productivity. In addition, ceramic membranes for ultrafiltration, nanofiltration and gas separation range need repeated coating, sintering or reaction processes to apply thin separation layers on the surface of porous ceramic substrates to maximize their permeability. Still, the preparation of ceramic composite membranes with both high permeability and nano-size pores is limited for large area production. Here, we newly developed a simple and facile pre-coating method to prepare defect-free, ultrathin film composite ceramic hollow fiber membranes. Prepared composite membranes showed outstanding separation performance compared to membranes prepared by the conventional method. The thin separation layers with the thickness under a few hundreds nanometers were successfully coated on highly porous substrates without any defects and pore-clogging. The results clearly showed superior molecular separation properties of prepared membranes and the potential for the applications in separation processes at harsh conditions such as organic solvents, high feed temperature or concentration.

Preparation of Cellulose NF Membrane for Selective Separation of Free Fatty Acid and Chlorophyll in Extra Virgin Olive Oil

Yongjun Ahn and Seung-Yeop Kwak; Seoul National University, Korea (the Republic of)
The traditional Mediterranean diet is characterized by the preferential consumption of vegetables, legumes, fruit, nuts, and cereals, and olive oil is the main dietary fat. Extra virgin olive oil (EVOO) is obtained from pressing Olea europea (olive) fruit. The characteristic aroma, taste and color of this oil distinguish it from other edible vegetable oils. The excellent organoleptic and nutritional properties of EVOO and the current tendency of consumers to select minimally processed food, have prompted a re-assessment of its consumption in daily diet. Recently, the consumption of olive oil blended with other refined vegetable oils is increasing for use as frying oil, due to economic reasons and customer desire for taking healthy components. However, as-extracted EVOO is still turbid and opalescent and, contains impurities such as free fatty acid (FFA), chlorophyll and pieces of fruit or stone that can compromise the quality of EVOO since they facilitate hydrolysis, fermentation and can cause the oil to become rancid.

The filtration process is considered to efficiently removes these damaging substances. In particular, nanofiltration (NF) is developed for molecular separation on the basis of size and charge differences. Beyond drinking water production and wastewater treatment, NF technology has also been applied for the separations carried in organic solvents such as in the pharmaceutical, petroleum and food industry. NF membrane can be expected to efficiently separate the damaging substance from EVOO.

Cellulose has emerged as an indispensable membrane material due to its abundant availability, low cost, and environment benignancy. However, this unique molecular architecture also leads to cellulose insolubility in the common organic solvents. Only very few usable solvents are known and those are often highly reactive, toxic or impractical for industrial use. Moreover, cellulose membranes typically have meso- or macro-pores, making them suitable only for ultra- or microfiltration. In previous our research, it was proposed that the morphology of cellulose can be controlled by the cellulose molar mass of the cellulose in an ionic liquid. Comparing to the typical cellulose membranes, cellulose formed from ionic liquid is expected to possess micropores suitable for nanofiltration that can separate from molecular level.

In this study, a simple method is provided to prepare cellulose NF membrane from cellulose hydrolyzed in cellulose, and then it was applied to the selective separation of FFAs and chlorophyll from EVOO. To verify the effects of pore size and surface functionality, a series of cellulose NF membrane with various pore size was prepared, and then they were functionalized by amine group to improve interaction of FFAs. The fatty acid composition and antioxidant content (total phenols and tocopherol) were analyzed to demonstrate the selective separation of the amino-functionalized cellulose NF membrane without a component conversion. To confirm the thermal stability, we observed the smoking point of EVOO filtrated by cellulose NF membrane and compared the smoking point with that of crude and physically refined EVOO. The surface functionalization and pore size of NF membrane significantly influenced the separation efficiency for FFAs and chlorophyll, respectively. It was found that the amine group on the surface of cellulose was necessary to improve the selectivity and adsorption capacity. It also demonstrated that the chlorophyll separation efficiency was optimized when the pore size was smaller than 7 nm. The resulting absorbent selectively removed 90% and 81% of FFAs and chlorophyll, respectively, without the composition change of fatty acids. This study can provide a facile method for enhancing thermal stability of EVOO and thus aid the development of better treatment process for crude oils using cellulose NF membrane.

**An Insight Investigation towards Aqueously Cathodic Deposition of MOF Membrane**

Heng-Yu Chi, Ruicong Wei and Zhiping Lai; Advanced Membranes and Porous Materials, Saudi Arabia

Electrochemical deposition has been developed and started attracting a number of research attentions in this decade for membrane production. Due to its ease of operation, low cost, and ability for continuous production, it has been widely accepted as a promising approach for large-scale industrial membrane production. Currently, the research in this area is still in its early stage with most efforts being gravitated towards MOF film fabrication. Recently, our group has developed an aqueously cathodic deposition (ACD) approach for ultra-facile membrane production without any post-synthesis treatment. The obtained defect-free membrane exhibits superior performance in C3H6/C3H8 separation. ACD can be extended for other types of MOFs and is considered as an attractive approach for scalable membrane fabrication. As a new approach, the mechanism behind of ACD was not well understood. Here, we conducted a detailed investigation to understand the fundamentals of ACD approach for membrane fabrication. Through this study, we achieved an in-depth understanding of cathodic reactions involved in membrane formation via cyclic voltammetry study. The influence of precursor compositions, current density and counter-electrode were demonstrated. Following these understandings, we are able to ultimately shorten the fabrication time from 60 min to 20 min, tune the thickness of the membrane from 100 nm to 500 nm, and enhance the membrane chemical stability for exceptional performance in gas separations.
Preparation of Perfluorosulfonic Acid Based Composite Membranes for Energy Conversion Devices
Seohhee Lim, Jong-Hyeok Park and Jin-Soo Park; Sangmyung Univ, Korea (the Republic of)

Many of half cell reactions for electrochemically driven energy conversion devices consist of movement of ions and electrons simultaneously during anodic and/or cathodic reactions to complete full electrochemical cells. In addition, ions generated at electrodes move from anode to cathode or vice versa for electron exchanges. Pathway for ions is normally in an aqueous phase. Regardless, the introduction of any aqueous phase in energy conversion devices causes many problems during fabrication, operation, maintenance, and so on. Thus, much efforts have been devoted to develop quasi-solid electrolytes such as gel polymer, ion exchangeable polymers, impregnation of ions in porous matrix and so on. One of major disadvantages to use polymeric electrolytes is significant Ohmic voltage decay due to high areal resistance compared to aqueous phases. An approach to minimize areal resistance of film-type polymeric electrolytes is to make film thickness as thin as possible. Free standing polymeric electrolytes, however, show low mechanical properties. Thus, composite membranes could be used by impregnating polymeric electrolytes into thin porous substrates. In this study, three-layered (electrolyte-skeleton/electrolyte-electrolyte) composite membranes with various thicknesses were prepared. A technique to impregnate polymeric electrolytes into hydrophilic or hydrophobic porous substrates were intensively developed so as to prepare void-free composite membranes. Characterization in terms of ion conductivity, ion exchange capacity, water uptake, dimensional stability, mechanical strength was carried out.

Bacterial Cellulose Based Membrane Electrode Assembly in Microbial Fuel Cells
Mehrdad Mashkour1,2, Federico Poli1, Mostafa Rahimnejad2, Mahdi Mashkour3, Carlo Santoro4, Mohammad Said El Halimi1,5 and Francesca Soavi1; 1University of Bologna, Italy; 2Babol Noshirvani University of Technology, Iran (the Islamic Republic of); 3Gorgan University of Agricultural Sciences and Natural Resources, Iran (the Islamic Republic of); 4UWE, United Kingdom; 5University Abdelmalek Essaadi, Morocco

Microbial fuel cell (MFC) has been nominated as an alternative to nonrenewable sources of energy capable of transforming organic matters directly into electricity by bacterial anaerobic respiration on the anode surface and oxygen reduction reaction on the cathode surface. It is low cost because of exploiting waste matters as fuel. But low electricity generation is a big challenge in this technology [1]. Two pathways are possible for bringing MFC to commercialization: i) increasing electricity generation; ii) using cheaper components like electrode and membrane. In MFCs, membrane play the role of separator for taking anode and cathode apart each other. Anode’s required condition is anaerobic while cathode needs oxygen. Therefore, the membrane should be impermeable to oxygen. On the other hand, the membrane’s capability in transferring hydronium ions or cations from anode to cathode compartment is in high level of importance. Although using membrane results in increase in internal resistance of MFC, but for long-term operation of MFC it can protects cathode against contaminant and microbial biofilm formation on the electrode surface [2].

In single Chamber MFCs the cathode can be used as membrane-less and or membrane assembly electrode (MEA). An MEA is an integrated electrode system resulting in electron and ion transfer to reach cathode surface in presence of oxygen. There are two main positive points in using MEA i) lower internal resistance of MFC in comparison with double chamber MFC; ii) higher durability of SCMFC’s compared to membrane-less ones. Therefore, making a cheap MEA with high performance for MFC is an interesting and vital field of research. Bacterial cellulose (BC) produced by some species of bacteria like *acetobacter xylinum* is a three dimensional network of nano cellulose fibers. The latter can be easily modified by carbon materials and conductive polymers to develop air-breathing cathodes. From this point of view, it has the potential to be used as a cheap substrate for high performance membrane specially compared with Teflon based composite cathodes [3].

Here we report about fabricating a novel cellulose based air-cathode coated with multi-walled carbon nanotubes (CNT) and polyaniline (PANI). Also BC was treated by nano-zycosil (Zyc) to be hydrophobic. The results of the electrochemical test are presented and compared to those obtained with conventional Teflon-based cathodes. Our
work aims at demonstrating new routes to develop a cheap, high performance and green MEA for MFC technology.

Magnetically Induced Self–Healing in of Iron Oxide–Poly(ethylene oxide) Nanocomposites Charlotte Teunisse, Sarah Dalakos, Vanessa Swepson, Grace Gionta, Donovan Weiblen, Deniz Rende and Rahmi Ozisik; Rensselaer Polytechnic Institute, United States

Current research aims to quantify self-healing capabilities of iron oxide (Fe3O4) nanoparticle (NP) infused poly(ethylene oxide) (PEO). Iron oxide NPs of varying surface chemistries (bare, aminopropyl triethoxysilane coated, and polyethylene glycol α-, ω–diphosphate coated) are used to prepare nanocomposites of varying concentrations less than 1% by weight. Each sample, in the form of a cylindrical disc, is indented using a LECO M400 Microindenter at five different locations between the center and edge. The indentation site is examined before and after being placed in an alternate magnetic field (AMF) to induce healing. The micrographs of each indent were collected with an Olympus PMEG microscope at the same imaging parameters. Healing efficiency is quantified using visual and software-based image analysis, identifying the percentage of healing as a function nanoparticle concentration and surface chemistry. Multiple methods of software-based image analysis were developed to perform this analysis. Nanoindentation experiments were also carried out to evaluate impact of surface coating and concentration on mechanical properties and viscoelastic behavior of these nanocomposites.

Comb Shaped Hydrocarbon Polymer Electrolyte Membrane for Fuel Cell with Well-Developed Microphase Separation Su Min Ahn1,2 and Tae-ho Kim1; 1Korea Research Institute of Chemical Technology, Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

Comb shaped polymer electrolyte membrane was synthesized by grafting highly sulfonated poly(arylene sulfide sulfone) side chain to poly(arylene ether sulfone) backbone, differing the molecular weight and the density of the side chain. Side chain, synthesized from A-B type monomer, was designed with monofunctional terminus to avoid crosslinking in grafting. Furthermore, side chain is highly sulfonated with one sulfonic acid group per one benzene ring, inducing well-developed microphase separation. Structure-property relationship was investigated by varying the architecture of graft polymer, comparing graft polymer structures with dense, short side chains to those with sparse, long side chains at similar ion exchange capacity. Analyses for proton conductivity, water uptake, dimensional change, and membrane electrode assembly performance have been conducted. Fuel cell performance of graft polymer at 0.6 V resulted in 0.7957 A cm-2 at 100% hydrated condition. Also, graft polymer endured 730 hours before the OCV drop and 17000 wet/dry cycles before reaching 2 mA cm-2, the Department of Energy (DOE) standard of fuel cross over, showing remarkable chemical and physical durability. The synthesized graft polymer may be a promising candidate as a polymer electrolyte membrane for fuel cell application.

Tuning Pore Size and Robustness of Membranes Formed by Scalable Self-Assembly of Random Copolymer Micelles Luca Mazzaferrro1, Ilin Sadeghi2 and Ayse Asatekin1; 1Tufts University, United States; 2Massachusetts Institute of Technology, United States
Membrane separations are energy-efficient, simple, and scalable. Yet, their broader use is limited by the separation capabilities of membranes prepared by conventional methods, typically confined to size-based separations. Self-assembly of functional polymeric materials is a powerful method for designing membranes capable of new separations, including the separation of organic compounds of similar size from each other. This can potentially be achieved by membranes that mimic biological pores such as porins, with pores that are only slightly larger than the target solute and functionalized with groups that selectively interact with one compound over another. Our group has developed a method for preparing such membranes by the spontaneous self-assembly of random amphiphilic copolymer in methanol into micelles that are then coated onto a support to form a selective layer of tightly packed micelles. These membranes, produced by a simple manufacturing process, have ~1-4 nm pores lined with carboxylic acid groups that enable charge-based separation of organic solutes. Additionally, the carboxylic acid groups can be converted to a wide range of possible functional groups through coupling reactions. This can provide selectivity towards solutes by affinity. Because of the distinctive geometry and selectivity of these membranes, it is valuable to assess the versatility of this technology. The goal of this study was to tune the pore size by changing the micelle size, and analyze the robustness of these thin film composite membranes. The pore size was tuned by interactions of dissolved metal ions with micelles while the robustness of the system was altered by different crosslinking procedures.

EN04.03.11
Self-Assembling Random Terpolymers Use to Fabricate Membranes with a Tunable Pore Environment
Samuel Lounder and Ayse Asatekin; Tufts University, United States

Water purification is necessary for the well-being of both people and the environment. While membranes are firmly established as the leading water purification technology, they still face a host of challenges that limit their performance. For conventional polyamide nanofiltration membranes, the main challenges are selectivity, fouling, and chlorine sensitivity. In the present work, we created a random terpolymer that can self-assemble into a membrane with a tunable pore environment. We added charge to the pores, which granted the membrane with selectivity comparable to commercial nanofiltration membranes. By virtue of the material, these membranes are also fouling resistant and chlorine tolerant. Self-assembly is defined as the formation of hierarchical structures from simple molecular building blocks. This process is driven by interactions between said building blocks, and can be used to engineer ordered structures ranging from nanometers to micrometers in size. Zwitterions are defined as molecules that contain an equal number of positive and negative charges. This charge disparity grants zwitterions an enormous dipole moment, which leads to powerful electrostatic forces occurring between neighboring zwitterions. These forces drive self-assembly, even in random copolymers with very short zwitterionic segments. In the present work, we show that random terpolymers comprised of zwitterionic, hydrophobic, and zwitterion-philic repeat units self-assemble to form a bicontinuous nanodomain of zwitterionic/zwitterion-philic and hydrophobic sections, each 1-2 nm in size. When these terpolymers are coated onto a porous support to form the selective layer of a thin film composite membrane, the zwitterionic/zwitterion-philic domain acts as a network of nanochannels for the permeation of water and other solutes. Through pragmatic choice of the zwitterionic-philic repeat unit, it is possible to tune the properties of these nanochannels. Here, we show that the random terpolymer poly(trifluoroethyl methacrylyate-r-sulfobetaine methacrylate-r-methacrylic acid) (PTFEMA-r-SBMA-r-MAA) can be used to fabricate nanofiltration membranes that address the challenges faced by conventional polyamide membranes. The presence of charged groups, through dissociated MAA repeat units segregated into these nanochannels, leads to the selective rejection of salts and charged organic compounds. These membranes are also resistant to fouling and exposure to chlorine. Furthermore, we demonstrate that the properties of the nanochannels and the selectivity of the membrane can be further tuned by the functionalization of carboxylic acid groups on MAA repeat units to access additional separations. These features demonstrate the promise and versatility of this new polymer family for a wide range of membrane applications.

Study of Structural, Thermal & Electrical Properties of Electrolytes Composites (1-x) CsH2PO4 + xZrO2 For Fuel Cells by Silver Deposition Advanced Electrode
Pawan Kumar1, Deshraj Singh2, Jitendra Singh2, Arvind Kumar3 and Ram S. Katiyar4; 1Gurukul Kangri Vishwavidyalaya, Haridwar, India; 2K.G.K. College, Moradabad, India; 3Kalindi College, India; 4University of Puerto Rico, United States

Composites proton conducting material based on cesium dihydrogen phosphate were prepared and doped with
zirconium oxide and observed the structural, thermal and transport properties of composites proton electrolytes in terms of X-ray diffraction (XRD) analysis, Fourier Transform Infrared Spectroscopy (FTIR), Differential Scanning Calorimetry (DSC), Raman spectroscopy and conductivity measurements. We have investigated that the ionic conductivity of undoped CsH$_2$PO$_4$ increases up to three order of magnitude within the transition temperature 230°C to 250°C, which is in small limit range and unstable. We doped ZrO$_2$ with different composition (1-x) CsH$_2$PO$_4$/x ZrO$_2$ (0≤x≤0.4). CsH$_2$PO$_4$ transition temperature range is (230°C -250°C) after doping of ZrO$_2$ its transition temperature range increases from 230°C to 280°C. The stability, ionic conductivity and fuel cell performance were investigated within the temperature range 230°C to 280°C under environments atmospheric humidification. The superprotonic transition of CsH$_2$PO$_4$/ZrO$_2$ Composites was identified with advanced silver electrode by vapor deposition of silver.

EN04.03.13
Design, Fabrication and Characterization of 3D Printed Membrane Structure for Efficient PM Removal
Yejin Kim$^{1,2}$ and SeungBin Park$^2$; $^1$Korea Institute of Energy Research, Korea (the Republic of); $^2$Korea Advanced Institute of Science and Technology, Korea (the Republic of)

3D printing (additive manufacturing) can be applied in various ways because of its infinite versatile approaches in its structure and materials, etc. In addition, the application range can be expanded without restrictions when applied with different material. For this point of view, optimization of printing scheme and printed material property (frame material, structure, pore distribution, shape and particle size etc) with respect to the appropriate purpose could be essential factor for maximizing efficiency of printed output.

In addition, various studies have been carried out on the fine dust (PM 2.5), which is one of the global disasters as an urgent field to understand the generation behavior and occurrence of PM these days. The designed 3d printed structure and defined distribution with the inner flow pattern could be a good tool for understanding the complex action of various factors for removal characteristics with controlled condition.

For this purpose, we have applied various methods to fabricate porous structures of various structures through FDM 3D printing and to obtain basic data for evaluating complex reaction characteristics of precursors for PM secondary particle production.

Here we introduce the relationship between the structural parameters of the reaction kit and adsorption characteristics of the prepared filter were confirmed in two aspects. First, a reaction kit was designed, fabricated and the inner flow characteristics were defined. Second, the 3d printed structures for adsorption/desorption behavior of PM precursor (NH$_3$, SO$_x$) were studied for each physicochemical conditions by using various zeolites with different pore variance as adsorbent, and their reaction characterized through the analysis of adsorption/desorption behavior - breakthrough curve analysis.

We expect that this study on the relationship with the structural parameters of the designed filtration provide important basic knowledge for design efficient membranes for removal of PM.

EN04.03.14
Thermal and Mechanical Analysis of Chemically Stable Aromatic Anion Exchange Membranes
Luke Cherniack, Ding Tian, Jong Yeob Jeon and Chulsung Bae; Rensselaer Polytechnic Institute, United States

Anion exchange membrane (AEM) fuel cells is a promising alternative to proton exchange membrane (PEM) fuel cells through the ability to operate with a non-precious metal catalysis and faster kinetics of the oxygen reduction reaction; however, AEMs are not widely commercialized due to their inferior hydroxide ion conductivity, inadequate mechanical properties, and lack of chemical stability under alkaline conditions. Recently, biphenyl and terphenyl based polymers were synthesized and exhibited favorable electrochemical properties. In this study, the thermal and mechanical properties of these polymers were analyzed by thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and dynamic mechanical analysis (DMA) to determine their capability of manipulating membrane electrode assembly for fuel cell applications. A two-day annealing process was also performed and studied to evaluate its effects on mechanical properties. Thermal analysis results indicated that these AEMs remained both chemically and mechanically stable within a fuel cell operating temperature range. The glass transition temperature (Tg) of mTPBr and BPBr are 174°C and 188°C respectively. After quaternization, mTPN1 and BPN1 didn’t show a Tg.
Desalination and Nanofiltration through Multilayered Graphene Oxide Membranes on Polymer Substrates
Balgin Zhanibek1, Kurbangali Tnyshtykbaev1 and Zinetula Z. Insepov1,2; 1Nazarbaev University, Kazakhstan; 2Purdue University, United States

In recent years, GO-based filtration membranes have received a lot of attention in the field of filtration technology. In this study, the feature of the multilayered reduced graphene oxide (rGO) membranes on different polymer substrates (Polyvinylidene difluoride (PVDF), Polytetrafluoroethylene (PTFE) and Anodic Aluminum Oxide (AAO) membranes (Millipore) are given. GO powders were prepared from graphite powder by the modified Hummers method. For comparison, GO of Sigma-Aldrich brand was also used. rGO membranes prepared by vacuum filtration and drying of the powders GO in water with the subsequent ultrasonic influence within 30 min. Later GO was deposited on a polymeric PVDF membrane. rGO suspensions and membranes were characterized by Fourier Transformation Infrared Spectroscopy (FTIR) using NicoletiS10 FTIR, Raman spectroscopy, scanning electron, and atomic force microscopy. Filtration abilities were measured by pH meter (Mettler Toledo S20-KS SevenEasy) and desalination rate was measured by Ion Chromatography (Metrohm 930 Compact IC Flex). Experimental salt solution (pH=8.5) was used for desalination experiments. The possibility of efficient rGO/PVDF membranes creating by using GO on the surface in standard polymeric PVDF membranes is shown. rGO/PVDF membranes have the best effectiveness of filtration than standard polymeric PVDF membranes. The increasing of water transportation speed across rGO/PVDF membranes with a decreasing of the sizes of membrane nanochannels are observed. It is experimental fact is explained by a decrease of activation energy of shear viscosity of the liquid in nanochannels.

Water Nanofiltration through 2D Nanomembranes Using Reverse Osmosis Method
Abat Zhuldassov1 and Zinetula Z. Insepov1,2; 1Nazarbayev University, Kazakhstan; 2Purdue University, United States

Fluid flow process in an isolated system at nanometer scale has great fundamental importance in nanofluidics. Nanofiltration process through advanced two-dimensional nanomembranes using reverse osmosis method has a particular interest in water desalination and purification. In this work, computational model was created, in order to simulate a process of water filtration through 2D materials such as graphene, grapheme oxide, MoS2 and BN using molecular dynamics method. All 2D materials had a hexagonal structure, the diameter of pores were between 6 Å and 10 Å. The volume of water containing ions was 28,830 Å³, the volume of water was 15360 Å³. The piston pressure was 3.5 GPa. To assess the structural relationship in the liquid solution, the radial distribution function was calculated. Obtained data have a good agreement with the experimental results. Our computer simulation results clearly indicated that nanomembranes based on two-dimensional materials were able to reject salt ions, providing a high flow of water molecules. The highest water flow rate and lowest salt penetration ratio was observed in MoS2 membranes, due to the low energy barrier and unique pore structure, with alternating hydrophobic and hydrophilic edges. Thus, the computational model of a nanofiltration system using 2D materials and reverse osmosis method was created. Our computer simulation results showed that 2D nanomaterials can be used as new generation desalination membranes. Such membranes are expected to be more energy-efficient in comparison with other modern membranes used today.

Low Temperature Electric Field-Assisted and Conventional Sintering Samaria-Doped Ceria/Alkali Halide Carbonate Ceramic Membranes
Sabrina G. Carvalho1, Eliana N. Muccillo1, Fernando Marques2 and Reginaldo Muccillo1; 1Energy and Nuclear Research Institute, Brazil; 2University of Aveiro, Portugal

Samaria-doped ceria (SDC) oxide ion conductors and mixed alkali salts (e.g., Li, K) were proposed as electrolytes for intermediate temperature (500 °C-700 °C) solid oxide fuel cells and as membranes for high temperature CO2 separation. In this work, dual-phase composite membranes were obtained by two techniques: i) producing a porous GDC pellet using alkali halides as sacrificial pore former, followed by molten carbonate vacuum infiltration, and ii)
electric field-assisted sintering by applying a low voltage at 420 °C to a (75 wt.% GDC+25 wt.% eutectic Li-K carbonate mixture) pressed green pellet. The microstructure of the impregnated porous ceramic and the electrical field assisted sintered pellet were observed by scanning electron microscopy to evaluate the distribution of carbonates. The electrical behavior of the membranes was assessed by electrochemical impedance spectroscopy measurements in the 350 °C-550 °C range, and these data used to draw Arrhenius-type plots. Membranes obtained by electric field-assisted sintering have electrical conductivity higher than those based on impregnated porous ceramics.

EN04.03.19
Neural Network for the Phase Separation of Polymer Mixtures
Issei Nakamura; Michigan Technological University, United States

Polymer-containing liquid mixtures can exhibit macroscopic phase separation and microphase separation. For example, diblock copolymer melts show the phase transition from a homogeneous to a lamellar phase when the temperature is decreased. Molecular simulations such as molecular dynamics and Monte Carlo simulations and thermodynamic theories are conventional approaches to understanding the phase behaviors of polymer mixtures. However, more computationally fast simulation methods that are fairly robust against the choice of force fields and applicable to various phase behaviors are greatly needed because we must analyze the abundant and diverse experimental data obtained concurrently. To address this challenge, we develop deep neural networks (DNNs) as a third approach to assist with the existing theories and simulations and experimental analyses. In this talk, we discuss our new hidden layer that is constructed through coarse-grained mean-field theory and the scaling laws in polymer physics. This characteristic hidden layer enables us to perform the learning process efficiently with relatively small numbers of artificial neurons and provides the DNNs with reasonable predictive power. To demonstrate the efficacy of our DNNs, we will discuss the phase diagrams of polymer solutions, and the salt-free and salt-doped diblock copolymer melts. Moreover, we will show the predictive power of the DNNs by considering some experiments for the lithium salt-doped diblock copolymers such as PEO-b-PS.

EN04.03.20
Anisotropic Proton Conduction in a Coordination Polymer for Fuel Cell Membranes
Ali Javed1, Stephan Wöhlbrandt2, Norbert Stock2 and Michael Tiemann1; 1Paderborn University, Germany; 2Kiel University, Germany

In recent years, fuel cell technology has become an integral part in modern and sustainable concepts of energy storage and conversion. Proton-conducting polymer electrolyte membranes (PEMs) play a key role in this respect. Standard materials such as Nafion tend to be expensive and their proton conductivity is often strongly humidity-dependent. Metal-organic frameworks (MOFs) and other coordination polymers (CPs) have recently attracted attention as potential alternatives [1-3]. Still, profound knowledge of the underlying mechanisms of proton conduction in coordination polymers is scarce. Impedance spectroscopy is a powerful and versatile tool for studying proton conduction in coordination polymers [4]. It is usually applied to powders; we have recently reported on impedance measurements on MOF single crystals [5].

We present impedance spectroscopic studies of proton conductivity in a single-crystalline coordination polymer of composition \([\text{Ba}_2(\text{HSPP})(\text{H}_2\text{O})_2] \cdot \text{H}_2\text{O}\) that consists of \(\text{Ba}^{2+}\) ions connected by organic phosphonatosulfonate linker molecules (HSPP\(^4^-\) = \([\text{O}_2\text{PCH}_2\text{N}(\text{H})-\text{CH}_2\text{C}_6\text{H}_4\text{SO}_3\text{]}^4\)). From the crystal structure proton conduction by a proton 'hopping' mechanism could be anticipated [6]. However, the crystal structure also contains non-coordinated water molecules that may affect the proton conductivity. The material forms elongated crystals. We have measured impedance data by varying the temperature, relative humidity, and, especially, the orientation of the single crystal with respect to the contact electrodes. Proton conductivity turns out to dependent on said orientation, which implies anisotropic conduction paths in the crystal structure.

The 73 – 216 µm thick nanostructured membranes based on free two-layer films of nanoporous anodic alumina with pore diameters about 55 nm are discussed to be formed by the two-side anodization in the electrolyte of oxalic acid and further bipolar anodizing. The basic idea of the bipolar anodization is to use a two-chamber electrolytic bath, in which the alumina membrane with Al inclusions was placed as an insulating partition. One of the chamber is filled with the anodization electrolyte (7 % H$_2$C$_2$O$_4$), while the buffer electrolyte (10 % CuSO$_4$) is used in the second chamber. The cathode electrode (−) is placed in the first chamber and the anode electrode (+) is connected to the second one. When the current is switched on (U ~ 55 V), a positive charge appears on one side of the membrane opposite the Al inclusions. The membrane becomes an anode, and anodic oxidation (anodizing) of Al inclusions takes place. The second side of the membrane is charged negatively and becomes a cathode. The recovery of buffer electrolyte cations (Cu$^{2+}$) on the cathode side opposite the Al inclusions was observed with a guaranteed absence of sparks and burn-through of the oxidized layer in these zones. The volume growth coefficient in the conversion of Al to Al$_2$O$_3$ was 1.44 – 1.46. The membranes obtained demonstrated high resistance to cracking and the ability to save the form at high temperature exposures. Highly ordered nanostructured nature of their cellular porous morphology that can be controlled by electrochemical and temperature modes of the electrochemical anodizing process appears to have considerable promise.

The development of advanced hybrid materials based on polymers from biorenewable sources and mineral nanoparticles is currently of high importance. Lignin has a great potential as a sorbent for removal of transmission metals and organic pollutants from wastewater. By combining lignin with inorganic carrier, organic-inorganic hybrid composites with improved sorption properties can be obtained.

Lignin-based composites were synthesized by crosslinking of different amount of lignin on silica. For that, lignin solutions with concentration from 1 to 10 % were adsorbed on mesoporous silica surface. FTIR spectroscopy confirmed the creation of lignin layer on silica surface. Concentration of immobilized lignin was estimated using thermogravimetric analysis. Specific surface area and changes in pore size distribution with increasing of lignin concentration as composites component were estimated.

Synthesized hybrid composites were found to be effective as sorbents for the recovering of cobalt(II) from aqueous solutions.

Acknowledgment: This work has been financially supported by the Olle Engkvists Stiftelse (Grant Nr. 198-0329) and the ÅForsk Foundation (individual grant number 19-676).

In quest of a viable method for low-cost carbon capture and release, the integration of photoswitchable elements into porous materials in order to modulate their CO$_2$ adsorption and release properties on demand is of great interest. Serving as an attractive stimulus, light is naturally abundant, and it could be harnessed to replace conventional energy-intensive regeneration techniques. Among the light-responsive elements, azobenzenes interconvert from the thermodynamically stable form of trans to the cis configuration by rotation of the aromatic rings around the -N=N- bond upon UV and visible light irradiation, respectively. Considering amine functional groups as proven CO$_2$ adsorptive sites, the CO$_2$ capture and release
properties of an adsorbent could be tailored by the interplay between amine sites and photoresponsive azobenzene groups in a porous structure. Simply put, by accommodating amine groups on the far end of azobenzene pendant groups, the exposure of active amine sites to CO$_2$ molecules are regulated by light-driven isomerization. Despite the investigation of several photoresponsive systems for CO$_2$ adsorption, various challenges are yet to be addressed prior to achieving a concrete material design. More precisely, the photoresponsive adsorbents usually suffer from delayed response upon irradiation, largely due to sterically hindered azobenzene isomerization in the relatively small pore structure. Moreover, their cavity is partially occupied by the photoswitchable pendant groups, leading to lower CO$_2$ uptake capacity.

To tackle these constraints, in this work, we first conduct a structural optimization of the porous material hosting azobenzene groups by means of density functional theory (DFT) methods. In the following steps, the *cis*-isomer and *trans*-isomer contents in light-responsive adsorbents are determined by NMR after certain irradiation time to validate the effectiveness of irradiation. The CO$_2$ uptake amount of the as-synthesized adsorbents are subsequently investigated by applying UV and visible light for a range of time and intensity. Further characterizations including XRD, FTIR, BET surface area and UV-vis spectroscopy are also performed to discuss the effect of photoswitching on CO$_2$ adsorption properties of adsorbents.

SESSION EN04.04: Novel Membrane Structure and Chemistry for Controlled Transport I
Session Chairs: Yifu Ding and Haiqing Lin

Thin-Film Composite Membranes by Interfacial Polymerisation for Molecular Separations in Aqueous and Organic Liquid Systems Andrew Livingston; Imperial College, United Kingdom

Membranes have had a huge impact in molecular separations in aqueous systems, especially desalination. The workhorse membrane for reverse osmosis is the thin film composite (TFC) membrane formed by interfacial polymerisation. This presentation will focus on research into understanding the formation and function of TFC membranes for both desalination and Organic Solvent Nanofiltration (OSN) [1].

Advanced imaging and tomography has been used to understand the morphology of commercial TFC membranes and the flow paths through them [2]. To better reveal the relationship between fabrication and function, ultra-thin polyamide films (sub-10nm) have been formed by interfacial polymerisation and then used to fabricate composite membranes [3]. These ultra-thin polymer films 6-8nm thick are strong, and can be several centimetres in lateral dimension. Interestingly, the morphology of these films can be manipulated from smooth to highly crumpled, by adjusting the reaction conditions. The films can be applied in liquid filtration, and show unprecedented permeances in organic solvents, and high rejection of all solutes. Because the films can be prepared free-floating at a liquid-liquid interface, they can be used to explore how composite membranes function. This reveals that through matching of rough and smooth films with different supports, it is permeance rather than surface roughness, that determines fouling. Further, we find that the support permeance has a strong effect on the composite membrane permeance, for the same film placed on different supports [4], and that that the support rather than the thin film separating layer of a composite membrane leads to physical aging and flux decline. These insights are counter-intuitive to current thinking.

Intrinsic microporosity can be introduced into the ultra-thin polymer films through selection of contorted monomers for interfacial polymerisation. These intrinsically microporous polymer nanofilms provide higher interconnectivity of pores and greater permeance than films obtained from planar monomer systems [5]. Finally, the potential for ultra-high permeance membranes to impact on actual molecular separation processes will be discussed, including the relative merits of selectivity, permeance and stability [6].

The cylinder morphology has been extensively studied for isoporous membranes with channels on the nanometer length scale, but this morphology suffers from alignment issues: The channels must be oriented perpendicularly to the surface while also extending through the full thickness of the membrane. Gyroids, on the other hand, form networks of isoporous channels that are connected in all three dimensions, thereby avoiding the orientation challenge of cylinders. Thus, the gyroid morphology is of great interest, but the fabrication of such materials presents a challenge with both synthesis and processing.</p><p>The synthesis and characterization of three different gyroid-forming di-block copolymers will be presented. In these materials, one block is made of the easily degradable polylactide (PLA) and the other features a functionalized polystyrene block to offer rigidity. Anionic polymerization in conjunction with organocatalytic ring-opening polymerization was used to provide BCPs with low polydispersity and a high degree of control over the relative volume fraction. These materials can be made reproducibly and on multigram scales.</p><p>Thin films of the materials were studied before and after the removal of the PLA block and processes were developed to overcome wetting layers that close the surface of the gyroid film. Atomic layer deposition was explored as a means of changing both the pore dimension and surface energy. These BCPs have been combined with a polyethersulfone (PES) layer to generate composite membranes composed of a thin, selective gyroid layer and a mechanically strong, porous PES layer. These composite membranes were investigated for applications in batteries, gas separation, and water purification.</p><p><strong>9:15 AM EN04.04.03</strong><br>Selectivities and Permeabilities in Anisotropic Membranes for Gas Separations Juan M. Restrepo-Florez¹,², Martin Maldovan¹ and Katie Dongmei Li-Oakey³; ¹Georgia Institute of Technology, United States; ²University of Wisconsin–Madison, United States; ³University of Wyoming, United States</p><p>The design and synthesis of membranes for gas separations has mainly relied on isotropic materials. Physically, isotropic materials control the magnitude of the flux and separations in isotropic systems occur as a result of different flux magnitudes of the species of interest. We have recently introduced a novel approach for the design of membranes based on anisotropic materials in which flux directional control is induced to perform separations. Remarkably, the use of anisotropic materials provide membranes in which selectivities and permeabilities are spatially dependent. In this talk, we discuss the capabilities of these novel anisotropic membranes for gas separations under planar configurations and provide unprecedented selectivities for separations of binary mixtures. We also discuss how anisotropic materials can be used to improve the separation ability of current isotropic membranes, pushing the limits of existing technologies. Furthermore, we discuss the existence of a unique trade-off relation between selectivity, permeability and collected fraction of permeate. Our findings are applied to the separation of binary mixtures of O₂/N₂ and H₂/CH₄.</p>
Polymer Membranes with Spatially Controlled Gas Permeability
Adrienne Blevins1, Lewis Cox2, Jason Killgore3 and Yifu Ding1; 1University of Colorado Boulder, United States; 2Montana State University, United States; 3National Institute of Standards and Technology, United States

Polymer membranes utilize the difference in permeability between molecules and ions to achieve molecular separation. For both gas separation and desalination processes, the transport of permeates through polymeric barrier layer films occurs through a solution diffusion process. Typically, the transport is modeled as one-dimensional, i.e. along the thickness direction of the barrier layer. However, recent evidences suggest that these films are often heterogeneous in terms of structure and composition. The effect of spatial heterogeneity, both in terms of length scale and spatial arrangement, on the transport behavior (especially permeability) remains unclear. Besides homogeneous membranes, recent developments in mixed matrix membranes aim to use more permeable additives (e.g. metal organic framework or MOF particles) to enhance the permselectivity of the matrix membranes.

In this work, we demonstrate a new type of polymeric membrane with tunable, well-defined, spatially heterogeneous permeability. This is achieved by photopatterning over a two-stage thiol-ene polymer network, which leads to spatially varying rubbery and glassy networks with nearly identical chemistry but different permeability. This talk will discuss the materials formulation; photopatterning with regards to both resolution and spatial arrangements; mechanical, and gas transport properties of these films. Further, the effects of both domain size, interfacial profile, and volume fraction of the glassy regions on the overall gas permeability of the membrane will be compared with composite models. Besides their potential applications in molecular/ion separation, the films are promising in areas of encapsulating nanodevices that require spatially varying permeability.

Ion Partitioning, Mobility, Permeation, Conduction and Association in Polymeric Membranes—A Unified Picture
Viatcheslav Freger1,2; 1Technion- Israel Institute of Technology, Israel; 2Technion–Israel Institute of Technology, Israel

Despite the wide use of ion-rejecting and ion-conducting polymeric membranes in processes such as nanofiltration (NF), reverse osmosis, electrodialysis (ED) separations, membrane electrolysis and fuel cells (FC), understanding ion transport and selectivity still presents a challenge. Mean-field models of charged nanopores (e.g., Donnan or Poisson-Boltzmann) have been the standard for last few decades, yet they fail to reproduce correctly some observed trends, e.g., multi-ion separations in NF or ion specificity in ED. These difficulties can be traced back to inherent flaws of mean-field models in charged low-dielectric media. On the other hand, simple phenomenological models with adjustable ionic permeabilities work well, but require ad hoc composition-dependent parameters and the physics behind this dependence remains obscure.

Here, we abandon the standard mean-field nanopore picture and introduce a simple solution-diffusion model of a homogeneous NF membrane that treats the strong departures from mean-field by adding ion association effects in a manner of classical Bjerrum theory. The model consistently explains our recent elaborate NF data for NaCl-CaCl₂ mixtures [1] and other published data, e.g., a high portion of nominal ion-exchange capacity in FC membranes inactivated by presumable “condensation” (association) of counter-ions on fixed charges [2]. It also addresses the fact that, in a non-mean-field treatment, ion uptake and mobility are no more decoupled (like in the Donnan model) and must be computed in a consistent manner from the same physical picture.

The results emphasize the importance of non-mean-field effects in general and ion association in particular for correct modeling of ion uptake, permeation and conductance in polymeric membranes. Our analysis also highlights the fact that simple continuum electrostatics is unable to supply an accurate quantitative description of effects such as association and solvation, for which the new model offers a simple and approximate yet physically sound and transparent way to treat the problem and define relevant ion-specific parameters.

**Borosulfate Anhydrous Proton Conducting Electrolyte Membranes** Matthew D. Ward, Brian Chaloux and Albert Epshteyn; U.S. Naval Research Laboratory, United States

Proton exchange membrane fuel cells are a potential zero emission power source to reduce and replace dependency on fossil fuels. While research and development efforts to date have concentrated on materials and systems that either function below the boiling point of water (25-100 C) or systems where the conductive medium is a ceramic or glass requiring very high temperatures (> 500 C), materials and systems that operate at intermediate temperatures (150-300 C) have received considerably less attention. Moving to this temperature regime can provide a number of advantages, including the requirement of a lower catalyst loading, reduced potential for catalyst poisoning, and reduced complexity from removing bulky and costly humidification systems, while also allowing for the use of lower cost non-precious catalysts. One of the key challenges to operating fuel cells at intermediate temperatures is the search for new proton conducting electrolyte materials that show conductivities >10^{-3} S/cm and good chemical stability under these conditions. Here we have explored a new family of solid-acid compounds, the borosulfates, as proton conducting electrolytes. These materials show promise, with measured conductivities on the order of 10^{-4} S/cm at ambient temperatures/humidity with further increases in conductivity to 10^{-3} S/cm above 100 C. TGA measurements show that these materials are stable to temperatures above 300 C, and we also demonstrate that this material can be consolidated into dense pucks at mild temperatures using a standard hydraulic press.

**Understanding the Correlation between Polymer Structure and Gas Transport Properties Using a Free Volume Model** Haiqing Lin; SUNY Buffalo, United States

Understanding the structure and property relationship is critical to designing high-performance membrane materials for gas separation, particularly for materials with balanced permeability and selectivity above or near the upper bound. Herein, a modified free volume is adapted to describe the upper bound for the separation of several gas pairs, such as O2/N2, He/CH4, CO2/CH4, and H2/CO2. The results are compared with conventional activation energy model reported in the literature. More importantly, this model can be used to predict the structure of polymers with targeted separation properties on demand. I will demonstrate that for the separation of specific gas pairs, polymers with specific free volumes can achieve the best performance. Such an understanding may be useful for the design of membrane materials through data mining or machine learning.

**Determination of Intrinsic Polymeric Membrane Permeability Using a Combined Experimental–Simulation Approach** Marielle Soniat1,2, Sarah Dischinger1,2, Lien-Chung Weng1,2, Daniel J. Miller1,2, Adam Z. Weber1,2 and Frances Houle1,2; 1Joint Center for Artificial Photosynthesis, United States; 2Lawrence Berkeley National Laboratory, United States

Membrane stability is a crucial determinant of the performance and lifetime of energy storage and conversion devices such as batteries, fuel cells, and photoelectrochemical CO2 reduction (CO2R) devices. In direct methanol fuel cells (DMFC) and CO2R devices, membrane stability is compromised by methanol, which solvates many polymeric membrane materials. Stability can be assessed by evaluating membrane permeability over time, with constant permeability suggesting a stable material and allowing for stable device performance. However, permeabilities obtained from experimental data are often average values and may include the effects of swelling, liquid-membrane boundary layers specific to the device architecture, and changing material properties. This talk reports a combined experimental-simulation study of methanol permeation through Nafion to determine intrinsic permeability, building on our prior modeling work examining time-dependent sorption in this system. Experiments provided independent measurements of swelling, sorption, and time-dependent permeation. Computational fluid dynamics simulations were used to generate an independent estimate of boundary layer thickness in the experimental system. A multiscale reaction-diffusion model was constructed using these data, and stochastic simulations were used to predict the intrinsic membrane permeability as well as apparent permeability for comparison to the experimental data. Deviations of experimental data from theoretical predictions using a standard permeation model as the system approaches equilibrium are explained. The approach we used is general, and is valuable for understanding and predicting the kinetics of structure-property-performance changes for polymeric membranes.
Microporous Polymer Derivatives for Energy-Efficient Gas Separations Katherine Mizrahi Rodriguez, Alexander Liu and Zachary P. Smith; Massachusetts Institute of Technology, United States

Current industrial gas separations, such as CO2 removal from natural gas, rely primarily on energy-intensive and environmentally unfriendly processes. Polymer membranes offer a promising alternative due to their potentially lower energy costs and ease of operation, but they are infrequently deployed because of performance limitations of currently available polymers. In this work, the effect of backbone functionalization and polymer packing structure on transport performance was investigated for a high-performance polymer of intrinsic microporosity, PIM-1. Through post-synthetic modification reactions, the PIM-1 backbone was altered in various ways. First, carboxylic acids (PIM-COOH) and amines (PIM-NH2) were introduced to promote hydrogen bonding and improve the affinity between the polymer and CO2. Second, bulky protecting groups (PIM-PROT), which could subsequently be removed to manipulate packing structure, were also considered. A facile and time-efficient PIM-1 hydrolysis method has been developed, yielding solution-processable PIM-COOH with greater than 90% conversion. Transport measurements reveal that when converted to PIM-COOH, permeability decreases and selectivity increases for CO2-related gas pairs, while, when converted to PIM-NH2, permeability and selectivity for CO2-related gas pairs both decrease. These trends are mechanistically evaluated through a suite of materials characterization tests including surface area measurements and positron annihilation lifetime spectroscopy (PALS). Additionally, a deconvolution of sorption and diffusion up to high pressures (i.e., > 30 bar) is presented to assess how changes in backbone chemistry and packing structure influence transport behavior. Moreover, plasticization behavior is presented. The PIM-COOH sample shows reduced plasticization resistance as compared to PIM-NH2, and these results are likewise assessed from the framework of the solution-diffusion model.

Mechanisms Controlling Molecular and Ion Transport through Polymer Membranes Alexei Sokolov1,2; 1Univ of Tennessee, United States; 2Oak Ridge National Laboratory, United States

We present an overview of mechanisms controlling molecular and ion transport in polymer membranes. Molecular permeability is controlled by solubility and diffusivity. Elastic forces provide the major resistance to molecular diffusion. The polymer shear modulus G, the size of the molecule R, and available free volume define the energy barrier controlling molecular diffusion through a polymer membrane. This leads to the exponential dependence of diffusion on molecular size [1] and provides the basis for the size-sieving selectivity approach used in most of the glassy membranes for gas separation. We show that Anderson-Stuart model [1] provides reasonable description of molecular diffusion in many polymers. However, when molecular size are comparable (e.g. CO2, N2, O2), selectivity in solubility becomes the most important parameter controlling selectivity of molecular permeability through the polymer membrane. It also provides the main selectivity for transport through rubbery membranes where elastic forces have rather low energy barrier due to much lower G. We show examples of some rubbery polymers where by tuning molecular solubility one can significantly improve selectivity for permeability of CO2 vs N2 [2,3].

In the case of ion transport, coulombic interactions provide additional resistance for ion diffusion. The energy barrier in that case varies inversely with the ion size. As the result the energy barrier for ion transport has a non-monotonous dependence on the ion size. Indeed analysis of the energy barrier controlling ion diffusion in polymerized ionic liquids has a minimum, and increases sharply for small ions, such as Li, due to strong coulombic interactions, and then increases with ion size for large ions, such as TFSI, due to elastic forces [4,5]. We demonstrate that Anderson-Stuart model [1] can describe well the energy barrier controlling ion diffusion in polymers. We suggest that this additional coulombic term is the major reason for improved water desalination performance by polymer membranes containing attached ions. We also demonstrate that the ion conductivity in polymers is strongly affected by ion-ion correlations (the so-called Haven ratio) that might reduce the ionic conductivity by more than 10 times [4,5]. At the end we propose polymer structures that might provide significant
ionic conductivity at ambient temperature even in the dry state.

Tunable Poly(Ethylene Glycol)-Based Network Polymer Membranes for Simultaneous CO2 and H2S Removal from Natural Gas Daniel Harrigan, Benjamin Sundell and John Lawrence; Aramco, United States

Processing sub-quality natural gas remains an economic and environmental challenge, especially as natural gas demand increases. Toxic and/or corrosive sour gas contaminants, such as hydrogen sulfide (H2S) and carbon dioxide (CO2), must be removed from methane (CH4) to meet pipeline specifications. Gas separation membrane technology offers a low cost alternative to traditionally energy intensive adsorption-based separations. This work describes a series of hydrophilic network polymer membranes synthesized for sour gas applications. Oligomeric poly(ethylene glycol) (PEG) of varying molecular weight was reacted with stoichiometric amounts of a trisiloxane crosslinker to create highly crosslinked amorphous gels cast directly on top of membrane supports. Polymer network structure was confirmed by FTIR, DSC, and DMA. Thermal characterization showed dramatic increases in polymer Tg as PEG chain length between crosslinks decreased from 2000 Da to 200 Da, transitioning from rubbery to glassy around 600 Da. Predictably, gas permeabilities decreased over the same range of PEG molecular weights due to the higher crosslink density and corresponding network rigidity. However, pure gas CO2/CH4 followed a bell-shaped trend with maximum selectivity achieved by the 600 Da PEG membrane, subverting expected tradeoff relationships. High pressure mixed gas permeation tests performed at 800 psi with simulated sour gas feeds containing up to 20% H2S by volume demonstrated superior membrane performance and stability of the PEG-based materials compared to commercial controls. The highest performing PEG membrane exhibited 3.0 times higher H2S permeability and 1.9 times higher H2S/CH4 selectivity than cellulose acetate as well as 1.8 times higher CO2/CH4 selectivity and 1.2 times higher H2S/CH4 selectivity compared to commercially available Pebax. Finally, we explore the amenability of this technology to thin film processing to improve membrane productivity.

2:15 PM EN04.05.03
Understanding the Role of Architecture, Polarity and Charge Spacing in Precise Network Polymerized Ionic Liquids on Aggregation and Ionic Conductivity Christopher Evans, Qiujie Zhao and Chengtian Shen; University of Illinois at Urbana-Champaign, United States

We have investigated nearly identical linear and network PILs containing precise linker lengths between ammonium cations. Two different linker chemistries, either an 11 atom hydrocarbon (HC) or 11 atom ethylene oxide (EO) chain, to vary the polarity. Wide-angle X-ray scattering measurements revealed that the ionic aggregation peaks were less intense in the EO systems, consistent with a more polar chemistry providing better ion solvation. Network PILs of both HC and EO linkers had a more pronounced ionic aggregation peak intensity than their linear counterparts, indicating that polymer architecture impacts ion clustering. In addition to a more pronounced aggregation peak, the EO network showed a two order of magnitude increase in conductivity relative to the linear analogue at Tg + 10 °C. Conversely, linear and network PILs with HC linkers show identical Tg normalized conductivities. In the HC networks, we systematically increased the length from 4 to 12 carbons and observed pronounced odd-even effects on Tg and conductivity which shifted as much as 50 K and 2 orders of magnitude, respectively, by adding one carbon between ionic sites. This systematic study provides a new insight on how polymer architecture, polarity, and precision can influence aggregation and transport of ions in PILs.

2:30 PM EN04.05.04
Molecular Design of Polymerized Ionic Liquid Membranes for the Separation of Toluene/Heptane Grant S. Sheridan and Christopher M. Evans; University of Illinois at Urbana-Champaign, United States

Precise network polymerized ionic liquid membranes (PILMs) with tethered imidazolium cations, variable anion, and controlled crosslink density were developed to understand how molecular structure impacts solubility and diffusion in the context of toluene/heptane separations. Switching the anion from tetrafluoroborate (BF4) to
bis(trifluoromethane)sulfonimide (TFSI) led to a 25 K drop in the glass transition temperature, concomitant increase in penetrant diffusion coefficients, and increased solubility of toluene relative to heptane. Reducing crosslink density led to an increase in toluene swelling, while heptane uptake remained relatively low and constant. Differences in toluene and heptane diffusion coefficients exhibited a maximum selectivity at intermediate crosslink density. It is hypothesized that a fully crosslinked network has a mesh size small enough to impede transport while lower crosslink densities allow toluene to swell the system to a greater extent in contrast to heptane. The interplay of diffusion and solubility effects lead to a non-monotonic trend in selectivity, which will inform the design of membranes as effective organic liquid separations media.

2:45 PM EN04.05.05
Supported Ionic Liquid Membranes Using π Electron Cloud Interactions for Specific Separation

Sumith R. Wickramasinghe, Ronald Vogler, Mahmood Jebur, Mohanad Kamaz and Arijit Sengupta; University of Arkansas, United States

Development of membranes for highly specific separations is challenging and will depend on specific surface interactions. Here we have investigated the feasibility of using ionic liquids and polyionic liquids containing imidazolium groups trapped within the pores of a membrane (supported ionic liquid membrane) to separate compounds with differing p-electron cloud densities due to their interactions with pi-electron clouds. In this study, these supported ionic liquid membranes are used for the separation of stereoisomers, amino acids as well as similar heterocyclic compounds. A 0.45 micron pore size polypropylene microfiltration membrane is used to trap 1-hexyl-3-vinylimidazolium bromide within the membrane pores. The separation of furan and thiophene in hexane (organic solvent) and cytosine, guanine, and thymine in water (aqueous solvent) has been investigated. The specificity for separation was found to be related to the affinity of the ionic liquid towards the p electron cloud density and extent of conjugation in the solute. Polyionic liquids that are formed from 2-vinyl pyridine or 4-vinyl pyridine are used to separate stereoisomers. The ability of the polyionic liquids to separate stereoisomers at ambient temperature indicates their potential for energy-efficient separations of similarly structured compounds with varying pi-electron clouds. The incorporation of ionic liquids and polyionic liquids into the membrane is verified using infrared spectroscopy and/or imaging with scanning-electron microscopy. The results obtained here indicate that membranes for highly specific separations could be developed based on p electron cloud interactions.

Advanced Membrane Characterization Enabled by Molecular Layer-By-Layer Deposition of Polyamides

William D. Mulhearn, Peter A. Beaucage, Velencia J. Witherspoon, Ryan C. Nieuwendaal and Christopher M. Stafford; National Institute of Standards and Technology, United States

The state-of-the-art membranes for desalination are comprised of thin film composites where the permselective layer is a thin, interfacially polymerized polyamide. Although effective, the rapid polymerization rate and reaction conditions produce films with rough surface structures and chemical heterogeneity, which precludes some exquisite characterization techniques for probing thin and ultrathin films. In 2011, we proposed a paradigm shift in how these types of membranes are fabricated, where the selective layer is created layer-by-layer through a reactive deposition process. Even so, there are still many challenges yet to overcome, from membrane support design to membrane characterization. In this talk, I will describe our efforts to meet these challenges through judicious experimental design and materials selection. Specifically, I will describe efforts to measure the internal structure of these membranes using resonant and non-resonant x-ray scattering, as well as measure the dynamics of water and salt in these membranes using quasi-elastic neutron scattering and electrochemical impedance spectroscopy, respectively. Then, I will discuss how these measurements have challenged our thinking in how these materials selectively pass water while rejecting salt.

4:00 PM EN04.05.07
Highly Permeable MOF-Based Mixed Matrix Membranes for Energy-Efficient CO2 Capture

Shouliang Yi1,2 and David Hopkinson1; 1U.S. Department of Energy – National Energy Technology Laboratory, United States; 2Leidos Research Support Team, United States

Membrane-based separation processes have been considered as one of the most promising technologies for post-

Final Program 1/13/2020 558
combustion carbon capture due to lower energy consumption, smaller environmental footprint, and the potential to be installed in an existing power plant as a true bolt-on technology. However, polymeric membranes, currently considered the most promising candidate for industrial application, are limited by a trade-off upper bound between the productivity and separation efficiency. Metal–organic frameworks (MOFs) are promising candidates to overcome the limitations of polymer membranes, by fabricating mixed matrix membranes (MMMs) due to their high surface area and porosity, diverse functionalities and tunable pore structures.

In this presentation, several MOF-based mixed matrix membranes were developed by incorporating different types of MOF crystals (e.g., surface functionalized Uio-66 and nano-sized zeolitic imidazolate framework-8) into a variety of polymers (e.g., polymers of intrinsic microporosity, poly(ether-block-amide) copolymers, polymer blends composed of PIM-1 and MEEP80 polyphosphazene) for highly energy-efficient carbon capture. The mixed gas permeation results showed that these MOF-based mixed matrix membranes have displayed superior separation performance (the CO2 permeability of up to 6000 Barrers with a CO2/N2 selectivity of higher than 22), surpassing the 2008 Robeson upper bound. Testing these membranes using real flue gas streams at the National Carbon Capture Center (Wilsonville, Alabama) will also be presented. We demonstrated that the excellent CO2/N2 separation performance makes MOF-based mixed matrix membrane a very promising platform for practical CO2 separations.

Separation Performance of Modified Novel Poly(ether-b-amide) Membranes for Acid Gas Removal from Natural Gas John Yang1, Daniel Harrigan1, Milind M. Vaidya2, Sebastien A. Duval2 and Michelel Ostraat1;
1Aramco Services Company, United States; 2Saudi Aramco, Saudi Arabia

Natural gas use as a primary energy source has expanded rapidly over the past several decades. A 69% increase in worldwide consumption for natural gas over the 2012 level is anticipated by 2040. However, raw natural gas from some wells can contain significant amounts of other gas components, including H2S, CO2, N2, water, and other hydrocarbons (C2+). Among these contaminants, the acid gases (H2S & CO2) must be treated to avoid corrosion of transportation pipeline and to meet the standard pipeline specifications of sales gas. Polymeric membrane-based technologies have gained great industrial attention for natural gas upgrading and treatment due to their relatively energy-efficient and environment-friendly footprint. Current commercial rubbery polymer membranes for acid gas removal from natural gas, such as poly(ether-b-amide) copolymer (PEBAX), show a decline separation performance under industrially relevant feed streams and testing conditions. In this talk, we describe a modification of the polymer backbone by blending and crosslinking to develop novel PEBAX membrane materials for simultaneous CO2 and H2S removal from natural gas. Modified PEBAX membrane materials comprised of crosslinked polyethylene glycol as a CO2-pohilic additive were produced via either UV crosslinking of diacrylated-terminated polyethylene glycol or chemical crosslinking of a diisocyanated-terminated polyethylene glycol by controlling crosslinking moieties and crosslinked networks in the membrane matrix. High-pressure pure and mixed sour gas transport properties of these modified PEBAX membranes were investigated as a function of loading, feed pressure, temperature, and gas composition at moderate to high H2S% concentration. The modified PEBAX membranes demonstrate improvements in gas separation performance (16% and 12% increase in H2S/C1 and CO2/C1 selectivities) and enhanced membrane stability (64% and 100% increase in mechanical strength and swelling resistance) compared to neat PEBAX membrane under industrially relevant feed streams and testing conditions (e.g. feed pressure of 800 psi and 20% H2S). Based upon the enhanced membrane performance, this modified PEBAX membrane material can be a potential candidate in combination with amine absorption system for acid gas separations from natural gas.

4:30 PM EN04.05.09
Spatially Directed Immobilization of Kinetically Matched Enzyme Cascades in Membrane Flow Nanoreactors Deniz T. Yucesoy1,1, Susrut Akkineni1, Candan Tamerler1,1,2, Bruce Hinds1 and Mehmet Sarikaya1,1,1;
1University of Washington, United States; 2University of Kansas, United States

Enzymatic pathways that perform multi-step biochemical reactions in biological cells constitute a crucial part of life. Biomimetic reconstruction of these metabolic pathways by incorporating multiple enzymes and relevant cofactors in a confined environment holds tremendous promise for sustainable green synthesis of fine chemicals e.g., pharmaceuticals, biofuels, and consumer products, as well as developing efficient biomolecular devices. Controlled localization of enzyme immobilization onto support platforms, however, remains a major challenge. In metabolic pathways, enzymes are spatially coupled to prevent unfavorable side-reactions, eradicate inhibitory products and channel metabolites sequentially from one enzyme to another. Biomolecular assemblies mimicking natural cascades
can be reconstructed using monolithic mesoporous anodized aluminum oxide (AAO) membranes that allow sequential mass transport of catalytic products between spatially immobilized enzymes under convective flow. Here, we developed a peptide-guided approach for spatially controlled immobilization of a bi-enzyme model, L-Lactate dehydrogenase and Formate Dehydrogenase, with high precision for cascadic biosynthesis. Each enzyme is fused with a solid-binding peptide to direct self-directed immobilization across the membrane that facilitates sequential production of L-lactate with the concomitant regeneration of nicotinamide adenine dinucleotide (NADH). Catalytic turn-over rates of immobilized enzymes are found to be consistent with homogeneous solution rates. The 85% overall sequential reaction efficiency is achieved at a flow rate that kinetically matches the residence time of the slowest enzyme. Furthermore, 84% of initial catalytic activity is preserved after 10 days of continuous operation. Peptide-guided immobilization described herein is an effective strategy to build robust bioreactors and diagnostic devices involving cascadic systems. The study was supported by NSF-DMREF program through the grant DMR-1629071 and NSF-CBET Program through the grant 1460922.

SESSION EN04.06: Novel Membranes for Enhanced Water Treatment

Modifying Ion Transport in Nanoporous, Ionic Lyotropic Liquid Crystal Polymer Membranes via Situ Polymerization of Reactive Counterions in the Pores
Michael McGrath, Samantha Hardy, Andrew Basalla, Gregory Dwulet, Bryce Manubay, Zhangxing Shi, Hans Funke, Doug Gin and Richard Noble; University of Colorado, United States

Cross-linked, ionic lyotropic (i.e., surfactant) liquid crystal (LLC) assemblies have periodic, uniform-size, charged pores in the 0.7–1.0 nm range that allow them to be used as new type of polymer membrane material for molecular size separations in water. Ordered, 3D-nanoporous LLC networks with a type I bicontinuous cubic (Q) phase can be prepared from an imidazolium bromide-based gemini LLC monomer blended with glycerol. These Q assemblies can be readily processed and polymerized into supported thin-film composite (TFC) membranes that have 0.96-nm-wide annular pores with fixed cationic imidazolium sites in the walls and mobile bromide counterions in the pore interior. After exchange of water for glycerol in the pores, the resulting TFC Q membranes can exclude dissolved molecular solutes and small salt ions from water via a combination of size sieving and charge repulsion effects in the pores. In addition to water purification, these charged, nanoporous membranes may be useful for selective ion conduction applications, such as separator membranes for aqueous flow batteries. However, one of the liabilities of this ionic membrane material is that the mobile counterions can be easily exchanged with other anions from external salt solutions, thereby resulting in unwanted changes in effective pore size and water/salt transport properties during application. Herein, we show that the cationic pores of this cross-linked Q LLC material can be modified by exchange of the original Br– ions in the pores with polymerizable organosulfonate anions, followed by in-situ polymerization of the reactive counterions inside the Q pores. The resulting ordered ‘snake-in-cage’ nanocomposite was found to be highly resistant to ion-exchange: the formed anionic polymer was found to remain inside the nanopores even when the bulk material is exposed to concentrated (i.e., 1 M) aq. salt solutions for long periods of time. After polyanion formation inside the pores, the LLC material loses its overall ion-exchange capacity, presumably due to ionic cross-linking between the cationic pore walls and the anionic groups on the confined polymer chains. However, the pore environment remains ionic, as confirmed by water and salt sorption measurements. Aqueous ion transport tests on TFC membranes made from the modified Q material with polyanion chains in the pores show that salts such as MgCl2 and K2SO4 permeate through at significantly different rates than unmodified TFC Q membranes with mobile counterions in the pores. This relatively simple modification procedure provides a new way to modify and stabilize the transport properties of nanoporous ionic LLC networks for use in selective ion transport applications. The relative merits and avenues for control of this approach will be discussed.

Facile Grafting of Zwitterions on Membrane Surface Using Bio-Inspired Polydopamine
Haiqing Lin and Nima

Final Program 1/13/2020 560
Shahkaramipour; SUNY Buffalo, United States

Water purification membranes usually suffer from surface fouling, which dramatically decreases water permeance. The fouling is often mitigated by hydrophilizing the membrane surface, such as coating by hydrophilic zwitterions (ZW) and poly(ethylene glycols) (PEGs). We demonstrate a facile method to graft the ZWs and PEGs onto the membrane surface by co-depositing with dopamine. Dopamine can be easily polymerized to polydopamine (PDA), which can covalently bind ZWs or PEGs containing acrylate or amine functional groups through Michael Addition. Specifically, acrylate-terminated compounds include sulfobetaine methacrylate (SBMA) and PEG-diacrylate (PEGDA), and amine-terminated SB-amine and PEG-diamine were co-deposited with dopamine onto the silicon wafers and ultrafiltration (UF) membranes. The effect of the composition of coating solutions and coating time on the coating layer thickness, compositions, and hydrophilicity are investigated. The coating can deposit a layer of 10 – 50 nm containing 30 – 72% ZW or PEG. The effect of coating and surface chemistry on the membrane properties (including molecular weight cut-off and water permeance) will be systematically investigated to derive the structure/property relationship.

9:30 AM EN04.06.03
Zwitterionic-Containing Ultrathin Hydrogel Selective Layer for Fouling-Resistant Ultrafiltration Membranes
Alice O. Aguiar¹, Timothy M. Gronet¹, Ilin Sadeghi² and Ayse Asatekin¹; ¹Tufts University, United States; ²Massachusetts Institute of Technology, United States

Membrane fouling by organic compounds is still one of the main challenges faced by membrane separation processes. Advanced fouling-resistant membranes can be obtained by increasing the hydrophilicity of the membrane surface. Hydrogels are materials that can absorb large quantities of water and swell, which makes them inherently fouling resistant. Zwitterions, defined as neutrally charged molecules with equal numbers of cationic and anionic groups, and very high dipole moments, exhibit strong hydration layers and, accordingly, excellent fouling resistance. These properties make hydrogels, especially those incorporating zwitterionic groups, promising membrane materials. However, the applicability of hydrogels as fouling-resistant selective layers of thin film composite membranes has been hindered by the lack of a fabrication process that allowed for the formation of a thin, defect-free hydrogel layer on a porous support. We have recently demonstrated a new method, namely Interfacially Initiated Free Radical Polymerization (IIFRP), to address this challenge. In IIFRP, the monomer and photoinitiator are separated into two immiscible phases. The aqueous phase is impregnated into a porous support. Its surface is then covered with an organic phase containing a photoinitiator and exposed to UV light. The ultrathin hydrogel selective layer, as thin as ~80 nm, is then formed at the interface of the two phases, at the membrane surface. The goal of the present study was to explore the incorporation of zwitterionic (ZI) groups into hydrogel selective layers obtained by IIFRP. We have shown that the incorporation of ZI moieties can further increase membrane fouling resistance and improve membrane properties such as hydrophilicity and permeability. The partial substitution of poly(ethylene glycol) diacrylate (PEGDA) units in the hydrogel layer with the zwitterionic monomer sulfobetaine methacrylate (SBMA) led to an increase in permeance of almost an order of magnitude (from 3.9±0.4 L/h.m².bar to 34.7±0.8 L/h.m².bar). Moreover, although this substitution for SBMA also decreased the crosslinking density of the hydrogel, the rejection properties of these membranes remained essentially constant (99.2±0.6% and 98.7±0.6% myoglobin rejection, respectively). Furthermore, the zwitterionic-hydrogel membranes exhibited higher fouling resistance to oil emulsions compared to both commercial membranes and the zwitterion-free hydrogel membranes. Consequently, zwitterionic-containing ultrathin hydrogel selective layers obtained by IIFRP are very promising materials for fouling-resistant ultrafiltration membranes.

Development of Novel Scheme for Molecular Modeling of Membrane Separation with Multi-Component Feed Solution
Hayato Higuchi and Hiromitsu Takaba; Kogakuin University, Japan

Membrane has been applied to various separation systems, in particular, for the separation of aqueous or organic solvents. membrane separation is considered promising for reducing CO₂ emission in terms of energy efficiency. For a development of more efficient membrane process, better understanding of separation mechanism of solvent including multicomponent species is of fundamental. Molecular modeling becomes a powerful tool for prediction of membrane performance and design of membrane materials for particular separation systems. Our group has reported a novel simulation scheme of molecular dynamics for the permeation of feed solution through nano porous membranes. Molecular dynamics of multi component species in the feed, however, is still difficult to be simulated.
because a feed concentration of multicomponent such as ions cannot keep at a constant in our simulation techniques as well as other conventional non-equilibrium molecular dynamics scheme. In this paper, to model multicomponent solutions through nanofiltration or reverse osmosis membranes, we will present a novel molecular dynamics technique that can control the feed concentration including multicomponent species at constant. This simulation technique is completely new and first methodology that could model multicomponent solution systems in membrane separation from atomistic level, as long as our knowledge. We will report that this simulation technique works well and can produce the permeation of multicomponent feed solution. The flux and solute moleculars selectivity were calculated and compared to the theoretical values to examine the validity of our proposed scheme.

Controlling Water and Ion Transport in Hydrated Polymer Membranes via Chemical Functionality
Yuanyuan Ji, Hongxi Luo, Kevin Chang and Geoffrey M. Geise; University of Virginia, United States

Providing sustainable supplies of purified water and energy is a critical global challenge for the future, and polymer membranes will play a key role in addressing these clear and pressing global needs for water and energy. Controlling rates of water and/or ion transport in these membranes is critical for efficient separation processes (e.g., water purification or dialysis) and energy technologies (e.g., flow batteries or reverse electrodialysis). Much remains unknown about the influence of polymer structure on intrinsic water and ion transport properties, and these relationships must be developed to design next-generation polymer membrane materials. Here, we report and discuss measurements and modeling related to the influence of chemical functionality on rates of water and ion transport in hydrated polymers. Our results demonstrate how polymer properties (e.g., backbone rigidity, functional group type, and/or polarizability) can be engineered to enhance selective transport via thermodynamic and kinetic contributions to the transport process.

Nanostructured Thin Metallic Films on Polymeric Membrane Support for Reactions and Separation
Michael J. Detisch, John Balk and Dibakar Bhattacharyya; University of Kentucky, United States

Metallic thin films were deposited onto commercial ultrafiltration (UF) membranes to produce composite structures which show promise both for separations and for catalysis applications. Magnetron sputtering was used to deposit thin films of tantalum and MgPd alloy on top of polysulfone (PSf) membranes. The thin Ta films were found to have significant effects on flux and separation properties of the membranes. The composite membranes with MgPd films were subsequently dealloyed to produce nanoporous Pd, which performs well as a catalyst for wastewater remediation applications. Both types of composites will be presented here.

The addition of just a thin (10 nm) layer of Ta to the surface of the UF membrane was found to dramatically alter its properties as a membrane. Membrane flux dropped from 180 LMH/bar for the base UF PSf to 10 LMH/bar for the Ta composite system. Dye tagged dextran used as a model compound for the determination of molecular weight cutoff (MWCO). The UF PSf was found to have a MWCO above 70 kDa while the Ta composite membrane showed a MWCO below 5 kDa. Modifying the rejection characteristics of a membrane with only a 10 nm added layer is a valuable technique, especially as tantalum is a corrosion resistant metal. This makes this composite membrane applicable to both solvent based separations and separations in corrosive environments.

For the membranes with the MgPd film, a subsequent dealloying step in water was performed to remove the Mg component of the film and create a nanoporous film of Pd. This generates a high surface area, sponge-like structure of interconnected nanowires known as ligaments with characteristic size of <10 nm. The nanoporous palladium film was used as a catalyst with hydrogen gas for the degradation of pollutant compounds in wastewater. Specifically, PCB’s were dechlorinated while permeated in a water solution under pressurization with 5% hydrogen gas (remainder argon). In permeation testing over 60% of PCB-1 was degraded in solution with a single pass through the composite membrane at 40 LMH. Adding a high surface area nanostructure like a nanoporous metal to the surface of a membrane in this way produces a composite structure that can drive reactions as solutions are permeated through the membrane, giving favorable reaction rates. Furthermore, since this nanostructure is produced spontaneously as the MgPd alloy is dealloyed in water, production is straightforward and reproducible.

11:15 AM EN04.06.07
Direct Contact Membrane Distillation (DCMD) Using a Composite Electrospun Nanofiber Membrane for
Water Desalination Application Mahmoud Baniasadi, Momena Monwar and Francisco Cubas; Georgia Southern University, United States

Every year more than three million people die from water-related diseases. Having access to clean and good quality drinking water is a continuous challenge in our world. Increasing the world’s population together with the declining the water tables and increasing the salinity of water resources, resulting in a crisis that is already a major concern, while the situation getting worse every year.

Among various water desalination membrane technologies, Membrane Distillation (MD) is an emerging thermally-driven, membrane-based desalination technology highly suitable to treat hypersaline solutions. MD is a thermally driven process involving a nano/microporous, hydrophobic membrane through which only water vapor can diffuse. Compare to other membrane technologies, MD is a compact and low energy separation technology (the temperature requirement for MD is ~70°C). Although MD has been investigated by researchers, still it cannot compete with other technologies such as reverse osmosis (RO), mainly due to lower production rate, energy efficiency, consistency performance, energy efficiency, and fouling resistance to be named.

In the present study, modified PVDF electrospun nanofiber membrane composites with various support structures were studied for DCMD application. Hydrophobicity of the nanofiber membranes was investigated and different filler and parameter setting of the electrospinning process has been optimized in order to optimize the performance of the nanofiber membrane in the water desalination process. Surface modification of the nanofibers has been investigated using atomic force microscopy (AFM), in order to correlate the nanostructure of nanofibers, with the performance of the nanofiber membrane in DCMD. In order to enhance the performance of the system, nanofibers decorated with different nanoparticles were used to increase the hydrophobicity of the membrane. surface treatments were considered as another approach to enhance the performance of the desalination system using electrospun nanofiber membrane.

11:30 AM EN04.06.08
Water Filtration through Nanomembranes Actuated by Surface Acoustic Waves Zamart Ramazanova1, Zinetula Z. Insepov2,1,3 and Kurbangali Tnyshykbaev1; 1Nazarbayev University, Kazakhstan; 2Purdue University, United States; 3National Research Nuclear University MEPhI, Russian Federation

Nanofiltration technology for water desalination and other fluids purification from salts, germs, bacteria and viruses are based on the so called Nanopumping (NP) effect, when a fluid flow through nanomembranes and nanochannels is actuated using surface acoustic waves (SAW) is presented.

The paper considers processes of water nanofiltration through a carbon nanomembrane using SAWs under different RF powers and frequencies. A prototype device was build using LiNbO3 piezoelectric substrate and carbon nanomembranes on the substrate. The process of nanofiltration consisted of filtration of droplet volume of 3, 5 µl and in using SAW transducers with different frequencies from 34 to 58.2 MHz, with power range 0.1-1.23 W. The process of nanofiltration of water includes the processes of droplet moving, atomization and passage through nanopores.

We analyzed optimization of the basic characteristics of a SAW device, selection the optimum operating parameters of the SAW device and fabrication working prototype of the SAW device. This work is devoted to the development of an active model of the SAW device that demonstrates the work on water filtration using nanomembranes, in which liquid motion is driven with the help of sufficiently powered SAW. The dependences of the travel time of droplet moving and atomization of water on the power, the frequency vs. time, frequency vs. volume of the droplet are established.

It is shown that with increasing of power and frequency of SAW, the filtration process proceeds rapidly and has a power-law character. We investigated this problem both experimentally and numerically in 3D using COMSOL Multiphysics software.
Bunching and Immobilization of Ionic Liquids in Nanoporous Metal–Organic Framework

Anemar Bruno Kanj, Rupal Verma, Modan Liu, Julian Helfferich, Wolfgang Wenzel and Lars Heinke; Karlsruhe Institute of Technology, Germany

Room-temperature ionic liquids (ILs) are a novel class of designer organic solvents with unique properties of great interest in energy storage, supercapacitors and ion-based sensors and electronics. Metal-organic Frameworks (MOFs) are a unique class of designer nanoporous functional-material platforms compound of metal ions and organic linkers.

In our investigation of dynamic properties of IL embedded in porous hosts of MOF, specifically [BMIM][NTf2] in HKUST-1, we observe a drastic change in ion mobility from combined analysis of molecular dynamics simulation and experiment.

We found at low loading of ILs in MOF, ions drift in MOF pores along external electric field, forming a homogeneous flow; whereas at increased IL loadings, collective field-induced interactions of cations and anions lead to transient blockage of ion transport, suppressing ion mobility and tremendously decreasing the conductivity. At extreme loading as IL fills MOF pores, cations and anions travelling in opposite directions bunch-up to form a dense, inhomogeneous, and immobilized IL layer.

Novel molecular-level dynamics insights into IL in nanoconfinement provide guide lines in tuning of quantitative structure-property relationships of IL materials.

Our work is published as:

Polybenzimidazole-Derived Carbon Molecular Sieves with Microcavities and Ultra-Microporous Channels
Achieving Superior Membrane H2/CO2 Separation Properties

Hien Nguyen1, Maryam Omidvar1, Liang Huang1, Cara Doherty2, Anita J. Hill2 and Haiqing Lin1; 1University at Buffalo, United States; 2CSIRO, Australia

Membrane technology is highly attractive for H2/CO2 separation for pre-combustion CO2 capture, which requires membrane materials with both high H2 permeability and H2/CO2 selectivity at 100 – 300 °C. Herein, we present carbon molecular sieve (CMS) membranes with superior H2/CO2 separation properties via the pyrolysis of polybenzimidazole (PBI, a leading polymer for H2/CO2 separation). We thoroughly investigated the effect of the pyrolysis temperature on physical properties (pore size, d-spacing, density, solubility, diffusivity) and H2/CO2 separation properties of the CMS films. PBI exhibits H2 permeability of 27 Barrers and H2/CO2 selectivity of 14 at 150 °C, while the CMS films pyrolyzed at 600 °C, 850 °C, and 900 °C exhibit H2 permeability of 370 Barrers, 190 Barrers, and 54 Barrers at 150 °C, respectively, and their corresponding H2/CO2 selectivity of 8.9, 16, and 80, respectively. The pyrolysis forms micro-cavities leading to high gas permeability and ultra-microporous channels leading to strong size-sieving ability, which is also confirmed by the Positron Annihilation Lifetime Spectroscopy (PALS). As the pyrolysis temperature increases from 600 °C to 850 °C and then 900 °C, the free volume element size increases from 5.08 Å to 5.46 Å first and then decreases to 4.90 Å. When tested with a mixture containing 50% H2 and 50% CO2 at 150°C, CMS pyrolyzed at 900 °C show H2 permeability of 39 Barrers and H2/CO2 selectivity of 53, which surpasses the Robeson’s upper bound for H2/CO2 separation at 150 °C. The film shows stable mixed-gas separation performance for 40 h. When water vapor of 0.31 mol% is introduced, the H2 permeability slightly decreases to 37 Barrers while the H2/CO2 selectivity remains the same. The mixed-gas H2 permeability increases to 39 after the water vapor is removed. The stability and robust H2/CO2 separation properties demonstrate the potential of PBI-derived CMS for practical H2 purification and CO2 capture.
Design of Enhanced CO₂ Selective Inorganic Membranes

Fumiya Hirosawa and Hiromitsu Takaba; Kogakuin University, Japan

In this study, we investigate the separation properties of several type zeolite membranes by NEMD for CO₂/CH₄ separation, and suggest the ultra-selective membrane structure for CO₂ by utilizing the effect of grain boundary on ternary separation systems. In the non-equilibrium molecular dynamics (NEMD) simulation, a single crystal membrane model and two types of polycrystalline membrane models were considered. In the polycrystalline membrane models, two patterns were examined, one in which grain boundary is present inside the zeolite crystal and the other in which the grain boundary is exposed on the surface of the zeolite crystal. In the upper part of the membrane models, the gas molecules were made to appear at regular intervals to keep the partial pressure constant, and the gas molecules which permeated through the membrane were deleted at the lower part of the membrane. Our NEMD results indicates that the presence of grain boundary could increase the selectivity, which means that a control of grain boundary is a key factor to enhance the selectivity.

On the other hand, conventional natural gas is multi-component gas including trace components e.g. hydrocarbon, and there is a concern about the effect of the trace components for membrane performance. In addition to that, grain boundaries in inorganic porous membranes are known to degrade membrane performance, however, the detailed information of effect on selectivity for multicomponent gas systems still difficult to predict prior to the permeation test. The NEMD simulation is an atomistic-scale modeling, thus this can easily apply to the prediction of permeability and selectivity in multicomponent gas systems. The effect of trace components for membrane performance can be also investigated using NEMD. Since the structure of the membrane can be arbitrarily modeled in the NEMD simulation, it is possible to investigate the behavior of the multicomponent gas in the zeolite membrane having grain boundaries by using the NEMD method. In the conference, we will suggest an ultra-selective zeolite membrane based on the interesting phenomenon that the selectivity is enhanced by the structure of grain boundaries.

Propylene/Propane Separation by Advanced Mixed Matrix Membranes

Yang Liu¹, William Koros¹, Mohamed Eddaoudi², Zhijie Chen², Youssef Belmabkhout², Chen Zhang¹ and Gongping Liu¹; ¹Georgia Tech, United States; ²KAUST, Saudi Arabia

Membrane-based propylene/propane separation can reduce the operation cost in petroleum refining and petrochemical industries; however, developing advanced membranes with promising performance is still challenging due to the close size (~0.15 Å difference) between these two components. We hereby address such a critical scientific question by a novel strategy: first, attention to detailed conformational differences accessible to propylene and propane; next, identification of a suitable MOF pore-aperture to exploit the accessible conformational differences; thirdly, matching polymer properties with the MOF to achieve promising performance.

Specifically, with both C-C single bonds rotated (double eclipsed conformation), the C₃H₈ molecule exhibits its minimum end-on essentially triangular shape but with a rotation energy barrier. Our strategy is to design/screen a “triangular” pore-aperture to allow only the double eclipsed C₃H₈ conformer to pass through, effectively preventing all other C₃H₈ conformers from diffusion jumps. This combination of factors leads to a very low C₃H₈ diffusivity. On the other hand, the more compact C₃H₆ molecule can pass through the pore-aperture with relative ease. According to our theoretical calculations based on transition state theory, a membrane with such desired pore-aperture can offer a C₃H₈/C₃H₆ diffusion selectivity over a thousand. We further identified a MOF, Zr-fum-fcu-MOF, possessing the desired contracted triangular pore-aperture and fabricated mixed-matrix membranes using this MOF as an efficient filler. The fabricated hybrid membranes display very attractive C₃H₆/C₃H₈ separation performance, far beyond the current trade-off limit of polymer membranes. Back-calculations using composite theory suggests the MOF displays a diffusion selectivity, like the ideally targeted, above 1000. This is the highest value reported for the C₃ pair to date, and we refer to this phenomenon as “conformation-controlled molecular sieving effect”. Furthermore, we optimized the membrane performance by matching the polymer properties with the MOF to (i) achieve higher C₃H₆/C₃H₈ separation efficiency, and (ii) overcome the plasticization effect. The developed membranes show record performance on C₃H₆/C₃H₈ separation at high pressures (~ 900 kPa), surpassing all mixed matrix membranes reported by far. Our work establishes a novel bottom-to-up strategy to develop membranes for gas separation.

Correlation of Hydrogen Diffusion in Pd Membrane—A First-Principles Calculation Chaoping Liang1, Haoran Gong1 and Dingying Dang2; 1Central South University, China; 2University of Kentucky, United States

Pd membranes are widely used for hydrogen separation and purification attributed to their excellent combination of H selectivity and permeability. During (de)hydrogenation process, a large number of vacancies forms in the α Pd-H solid-solution phase and β-Pd hydride phase, so-called superabundant vacancies (SAV).1 The H atoms will be trapped near the vacant sites, which leads to a complexed H diffusion behavior.2 Recently, many researchers found the (de)hydrogenation process can also promote the multiplication of dislocations and nanotwins.3 However, the transport properties of H in the defected Pd membranes have yet to be well understood.

In present work, we use Pd vacancy as a typical example to study the correlation effect of a defected zone on the H diffusion in Pd membranes. The results show a strong biased interstitial diffusion around the Pd vacancy. The H is prone to sink into the first nearest neighbor shell of Pd vacancy. The second nearest neighbor shell, which has a very low jump rate, prevents the reverse diffusion of the H atoms. Using Koiwa’s matrix method,4 we have derived an analytical formula for the H diffusion around the vacancy. The correlation effect is then estimated for H diffusion as a function of Pd vacancy concentration. Our findings could possibly clarify the uncertainty on the H diffusion coefficient in pure Pd and also shield lights on the interstitial diffusion in other defected systems or alloyed cases.

An Ultra-Facile Aqueously Cathodic Deposition Approach for MOF Membrane Fabrication Ruicong Wei, Heng-Yu Chi and Zhiping Lai; King Abdullah University of Science and Technology, Saudi Arabia

Electrochemical deposition has emerged as a novel approach to fabricate MOF films. This approach requires relatively minor or none pre-treatment of the substrate, shorter synthesis time, and milder synthesis condition. It also allows for continuous production which acts as a major advantage compared with other methods for industrial scale-up. As a promising approach, research on electrochemical deposition of MOF is still at its infant stage with most of the efforts being focused on thin film production, only a few works have been published for membrane fabrication. The deposition procedure and set-up are mostly delicately controlled such as careful selection of electrolyte and reference electrode, using double electrolyte cell to eliminate the disturbance of the reactions occurred on the counter electrode, and prolonged post-synthesis treatment, which makes this approach challenging to be used for scale-up production. In addition, little publication has used this approach to achieve satisfactory performance in gas separation with both high permeance and selectivity.

Here, we developed an aqueously cathodic deposition (ACD) approach to fabricate ZIF-8 membrane without addition of any supporting electrolyte or modulator. The fabrication process used 100% water as solvent and a defect free membrane was obtained in only 60 min without any pre- or post-synthesis treatment. The membrane exhibited superior performance in C3H6/C3H8 separation with 180 GPU C3H6 permeance and 142 selectivity, making it sit at the upper bound of permeance vs selectivity graph, outperforming majority of the published data up to 2019. Notably, this approach uses water as the sole solvent, adopts an extremely low current density (0.13mA/cm²), and employs an ultra-facile apparatus set-up, enabling an attractive way for environmentally friendly, energy efficient and easily scalable MOF membrane fabrications. This approach also opens a door for aqueously electrochemical deposition of MOF membrane in the future research.

Structure Tailoring of Hierarchical Fibrous Composite Hydrophobic Membranes for State-of-the-Art Desalination Performance in Membrane Distillation Yunxia Hu, Xiaochan An and Baolei Xie; Tianjin Polytechnic University, China

Membrane distillation (MD) displays superiorities to alleviate the ever-increasing freshwater crisis through seawater desalination and/or wastewater recycling. However, MD faces critical challenges of fabricating high-performance membranes. Our study introduced a novel hierarchical fibrous composite (HFC) hydrophobic membrane with great
achievements in elevating the MD performance. This HFC membrane comprises of a thin active dense layer with nanofibers for the maximum mass transfer and a thick support layer with microfibers for the minimum heat transfer. By tailoring the structures of both active and support layers to solve the trade-off between mass transfer and heat transfer during the MD process, the optimized HFC membrane could obtain the reported highest water flux of as high as 79.21±4.17 L m⁻² h⁻¹ and salt rejection higher than 99.9% using 3.5 wt% NaCl as a feed under the temperature difference of 40°C in the direct contact membrane distillation (DCMD).

4:15 PM EN04.07.08

Fabrication of Novel Janus Membrane for High Temperature Oxygen Separation and Water Thermochemical Reduction

Yudong Chen, Xiao-Yu Wu, Georgios Dimitrakopoulos and Ahmed F. Ghoniem; Massachusetts Institute of Technology, United States

Mixed ionic and electronic conducting (MIEC) membranes have been applied to increase the efficiency of oxygen separation, and water and carbon dioxide thermochemical reduction [1, 2]. Both surface reactions and bulk diffusion can impact the oxygen flux depending on the operating conditions. Efforts have been focused on developing new membrane materials, i.e., doped perovskites and dual-phase materials, and catalysts to accelerate the oxygen permeation fluxes.

Herein, we present a novel Janus membrane [3] concept for MIEC oxygen permeable membranes, which have different properties on the two surfaces to favor the respective surface reactions based on thermodynamic considerations. The high oxygen chemical potential side consists of a material with high oxygen vacancy formation energy which favors oxygen incorporation or water reduction, while the material on the low oxygen chemical potential side favors oxygen evolution and reaction with fuel. As a result, this Janus membrane can achieve higher performance compared to membranes of uniform chemical compounds when surface reactions are the rate-limiting step. To demonstrate the concept, this study investigates the co-production of hydrogen (H₂) and syngas (a mixture of H₂ and CO) from H₂O-splitting and methane (CH₄) partial oxidation, respectively, using La₀.₈Sr₀.₂Cr₀.₉₅Co₀.₀₅O₃₋δ (LSCrCo) at the H₂O-splitting side and La₀.₈Sr₀.₂CoO₃₋δ (LSCO) at the CH₄ partial oxidation side.

One major challenge related to the feasibility of the concept is the fabrication of two intact layers with high mechanical and chemical stability. We have explored several ways, such as co-sintering and screen-printing. In the co-sintering approach, the two different materials in the Janus membrane may lead to different shrinkage during sintering due to the factors such as particle sizes and applied pressure. We optimized the parameters such as calcination temperature of the oxide powders, uniaxial applied pressure and heat treatment to avoid the shrinkage mismatch when sintering the Janus membrane. In the second approach, LSCO ink was screen printed on LSCrCo membrane. The viscosity of the ceramic paste was adjusted by adding terpineol based ink vehicle to the ceramic powder. The ink printed layer was heat treated at 1350°C for 3 hours to ensure adhesion.

Experiments showed that the single-layer LSCrCo membrane has high H₂ production rate equal to 0.45 μmol/cm² s when operating at 1000°C with 50% steam concentration diluted by nitrogen at the feed side and 20% CH₄ concentration diluted by argon at the sweep side. The performance of this material remained stable for more than 100 hours. With the second layer of LSCO added on the CH₄ side, the Janus membrane is expected to have enhanced performance due to the faster CH₄ oxidation kinetic on the side.

*Xiao-Yu Wu and Georgios Dimitrakopoulos contributed equally to this work

An Investigation into Chemical Stability of Dual-Phase Lanthanum Chromite-Based Perovskite and Stabilized Zirconia Fluorite Phases

Hooman Sabarou and Yu Zhong; Worcester Polytechnic Institute, United States

Dual-Phase ceramic membranes are a promising candidate for mixed ionic-electronic ceramic conductors. These composites have inherited good traits of both perovskite and fluorite phases in order to separate oxygen from air under harsh working conditions. While they are capable of working around 1000°C and under both oxidizing and reducing atmospheres (p(O2)=0.21 to 10^-22 atm), the long term compatibility between these two phases are still challenging. The current research investigates the chemical and structural stabilities of dual-phase membranes of perovskite and fluorite phases with changes in composition, temperature (T), and oxygen partial pressure p(O2).

Lanthanum chromite-based perovskite has been doped with Sr and Fe as A- and B-site dopants, respectively. Different compositions of the perovskite phase with change in A-site and B-site dopants and A-site deficiency have been considered. There different stabilized zirconia as the fluorite phase have been examined with the perovskite phase: ScYSZ, ScCeSZ, and YSZ. The interaction between these two phases under fabrication and processing conditions have been studied through experimental and computational thermodynamics. The results reveal the correlation between Cr:Fe ratio and the formation of secondary phases. XRD results with thermodynamics calculations show that valance stabilities of Fe and Cr ion species regarding applied T and p(O2) and defect chemistry of the perovskite phase are responsible to maintain structural integrity of composites. The formation mechanism of secondary phases and their effects have been discussed in the purpose of minimizing and controlling their formation. It is offered how to tune initial compositions of the perovskite phase to control the formation of most detrimental phases of SrZrO3 and La2Zr2O7. Owing to use of computational thermodynamics, it is discussed how applied T and p(O2) during either fabrication or processing leave effects on chemical/structural stabilities of dual-phase membranes. In fact, computational thermodynamics provides practical guidelines about controlling composition, T, and p(O2) to maintain structures and control desired stoichiometries. Structural stability of fluorite phases has been also examined via X-ray diffraction methods.

SESSION EN04.08: Transport and Applications of 2D Membranes

8:00 AM EN04.08.01
Surface Engineered 2D Hexagonal Boron Nitrides as Bidirectional Superionic Conductors

Jasneet Kaur1, Adel Malekhhoyan2, Gurpreet Singh Selopan3, Zhiming Wang1, Federico Rosei2 and Hadis Zarrin3; 1Ryerson University, Canada; 2Institut National de La Recherche Scientifique, Canada; 3Institute of Fundamental and Frontier Science, University of Electronic Science and Technology of China, China

In the era of smart wearable electronics and compact electric transportation system, there is an urge for the development of flexible, lightweight, solid-state and efficient energy storage devices. For realizing high performance energy devices, novel electrolyte materials with high energy density at enhanced power and longer life cycle are demanding. The recent development in the field of two-dimensional (2D) materials, including graphene, hexagonal boron nitride (hBN) and transition metal dichalcogenides, have exhibited promising applications in various areas, such as electrochemistry and clean energy storage devices. In particular, 2D hBN, also known as “white graphene” is an isomorph of graphene with similar layered structure in a hexagonal lattice, which is uniquely featured by its outstanding physicochemical properties along with mechanical robustness and thermal stability. Due to its remarkable electrochemical properties, it is considered as a promising candidate that can be integrated with other 2D materials for the next generation electrochemical energy storage and conversion applications including fuel cells, batteries and supercapacitors. Moreover, hBN possess electrically insulating behavior at wide range of humidity and temperatures, which makes it more versatile to be manipulated and used as an electrolyte membrane in electrochemical energy systems.

Herein, we have developed functionalized hexagonal boron nitride (FhBN) polymer electrolyte membranes (PEMs) and presented as a potential proton exchange membrane for electrochemical energy storage and conversion devices.
The dispersions and functionalization of FhBN nanosheets are produced by direct in-situ liquid phase exfoliation and functionalization. FhBN dispersions possess excellent dispersibility and stability over several months of few-layered FhBN nanosheets in the solution, which is indicated by highly positive zeta potential values of $+42.5 \pm 3.2$ mV of the dispersion. Physicochemical properties of FhBN nanoflakes are investigated by various spectroscopic and microscopic characterisation tests, confirming strong covalent interactions/attachment in the FhBN nanoflakes between the hBN lattice and sulfonic acid groups. Further to fabricate proton conductive FhBN PEMs, high concentration of FhBN nanoflakes are blended with Nafion solution to form a stable dispersion, which are thermally and chemically treated to form the membranes. The addition of FhBN nanoflakes with sulfonic groups provides additional proton conduction sites and enhances the ion exchange capacity of the nanocomposite FhBN-Nafion PEMs with lower swelling ratio compared to that of bare Nafion. The in- and through-plane proton conductivity of the FhBN-Nafion PEMs is significantly increased under various conditions relative to that of re-casted Nafion membrane. The maximum value of in-plane conductivity of FhBN75%-Nafion PEM is observed at 80°C - 80% relative humidity (RH) condition, which is 0.41 S/cm, i.e., 7 times higher than that of the recast Nafion, under the same conditions. Moreover, at 80°C - 80% RH, the through-plane conductivity of FhBN75%-Nafion PEM is 0.1 S/cm i.e., 14 times higher than that of the recast Nafion under the same conditions. The superionic transport characteristic of highly concentrated 2D FhBN PEMs provide promising solutions for various applications in electrochemistry and clean energy devices, including supercapacitors, polymer electrolyte membrane for fuel cells and water electrolysis.

8:15 AM EN04.08.02
Stable Functionalized Graphene Oxide—Cellulose Nanofiber Solid Electrolytes with Long-Range 1D/2D Ionic Nanochannels Wei Jia and Peiyi Wu; Fudan University, China

Solid electrolytes which could transport cations are widely used in energy-related and environmental applications. Herein, functionalized graphene oxide-cellulose nanofiber solid proton electrolytes (NPGOM-CN1F) were successfully prepared. Based on 1D CNF and 2D dopamine-functionalized GO (NPGO), long-range 1D and 2D ionic nanochannels are constructed in the membranes with perfluorinated sulfonic acid resin (PFSA). The proton conductivity of NPGOM-10-CN1F is as high as 0.4 S cm$^{-1}$ at 80°C-95 %RH, two times higher than that of commercialized Nafion117. The single-cell performance of NPGOM-10-CN1F-based MEA is 31% higher than that of Nafion117-based MEA at 60°C-100 %RH on account of higher proton conductivities and better H$_2$ impedance ability. Besides, NPGOM-CN1F membranes also possess outstanding stability in water and high methanol barrier performance, demonstrating great practical application potential in both proton-exchange membrane fuel cells (PEMFC) and direct methanol fuel cells (DMFC) areas.

8:30 AM *EN04.08.03
Diffusion and Partitioning of Organic Micropollutants in Graphene Oxide Membranes Baoxia Mi and Sunxiant Zheng; University of California, Berkeley, United States

Pharmaceuticals and personal care products (PPCPs) have recently been recognized as emerging contaminants that pose potential hazards to environment and human health. Conventional nanofiltration membranes relies heavily on the size exclusion and charge repulsion for the separation of contaminant from water and herein are less effective in rejecting neutral micropollutants. In this research, graphene oxide (GO) nanosheets were stacked into 50 nm thin film as a tight nanofiltration membrane to remove pharmaceuticals and PPCPs in water. The layer-stacked GO membranes has sub-nanometer-sized channels that enhance the interactions between GO and the targeting contaminants which lead to hindered diffusion of neutral micropollutants. The diffusion and partitioning coefficient of three representative PPCPs were for the first time characterized based on their adsorption kinetics into the GO thin films using quartz crystal microbalance with dissipation (QCM-D). The results suggest that the diffusion coefficient of caffeine, acetaminophen and carbamazepine in the confined GO nanochannels are more than four magnitudes slower than that in the bulk water. By comparing the solute flux measured experimentally using a nanofiltration system and the theoretical values calculated from the diffusion and partitioning coefficient, we can confirm the transport of neutral micropollutants in the GO membranes are dominated by the diffusion process.

9:00 AM EN04.08.04
Graphene-Polymer Thin-Film Composite Membranes as Energy Efficient and Anti-Fouling Membranes for Water Purification Sanju Gupta; Western Kentucky University, United States
Water is our planet’s most precious resources and life’s most basic indispensable component. Reverse osmosis (RO) filtration is highly adopted, growing technologies to produce clean water by removing undesired (charged or uncharged) solute species. However, polymer and ceramic membranes suffer from low permeability, structural breakdown and fouling. Graphene, a form of carbon, provides the foundation for the production of highly permeable membranes as an emerging technology for RO desalination. Adding oxygen to few-layer graphene nanosheets, i.e. graphene oxide (GO), opens allows efficient adsorption of charged ionic species (selectivity) and augmented flow of water molecules (ultrafast permeability). This works reports on the development of novel graphene oxide thin film nanocomposite (G-TFNC) membranes embedded with a thinner active polymer layer via interfacial polymerization to tackle the trade-offs among water flux transport and salt ionic species rejection, robustness and anti-fouling characteristics. This study overcomes the gap between drinkable freshwater demand and supply through nanotechnology-enabled high performance graphene composite membranes.

9:15 AM EN04.08.05
Spray-Coated Graphene Oxide Membranes for Water Filtration Aaron Morelos-Gomez1, Rodolfo Cruz-Silva1, Josue Ortiz-Medina2, Takumi Araki3, Ayaka Yamanaka3, Syogo Tejima3, Mauricio Terrones4 and Morinobu Endo1; 1Shinshu University, Japan; 2Universidad Panamericana, Mexico; 3Research Organization for Information Science & Technology, Japan; 4The Pennsylvania State University, United States

The demand of water is increasing along with population growth, where fresh water sources are decreasing and improved methods for water reclamation are needed. This is fundamental in order to create self-sustaining societies. Graphene oxide (GO) membranes have been widely studied for water desalination, pigment filtration and solvent separation, however there are few scalable methods to produce large membranes for water filtration. In addition, chemical stability and antifouling properties are needed in order to be promising candidates for real applications. In this work, we present a spray-coated GO membrane for water filtration. Its desalination performance was measured for a mixture of GO/few-layered graphene and only GO, where salt rejection can reach between 80% and 90% and a permeate flux of 0.1 - 0.4 m3m-2day-1. The membranes were kept in a solution of sodium hypochlorite (200 pm), a typical agent for industrial cleaning of filtration membranes. Here, the membranes with few-layered graphene exhibited an increased chemical resistance. Furthermore, protein fouling against negative and positive charged proteins bovine serum albumin and lysozyme, respectively, was carried out by monitoring variations in permeate flux and microscopy. The GO membranes demonstrated excellent anti-fouling against both membranes due to electrostatic interactions, hydrophilicity and surface smoothness. The present membranes have excellent scalable fabrication method, chemical resistance and anti-organic fouling necessary for real-world applications in water reclamation, desalination, food industry, etc.

9:30 AM EN04.08.06
Covalently Modified MoS2 Nanochannels for Water Purification Ries Lucie1,2, Philippe Miele1,2,3 and Damien Voiry1,4; 1European Institute of Membranes (IEM), United States; 2ENCSM, France; 3Institut Universitaire de France, France; 4CNRS, France

Membrane separation technology plays an important role in various fields including water treatment, chemicals and gas separation in many industrial processes, and food processing. There has been a renewed focus on 2D material for membrane application since their atomic thickness and confined interlayer spacing could theoretically lead to enhanced separation performance. Indeed, multilayer assembly of single nanosheets – forming nanolaminate membranes – creates 2D capillaries that can efficiently sieve chemical species depending on their size. Selectivity and size controlled diffusion of these nanochannels can be modified to tune the transport mechanism within the structure. For instance, chemical modifications of the surface of 2D nanosheets via functionalization have opened new avenues for tuning the membrane properties in both fields of molecular3 and gas sieving. Among the different building blocks of the nanolaminate membranes made of two-dimensional materials (2D), graphene oxide (GO) has been studied as a candidate for molecular sieving via size-limited diffusion in the 2D capillaries1. Unfortunately the high hydrophilicity of GO nanosheets make GO membranes unstable in water, while the poor control of the capillary width between the nanosheets limits the water permeance of membranes. Exfoliated nanosheets of transition metal dichalcogenides (TMDs) constitute attractive platforms for the realization of nanolaminate membranes. Recent works carried out on nanolaminate membranes made of molybdenum disulfide (MoS2) have demonstrated improved stability. Here, we report a novel type of nanolaminate membranes with well-controlled surface chemistry of the nanosheets. We will notably present our recent investigations on the performance of lamellar membranes based on chemically functionalized MoS2 nanosheets toward water desalination and
micropollutant removal. Our results open novel directions for fine tuning the sieving behavior of membranes based on 2D materials.

9:45 AM EN04.08.07
Two-Dimensional Molybdenum Disulphide Membranes for Organic Solvent Nanofiltration—Stability, Structural Manipulation and Separation Performances Sui Zhang; National University of Singapore, Singapore

Two-dimensional (2D) materials such as molybdenum disulfide (MoS2) present tremendous opportunities in membrane-based molecular separation. Compared to graphene oxide, MXene and other 2D inorganic materials, MoS2 show exceptional stability in organic solvents. A few studies have reported the preparation of MoS2 membranes for separation in aqueous solutions. However, there have been no investigations on the application of MoS2 membranes for organic solvent separation. In addition, multi-layer and mono-layer MoS2 nanosheets may be prepared by different approaches and have both been used for membrane preparation. Though studies have revealed that monolayer MoS2 structure is unstable in the ambient conditions, there have been no reports on the stability of MoS2 membranes.

This presentation covers our recent progress in 2D MoS2 membranes for organic solvent separation. In the first part, we prepared both multi-layer and mono-layer MoS2 nanosheets using different methods, and compared their structure, stability and performances after made into membranes. It’s found that multi-layer MoS2 membranes are looser in structure, and hence result in higher permeability to isopropanol and lower rejection to dyes. On the other hand, though mono-layer MoS2 membranes show better rejection to dyes in the short tests (within 3 hours), the rejection keeps decreasing over a 5-day tests, which is attributed to the limited stability of such nanosheets that lead to aggregation and breakage. To achieve high rejection and good stability, a ‘bridging’ agent is employed to regulate the interlayer spacing and nanosheet alignment of multi-layer MoS2 membranes, leading to improved rejection and stable performances over one week.

In the second part, mixed matrix membranes containing MoS2 nanosheets based on a 3-step layer-by-layer (LbL) method have been prepared, which provides a more cost-effective and scalable way to fabricate 2D membranes. Very interestingly, while the original LbL polyelectrolyte layer is impermeable to organic solvents, mixed matric membranes containing MoS2 nanosheets open the pathways to solvents while rejecting solutes whose molecular weight is around 300 Dalton. The phenomenon is attributed to the lower of surface energy by MoS2 and its bridging effects. With a thin layer of < 50 nm, the mixed matrix membrane can achieve ethanol permeance –selectivity that surpasses the hypothetical upper bound, e.g., 92.9 % rejection for Victoria blue B (VBB, MW 506.08) with an ethanol flux of 11.4 L m⁻² h⁻¹ bar⁻¹.

Graphene Oxide Membranes in Extreme Operating Environments—Concentration of Black Liquor and Water Recycling in Biomass Pretreatment Processes Sankar Nair; Georgia Institute of Technology, United States

Kraft black liquor (BL) is a corrosive (pH >12), high total solids (> 15 wt%), and high-volume byproduct (~500 million tons/yr worldwide) of biomass pretreatment for pulp and paper production [1]. BL contains lignin, hemicellulose, organic acids, inorganic salts, and water. Dewatering of BL is currently performed by multi-effect evaporators, which is highly energy-intensive (about 0.2 Quads/year in the US alone). Membrane-based concentration of black liquor [1,2] is attractive as an energy-efficient alternative, but challenging due to the harsh operating conditions, complex feed composition, and high fouling potential of BL. This talk will discuss our pursuit of chemically and mechanically robust, low-cost, and scalable GO membranes for black liquor concentration. We will discuss in detail the development and properties of graphene oxide (GO) nanofiltration and reverse osmosis membranes for rejection of lignin, other dissolved organics, and inorganic salts; including their operation in long-term testing under real BL conditions. We will overview our efforts for scale-up of GO membranes, and the development of an overall process for membrane-based concentration of BL streams with simultaneous production.
of usable process-quality water. A brief summary of the technoeconomic analysis for membrane-based BL concentration will also be presented.

Analytical Prediction of Gas Permeation through Graphene Nanopores of Varying Sizes—Understanding Transitions across Multiple Transport Regimes Zhe Yuan1, Rahul Prasanna Misra1, Ananth Govind Rajan2, Michael Strano1 and Daniel Blankschtein1; 1Massachusetts Institute of Technology, United States; 2Princeton University, United States

Nanoporous graphene is a promising candidate material for gas separation membranes, due to its atomic thickness and low cross-membrane transport resistance. The mechanisms of gas permeation through graphene nanopores, in both the large and small pore size limits, have been reported in the literature. However, mechanistic insights into the crossover from the small pore size limit to the large pore size limit are still lacking. In this study, we develop a comprehensive theoretical framework to predict gas permeance through graphene nanopores having a wide range of diameters using analytical equations. We formulate the transport kinetics associated with the direct impingement from the bulk and with the surface diffusion from the adsorption layer on graphene, and then combine them to predict the overall gas permeation rate using a reaction network model. We also utilize molecular dynamics simulations to validate and calibrate our theoretical model. We show that the rates of both the direct impingement and the surface diffusion pathways need to be corrected using different multiplicative factors, which are functions of temperature, gas kinetic diameter, and pore diameter. Finally, we utilize our newly developed model to predict the permeances of CO2, CH4, and Ar through graphene nanopores. We show that as the pore diameter increases, gas transport through graphene nanopores can transition from being translocation dominated (pore diameter < 0.7 nm), to surface pathway dominated (pore diameter 1–2 nm), and finally to direct pathway dominated (pore diameter > 4 nm). The various gas permeation mechanisms outlined in this study will be particularly useful for the rational design of membranes made out of two-dimensional materials like graphene for gas separation applications.

11:15 AM EN04.08.10
Ultra-Permeable Wafer-Scale SWCNT-Membranes for Efficient Dye/Salt Fractionation Melinda L. Jue, Steven F. Buchsbaum, Chiatai Chen, Eric R. Meshot, Sei Jin L. Park, Kuang Jen Wu and Francesco Fornasiero; Lawrence Livermore National Laboratory, United States

Enhanced fluid transport in single-walled carbon nanotubes (SWCNT) promises to enable major advancements in several membrane applications, from efficient water purification1 and low-cost recovery of high-value components, to advanced protective garments. Realization of the SWCNT-membrane potential in practical applications has been hampered so far by the challenge of fabricating large-area membranes with a high density of open, small-diameter, SWCNT pores. A high tube density is required to achieve flow rates outperforming those of commercial membranes, whereas small diameters enhance both size and charge based selectivity.

To demonstrate ultra-permeable large-area SWCNT membranes, we optimized the growth of vertically aligned SWCNTs to maximize number density (up to 2x10^{12} tubes/cm^2) and minimize average diameter (down to <2-nm) while simultaneously scaling up growth area (up to 4-in diameter). By filling the intertube gaps with a chemically resistant polymer and then opening the SWCNT caps with dedicated etching steps, we demonstrated wafer-scale SWCNT membranes with water permeances up to 250 LMH/bar, which greatly surpass those of commercial loose nanofiltration / tight ultrafiltration membranes. These SWCNT membranes display high rejection of nm-sized dyes (e.g., Rose Bengal) while permitting complete passage of salts like NaCl or Na2SO4. Contrary to conventional membranes for water treatment, aggressive cleaning methods did not affect detrimentally SWCNT membrane performances. This efficient fractionation and recovery of dyes/salts at modest applied pressures (far below the salt osmotic pressure) suggests that SWCNT membranes hold great promises for sustainable textile-water treatment.
Together with their ultrahigh permeance, the demonstrated chemical resistance of these membranes offers opportunities for energy-efficient nanofiltration/ultrafiltration processes in chemically demanding environments.

**Laser-Induced Graphene Enabled by Atomic Layer Deposition for Charged Membrane Applications** David S. Bergsman, Bezawit Getachew and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Membrane-based processes are becoming increasingly popular for water treatment due to their relatively high energy efficiency and low cost compared to other treatment methods. However, the advantages of membranes are mitigated by the need for additional pre-treatment steps that are required to maintain their effective operation. The treatment and prevention of membrane fouling, in particular, constitutes a large fraction of typical membrane operational costs. One potential approach to combat fouling is to design conductive membrane coatings that can prevent the attachment and growth of biofoulants both electrostatically and via electrochemical generation of reactive oxygen species. Despite their potential, these conductive membrane coatings are often expensive, requiring additional chemicals and non-scalable methods to produce, e.g. carbon nanotube mats or other graphitic coatings deposited by vacuum filtration. In this work, we explore the use of laser-induced graphene (LIG) for the creation of conductive ultrafiltration membranes. Porous polyethersulfone (PES) membranes are first coated in a thin layer of alumina using atomic layer deposition (ALD) before being irradiated with an infrared laser. We show that this alumina film, which can be scalably produced using spacial ALD, can localize LIG formation to the surface of the membrane, preventing the buried, un-lased areas of PES from melting and losing their porosity during the lasing process. This allows the top-most layer of the PES to be a conductive coating that can be used to charge the membrane surface and used to improve membrane performance (e.g. fouling mitigation). The formation of LIG is verified by scanning electron microscopy and Raman spectroscopy. The conductive layer is also shown to possesses relatively high conductivity, which is important for reducing power consumption in devices. Insight into the mechanism behind the improved stability to melting provided by ALD is provided by thermogravimetric analysis, differential scanning calorimetry, and Fourier-transform infrared spectroscopy. The effect of ALD film thickness and the use of sequential infiltration synthesis will also be explored. These insights are used to discuss the potential application of this approach to creating conductive coatings on other polymers using ALD-based approaches.

11:45 AM EN04.08.12
**Filtering of Sarin Gas by Nanoporous Graphene** Marco A. Maria¹,² and Alexandre F. Fonseca²; ¹Universidade Federal de Sao Carlos/ Sorocaba, Brazil; ²State University of Campinas, Brazil

One of the major worldwide concerns nowadays is the use of chemical warfare agents (CWAs) in events of terrorism or war. One of the compounds used as CWA is the sarin gas. Sarin is a nerve agent capable of bringing a person to death in about 15 minutes. This and other CWA gases are so toxic and lethal that their use is very limited even in research. In view of the need to find out safety protocols both for the handling and storage of this gas and for its detection, filtering and chemical transformation, it is important to develop new and effective methods of researching CWA properties. In particular, theoretical methods are very welcome to study the chemical and physical properties of CWAs at different physical conditions. In this work, we present the results of a computational study of the interaction of sarin molecules and graphene, towards the characterization of sarin-filtering properties of nanoporous graphene. Classical molecular dynamics (MD) are employed here in order to study relatively large system sizes and number of molecules as well as some conditions of concentration and temperature that are prohibitive in *ab initio* studies. A graphene structure of about 32 by 34 Å of lateral sizes with a relatively large hole of about 15 Å is placed in the middle of an 80 Å length environment separating two regions, one with the presence of gas molecules and the other with vacuum, so creating a pressure difference between the two regions. Two sets of
gas molecules are considered, one which has only sarin molecules and the other which has sarin and air (a mixture of 1% of Ar, 78% of N₂ and 21% of O₂) molecules. The aim of the study is to find out at which combinations of sarin concentration and temperature, the sarin molecule remains on one side or pass through the hole, as compared to the passage of air molecules. The MD simulations were carried out at four values of temperatures, 300 K, 500 K, 700 K, and 900 K, and two concentrations of sarin, 5% and 10% with respect to the total number of gas molecules. After 10 ns of simulation time, the results show that not a single sarin molecule went through the porous graphene for T = 300 K, regardless of sarin concentration. This is a remarkable result because the size of the hole is about three times the length of the sarin molecule. For the other values of temperature, the number of sarin molecules that crossed the hole was shown to depend on both temperature and concentration. In all MD simulations, the air molecules passed easily through the hole in graphene, and an interesting accumulation of sarin molecules around graphene structure was observed. We discuss these results on possible applications of porous graphene as a nanofilter of sarin gas.

SESSION EN04.09: Novel Membrane Materials, Metrologies and Applications
Session Chairs: Yunxia Hu and Haiqing Lin

1:30 PM EN04.09.01
Carbon Dioxide and Methane Selectivity of a Smectite Clay with Different Intercalated Cations Kristoffer W. Hunvik¹, Leide P. Cavalcantí², Martin Riess³, Patrick Loch³, Konstanze K. Seljelid¹, Vegard Josvanger¹, Roosevelt Droppa⁴, Dirk Wallacher⁵, Barbara Pacakova⁶, Paulo H. Michels Brito⁷, Kenneth Knudsen¹,¹, Josef Breu⁸ and Jon O. Fossum¹; ¹NTNU, Norway; ²Institute for Energy Technology, Norway; ³University of Bayreuth, Germany; ⁴Universidade Federal do ABC, Brazil; ⁵Helmholtz-Zentrum Berlin, Germany

Carbon dioxide and methane are the main greenhouse gases and their accumulation is responsible for worldwide environmental repercussions. In addition to the efforts to reduce their emissions, it is imperative to establish effective ways of capturing these compounds. The first step in this respect is to develop an understanding of what mechanisms are important for the interaction with potential sorption materials, with a goal of developing suitable capture materials with particularly high selectivity for CO₂ or CH₄.¹,² A possible solution to reduce anthropogenic CO₂ emissions is through enhanced gas recovery (EGR) operations, by releasing trapped CH₄ through an exchange process with CO₂. By employing such a process, some estimates suggest that additional gas recovery through CO₂ injection may have an indirect value of nearly 1 T$³. The presently unrecoverable methane in shale reservoirs is retained through interactions with organic content and clay minerals. To employ such strategies, the fundamental interactions between clay, methane and carbon dioxide needs to be investigated.

We have studied (Li, Na, Cs, Ca, Ba, Ni)-fluorohectorite⁴ with a capillary based high-pressure cell with synchrotron X-ray powder diffraction and by volumetric adsorption. Here we show how the kinetics of the adsorption depends on the specific cation, clay layer charge, temperatures and pressure. Our studies show crystalline swelling of Ni-Fh within seconds in response to CO₂ exposure. We have investigated CO₂ capture for three different layer charges, 0.3, 0.5, 0.7 per formula unit (Si₄O₁₀F₂), where we observe crystalline swelling for 5-10 bar, 10-15 bar and 30 bar respectively at room temperature. In our experiments Cs-Fh, Ca-Fh and Ba-Fh does not show any sign of crystalline swelling when exposed CO₂. However, when Ni-fluorohectorite is exposed to methane up to a pressure of 60 bar at -20°C we observe no intercalation. Our results show the selectivity of CO₂ over CH₄ in fluorohectorite clay.

Water Treatment Membranes Embedded with a Stable and Bactericidal Nano Diamond Material

Abelardo Colon1, Gerardo Morell1, Brad Weiner1, Dariel Ortiz2, Javier Avalos2, and Rafael Rios3; 1University of Puerto Rico at Rio Piedras, United States; 2University of Puerto Rico at Bayamón, United States

Water treatment using membranes have emerged as a critical technology in solving societally important problems such as waterborne diseases caused by poor water quality and sanitation issues. This high energy consumption technology confronts key challenges for the technology to drive such as membrane selectivity and permeability, fouling and membrane lifetime. Functional nanomaterials can be a solution to these challenges by changing the membranes’ mechanical and bactericidal properties by enhancing these properties in a synergistic way. The ultra-dispersed diamond (UDD) is a versatile carbon allotrope with a small particle size range (4-5 nm), with easy surface functionality and biocompatibility properties, ideal for use in water treatment processes. This research studies UDD’s bactericidal and functionality properties embedded in membranes for water purification systems. Scanning and electron transmission microscopy (SEM) and Fourier Transmission IR (FTIR) techniques were performed to study the membrane surface and identify functional groups present in the nanoparticle. Tensile strength test was done to measure the nano composite membrane mechanical properties. Coliscan Membrane characterization was performed to obtain fecal coliforms forming units CFU on filtered samples and microorganism reduction significance was obtained using T-test analysis at a 95% level of confidence. This research aims to demonstrate how current water purification membranes can be enhanced by adding nano diamond particles to reduce bio-fouling problems, strengthen its mechanical stability, and increase its lifetime for water purification.

Increasing Water Flow Rate via Membranes by Applying High-Frequency Acoustic Pressure

Nurkhat K. Zhakiyev1, Zamart Ramazanova1, K.B. Tynshytkbayev1 and Zinetula Z. Insepov1,2,3; 1Nazarbayev University, Kazakhstan; 2Purdue University, United States; 3National Nuclear Research University (MEPhl), Russian Federation

Ion-exchange membrane technologies used for water purification, in flow batteries for energy storage. To improve the transmission characteristics of the membranes, various methods are used, such as passivation of dangling bonds, increase inlet pressure, use of reverse osmosis, the design of optimal geometry, taking into account natural convection conditions and etc. We have investigated the impact of high-frequency acoustic pressure on the convection rate capacity of the membranes. This study is a continuation of previous works [1, 2]. Typically, vortex shedding takes place in the vicinity of the slit region. At medium to high sound pressure levels, the local particle velocity in the narrow region of the perforate or slit can be so large that the linear assumptions of acoustics break down. Thus, non-linear characteristics of acoustic waves interacting with the membrane simulated using advanced approached of finite-element modelling (FEM). FEM packages used to solve equations for unsteady state two-dimensional fluid flow coupled with acoustic pressure, species transport. In this work, we present our findings relating to increasing the convection rate using acoustic waves. Experimental test for flow rate increasing and simulating performance of the process done by using FEM. Acoustic waves Influencing approach offers interesting solutions for low cost increasing performance of water filters or Vanadium Redox Flow Battery energy storages.

Monolithic Janus Membrane via Pulsed Laser Heating for High-Performance Solar Steam Generation

Minsu Kim1, Kwansoo Yang1, Pilgyu Kang2, Yun Ho Kim1 and Byoung Gak Kim1; 1Korea Research Institute of Chemical Technology, Korea (the Republic of); 2George Mason University, United States

Utilization of abundant source of solar energy to generate steam has a broad range of applications such as power generation, desalination, water purification, and sterilization. Micro/nanostructured Janus photothermal materials with asymmetric surfaces and thermal properties have been widely sought for use in high-performance solar steam generators. Many approaches to constructing Janus structures that incorporate graphene based light absorbing materials fulfill the requirements of self-floating solar steam systems, such as light absorption, thermal insulation, and capillary action. However, achieving multiscale-structured materials remains a challenge due to processing requirements of high thermal/chemical energy, and lengthy period of time consumption. Herein, we demonstrate a simple and scalable laser-based photothermal method for directly producing monolithic Janus membranes of
hierarchically porous graphitic carbon and polyimide foam for use in floating solar steam generators. Our monolithic Janus membrane performs not only outstanding solar steam generation, with an energy conversion efficiency of 84%, but high salt rejection ratios of 99.9% in the solar desalination systems. The laser photothermal method to obtain monolithic bilayer membrane has future potential to substantially reduce the cost of high-efficiency solar-thermal systems for scalable solar steam generations.

2:30 PM EN04.09.05
Electrochemical Impedance Spectroscopy as a Performance Indicator of Water Dissociation in Bipolar Membranes
Marijn Blommaert, David Vermaas, Boaz Izelael, Ben ‗t Veen and Wilson Smith; *T*U Delft, Netherlands; ‡Aquabattery B.V., Netherlands; §Shell Global Solutions International B.V., Netherlands

A bipolar membrane (BPM) can be used to maintain a pH difference in an electrolysis cell, which provides freedom to independently optimize the environments and catalysts used for paired redox reactions. A BPM consists of two physical layers, of which one is selective for the exchange of cations and the other for anions. The water dissociation reaction (WDR) splits water into protons and hydroxide ions under an electric field that concentrates at the interface of the two membrane layers. However, salt ions in commonly used electrolytes influence this WDR when they are present at the interface. Using electrochemical impedance spectroscopy (EIS), we observed the rate of water dissociation decrease in the presence of salt ions while also observing the diffusion and migration of these salt ions, showing a clear link between the peaks observed in EIS and ion crossover.

Our work comprises the first detailed impedance study using modern, commercial BPM’s in different electrolytes while varying the current density. This unique series of experiments allows the ability to obtain important fundamental knowledge of a BPM, i.e. insights on the voltage behavior around the plateau current density. This information shows a direct correlation between ion crossover and electrolyte composition, which is a highly debated and controversial topic in the BPM field. In addition, we have found that using electrochemical impedance spectroscopy, it is possible to observe the degradation of individual components of a BPM, which has immense implications for industrial applications.

Covalently-Functionalized Three-Dimensional Graphene Nanosheets as a Stationary Phase Material for Chiral Liquid Chromatography
Lindsay Candelaria, Liliya Frolova, Brian Kowalski, Kateryna Artyushkova, Alexey Serov and Nikolai Kalugin; *New Mexico Tech, United States; ‡The University of New Mexico, United States; §Pajarito Powder LLC, United States

Carbon-based stationary phases for chromatographic separation are known to be highly resistant to aggressive mobile phases and extreme pH values of solvents and eluents, a significant advantage compared to commercial silica-based alternatives. We report on a new variant of carbon-based stationary phases for liquid chromatography, specifically developed for chiral separation.

The recent interest in carbon-based chiral separators is related to the implementation of new forms of carbon: graphene, graphene oxide (GO) and reduced graphene oxide (rGO). Recent papers report on the attempts of chiral separation and sensing, where GO or rGO was used as one of components of modified electrodes or as a part of (quasi)stationary phases for capillary electrochromatography. We have to mention recent suggestions of separation membranes made out of chemically functionalized graphene-based materials. including the idea of using holes in planar graphene for transport of chiral compounds across graphene layers, reports about the usage of L-glutamic acid-functionalized GO membranes for the separation of phenylalanines, and attempts of making intrinsically chiral mesoporous carbon synthesized via carbonization of chiral ionic liquids. Despite the achieved progress, no previous reports have so far demonstrated carbon nanotubes- or graphene-based CSPs for use in high performance liquid chromatography that are fully competitive with commercial silica-based immobilized CSPs. In our work, mesoporous three-dimensional graphene nanosheets (3D GNS), functionalized with tetracyanoethylene oxide (TCNEO) and (S)-(−)-2-pyrrolidinemethanol, used as Chiral Stationary Phases (CSPs),
demonstrate separation performance parameters competitive to currently commercially available CSPs. The modification of graphene with tetracyanoethylene oxide (TCNEO) introduces reactive cyano groups to the material, opening a wide spectrum of possible secondary modifications and uses. Demonstrated graphene-based CSPs are chemically stable, and up to an order of magnitude less expensive comparing to commercial silica-based analogues.

Studying the Impact of Ink and Process Parameters on Electrospun Fibers for Electrocatalytic Applications
Nisha Sharma, Sunil Kumar, Sadia Kabir, Scott Mauger, Kenneth Neyerlin and Michael Ulsh; Chemistry & Nanoscience Center National Renewable Energy Laboratory, United States

The world is facing several challenges related to climate and environmental issues. Current research is focused on solutions such as CO₂ reduction and polymer electrolyte membrane fuel cells (PEMFC), which have the potential to address such issues. These technologies can enable clean and affordable energy. Among the latest innovations, PEMFCs are quite promising, due to their low operating temperature and high-power output. Commercialization is one of the major challenges due to high cost. One potential cost reduction method under research is using the electrospinning technique to fabricate nanofibers which are rich in catalytic material. Nanofibers fabricated with intra-fiber porosity result in well distributed catalyst and ionomer, which has high surface area for electrochemical reaction and catalyst mass activity (1). Such electrospun cathodes are highly durable (2) and promising for cost reduction. However, to achieve our goal of fabricating nanofibers with high electrochemical surface area and high catalyst mass activity we are studying the impact of polymer solution properties and electrospinning process parameters on spinnability. The presence of carboxylic acid groups in poly (acrylic acid) (PAA), enhances polymer chain entanglement and is known for adding viscosity to the polymer solvent solution (3). We have studied the fabrication of PAA by itself and with a blend of Nafion ionomer and catalyst, such as Pt-Vulcan, in this work. These experiments improve our understanding of the morphology and diameter of these different blends of polymer solvent solutions with respect to their viscosity at different polymer concentration, and different processing and ambient parameters of electrospinning.

This study was conducted to better understand the morphology and diameter of fibers with different concentration of PAA, ranging from 5 – 20 wt.%, with and without Nafion and the catalyst (Pt-Vulcan). The PAA polymer was dissolved in a 2:1 ratio of isopropanol and water solvent. This work will be conducted at different processing conditions (ranging from needle-to-drum distance of 8-12 cm, voltage of 10-20 KV, and flow rates of 0.75ml/hr. and 1 ml/hr.). Further, these conditions will be then tested at different humidity condition ranging from (25-45 % RH). The polymer solvent solution with and without Nafion and catalyst were mixed for approximately 72 hours. Fiber size and morphology were measured using scanning electron microscopy, and the Image J software (NIH, Bethesda, MD, USA) was used for automated fiber diameter determination and statistics.

This work demonstrates the effect of ink (e.g. viscosity) and process parameters with respect to spinnability of the fibers at different weight percent (ranging from 5-20 wt.%) of poly (acrylic acid) (PAA) polymer solvent solution with and without blend of Nafion and catalyst.

Dendrolytes – A New Generation of Free-Standing Ion Selective Membrane Materials Based on Hyperbranched Polyglycerol for Bioelectronics Tobias F. Abrahamsson¹, David J. Poxson¹, Erik O. Gabrielsson¹, Mikhail Vagin¹, Mats Sandberg², Magnus Berggren¹ and Daniel T. Simon¹; ¹Department of Science and Technology, Linköping University, Sweden; ²RISE Acreo AB, Sweden

Hyperbranched polymers constitute a category which fundamentally outlines as polymers with multiple covalent branching points of structural arrangement, rendering an intrinsically spherical-like conformation. We present hyperbranched polyglycerols multi-functionalized with tuneable degrees of unsaturated groups utilized for click cross-linking and ionic groups for electrolytic properties. The resulting ‘dendrolyte’ polymers have been applied in organic electronic devices in a one-step process to achieve free-standing monolithic ion-selective membranes for controlled electrophoretic ion delivery¹. This new generation of organic ion-conductive materials showcase the capability of performing selective electrophoretic transport of large charged aromatic compounds, coupled with the opportunity for miniaturized manufacturing² and processing for applications in organic (bio)electronic devices, broadening the possibilities for communication with biological systems³ with specificity and high spatiotemporal resolution.

“All Electric” Ion Pumps for Small Scale Water Desalination Gideon Segev¹,¹,², Shane Ardo³,³, Rylan J. Kautz³, David M. Larson¹,¹, Joel Ager¹,¹,⁴ and Francesca Maria Toma¹,¹; ¹Lawrence Berkeley National Laboratory, United States; ²Tel Aviv University, Israel; ³University of California, Irvine, United States; ⁴University of California, Berkeley, United States

The high capital and energetic costs of reverse osmosis based water desalination technology limits its adoption in remote communities. Furthermore, the immense capital costs associated with constructing and maintaining a national scale water distribution make this technology practically irrelevant to considerable parts of the world. For this reason, a small scale, energy efficient water desalination technology is called for. Electrodialysis and capacitive deionization technologies were suggested as technologies that can fill this gap. However, the need for energy intensive chemical reactions in electrodialysis and the capacitance limitations in capacitive deionization technologies impose significant barriers to these technologies. Hence, an ion pumping technology that can operate in steady state without requiring lossy chemical reactions can provide a significant step forward towards a viable, small scale water desalination technology. We have demonstrated a first of its kind ratchet based, all electric ion pump. Electronic ratchets are devices that utilize modulation in a spatially varying electric field to drive steady state current. Similar to peristaltic pumps, where the pump mechanism is not in direct contact with the pumped fluid, electronic ratchets induce net current with no direct charge transport between the power source and the pumped charge carriers. Thus, electronic ratchets can be used to pump ions in steady state with no electrochemical reactions between the power source and the pumped ions resulting in an “all electric” ion pump. In this contribution we analyze the applicability of this technology, its challenges and its advantages for small scale water desalination. The pumping efficiency is shown to be limited by series resistance and is heavily affected by the pore size.

Sustainable Nanocellulose Membranes for PEM Fuel Cells George Cai¹, Songze Wu², Songtao Li³, Aniket M. Raut⁴, Likun Wang⁴, Sunil K. Sharma⁴, Priyanka Sharma⁴ and Miriam Rafailovich⁴; ¹Wayzata High School, United States; ²High school affiliated to Remin University, China; ³Princeton International School of Mathematics and Science, United States; ⁴Stony Brook University, The State University of New York, United States

Carboxycellulose nanofibers (CNFs) promise to be a sustainable and inexpensive alternative material for polymer electrolyte membranes compared to the expensive commercial Nafion membrane. However, its practical applications have been limited by its relatively low performance and reduced mechanical properties under typical operating conditions. In this study, citric acid cross-linked carboxycellulose nanofiber (CA/CNF) membranes were
prepared by solvent casting method. Carboxycellulose nanofibers were derived from wood pulp by using chemical oxidation of hydroxy group present on C6 position of the cellulose chain. Results from FT-IR spectroscopy, $^{13}$C NMR spectroscopy, and XRD reveal a chemical crosslink between the citric acid and CNF, and the optimal fuel cell performance was obtained crosslinking 70 mL CNF suspension with 0.3 mL of 1.0 M citric acid solution. The membrane electrode assemblies (MEAs), operated in oxygen atmosphere, exhibit maximum power density of 27.7 mW/cm$^2$ and maximum current density of 111.8 mA/cm$^2$ at 80 °C and 100% relative humidity for the CA/CNF membrane with 0.1 mg/cm$^2$ Pt loading on anode and cathode, which is approximately 30 times and 22 times better respectively than the uncrosslinked CNF film. The surface morphology of Carboxycellulose nanofibers and corresponding membranes were characterized SEM, EDX, TEM, and AFM techniques.

Acknowledgments: We gratefully acknowledge support from the Louis Morin Charitable Trust and NYS Department of Economic Development.

Investigation of In-Situ Iron Oxide Nano-Particles Produced with Air-Diffusion Cathode in Iron-Electrocoagulation
Arkadeep Kumar$^1$, Siva Bandaru$^2$, J. Nathan Hoehman$^3$ and Ashok Gadgil$^1$; $^1$Lawrence Berkeley National Lab, United States; $^2$University of California, Berkeley, United States; $^3$University of Connecticut, United States

Iron-electrocoagulation (Fe-EC) is a method producing in-situ iron (oxyhydr)oxide nano-particles which attach with contaminants such as Arsenic and other heavy metals, coagulate and settle down- thus making water safe for use. Fe-EC is rate limited by amount of dissolved oxygen which is key in oxidizing Fe(II) dissolving from sacrificial anode to Fe(III). We present an improved process using gas-diffusion cathode or air-cathode, which generates in-situ hydrogen peroxide, a stronger oxidant than dissolved oxygen. We investigate the iron-oxides in conventional Fe-EC and air-diffusion cathode enabled Fe-EC. The findings from this research will guide future development of the Fe-EC process.
Chemistries and Architecture for Stable Lithium Metal Anode Ping Liu; University of California, San Diego, United States

Rechargeable lithium metal batteries can reduce the cost of energy storage for both transportation and grid applications. In order to combat issues of infinite volume change, dendrite growth, and parasitic reactions with electrolytes, we have employed several approaches. We have designed a multifunctional 3D host structure with built-in electrolyte additives which promotes dendrite free deposition by reducing effective current densities while improving current efficiency. In terms of electrolyte chemistry, our guiding principle has been the minimization of reactivity with lithium. In this regard, new multicomponent ether-based electrolytes have shown promise. In addition, we emphasize the importance of the chosen electrolyte to be compatible with leading cathode chemistries such as sulfur and transition metal oxides. Performance of lithium metal cells utilizing different cathodes based on the ether electrolytes will be discussed. Finally, we have pursued the formation of surface coatings that can promote uniform lithium ion flux on the electrode surface to enable dendrite free lithium deposition. Our approach favored the use of in-situ chemical reactions in the electrolyte to form protective coatings, which range from lithium organic carbonates to polymeric lithium ion conductors.

Lithium Metal Protection Layer for High Performance Lithium Metal Batteries Taeseup Song1, Seho Sun1, HyukSu Han2 and Ungyu Paik1; 1Hanyang University, Korea (the Republic of); 2Hangik University, Korea (the Republic of)

Lithium metal has been considered as an ultimate anode material due to the advantages of the high specific theoretical capacity (3860 mAh g⁻¹) and the lowest electrochemical potential (-3.04V vs the standard hydrogen electrode) for the next generation lithium ion batteries (LIBs). However, its practical use has been hindered by the Li dendrite growth, large volume changes and the low Coulombic efficiency during cycling, which finally leads the cell failure and safety issues. Various approaches have been suggested; i) Physical suppression of the Li dendrite growth. ii) Regulating Li deposition with dense and planar structures. iii) SEI layer reinforcement iv) Composite electrode engineering. We have focused on the Li protection layer for the control of the Li-ion flux on the Li/electrolyte interphase and the increase of Sand’s time. Herein, we report the novel Li metal protection layer and its application for the stable and high performance of Li metal batteries (LMBs). The mechanical property, electronic conductivity and ionic conductivity have been considered for the design of Li metal protection layer. The designed protection layer could effectively retard the Li dendrite growth with the uniform Li-ion flux and the prevent of the repeated electrolyte decomposition during cycling.

Rethinking How External Pressure Can Suppress Li Dendrites Stephen J. Harris1, Q. Jane Wang2, Xin Zhang2, Katherine Harrison2, Katherine J. Jungjohann2 and Peter Attia4; 1Lawrence Berkeley National Laboratory, United States; 2Northwestern University, United States; 3Sandia National Laboratories, United States; 4Stanford University, United States

Lithium metal anodes are critical enablers for high energy density next generation batteries, but they suffer from
poor morphology control and parasitic reactions. Recent experiments have shown that an external packing force on Li metal batteries with liquid electrolytes extends their lifetimes by inhibiting the growth of dendritic structures during Li deposition. However, the mechanisms by which pressure affects dendrite formation and growth have not been fully elucidated. For example, beneficial pressure effects have been observed even for thin polymer separators whose mechanical properties are not expected to be able to hinder dendrite growth. In this paper we offer an explanation for how dendrite growth can be inhibited when the cell is subjected to an external load, even with a relatively soft separator. We carried out a three-dimensional contact mechanics model based on the semi-analytical method for tracking Li surface and sub-surface stresses for a pouch cell architecture with realistically (micron-scale) rough electrode surfaces subjected to a packing force. Our work shows that the picture normally used to understand dendrite penetration, where micron-scale Li metal protrusions under a fixed local current density press conformally against a separator, is oversimplified. At the larger, sub-mm scales studied here, contact between the Li metal and the separator is highly heterogeneous and far from conformal for surfaces with realistic roughness: the load is carried at a relatively small number of the tallest asperities, while the rest of the Li surface feels no force at all. Yet, dendrite growth is suppressed over the entire Li surface. To explain this observation, we suggest that (1) local contact stresses can be high enough (tens of MPa) at the peaks of Li protrusions (incipient dendrites) so that incremental Li⁺ ions plate instead in regions of low or zero stress; and (2) creep ensures that Li protrusions are gradually flattened. These mechanisms cannot be captured in micron-scale analyses of dendrite growth.

Compression Mechanics of Lithium Metal Alvaro Masias¹², Nando Felten¹ and Jeff Sakamoto¹; ¹University of Michigan, United States; ²Ford Motor Company, United States

Recent technological advances such as modern electric vehicles and portable personal electronics have enabled by advances in lithium ion batteries. This technology has improved at a relatively steady 8% per year (in terms of specific energy, Wh/kg) since introduction in 1991. To grow the rate of electrified vehicle adoption, larger improvements in battery technology are needed. While there is a range of competing chemistries for next generation batteries, most would benefit from the use of lithium metal anodes as one of the primary means of improving energy density.

Despite the considerable interest and dependence on lithium anodes in future generation batteries, its mechanical properties are poorly understood. Recently our group investigated the elastic, plastic and creep behavior of lithium metal [1]. This presentation will extend the scope from our previous study to battery specific mechanical environments, specifically aspect ratio, temperature and strain speed.

Measuring Mechanical Deformation of Energy Storage Materials at Small Length Scales with Nanoindentation Kurt Johanns¹ and Erik G. Herbert²; ¹KLA, United States; ²Michigan Technological University, United States

The lifetime, efficiency and reliability of energy storage devices depends strongly on the complex relationships between chemistry and mechanical properties of the materials within the device. As defined by this symposium, there is a need to characterize the mechanical properties of energy storage materials to provide relevant information for chemo-mechanical simulations and models. Here, we cover the measurement of mechanical properties and deformation using nanoindentation techniques. Specifically, elastic modulus, hardness, and creep deformation will be discussed with reference to the relationship between strength, defects, and length scale. The importance of incorporating as-processed material properties with respect to “bulk” property measurements into simulations will be highlighted. Nanoindentation measurements of elastic modulus, hardness, and creep of lithium, ceramic separators, and thin films will be provided to show current capabilities and the experimental challenges of understanding material deformation at the nanoscale. Challenges include film thickness, surface roughness, and large time dependent deformation at room temperature. Because of these challenges, we have performed
Nanoindentation experiments that allow for elastic modulus measurements below 10nm of indentation depth, statistically significant hardness measurements on rough surfaces, and creep deformation measurements at fractions of the time required for standard creep testing. To summarize, nanoindentation can be used as a method for examining mechanical behavior of the materials in energy storage devices, but it is important to understand experimental challenges and what can be done today and, in the future, to overcome those challenges.

How the Intersection of Thermo-Mechano-Electrochemical Behaviors Affects Battery Safety and Performance  
Corey T. Love¹, Rachel Carter¹,², Robert W. Atkinson³, Emily J. Klein¹, Conner Fear⁴ and Partha Mukherjee⁵; ¹U.S. Naval Research Laboratory, United States; ²National Research Council, United States; ³EXCET, Inc., United States; ⁴Purdue University, United States

Interfaces in Li-ion batteries play a crucial role in the reversibility of intercalation or plating behaviors. These interfaces are influenced by the coupling of electrochemical reactions, thermal conditions and mechanical changes. As batteries are exposed to a varying environments (low temperature or aggressive charging rates) performance and safety are altered. These variations can enable undesired side reactions like SEI growth or lithium plating. Herein, plating prone conditions, specifically low temperature and thermal shock) are characterized in experimental and commercial Li-ion batteries. Electrochemical behavior is carefully analyzed with (impedance spectroscopy and incremental capacity) and the physical implications on the system are assessed with non-destructive µ X-ray CT (computed tomography). This combined analysis identifies lithium plating and jellyroll collapse as dominate capacity loss mechanisms in abuse scenarios. An accelerated rate calorimeter (ARC) modified with high temperature borescope is used to assess the implications of these conditions (lithium plating or jellyroll collapse) on thermal runaway behaviors. The careful analysis of failure modes identifies thermal gradients as a high risk condition for lithium plating. Coin cell assemblies were utilized to probe this behavior further. These studies reveal the ability to modulate lithium plating behavior in Li-ion and Li-metal systems with external thermal gradients. This observation emphasizes the importance of temperature uniformity in commercial systems and provides an avenue for design of high performance lithium metal anodes.

Mechanical Property Measurements of Electroplated Mossy Lithium at Room Temperature  
Dingying Dang¹, Yikai Wang¹, Ming Wang¹, Xingcheng Xiao² and Yang-Tse Cheng¹; ¹University of Kentucky, United States; ²General Motors Global Research and Development Center, United States

Lithium (Li) dendrites and mossy Li remain the major obstacle for the application of Li metal electrodes in liquid electrolyte-based batteries because they excessively consume the electrolyte, can penetrate through the separator, and form dead Li. While new electrolytes and artificial solid electrolyte interphases (SEIs) are being developed, mechanical suppression by, for example, applying proper external pressure, functional separators, and surface coatings, is emerging as an effective approach to improve the cycling stability of Li metal electrodes (even with mossy Li) in liquid electrolyte-based batteries. To better design mechanical suppression approaches, it is indispensable to gain a fundamental understanding of the mechanical behavior of bulk Li as well as mossy Li. Although recent progress has been made in measuring the mechanical properties of bulk Li, the mechanical behavior of electroplated mossy Li is unknown. To fill this knowledge gap, we investigated the mechanical behavior of electroplated mossy Li at room temperature using flat punch indentation inside an argon-filled glovebox. It is found that the Young’s modulus of mossy Li depends on the porosity and is smaller than that of bulk Li. Both the mossy and bulk Li show clearly indentation creep behavior. Despite the highly porous microstructure, the impression creep velocity of the mossy Li is far less than that of bulk Li under the same compressive stress. We proposed possible mechanisms for the significantly higher creep resistance of the mossy Li over bulk Li. These findings may be helpful for developing mechanical suppression approaches to improve the cycling stability of Li metal electrodes.
Stress Evolution in Lithium Metal Electrodes and the Impact of Artificial Passivating Layers Jung Hwi Cho¹,
Xingcheng Xiao², Kai Guo¹, Huajian Gao¹ and Brian W. Sheldon¹; ¹Brown University, United States; ²General
Motors Global R&D Center, United States

The potential advantages of lithium (Li) metal anodes have been widely touted (lowest reduction potential, etc.). However, the poor stability of Li metal / liquid electrolyte interfaces leads to chronic problems, such as dendrite formation and capacity loss. The possible impact of mechanical effects on interface stability and dendrite formation leads to critical questions that are difficult to probe directly. An important part of this are the stresses that arise during battery cycling. These were measured with in-situ wafer curvature. Using this technique during Li plating and examining film thickness effects, it was possible to separate contributions from the bulk lithium metal and the solid electrolyte interphase (SEI). These investigations show that significant stresses are created in the SEI films. Similar stress evolution measurements were also performed during lithium plating and stripping using both soft (PEO) and hard (LiF) artificial surface layers. The results indicate that stresses in surface films can be tuned to improve performance when artificial SEI layers are employed. A basic chemo-mechanical model indicates that hybridizing the two layers may benefit interface stability and performance in Li metal anodes.

Morphological Changes of Alkali Metal Anode in SO₂-Based Inorganic Liquid Electrolyte Juhye Song¹, Goojin Jeong² and Hansu Kim¹; ¹Hanyang University, Korea (the Republic of); ²Korea Electronics Technology Institute, Korea (the Republic of)

Dendritic growth of alkali metal anode during cycling is one of major issues to be addressed for practical application of alkali metal based rechargeable batteries. In this work, morphological changes of Na and Li metal anode were investigated using SO₂ solvated inorganic liquid electrolyte. We found that Na metal anode showed highly stable cycle performance without dendritic formation during cycling in non-flammable and highly Na⁺-conductive NaAlCl₄-2SO₂ inorganic electrolyte, as a result, showing superior electrochemical performances to those in conventional organic electrolytes, which was possible by inducing polygonal growth of Na deposit using a highly concentrated Na⁺-conducting inorganic electrolyte and also creating highly dense passivation film mainly composed of NaCl on the surface of Na-metal electrode. We also found that surface modification of Li metal with Na-containing SO₂ electrolyte can be an effective way to prevent dendritic Li growth during cell operation. The surface-modified Li metal anode exhibited no dendritic deposits even under a high areal capacity (5 mA h cm⁻²) and a high current density (3 mA cm⁻²), while the unmodified anode showed typical filamentary Li deposition. The surface-modified Li metal anode also demonstrated significantly enhanced electrochemical performance, which could be attributed to the newly-formed Na-containing inorganic surface layer that exhibits uniform and dense properties.

Stress-Composition Coupling in Li-Alloys and Their Applications Sangtae Kim¹ and Jong Min Yuk²; ¹Korea Institute of Science and Technology, Korea (the Republic of); ²Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The stress inevitably imposed during electrochemical reactions is expected to fundamentally affect the electrochemistry, phase behavior and morphology. Using graphene liquid cell electron microscopy, we recently unveiled the strong stress-composition coupling in lithium binary alloys in the nanoscale. During lithiation of core-shell nanoparticles, the generation of non-uniform composition field is directly visualized with in situ graphene liquid cell electron microscopy imaging. Based on this coupling, we demonstrate that we can directionally control the lithium distribution by applying different stresses to lithium alloy materials. We show a few device concepts of
stress-composition coupling, including electrochemically driven mechanical energy harvesters and non-volatile electrochemical actuators.

Operando Quantification of Gas Evolution During Lithium Plating-Stripping in Carbonate Electrolytes
Gustavo M. Hobold and Betar M. Gallant; Massachusetts Institute of Technology, United States

Despite possessing physical properties that justify their use in high voltage, high power aprotic battery chemistries, carbonate-based electrolytes and their resulting solid electrolyte interphases (SEI) do not generally enable morphologically homogeneous plating and stripping to and from metal electrodes. Instead, due to interphase breakdown, freshly plated metal is continuously exposed to the electrolyte. High electrode-electrolyte reactivity causes loss of coulombic efficiency and promotes dendrite growth, ultimately leading to catastrophic cell failure. Efforts to circumvent this issue have often focused on the ex-situ design of an artificial inert SEI or on engineering customized electrolyte systems that are hypothesized to form stable interphases in-situ. Still, due to the difficulty in probing the SEI at the molecular scale, little is known about the dynamics of its formation and breakdown during plating and stripping, and the products thereof. Here we investigate the gas phase products resulting from lithium plating and stripping under operando conditions using a custom electrochemical cell coupled to a gas chromatograph. Under electrochemical activity, we quantify the evolution of several C1-C2 species, as well as CO, CO2 and H2, that are dynamically formed due to electrolyte decomposition and SEI formation and breakdown. The operando nature of our experiments enables the identification of gases evolved through pathways that have rate-limiting electron-transfer steps, as well as gases that have chemical reactions as rate-limiting steps. Moreover, we show that SEI transformations, such as the chemical conversion of interfacial Li2CO3 into Li2O, release detectable gas signatures, which are then correlated with interfacial composition measured by X-ray photoelectron spectroscopy. Because some species are formed exclusively by pathways involving electron transfer, we correlate gas evolution with plating-stripping coulombic efficiency, and hence capacity loss. By varying galvanostatic conditions, we observe rate-dependent gas evolution, which we link to surface morphology using ex-situ scanning electron microscopy. We then investigate electrolyte systems that are known to enable morphologically homogeneous plating-stripping, in which gas evolution is expected to be suppressed due to the formation of a likely stable SEI. Finally, we suggest that operando gas analysis can be effective in identifying species and their formation mechanisms that result from parasitic electrode-electrolyte reactions, the evolution of which needs to be suppressed to achieve high cycling stability.

2:30 PM EN05.02.04
Atomistic Conversion Reaction Mechanism of WO3 in Secondary Ion Batteries of Li, Na and Ca
Yang He1, Meng Gu2, Haiyan Xiao3, Langli Luo4, Yuyan Shao1, Fei Gao5, Yingge Du1, Scott X. Mao6, Chongmin N. Wang1 and Linze Li1; 1Pacific Northwest National Laboratory, United States; 2Southern University of Science and Technology, China; 3University of Electronic Science and Technology of China, China; 4Tianjin University, China; 5University of Michigan, United States; 6University of Pittsburgh, United States

Intercalation and conversion are two fundamental chemical processes for battery materials in response to ion insertion. The interplay between these two chemical processes has never been directly seen and understood at atomic scale. Here, using in situ HRTEM, we captured the atomistic conversion reaction processes during Li, Na, Ca insertion into a WO3 single crystal model electrode. An intercalation step prior to conversion is explicitly revealed at atomic scale for the first time for Li, Na, Ca. Nanoscale diffraction and ab initio molecular dynamic simulations revealed that after intercalation, the inserted ion-oxygen bond formation destabilizes the transition-metal framework which gradually shrinks, distorts, and finally collapses to an amorphous W and M2O (M=Li, Na, Ca) composite structure. This study provides a full atomistic picture of the transition from intercalation to conversion, which is of essential importance for both secondary ion batteries and electrochromic devices.

Controlling Electrochemical Lithium Deposition and Sulfur Reduction Mechanism through Liquid Electrolytes
Heng-Liang Wu; National Taiwan University, Taiwan

Lithium metal anode has been regarded as the "Holy Grail" of next-generation battery technologies. In order to stabilize the electrodeposited Li metal for safe and high energy batteries, highly concentrated electrolytes (solvate electrolytes) have been proposed to suppress the formation of Li dendritic structure and polysulfide dissolution in
lithium-sulfur (Li-S) batteries. (1-5) In this talk, we use in situ transmission X-ray microscopy (TXM) to study the effect of solvate electrolyte on Li plating/stripping process. In situ TXM images show that electrodeposited Li particles with uniform density are formed in solvate electrolyte during initial plating process. The effect of solvate electrolyte on the mechanism of Li growth is studied in detail. Additionally, in situ spectroscopy including Raman and X-ray spectroscopy (X-ray diffraction and X-ray absorption spectroscopy) are used to investigate sulfur reaction mechanism and the interaction between polysulfide and solvate electrolyte. We found that the sulfur species formed in the solvate electrolyte are different from the sulfur species formed in conventional DOL/DME electrolyte. These results suggest that solvate electrolyte changes both polysulfide solubility and sulfur reaction mechanism. We next propose different solvate electrolytes with low polysulfide solubility and high stability toward Li metal to enhance the capacity retention of Li-S batteries.

Si Anodes for Li-Ion Batteries from Electrospray/Spin Particle-Polymer Nanofibers Abhishek N. Mondal¹, Ryszard Wycisk¹, Peter Pintauro¹, Ethan C. Self² and Jagjit Nanda¹; ¹Vanderbilt University, United States; ²Oak Ridge National Laboratory, United States

Presently, there is a high demand for rechargeable batteries which provide high energy and power densities. Generally, the usage of portable electronic devices is limited by the short lifetime and charge capacity of batteries. Therefore, to cope with the increasing demand of consumers, novel battery electrodes with enhanced volumetric, gravimetric and areal capacities under fast charging rates need to be developed. This demand has prompted intensive research efforts for developing next generation Li-ion battery electrodes, e.g., to replace conventional slurry cast carbon anodes. Electrospinning is considered to be a convenient and promising approach for the fabrication of porous mats with tailored micron/sub-micron diameter fibers containing nanoparticles and polymer binder.¹,² Electrospun anodes for Li-ion batteries have superior characteristics including: (i) high electrode/electrolyte interfacial area, (ii) flexible interfiber void space of an electrode mat to facilitate electrolyte infiltration, and (iii) micron/sub-micron sized fibers with a high nanoparticle content (short Li⁺ ion transport pathways in the radial fiber direction). Pintauro and co-workers have examined and reported on several different types of electrospun anodes for Li-ion batteries with TiO₂/C³, Si/C⁴ or PVDF/C⁵ nanoparticles with either poly(acrylic acid) (PAA) or poly(vinylidene fluoride) (PVDF) as the polymeric binder. In our current work we are focusing on an electrospun/electrosprayed system where a Si/binder ink was electrosprayed into fiber with the simultaneous electrospinning of a C/binder ink. Preliminary half-cell charge/discharge data are very promising. For example, an anode containing 61 wt.% Si-PAA fibers (40 wt.% PAA) and 39 wt.% C-PVDF droplets (37 wt.% PVDF) exhibited a terminal discharge gravimetric capacity of 1100 mAh/g (based on the total anode weight) at 0.1C and 600 mAh/g at 1C, with remained constant for 50 charge/discharge cycles. For this anode, the areal capacity was 1.2 mAh/cm² and the coulombic efficiency was ~99%. During this presentation, details will be given on the fabrication method and structure of the fiber/sprayed anodes, along with charge/discharge data at different C rates. The effects of binder type and Si/C weight ratio on anode performance (gravimetric, volumetric, and areal capacities) at different C-rates will be discussed.

The Impact of Oxide Content on Cycle Life and Stress Evolution in Silicon-Based Composite Electrodes
Mok Yun Jin¹, Elizabeth Healy¹, Xingcheng Xiao² and Brian W. Sheldon¹; ¹Brown University, United States; ²General Motors Global R&D Center, United States
Silicon has received much attention as a promising negative electrode material, however, it undergoes extremely large volume changes during lithiation/delithiation. This leads to substantial stresses inside of particle-based electrodes, which are believed to cause poor cycling performance. Composite electrodes that also incorporate oxidized silicon are a cost-effective way to accommodate these stresses and extend cycle life. To obtain fundamental information about chemomechanical phenomena in these composite structures, several different types of materials are being investigated: (1) Si nanoparticles with oxide shells, (2) Si thin films with oxidized surface layers, and (3) composite SiOx particles. The evolution of internal stresses in all of these structures was monitored with precise in-situ curvature in conjunction with parallel electrochemical measurements. Ex situ characterization with electron microscopy, x-ray diffraction, and XPS provide important complementary information about changes in the materials. The different types of materials used for this work make it possible to systematically investigate key length scales, by independently varying oxide layer thicknesses and particle sizes. Analysis of these results requires assessments and models of both the chemical and mechanical effects oxide surface layers and silicon encapsulation. The implications for optimizing these composite electrode structures will also be presented.

Long Cycle-Life and High-Rate Magnesium-Ion Battery Anode Enabled by Self-Healing through Near-Room-Temperature Solid-Liquid Phase Transition
Lin Wang, Samuel S. Welborn, Hemant Kumar Kumar, Vivek Shenoy and Eric Detsi; Univ of Pennsylvania, United States
Resources used in lithium-ion batteries are becoming more expensive due to demand, and the global cobalt market heavily depends on supplies from countries with high geopolitical risks. Alternative battery technologies including magnesium-ion batteries are therefore desirable. Progress toward practical magnesium-ion batteries have been impeded by an absence of suitable anodes that can operate with conventional electrolyte solvents. Although alloy-type magnesium-ion battery anodes are compatible with common electrolyte solvents, they suffer from severe failure associated with huge volume changes during cycling. Consequently, achieving more than 200 cycles in alloy-type magnesium-ion battery anodes remains a challenge [1]. In this talk I will an unprecedented long-cycle life of 1000 cycles, achieved at a relatively high (dis)charge rate of 3C (current density: 922.5 mA/g) in Mg2Ga5 alloy-type anode, taking advantage of near-room-temperatures solid-liquid phase transformations between Ga(liquid) and Mg2Ga5(solid)[2]. A combination of Finite-Element Modelling (FEM), electrochemical characterization, and operando wide-angle X-ray scattering (WAXS) is used to investigate this remarkable cycling performance[2]. This concept should open the way to the development of practical anodes for the next generation magnesium-ion batteries.

Keywords: Beyond lithium, Magnesium-ion battery anode, self-healing, solid-liquid phase transformation, operando X-ray scattering.

[2] L. Wang, S.S. Welborn, H. Kumar, Z. Wang, M. Li, V. Shenoy, and E. Detsi: High-Rate and Long Cycle-Life Alloy-Type Magnesium-Ion Battery Anode Enabled through (De)magnesiation-
A 0.7 mAh LiFePO4/graphite Li-ion pouch cell with a 1.0 M LiPF6 1:1 Ethylene Carbonate:Ethyl Methyl Carbonate v/v electrolyte was overdischarged by a fixed 35.7 kOhm resistive load applied continuously for 2 weeks. The resistive load was applied after the 5th conditioning cycle discharge by constant 0.07 mA current to 2.5 V cell voltage. 3-electrode measurements show that the anode increases to 3.4 V vs. Li/Li+, which is greater than the copper oxidation potential, after about an hour after application of the fixed resistive load as the cell voltage decreases to ~200 mV. At about the 6th hour of the fixed resistive load overdischarge step, the cell voltage rapidly (~5 minutes) increases from 200 mV to about 1.5 V, plateaus for about 4 hours then decreases during the next ~4 hours to 0.0 V. The 3-electrode results show that the cell voltage increase is driven by the anode potential rapidly decreasing from 3.4 V vs. Li/Li+ to about 1.5 V vs. Li/Li+ at the 6th hour for about 4 hours. The cathode potential rapidly decreases from 3.5 to ~3.0 V vs. Li/Li+ at the 6th hour and plateaus for about 4 hours. The cathode and anode potentials then decrease to ~1.0 and ~0.5 V vs. Li/Li+, respectively, during hours 10-14 of the fixed resistive load step until the electrode potentials asymptote together and increase to about 2.6 V vs. Li/Li+ during the remaining ~322 hours of the fixed resistive load step. When the cell was recharged after the 2 week fixed resistive load overdischarge step the cell charge/discharge capacity increased by about 0.08 mAh. The electrode potential characteristics also changed consistent with an increase in the reversible lithium available in the cell compared to before the fixed resistive load overdischarge.

Visual inspection of the anode shows darkening in some areas of the composite surface. Scanning electron microscopy (SEM)/energy dispersive x-ray (EDX) and x-ray photoelectron spectroscopy (XPS) results show a significant, non-uniform change to the interfacial chemistry of the anode with an increase in the presence of fluorine, phosphorous, copper and lithium on the surface compared to a control cell that was not overdischarged. The increased presence of the phosphorous, lithium and fluorine was more substantial in the visually darkened areas. High resolution XPS scans of the Phosphorous 2p, Fluorine 1s, and Oxygen 1s show the 2 week fixed resistive load overdischarge increases the presence of LiPFy, LiF, LiPOyFz and P4O10 compounds on the surface of the anode, particularly in the visually darkened areas of the anode. Time-of-flight secondary ion mass spectroscopy (ToF-SIMS) of dried electrolyte samples shows an increase in copper content of the electrolyte in an overdischarged cell compared to a cell that was not overdischarged.

The next generation high-energy batteries comprise light element metals for the cathode, electrolyte, and anode (Li-S, Li-O, and solid electrolytes, respectively) and will be replacing its non-transition metals counterpart. The former materials, however, are known to be highly reactive – the materials are very sensitive to air and electron beam. Sample preparation and experimentation are challenging because it is necessary to transfer samples between milling
systems and microscopes while simultaneously maintaining the material’s integrity. A critical requirement in developing these materials for tangible applications is the ability to characterize the materials in a pristine state, without environmental modifications or contamination. Furthermore, transmission electron microscopy (TEM) is a critical analytical technique for battery research and development. Following the advancement of cryo-electron microscopy (cryo-EM) in life sciences, cryo-EM has been adapted for Li battery research, which allows for the preservation of the Li battery materials’ native state during imaging at the atomic scale. This study presents robust controlled environments that protect the material during the sample preparation phase (bulk to focused ion beam [FIB] preparation) and through the multi-length scale electron microscopy characterization phase. At the micrometer scale, scanning electron microscopy (SEM) characterization will show the morphology of the solid electrolyte while the sub-angstrom scale using the TEM providing interfacial chemistry and morphology. High quality, Li ion battery TEM specimens that are free from amorphous and Ga damage will be prepared and imaged under cryo-EM conditions.

The controlled environments workflow for SEM and TEM sample preparation and microscopy characterization involved the preparation of the bulk sample using broad ion beam (BIB) Ar⁺ milling to remove surface oxides. A vacuum/inert gas transfer capsule protected the sample post-BIB milling. A glove box with a positive pressure environment was used to transfer the bulk sample from the vacuum/inert gas transfer capsule to a FIB transfer system, and thereafter, to a FIB system for morphology and elemental characterization and subsequently TEM specimen preparation. A TEM half grid was secured in the cartridge of a vacuum transfer specimen holder. This cartridge was inserted into the FIB by means of the FIB transfer system. A TEM specimen was prepared using standard lift-out methods and polishing steps (30 and 5 kV) in the FIB. The cartridge with the TEM specimen was moved into the FIB transfer system and then to the glove box. Subsequently, the cartridge was mounted on the vacuum transfer specimen holder within the glove box. The TEM specimen holder was then moved to a concentrated Ar⁺ beam milling system. Ar⁺ milling was performed by rastering the beam within a defined area of the TEM specimen at decreasing milling energies. Subsequently, the TEM specimen was loaded on a cryo TEM holder inside the glove box; a glove bag with inert gas protected the TEM specimen during insertion of the cryo holder in the TEM. The cryo holder was then cooled in the TEM.

Cryo-EM imaging and analysis using energy dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS) before and after ion milling to quantify the removal of FIB-induced damage and the workflow’s ability to prevent specimen oxidation and contamination will be presented.

Maintaining the Contact between Solid Polymer Electrolyte and Lithium Metal Anode Using an Adaptive Buffer Layer Nian Liu and Haochen Yang; Georgia Institute of Technology, United States

Solid polymer electrolytes (SPEs) have the potential to enhance the safety and energy density of lithium batteries. However, poor interfacial contact between the lithium metal anode and SPE leads to high interfacial resistance and low specific capacity of the battery. In this presentation, I will show a novel strategy to improve this solid–solid interface problem and maintain good interfacial contact during battery cycling by introducing an adaptive buffer layer (ABL) between the Li metal anode and SPE. The ABL consists of low molecular-weight polypropylene carbonate, poly(ethylene oxide) (PEO), and lithium salt. Rheological experiments indicate that ABL is viscoelastic and that it flows with a higher viscosity compared to PEO-only SPE. ABL also has higher ionic conductivity than PEO-only SPE. In the presence of ABL, the interface resistance of the Li/ABL/SPE/LiFePO4 battery only increased 20% after 150 cycles, whereas that of the battery without ABL increased by 117%. In addition, because ABL makes a good solid–solid interface contact between the Li metal anode and SPE, the battery with ABL delivered an initial discharge specific capacity of >110 mAh/g, which is nearly twice that of the battery without ABL, which is 60 mAh/g. Moreover, ABL is able to maintain electrode–electrolyte interfacial contact during battery cycling, which stabilizes the battery Coulombic efficiency.

This presentation is based on our recent publication: *ACS Appl. Mater. Interfaces*, 2019, 11 (31), 27906-27912 https://doi.org/10.1021/acsami.9b08285
Battery cathode materials that could host both cationic and anionic redox activities have demonstrated an impressive capacity and, therefore, are the subject of intense research. The interplay among the co-existing redox centers is critical to battery performance. While tremendous efforts have been devoted to investigating the electrochemically-driven redox evolution on the surface and in the bulk of the high-energy-density cathodes at room temperature, their behavior under elevated temperature is an area that lacks in-depth investigation.

In this presentation, I will show our recent systematic investigation of the thermally-driven redox coupling effect in lithium- and manganese-rich (LMR) materials using Li$_{1.2}$Ni$_{0.15}$Co$_{0.1}$Mn$_{0.55}$O$_2$ as an example. Under thermal abuse conditions, we report the structural degradation from the atomic scale up to the particle level. In particular, under mildly elevated temperature (~100 C), we observed long-range charge transfer between the oxygen anions in the bulk and the transition metal cations on the surface. Our results suggest that the thermally-activated ionic mobility in the hosting LMR lattice could lead to the redistribution of lithium-ions, which facilitate the long-range redox coupling effect and maximizes the entropy of the system as it settles to a new equilibrium.

These findings highlight the dynamic nature of redox couples in LMR material at even slightly elevated temperature. Such temperature sensitivity can have profound impacts on both the battery safety and electrochemical performance.

We assess the heterogeneous electrochemistry and mechanics in a composite electrode of commercial batteries using synchrotron X-ray tomography analysis and microstructure-resolved computational modeling. We visualize the morphological defects at multi-scales ranging from the macroscopic composite, particle ensembles, to individual single particles. Particle fracture and interfacial debonding are identified in a large set of tomographic data of active particles. Mechanical failure in the regime near the separator is more severe than toward the current collector. The active particles close to the separator experience deeper charge and discharge over cycles and thus are more mechanically loaded. The difference in the Li activity originates from the polarization of the electrolyte potential and the non-uniform distribution of the activation energy for the charge transfer reaction. We model the kinetics of intergranular fracture and interfacial degradation to confirm that the various Li activities are the major cause of the heterogeneous damage. The interfacial failure may reconstruct the conductive network and redistribute the electrochemical activities that render a dynamic nature of electrochemistry and mechanics evolving over time in the composite electrodes. We further quantify the influence of the mechanical damage on the metrics of battery performance. We simulate the electrochemical impedance profile to build a relationship between the interfacial debonding and the impedance of electron transport and surface charge transfer. The mechanical failure disrupts the conduction path of electrons and results in significant polarization and capacity loss in batteries.

We have devised an approach to fabricate dense textured V$_2$O$_5$ thin films, which allows us to scrutinize the root cause of capacity fade in V$_2$O$_5$ cathodes of Li-ion batteries. Specifically, we performed in-situ measurements of stress of V$_2$O$_5$ thin films during 50 electrochemical cycles. Surprisingly, electrochemical cycling appears to induce elastic and rate-independent deformation over a voltage range relevant to battery operation (4 - 2.8 V). However, the
compressive stresses gradually increase with cycle number during the first few cycles, likely due to side reactions and/or residual Li left in the V$_2$O$_5$, even after delithiation (to 4 V). Further cycling leads to accumulated mechanical (e.g., fracture, delamination) and structural changes which ultimately result in severe capacity fade.

Transition Metal Dissolution from LiNi$_{0.8}$Mn$_{1.5}$O$_4$ Cathode Investigated by Ab Initio Free Energy Simulations
Vitaly Alexandrov$^1$, Nadia Intan$^1$ and Konstantin Klyukin$^2$; $^1$University of Nebraska-Lincoln, United States; $^2$Massachusetts Institute of Technology, United States

Dissolution of transition metals (TMs) from the cathode and their subsequent accumulation on the anode contributes to the capacity fading of lithium ion batteries (LIBs) regardless of the chemical nature of the cathode. In recent years this stability aspect of LIBs has received growing attention in the community, however, mechanistic understanding of the associated processes is hampered by the complexity of electrochemical interfaces under study. Here, we present the results of our first-principles molecular dynamics based investigation of TM dissolution from the high-voltage spinel-structured LiNi$_{0.8}$Mn$_{1.5}$O$_4$ cathode into the liquid organic electrolyte. By employing accelerated free-energy simulations with explicit treatment of the organic electrolyte, we analyze a number of factors affecting the kinetics of TM dissolution including the nature of TM (Ni, Mn) and electrolyte species, the presence of surface protons and oxygen vacancies. The obtained results also suggest a clear correlation between the adsorption strength of electrolyte species and TM dissolution barriers enabling materials screening toward systems less prone to TM dissolution.

A Resistor-Network Method for the Investigation of Structure-Transportproperty Relations in Granular Cathodes of Lithium-Ion-Batteries
Oleg Birkholz and Marc Kamlah; Karlsruhe Institute of Technology, Germany

The properties of lithium ion batteries (LIB) depend critically on the transport properties in the electrodes. In this work, we focus on the effective transport properties of the granular cathode consisting of active material particles, liquid electrolyte, and additives, i.e. a mixture of binder and carbon black. To study the impact of the granular structure through the effective transport parameters on the cell performance is our objective in this work. The classical Newman cell model requires effective transport parameters, electronic and ionic, in the solid and liquid phases. Typically, they are obtained by empirical theoretical models such as the well-known Bruggeman relation. In our approach, we compute all needed effective transport properties by resistor network methods, as well as the structural data such as porosity and specific surface area. To this end, either tomographic real data or statistically equivalent virtual structures are imported from project partners. To study the structure property relations of the cathode, we simulate half cells with a lithium foil and a separator of which the effective transport parameters are obtained from Bruggeman relations, for simplicity. The active material in the cathode is represented as an assembly of spherical particles of a given size and at a given packing factor. A resistor network method will be presented to model the effective transport through this phase. In this approach, each particle corresponds to a node with a certain potential and the edge to a connected neighbor defines a resistor as a function of the bottleneck geometry. This computationally efficient and simplifying approach was validated by comparison to spatially resolved finite element models. Furthermore, a resistor network method will be introduced for the effective transport property in the space surrounding the particles. In this case, the so-called Voronoi tessellation is used where the corners of the resulting cells are the nodes and resistors are assigned to the edges based on the throat geometry in the space between particles. This method was validated by comparison to finite element simulations as well.

In the next step we account for the fact that the space between active material particles is filled by an additive, consisting of a binder-carbon black mixture, on the one side and liquid electrolyte, on the other. A method is presented how to calculate the effective electronic conductivity of the additive phase and verified by comparison to experiments in literature. Depending on the volume fraction of liquid electrolyte in the remaining space between active material particles, the effective ionic conductivity and diffusivity are is determined. In this way, all effective transport properties needed for cell modeling, are obtained from structural data of cathodes. We present and discuss values of structural and transport properties for some real electrodes. Furthermore, cell simulation shows the C-rate dependence of specific capacity. A characteristic drop at a certain C-rate is found which depends on the electrode thickness. These trends are in good agreement with experimental results by project.
partners. Finally, we will present a parameter study concerning electrode thickness, particle size, porosity, and specific surface area in view of the effect of these parameters through the related effective transport properties on the cell performance.

Electrochemical-Shock Resistant Single-Crystal Ni-Rich Layered Cathode Materials Linsen Li, Guannan Qian and Zi-Feng Ma; Shanghai Jiao Tong University, China

Ni-rich layered oxides LiNi$_x$M$_{1-x}$O$_2$ (x>0.6, M = Co, Mn and/or Al) are technologically important cathode materials for lithium-ion batteries due to their high energy density and good power capability. These materials are usually prepared by a co-precipitation and post-calcination method that produces micron-sized polycrystalline (PC) particles consisting of nanoscale grains. The unique microstructure and anisotropic Vegard coefficient make them vulnerable to grain-boundary fracture (“electrochemical shock”), a major cause for impedance growth and performance degradation. We have recently developed a scalable method to prepare a variety of single-crystal (SC) Ni-rich cathode materials. SC-NMC622 outperforms the commercial PC-NMC622 in cycling stability, rate performance, and thermal stability. Post-cycling structural characterizations reveal that the SC-NMC622 do not crack and its surface undergoes less phase transformation than PC-NMC622. The fracture mechanism of PC and SC layered oxide cathode materials will be discussed and compared. SC Ni-rich cathode materials are critical to fabricating mechanically reliable solid-state batteries and provide a unique platform for studying doping and surface modification methods.

11:15 AM EN05.03.08
Observation and Elucidation of Stress-Induced Non-Uniform Reaction Behavior in LiFePO$_4$ Secondary Particles Fan Wang, Kaiqi Yang and Ming Tang; Rice University, United States

Particle-level reaction heterogeneity in lithium ion batteries can lead to formation of microcracks, local over-charge/discharge, and thus loss of capacity and shortened cycle life. The origin of this phenomenon is still not well understood, with many factors in play including particle morphology, thermodynamic properties, nonuniform electronic connections as well as the applied cycling conditions. In this work, operando measurements using synchrotron-based transmission X-ray microscopy (TXM) are conducted for LiFePO4 (LFP) secondary particles upon slow charging. We show that persistent nonuniform distribution of state-of-charge (SOC) exist during the entire charge process. Unlike the core-shell structure often observed in the cycling of single-crystalline electrode particles, the delithiated phase nucleates at a small number of “hotspots” and grows outwards in a highly anisotropic, finger-like pattern. Our phase-field simulation well captures the experimental phase morphology and explains the observed phase evolution behavior. We propose the incompatibility of lattice expansion among randomly oriented primary particles as the source of the reaction heterogeneity. It induces non-uniform Li-insertion stress among primary particles, which results in spatially varied nucleation and growth energy barriers. As a result, new phase preferentially nucleates at grains where adjacent grains can expand coordinately and follows a growth pathway with the least elastic energy penalty. As many battery compounds exhibit anisotropy in lattice expansion and elasticity, our observation may represent a general phenomenon for secondary electrode particles.

11:30 AM EN05.03.09
Structural Inclusions-Induced High-Rate and Long Cycle-Life in Bulk Na$_{2/3}$[Ni$_{1/3}$Mn$_{2/3}$]O$_2$ Sodium-Ion Battery Cathodes Jintao Fu$^{1}$, John Corsi$^{1,2}$ and Eric Detsi$^{1,2}$; $^{1}$University of Pennsylvania, United States; $^{2}$Vagelos Institute for Energy Science and Technology (VIEST), United States

Recently, sodium-ion batteries (SIB) have been considered as a promising alternative to lithium-ion batteries due to the abundance of sodium resources (Na is the Earth’s 6th most abundant element, while Li is 33th) and its low extraction costs. Among various SIB candidate cathode materials, the layered oxides Na$_x$Ti$_3$O$_7$ (Ti=3d transition metal elements and their mixture) made of earth-abundant elements can reversibly store sodium by intercalation at relatively high voltages (up to ~3.8 V vs Na/Na$^+$). However, these cathode materials suffer from a poor rate capability and short cycle life. In this talk, I will present a novel bulk Na$_{2/3}$[Ni$_{1/3}$Mn$_{2/3}$]O$_2$ structure containing void-type inclusions, which we have developed using ultrafine three-dimensional (3D) bicontinuous nanoporous nickel (NP-Ni) scaffold as template. During the conversion of this 3D NP-Ni scaffold into Na$_{2/3}$[Ni$_{1/3}$Mn$_{2/3}$]O$_2$ through solid-state reaction, the void space in the NP-Ni gives rise to structural inclusions in the bulk of the Na$_{2/3}$[Ni$_{1/3}$Mn$_{2/3}$]O$_2$. The as-synthesized cathode materials exhibit outstanding cycling stability with ~94% capacity
retention at 5C after 1000 cycles. When cycled at ultra-fast rates of 50C, the material still shows an unprecedented rate capability with roughly 50% capacity retention. Kinetic analysis at a scan rate of 1 mV/s reveals that ~86% of the overall capacity originates from the capacitive contribution, suggesting that sodium storage between the layers is not diffusion-limited. Therefore, High-resolution Transmission Electron Microscopy (HRTEM) analysis was performed to understand the origin of the ultra-fast Na-ion migration in and out of the material. It was found that the Na-intercalation layer spacing increased by ~16% due to inclusions, compared to pristine material counterparts without inclusions. These structural inclusions were further studied using Small/Wide-angle X-ray Scattering (SAXS/WAXS). Such void inclusion-induced structure can be applied to a wide range of material systems, and will shed new light on the design of high-performance cathode materials.

11:45 AM EN05.03.10
Effect of Sn Doping on the Enhanced Charge Transport Properties of V_2O_5 Cathode of Li-Ion Batteries—A First-Principles Study
Suwit Suthirakun1,1, Lappawat Ngamwongwan1,1, Sirichok Junghawan1,1 and Sukit Limpijumnong2; 1Suranaree University of Technology, Thailand; 2The Institute for the Promotion of Teaching Science and Technology (IPST), Thailand

Vanadium pentoxide (V_2O_5) is one of the most promising cathode materials used in metal-ion batteries due to its high theoretical capacity. However, it still suffers from several limitations such as slow electrochemical kinetics. Although the introduction of Sn impurities in V_2O_5 has been proposed to alleviate the kinetic drawback of the cathode, the origin of the enhancement is still vague. To find fundamental explanations and better understand the role of Sn dopants, we carried out the density functional theory (DFT+U) calculations to identify the most thermodynamically stable defects in the presence of Sn dopants. Specifically, we computed the defect formation energies of various point defects, charge carriers, and defect complexes to determine their relative stabilities in the lattice. We find that Sn could be inserted in the lattice or substituted at a V site. Sn insertion exhibits mixed ionic/covalent interaction with the lattice and donates two electrons which are localized at the two nearby V centers. Alternatively, Sn is found to be more stable to replace at the V lattice site when an oxygen vacancy (V_O) is created at the nearest neighbor position. The Sn-V_O defect complex generates one extra electron localized at the nearby V center. These extra electrons created upon the defect formations are trapped at the V sites which in turn induce distortion of local structure and form small polarons. Small polarons can undergo thermally activated hopping from one V site to the nearby site throughout the lattice where their transport properties could affect the diffusion of Li^+ ions. In order to study the transport properties of ions and polarons, we employed nudged elastic band (NEB) method to calculate their migration barriers. Overall, computations show that Sn doping increases number of charge carriers in the V_2O_5 cathode. Structural distortion upon doping increases stabilities of Li insertion while does not diminish migration properties of charge carriers. The obtained fundamental understanding of the defect formation in the V_2O_5 based cathode materials could be one way to promote the improvement of the battery technologies.
densities of states near the Fermi level and reduce the work function, hence efficiently enhancing its oxygen reduction activity. In addition, we demonstrated the critical role of structural H2O. The results suggest that the H2O-solvated Zn2+ possesses largely reduced effective charge and thus reduced electrostatic interactions with the V2O5 framework, effectively promoting its diffusion. We also identified the exciting electrochemical properties (including high electric conductivity, small volume change and self-preserving effect) and superior sodium storage performance of alkaline earth metal vanadates through preparing CaV4O9 nanowires. Furthermore, a novel assembled nanoarchitecture was also presented, which consists of V2O5 nanoparticles embedded in amorphous carbon nanotubes that are then coassembled within a reduced graphene oxide network. The naturally integrated advantages of each subunit exhibit highly stable and ultrafast sodium-ion storage. Our work presented here can inspire new thought in constructing novel one-dimensional structures and accelerate the development of energy storage applications.

Material-Gene and Structure Chemistry of Li-Ion Battery Feng Pan and Tongchao Liu; Peking University Shenzhen Graduate School, China

Insight into relationship between Crystal/Interface structure and properties of capacity, stability and rate capability by methods of material-Gene and structure chemistry are important for developing advanced Li-ion batteries. (Ref. 1) Using theoretical calculations combined with experimental in-situ tests, we did extensive studies on the kinetic of Li-ion diffusion for two representative cathode materials: layered Li(NixMnyCoz)O2 (NMC) (x + y + z = 1) and LiFePO4. We not only focus on the bulk kinetics, but also the kinetics across electrode/electrolyte solid-liquid interface and in the electrolytes.(Ref. 2) Using ab initio calculations combined with experiments, we clarified how the thermal stability of NMC materials can be tuned by the most unstable oxygen. In NMC, insight of Ni/Li disorder has be investigated by theory and experimental e.g. neutron powder diffraction experiments and magnetization measurements. Thus, the variation of Li/Ni exchange ratio vs. TM mole fraction in NMC with different compositions can be well understood and predicted in terms of magnetic frustration and superexchange interactions. (Ref. 3) The formation of the SEI between a graphite anode and a carbonate electrolyte are investigated through combined atomic-scale microscopy and in situ and operando techniques. The insight of “H2O in Salt” and related structure vs. electrochemical window are revealed . (Ref. 4)

Design and Operation of Electro-Chemo-Mechanical Actuators Evgeniy Makagon, Eran Mishuk, Sidney R. Cohen, Ellen Wachtel and Igor Lubomirsky; Weizmann Inst of Science, Israel

The electro-chemo-mechanical (ECM) effect causes dimensional change in a solid due to change in chemical composition induced by a Faradaic electric current. The ECM effect seriously impairs the functioning of batteries or
fuel cells, limiting their lifetime and degrading their performance. However, it is was recently suggested that the electro-chemo-mechanical coupling has the potential for use in actuation\cite{1}. To explore this idea, we propose the following scheme as a basic design for an ECM actuator: electrode1\WB1\solid-electrolyte(SE)\WB2\electrode2, where WB denotes a working-body comprising a mixed ionic-electronic conductor with a large chemical expansion coefficient.

Theoretical analysis of this actuator design indicates: 1. The speed of actuation is limited by the ionic diffusion coefficient in WBs but not in SE. 2. ECM actuation has several potential advantages: (a) ECM actuators can simultaneously deliver large strain and large stress, which is difficult to achieve with other actuation mechanisms; (b) ECM actuators maintain their state after external voltage is removed; (c) displacement and force generated by an ECM actuator are determined by the amount of charge transferred, which is more readily controlled than electric field-driven devices. 3. The only major shortcoming of ECM actuation is that its energy conversion efficiency cannot exceed a few percent.

To demonstrate the concept, we have constructed a room temperature, nanocrystalline ECM membrane actuator (2mm diameter and »2µm thick) with Gd-doped ceria as SE. We tested two alternative compositions for WB’s: (1) metal/(metal oxide) or (2) nanocrystalline ceria/metal composite. Electrical and electromechanical measurements demonstrated that the actuator response with metal/metal oxide WB’s is limited by the rate of oxygen diffusion from the solid electrolyte to the metal surface. Actuators with ceria/metal composite WB’s provide shorter response time (»20sec) and larger vertical displacement (>3.5µm). These findings suggest that the ECM effect may indeed become a valuable actuation mechanism for MEMS applications.

Explicit Consideration of Carbon Binder Domains in 3D-Resolved Model to Optimize Fabrication Process
Mehdi Chouchane1,2, Alexis Rucci1,2 and Alejandro A. Franco1,2,3; 1Laboratoire de Réactivité et Chimie des Solides, France; 2RS2E, France; 3ALISTORE-ERI (CNRS), France

In the literature, reported 3D-resolved battery models rely on oversimplifications, such as an implicit representation of the carbon-binder domains (CBD) through the use of effective parameters for porosity and tortuosity or by merging CBD with the Active Material (AM) as a single solid phase.

This work’s novelty relies on the explicit representation of CBD, leading to a new level of accuracy in terms of electrochemical modeling. This achievement is made possible thanks to an in-house algorithm, INfinite Number Of phases meshing through Voxelization (INNOV)\cite{1}. INNOV can generate a volumetric mesh from data of different types due to its flexible input format. INNOV takes as input binary stack of images to reconstruct the 3D structure. Such an input can arose from tomography imaging, from slicing a 3D object or from Coarse Grained Molecular Dynamics(CGMD) simulations\cite{2}. For the latter a function has been developed to convert its output (coordinates of the centers and radii of the particles) into a binary stack of images. This algorithm is designed in the scope of the ARTISTIC Project\cite{3} to import a multi-phase volumetric mesh of an electrode (from a CGMD simulation) into COMSOL Multiphysics to simulate the performances of the cell.

The segmentation method of Nielson and Franke\cite{4} has been translated and optimized for MATLAB language and modified to suit the COMSOL Multiphysics meshing importation process. To tackle the computational cost of a 3 phases mesh, a “precision” parameter is introduced to downsample the number of nodes, faces and elements. Time-efficient meshing is achieved thanks to the simplicity of the operations and to an optimization through a matrix formalism in MATLAB.

The core of this work is to increase the current level of precision of the modeling of batteries by separating active and inactive materials. In doing so, one must not sacrifice the integrity of the mesostructure geometry. To ensure this, INNOV provides a number of observables, which can be compared to experimental numbers (e.g. arising from tomography characterizations). Among them, two distinct values of porosity are displayed by INNOV: the porosity of the mesh and the porosity of the stack of images. Furthermore, the volume ratio of each phase in the mesh is compared to its value in the stack of images. This can render proof of the overall volume conservation of each phase; however, these are average values and cannot highlight local deformations within the mesh. Another useful
insight is the surface coverage between different phases.

Once the integrity of the mesh is ensured, electrochemical simulations can be done to characterize the two structures along different hypotheses for the CBD behavior. The first approach is to consider the CBD as blocking, i.e. there is no diffusion nor intercalation of Li inside the CBD. The second one is transparent CBD, the Li diffuse inside the CBD with the same diffusion coefficient as in the electrolyte but there is still no intercalation. Such study can highlight the importance of the CBD morphology in a 3D-resolved battery model beyond its role as an electronic conductor.

In conclusion, INNOV offers a time-efficient tool to perform meshing without requiring substantial computational resources. Simulations can later be performed to characterize these meshes with the CBD explicitly considered. It can lead to new approaches to characterize battery microstructures and the impact of each components.

Designing the Additives to Prevent Spontaneous Structural Degradations of the Ni-Rich Cathode Yongwoo Shin1, Yoon-Sok Kang2 and Dong Young Kim2; 1Samsung Research America, United States; 2Samsung Advanced Institute of Technology, Korea (the Republic of)

Ni-rich layered oxides have been attracting the research interests due to their low price and high discharge capacities comparing the commercial Co-based Li-ion battery (LIB). However, one of the critical obstacles to commercialize the Ni-rich cathode is the capacity fade during early cycles which has been widely observed in Ni-rich layered oxide systems (i.e., LiNiO2, LiNi1−xMxO2, LiNi1−x−yMxMy′O2, and Li[Ni1−x−yCoxMny]O2: M, M′=metal). Indeed, the capacity loss is directly associated with the structural degradation of the cathode, which has been attributed to the cation mixing from the partial reduction of the Ni-ions. In other words, the production of inactive Ni is the main factor of the capacity fade, which is strongly related to oxygen loss. Convincingly, preventing the spontaneous oxygen evolution from the cathode surface could be a critical breakthrough for commercializing the Ni-rich layered oxide.

In this research, we studied the degradation mechanisms of the Ni-rich layered oxide and their protective procedures by introducing the new additives; which has been investigated using the Ni-rich LiNi0.8Co0.1Mn0.1O2 (NCM)/graphite 18650 cylindrical-type cells as well as the first principles Density Functional Theory (DFT) computations. First of all, we comprehended the structural degradations of NCM via the Electron Energy Loss Spectroscopy (EELS), Scanning Transmission Electron Microscope (STEM) High Angular Annular Dark Field (HAADF) and DFT calculations. Here, we confirmed that the reduced Ni-ions on the surface has been penetrated to the bulk by cycling along with the spontaneous oxygen evolutions from the cathode surface. Besides, we proposed the novel functional electrolyte additives to stabilize the surface Ni via ab initio computations. We found the generic trends of COx, SOx, and POx compounds in the local atomic environments of Ni-rich cathode surface through computing the intrinsic oxidation/reduction energies, protonation energies, dehydrogenation energies, Li+ interactions, and Ni2+ interactions. Finally, we studied the additives effect on the cathode surface by close collaboration with the computations and experiments. The cathode surface interacts with the electrolyte and additive molecules which can enhance or prevent the structural degradations. Consequently, incorporating the surface protecting substances on the electrolyte would be an efficient procedure to preserve the cathode surface. Therefore, we investigated the electronic structure, adhesive energy, and surface oxygen protection potentials for the candidate additives, which are phosphorus-based, carbon-based, sulfur-based, and phenyl-based molecules. Our computations and experiments illustrated the spontaneous oxygen evolutions on the surface and sub-surface layers for the charged cathode system, which oxygen evolutions were prevented with the functional additives. In the candidate list, four molecules have been shown strong adhesive tendency on the charged cathode surface, and that molecules successfully prevent the spontaneous oxygen evolutions. Therefore, our proposed functional additives instruct the designing aspect of additives to protect the Ni-rich cathodes. Consequently, we provided an effective procedure to overcome the most significant obstacle
The energy generators for human activities, which converts human-induced energies into electricity, is emerging as a next-generation energy harvester for various applications, such as wireless sensors and Internet of Things (IoT) consisting of small-scale elements that are difficult to be integrated with the battery. Previous studies have primarily focused on improving energy generation efficiency of devices through simply merging various energy harvesters with different mechanisms. However, optimizing energy harvesting performance that are diversified depending on the time scale of external stimuli has not been much explored, although it is one of the most important task for practical applications. In this study, the dual energy generator consisting of the tiled arrangement of PDMS and Bismuth telluride is proposed as the efficient energy harvester using thermoelectric–triboelectric mechanisms, induced by the mechanical contact of human skin, and design optimization strategies are suggested according to the input stimuli frequency (0.5–2.5 Hz) and temperature gradient, which is determined by the input variables in operating environment.

To fabricate the dual energy generator, Ag electrode for triboelectricity is deposited on a poly(ethyleneterephthalate) (PET) substrate by a sputtering method, while bismuth telluride tiles involving P-N junctions are attached for thermoelectricity. The empty spaces between tiles are filled with PDMS which acts as a separating and guiding layer for thermoelectric components and transaction of charge carries, respectively.

Depending on the frequency at which human skin contacts the device surface, complex heat transfer of convection and conduction occurs by body temperature, and it leads to various patterns of thermal saturation and temperature distribution. PDMS layer serves both as a triboelectric layer in single electrode mode and an insulation layer that maintains the thermal gradient among bismuth telluride. Interfacing thermoelectric materials with PDMS also increases the amount of generated triboelectricity due to their dielectric properties, leading to feature-size dependent triboelectric energies. The hybrid energy harvester exhibits dominantly triboelectric energy when the touch motion exhibits high frequency. In the opposite case, thermoelectric power dominates the average power due to its continuous power generation.

We establish balanced design guidelines based on this simple rationale, providing detailed analyses of the heat transport properties upon human touch and the optimization strategies for the hybrid energy harvesters. These results outperform the simple merge of hybrid energy harvesters and can be widely applicable to wireless sensors and IoT technologies where human touch occurs environmentally.

Polymeric binder has turned out to be very critical for stable operation of high capacity battery electrodes including silicon (Si) anodes, as the binder could stabilize the electrode films even during the large volume change of active materials. In this talk, I will present novel binder designs focusing on supramolecular chemistries targeting high capacity battery materials represented by silicon. Such binder designs include 1) the use of mussel-inspired catechol functional group, 2) multi-dimensional cross-linkable hydrogen bonding network, 3) self-healing polymer network, 4) host-guest interaction network, and finally 5) elastic binder network incorporating molecular machines. The series of these investigations suggest the usefulness of noncovalent polymer interactions and the future role of supramolecular chemistry in the binder development. The same design principles were also applied to Li metal electrodes, with high elasticity being proved as a unique functionality.

The development of solid-state batteries has encountered a number of problems due to the complex interfacial
contact conditions between Li metal and solid electrolytes (SE), where high interface resistance can limit Li ion transport and where dendrite penetration can lead to cell failure. Recent experiments have shown that applying a stack pressure can ameliorate these problems. To understand quantitatively the relationship between pressure, Li microstructure, and the Li-SE interface resistance, we have developed a 3D, time-dependent, and multi-scale contact model for describing the Li-SE interface evolution under a stack pressure. Our simulation considers the surface roughness of the Li and the SE, Li elastoplasticity, Li creep, and the Li metal plating/stripping process. Our results show that the Li-SE projected contact area does not depend only on the stack pressure; instead, it depends primarily on the ratio between stack pressure and Li yield strength, which has been reported to depend on the scale of the Li microstructure and on the presence of Li impurities. Contact elastoplasticity is related to the ratio between the Li yield strength and surface roughness, which is revealed to play a key role in the evolution of Li dendrites and voids. During charge/discharge, there is a competition between Li plating/stripping and creep, where the latter gradually results in a more conformal Li-SE contact and a more homogeneous contact stress field. However, the surfaces do not become conformal as long as there is any charging or discharging, since newly-deposited and newly-stripped Li occurs only at contact points. Simultaneous fitting to very recent experiments from two different research groups requires an effective yield strength of the Li used in those experiments of 16 ± 2 MPa. We suggest that the preferred stack pressure is between 20 and 50 MPa, in order to maintain a relatively small interface resistance and stable stripping without void formation, while limiting material damage and fracture.

Demonstration of the Nanosize Effect of Carbon Nanomaterials on the Dehydrogenation Temperature of Ammonia Borane
Soon Hyeong So; Seoul National University, Korea (the Republic of)

Ammonia borane (AB, NH₃BH₃) is a highly promising hydrogen storage material, but, its high dehydrogenation temperature hinders its wider use in practice. The infiltration of AB into the pores of porous materials can lower the dehydrogenation temperature by what is known as the nanoconfinement effect. Nonetheless, it is unclear as to whether this phenomenon stems from a catalytic effect or the nanosize effect. In this work, carbon nanomaterials with an uniform pore size and with inertness to AB were chosen as nanoscaffolds without catalytic sites to control the particle size of AB. It is proved experimentally that the dehydrogenation temperature from AB is inversely proportional to the reciprocal of the particle size, which means that the nanoconfinement effect can be caused solely by the nanosize effect without a catalytic effect.

EN05.05.02
Unusual Trends in the Enhanced Ce³⁺ Surface Concentration in Ceria-Zirconia Catalyst Materials and Its Relation with the Catalytic Activity
Weizi Yuan¹, Qing Ma², Yangang Liang³, Hao Yong⁴, Michael J. Bedzyk¹, Ichiro Takeuchi³ and Sossina M. Haile¹; ¹Northwestern University, United States; ²DND-CAT, Northwestern Synchrotron Research Center at the Advanced Photon Source, United States; ³University of Maryland, United States; ⁴Chinese Academy of Sciences, China

Ceria and ceria-zirconia solid solutions are important catalytic materials, either serving directly as catalysts themselves or serving as supports for metal nanoparticle catalysts. On the basis of extensive studies of these materials, there is a growing consensus that the catalytic activity correlates with the concentration of reduced Ce³⁺ species. However, the extent of reduction at the surfaces of these oxides, where catalysis occurs, is largely unknown. To address this gap, we employ angle-resolved X-ray Absorption Near Edge Spectroscopy (XANES) to quantify, under technologically relevant conditions, the Ce³⁺ concentration in the surface (2-3 nm) and bulk regions of well-defined ceria-zirconia films. Under all measurement conditions, we find an extraordinary level of surface enhancement of the Ce³⁺ concentration in the surface regions of the films, relative to that in the bulk. Moreover,
although the Ce$^{3+}$ concentration generally increases in the bulk with increasing Zr concentration, the opposite is true in the surface regions, although the surface enhancement remains substantial. Such behavior is entirely unexpected. On the other hand, we measured the relevant surface reaction constant of Zr doped and undoped ceria using electrical conductivity relaxation method (ECR), the result of which shows that adding Zr slows down the reaction by more than one order of magnitude. This suggests that high Zr concentration, which is desirable for increasing thermal stability and bulk oxygen storage capacity, may be detrimental in terms of area-specific catalytic reaction rates.

EN05.05.03
Electric Field Dependent Ionic Transport in Passive Corundum Al$_2$O$_3$ from DFT—Application to Localized Corrosion
Aditya Sundar and Liang Qi; University of Michigan, United States

Thin passive oxides (5-10 nm) such as corundum play crucial roles in several technologies including corrosion inhibition in metals, solid electrolyte interfaces in batteries, gate oxides in microelectronics etc. While these oxides are chemically and electronically inert under normal operational conditions, exposure to high anisotropic electric fields can significantly accelerate ionic transport in such oxide films. One particular example is localized corrosion of metallic Al, Cr surfaces, where passive oxides Al$_2$O$_3$, Cr$_2$O$_3$ are known to locally disintegrate in the presence of corroding agents such as halide electrolytes. According to the well-known point defect model, the diffusion flux of ionic species play important roles in determining the rates of localized corrosion, but the underlying mechanisms of ionic diffusion under electrochemical conditions are not clearly understood at the atomic level. In this work, we compute the effect of electric fields (0-10 MV/cm) on the migration barrier of Al$^{3+}$ and O$^{2-}$ ions in hexagonal Al$_2$O$_3$. The migration barriers are then integrated with a lattice kinetic Monte Carlo simulation to compute average diffusion fluxes at different temperatures. Calculations of Al$^{3+}$ migration barriers in the absence of electric field reveal the diffusivity of Al$^{3+}$ to be 10$^{-26}$ cm$^2$/s at 300 K. This value is too small to contribute to localized corrosion behavior at room temperature. These zero field barriers are computed using the climbing image nudged elastic band method. Further calculations are performed by computing the ground state of the previously generated replicas (for CI-NEB) under homogeneous potential gradients.
An electric field with magnitude up to 10 MV/cm (measured in corrosive environments) is applied perpendicular to the basal plane in Al$_2$O$_3$. The energy barriers are found to be asymmetric; favouring Al$^{3+}$ hopping in the direction of the electric field.

EN05.05.04
A Core-Shell Structured Nanocarbon as an Anode Material for Sustainable Microbial Fuel Cells
Yu-Chen Liu1, Yu-Hsuan Hung1, Tzu-Yin Liu1, Chia-Liang Sun2 and Han-Yi Chen1; 1National Tsing Hua University, Taiwan; 2Chang Gung University, Taiwan

In recent years, energy crisis has become one of the most urgent issues that people try to deal with. Microbial fuel cell (MFC) is an environmentally friendly, sustainable technology that converts chemical energy to electricity directly. Biofilms attached on the anode oxidize organic matters during metabolism and produce electrons and protons. Since MFCs can generate electricity and achieve wastewater treatment simultaneously, this novel technology is regarded as a promising solution for increasing energy needs. Although MFCs have high potential for power generation, low power density is the major problem that limits MFCs’ application. Anode materials of MFCs are generally recognized as a key factor for electricity generation, which can directly affect biofilm formation and charge transfer efficiency. Therefore, modifications on anode materials have been widely investigated to improve MFCs’ performances.

In our work, a core-shell structured carbon nanotube (CNT)@graphene oxide nanoribbon (GONR) prepared through a simple unzipping process was proposed as the anode material for MFCs. First of all, the microstructures of CNT@GONR anodes are characterized by scanning electron microscopy, transmission electron microscope, Brunauer–Emmett–Teller method. Secondly, X-ray photoelectron spectroscopy, X-ray diffraction, and Raman spectroscopy are used to analyze elemental composition. Furthermore, the electrochemical properties of the MFCs have been investigated by linear sweep voltammetry, cyclic voltammetry, and electrochemical impedance spectroscopy in our study. CNT@GONR provides large specific surface area, high conductivity, and high electron transfer ability that can improve the power output of MFCs significantly. With comparison to the pure CNT anode, the devices with CNT@GONR anodes performed higher power density (more than 3 times), demonstrating its great
potential for enhancing the performances of MFCs.

EN05.05.05
High Catalytic Activity towards ORR on Iron/Carbon Nanostructures in Fuel Cells for Space Applications
Armando Pena-Duarte1, S.H. Vijapur2, T.D. Hall2, S. Snyder2, E.J. Taylor2, Jeffrey Sweterlitsch1 and Carlos R. Cabrera2; 1University of Puerto Rico, United States; 2Faraday Technology Inc, United States; 3NASA/Johnson Space Center, United States

Fuel cells are promising candidates for clean energy conversion for terrestrial and space applications such as human space travels, which require several technological developments that support the energy-efficient production and preservation of closed systems in microgravity spacecraft environments [1]. The overpotential required for the Oxygen Reduction Reaction (ORR) is the main electrochemical factor that diminish practical application of fuel cells [2]. ORR in aqueous solutions occurs mainly by two pathways: the direct four-electron reduction pathway from O2 to H2O, and the two-electron reduction pathway from O2 to hydrogen peroxide (H2O2). In fuel cell processes, the four-electron direct reaction is highly preferred. The two-electron reduction pathway is used in industry for H2O2 production [3]. Carbon nanostructures (Nanocarbons), such as Vulcan and carbon nano-onions (CNOs), have been previously used as catalyst due to high stability and surface area, high electrical conductivity, and mesoporous structure. Studies have revealed that carbon nanostructures and metal-carbon structures show catalytic activity in ORR [5,6]. Rotating disk slurry electrodeposition technique (RoDSE), as electrodeposition process without high temperatures, hazardous compounds, and nor energetic procedures, has been used to deposit metal nanoparticles on carbon to prepare a hybrid catalyst in powder form, [7]. Accordingly, in order to evaluate the ORR essential role in fuel cells in microgravity conditions and space applications, iron nanoparticles supported on Nanocarbons (FeNanocarbons) were synthesized and characterized by RoDSE. The structural properties of the FeNanocarbons were investigated using X-ray diffraction, Raman spectroscopy, scanning electron microscopy, induced coupled plasma, and X-ray photoelectron spectroscopy. FeNanocarbons electrochemical characterization revealed higher performance than Nanocarbons, due to Fe nanoparticle enhances the electronic conductivity and specific capacitance. An analysis of the rotating disk electrode (RDE) technique data was done to evaluate the ORR kinetics, including n-values which are related to the mechanism of oxidation, at the FeNanocarbons, using the Koutechy-Levich (K-L) equation. ORR over FeNanocarbons and Nanocarbons was evaluated in O2 saturated 0.1 M KOH, by a scan rate of 10 mV/s at different rotation rates: 800, 1200, 1600, 2000, and 2400 rpm. Initial fuel cell tests at 6V utilizing oxygen and RO water, showed that Fe/Nanocarbons and Nanocarbons can generate 0.055 and 0.025 w/w% peroxide concentration, respectively. The system output current was 0.38 amps for Fe/Nanocarbons and 0.25 amps for Nanocarbons. These results suggested that Nanocarbons performs high selectivity toward a two-electron pathway reduction process, whereas Fe/Nanocarbons catalyzes a four-electron route. Therefore, our approach would be promising to control of four- or two-electrons route kinetics of ORR in fuel cells for space technologies, by the nanocarbon source and metal-nanocarbon configurations. EN05.05.06
Activation of Solid-Oxide Fuel Cell Cathode by Reversing Dopant Segregation with Anodic Polarization
Dongha Kim and Bilge Yildiz; Massachusetts Institute of Technology, United States

Perovskite oxides (ABO3) are considered key players in clean energy conversion applications, including solid oxide fuel/electrolysis cells (SOFC/EC) and solar-to-fuel conversion. However, most of the state-of-the-art SOFC materials, such as (La,Sr)MnO3 (LSM) and (La,Sr)CoO3 (LSC), suffer from degradation of surface chemistry and oxygen exchange kinetics at elevated temperatures, which limit their long-term application. This degradation is primarily because of Sr segregation and concomitant formation of SrO-like insulating phases at the surface which block the electron transfer and oxygen exchange pathways[1,2]. The formation of inactive surface oxide phase therefore leads to a severe drop in oxygen reduction reaction (ORR) kinetics.
Numerous previous studies observed that applying cathodic polarization induced significant increase in oxygen exchange kinetics at the LSM surface by up to 50-fold. In virtue of in-situ X-ray techniques, it was shown that cathodic polarization actually suppressed Sr segregation and removed the SrO-like secondary phases at the surface[3]. However, several previous studies go against or obscure this observation. For example, a number of previous studies observed that cathodic polarization rather promoted Sr segregation instead of suppressing it, which contradict the observed increase in cathode performance during the activation process[4]. Also, other possible origins of activation process that are also induced under cathodic polarization cannot be simply excluded, such as the formation of oxygen vacancies or extension of the active area by spreading of Mn(II) onto the electrolyte surface. To elucidate if dopant segregation indeed contributes significantly to the activation process, it is important to first understand how polarization affects the dopant segregation behavior of perovskite oxides. Recent study by our group revealed that the segregation behavior of La0.8D0.2MnO3 (D=dopant) can be explained by the sum of two driving forces; electrostatic (E_{elec}) and elastic energy (E_{ela})[5]. We observed that these two driving forces change with electrical polarization oppositely to each other; E_{elec} decreased with polarization while E_{ela} increased with polarization. The convolution of these two driving forces therefore makes a valley-shaped segregation graph. In case of La0.8Ca0.2MnO3 (LCM), however, the contribution from E_{ela} is negligible due to the negligible size misfit between Ca and La, thus showing monotonically decreasing segregation graph; the higher anodic polarization, the less segregation.

Inspired by the segregation graph of LCM, we studied if applying anodic polarization could remove the dopant oxides at the surface of LCM and if this could consequently activate the surface oxygen exchange kinetics of LCM. By using X-ray photoelectron spectroscopy (XPS), we show that insulating dopant oxide at LCM thin film can actually be removed with anodic polarization and this process is high controllable by following its segregation graph. In-situ electrochemical impedance spectroscopy (EIS) shows that applying anodic polarization for a short time reactivates the initially degraded surface of LCM by removing dopant oxide at the surface. This activation process is distinguished from the previous reports on the activation of LSM in that the process is induced under anodic polarization instead of cathodic one, thus confirming the bipolarity of the activation process. By investigating the kinetics of activation process in combination with X-ray absorption spectroscopy (XAS), we propose a new mechanism behind this exotic activation process under anodic polarization.

EN05.05.07
Surface Modification of Ce(Mn, Fe)O2 / La(Sr)Fe(Mn)O3 Ceramic Anode for Propane Fueled Solid Oxide Fuel Cells Minkyu Kim, Young Wook Lee and Tae Ho Shin; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Propane, which is the main component of Liquified Petroleum Gas (LPG), is commonly used as a fuel for internal combustion engines (ICEs), portable stoves and residential heaters because of its high volumetric energy density and simplicity for storage and transportation in a liquid state. Thus, propane could be a superior candidate fuel for portable fuel cells and remote power generation applications such as an unmanned aerial vehicle (UAV). Direct utilization of this propane is one of the attractive projects in Solid Oxide Fuel Cells (SOFCs) as well application due to its high energy conversion efficiencies and the possibility for simplification of the systems. However, the use of propane directly has been limited due to several challenging issues such as low anode activity and carbon coke. We previously reported Ce(Mn, Fe)O2 (CMF) and La(Sr)Fe(Mn)O3 (LSFM), oxidation-tolerant oxide anode for SOFC with reasonably high performance and good tolerance to coking, even when using dry propane as a fuel.

In this study, to enhance catalytic performance and electron conductivity of previous oxide anodes, two ways of surface modification of these oxide anodes were investigated. First, a composite oxide of CMF-LSFM (LSFM@CMF) with a nano-composite particle structure was prepared by a wet process. Nano-sized CMF successfully deposited on LSFM backbones and it was found that surface activity of this composite oxide was much improved compared to simply mixed one. Remarkably high maximum power density of 0.76 Wcm⁻² and 1.24 Wcm⁻² was achieved at 800 °C for hydrogen and propane as a fuel. Secondly, we evaluated the surface modification of previous ceramic anode with various transition metal (Ni, Co, Fe, Cu, Ru, Pd), prepared by infiltration method. In particular, Co infiltrated CMF (CMF-Co) and LSFM (LSFM-Co) shows fairly good maximum power density of
EN05.05.08
Activity and Selectivity of Electrochemical CO2 Reduction at High Temperature—A First-Principles Study
Jianguo Yu, Yipeng Gao, Hanping Ding, Lucun Wang, Wei Wu, Wenjuan Bian and Dong Ding; Idaho National Laboratory, United States

It has maintained an extensive interest in developing advanced direct electrochemical reduction of CO2 into value-added fuels and specialty chemicals using renewable energy as an input. However, its application is still constrained partly due to chemomechanical and interfacial challenges related to activity and selectivity toward the particular product of interest. Detailed ab initio molecular dynamics simulations are invaluable in complementing the experimental investigations to unravelling important aspects of the electrochemical reduction reaction mechanisms for various type of catalysts. Here, we present advances in the understanding of reactivity and selectivity in the electrocatalysis of converting CO2 into methanol using density functional theory and thermodynamics. We will also discuss the role of protons and electrons transfer, the effect of doping and oxidation, and possible processes through different surface-bound reaction intermediates in order to steer catalyst selectivity among the vast number of possible carbon-based products.

EN05.05.09
A Unique Encapsulation of Insoluble Powders into Nanofibers for Electrode Composites
Hiep Pham and Jonghyun Park; Missouri University of Science and Technology, United States

Lead (Pb)-embedded polyacrylonitrile-based carbon nanofiber (PAN-CNF) anodes for lithium-ion batteries were prepared via the electrospinning method. PAN is a well-known polymer precursor to prepare CNF that has demonstrated high electrical conductivity and cycling stability over numerous cycles. The use of lead-based anodes with high amounts of carbon has been shown to improve the cycling performance of batteries through increased capacity retention and cycling stability. Despite this, encapsulation of Pb directly into a PAN-based electrospinning solution is not feasible due to the incompatibility of Pb solutions with PAN. In this work, we report the first demonstration of Pb encapsulated in PAN-CNF as anode materials and elucidate the mechanism which allows Pb to be indirectly embedded into PAN-CNF to yield significant enhancement to the specific capacity and cyclability of lithium-ion batteries.

SESSION EN05.06: Electrolytes and Interfaces I

All-Solid-State Batteries Based on Closo-Borate Electrolytes
Léo Duchêne, Ryo Asakura, Seyedhosein Payandeh, Ruben-Simon Kühnel, Arndt Remhof and Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Closo-borates represent a promising but yet under-explored alternative class of electrolytes for all-solid-state batteries. We recently reported ionic conductivities of 1 mS/cm and an electrochemical stability window of 3 V at room temperature for Na4(B12H12)(B10H10).[1] The mixed-anion configuration stabilizes the ion-conducting high-temperature phase at room temperature.[2] We further demonstrated stable cycling for a 3 V class all-solid-state battery based on this electrolyte consisting of a sodium metal anode and a NaCrO2 cathode.[3] The cathode composite can be assembled by simple cold pressing, but cycling performance is enhanced through a preliminary solvent-based impregnation step of the cathode particles by a thin electrolyte coating. This coating guarantees intimate contact between cathode particles and electrolyte resulting in reversible and stable cycling with 85%
capacity retention after 250 cycles at C/5. We recently extended this approach by demonstrating that closo-borates can also be infiltrated into porous electrodes, where they crystallize into their highly conductive phase.[4] I will further discuss routes to translate these results to lithium analogues and our efforts to establish low-cost synthesis routes for these non-toxic materials.[5] Our results demonstrate that owing to their physical properties and processability, closo-borate-based electrolytes could play a significant role in the development of a competitive all-solid-state battery technology.

9:00 AM *EN05.06.02
Lithium Thiophosphate Based Solid Electrolytes and Cathode Interfaces Jagjit Nanda; Oak Ridge National Laboratory, United States

Advances in solid electrolytes (SEs) with superionic conductivity and stabilized electrode-electrolyte interfaces are key enablers for all solid-state batteries (SSBs) to meet the energy density and cost targets for next generation batteries for electric vehicles. Compared to their oxide counterparts, sulfide- and thiophosphate-based electrolytes offer several key advantages, including (i) exceptionally high ionic conductivities up to 10⁻² S/cm (comparable to nonaqueous liquid electrolytes) as recently reported for Li₁₀GeP₂S₁₂ and Li₉.₅₄Si₁.₇₄P₁.₄₄S₁₇Cl₀.₃ (2), (ii) availability of low temperature and inexpensive synthesis routes to produce glass, glass-ceramic, and crystalline structures, and (iii) soft mechanical properties, which facilitates material processing. Among their drawbacks, sulfides have a narrow electrochemical stability window and hence limited stability against lithium metal and cathodes. They also suffer from poor chemical stability and are highly sensitive to moisture. Despite rapid progress in achieving higher bulk ionic conductivities of SEs the rate capability of SSB’s is affected by interfacial side reactions that increase the cell resistance during electrochemical cycling. Computational modeling based on density functional theory (DFT) predicts narrow electrochemical stability windows (typically 1.6-2.5 V vs. Li/Li⁺) for most thiophosphate-based compositions. Due to their narrow thermodynamic stability range, most SEs rely on formation of kinetically stabilized interfacial layers with reasonable ionic conductivity and very low electronic conductivity. In addition to the thermodynamical instability, significant mechanical stresses develop in SE due to (i) volume changes of the electrode material during repeated lithiation (delithiation) and (ii) interface roughening from side reactions upon extended cycling. This “chemo-mechanical effect” results in poor interfacial contact between the SE and cathode. The talk will review recent progress on synthesis and characterization of new thiophosphate based cathodes for SSB based on catenation reaction with sulfur to the ionically conductive Li₃PS₄ framework. In addition various approaches to address the high interfacial resistance between the thiophosphate SE and cathode interfaces will be presented.

Developing All-Solid-State Batteries with Organic Electrode Materials Yan Yao; University of Houston, United States

Attaining stable cathode-solid electrolyte interfaces is a great challenge in sulfide-based all-solid-state sodium batteries (ASSSBs). Currently, these ASSSBs experience low specific energy and poor cycling performance due to the interfacial incompatibility between cathode materials and sulfide electrolytes. A resistive layer forms at the interface when cathode is charged above the anodic stability potential of sulfide electrolyte. We have demonstrated some of the longest-cycling cathode materials and Na anodes through the control of interfacial structure and electrolyte decomposition. For instance, we demonstrated an organic cathode material, pyrene-4,5,9,10-tetraone (PTO), that induces reversible cathode-electrolyte interfacial resistance evolution during cycling as the result of the
reversible conversion between the superionic conductor \( \text{Na}_3\text{PS}_4 \) and the resistive oxidation products \( \text{Na}_4\text{P}_2\text{S}_{10}/\text{Na}_2\text{P}_2\text{S}_6 \). Structural and mechanical analyses further showed that a low-modulus cathode material like PTO (Young’s modulus = 4.2 ± 0.2 GPa) can effectively accommodate interfacial stress and maintain intimate interfacial contact with solid electrolytes. The reversible electrolyte decomposition, revealed by time-of-flight secondary ion mass spectrometry (ToF-SIMS), the consistently intimate interfacial contact, visualized by focused ion beam-scanning electron microscopy (FIB-SEM), and the soft nature of cathode material, characterized by nanoindentation, are all first-time reports in the field of solid-state batteries, and they have collectively led to a high specific energy (587 Wh kg\(^{-1}\)) at the active-material level and an 89% capacity retention over 500 cycles, a record cycling stability among all-solid-state Na batteries.

Universal Chemomechanical Design Rules for Solid-Ion Conductors to Prevent Dendrite Formation in Lithium Metal Batteries Victor Venturi\(^1\), Zeeshan Ahmad\(^1\), Venkatasubramanian Viswanathan\(^1\), Brett A. Helms\(^2\) and Chengyin Fu\(^3\); \(^1\)Carnegie Mellon University, United States; \(^2\)Lawrence Berkeley National Laboratory, United States; \(^3\)Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Lithium metal anodes could enable the next generation of high energy density lithium ion batteries required for increased adoption of electric vehicles. The formation of dendrites on charge/discharge cycles, however, is a safety hazard that hinders their commercialization. The use of solid-ion conductors (SICs) as electrolytes may allow for stable, dendrite-free, lithium electrodeposition, provided the properties of the electrode-electrolyte interface obey certain criteria related to the mechanical and chemical properties [1, 2]. Optimal SIC candidates must have properties that are either pressure-driven dendrite-blocking, or density-driven dendrite-suppressing, but not both. This division between two regimes of stable electrodeposition stems from the opposite influences of the SIC shear modulus and those of the partial molar volume of Li\(^+\) relative to those of the lithium anode. In this work, we use density functional theory (DFT) simulations to investigate a SIC soft polymer composite – LiF@PIM hybrid – in the dendrite-suppressing regime. Lithium ion motion through this material was studied using the nudged elastic band (NEB) method on a LiF surface. The activation energy for lithium movement computed in this manner shows good agreement with experimental results. The molar volume of Li\(^+\) in the composite, which is experimentally challenging to obtain, was determined using Bader charge analysis. The effects that functional groups representative of the PIM polymer matrix have on our calculated values were also investigated. Our results confirm the electrodeposition stability of this composite, which has been demonstrated to extend cell cycle-life (>300 cycles against ~100 cycles for control cells) [3]. Such nanostructured composites may be integrated into the battery manufacturing and provide a path forward for commercialization of metal anode batteries.

Interfacial Chemistry of Carbonaceous Anodes in Alkali Metal Ion Batteries Yaxiang Lu, Hong Li and Yong-Sheng Hu; Chinese Academy of Sciences, China

Alkali metal ion batteries (AMIBs), which employ alkali metal ions (AMIs) as charge carries, have been intensively investigated for storing the electricity from renewable energy due to the simple working principle and high energy efficiency. Among all available anode candidates, carbonaceous materials show the superior overall performance and low production cost, where the formed solid electrolyte interface (SEI) on the carbonaceous anode is essential to the long-term cycling life of AMIBs. Even though the presence of the anode SEI is critical, its formation and growth together with the influence on the battery performance are less understanding, in particular, when different AMIs are stored. In this work we investigated the interfacial chemistry by choosing different parameters including various AMIs, type of carbonaceous anode, electrolyte composition and concentration as well as electrochemical condition, attempting to understand the formation and functionality of SEI on the initial capacity loss, rate capability and cycling stability of AMIBs. The understanding gained potentially provides reference for the optimization of electrode/electrolyte interface and artificial design of SEI on the carbon anode for AMIBs.

Resolving Local Dynamics and Grain Boundary Resistance in Glass-Ceramic Solid-State Electrolyte Jiangyu Li; Shenzhen Institutes of Advanced Technology, China

Glass-ceramic electrolytes are promising for all-solid-state batteries, yet their enhanced ionic conductivity is not well understood. We investigate the structural difference between ceramic and glass-ceramic Li$_{1.3}$Al$_{0.3}$Ti$_{1.7}$(PO$_4$)$_3$ tuned by boron, which is found to enhance conductivities of glass-ceramic by one order of magnitude, yet reduces that of ceramics. Raman and Magic Angle Spinning Nuclear Magnetic Resonance spectra indicate boron are primarily contained in glass phase, while electron energy-loss spectroscopy and high-resolution transmission electron microscopy reveal inhomogeneous distribution of boron, glassifying and relaxing its grain boundaries. This substantially reduces interfacial resistance at grain boundaries with little effect on bulk resistance, which is further supported by spatial and spectrscopic electrochemical strain microscopy that resolves the local dynamics. The grain boundary resistance of ceramics, on the hand, is increased by boron. We thus establish lower interfacial resistance at glassified grain boundaries is responsible for higher conductivity in glass-ceramics, while boron can relax their grain boundaries even further.

Sulfide Solid Electrolyte—Core-Shell Structure and Interfacial Coatings Luhan Ye, William Fitzhugh, Fan Wu and Xin Li; Harvard University, United States

Solid electrolyte is the key component for solid-state batteries. Among different electrolytes, ceramic sulfide electrolyte shows the highest ionic conductivity. However, narrow intrinsic electrochemical stability window of the electrolyte and interfacial reactions between electrolytes and electrodes remain a problem for the application in solid state batteries. Here we show our unique understanding and strategies to improve electrochemical window and interfacial stability of sulfide electrolyte. A core-shell structured Li$_{9.54}$Si$_{1.74}$P$_{1.44}$S$_{11.7}$Cl$_{0.3}$ (LSPS-Cl) and Li$_{10}$GeP$_2$S$_{12}$ (LGPS) were designed, synthesized and tested. The sulfide electrolytes with core-shell structure show improved stability windows in both electrochemical test and theoretical simulation. The interfacial reaction was alleviated by applying coating materials to separate the sulfide electrolyte from the electrode materials. A high-throughput screening from computational simulation helps find functional coating materials, and the stability between coating materials and electrolyte/electrode materials were demonstrated by experiments. All-solid-state batteries with LiCoO$_2$ or LiNi$_{0.5}$Mn$_{1.5}$O$_2$ high voltage cathode and Li$_{1.3}$Ti$_3$O$_{12}$ or lithium metal anode were demonstrated with good cycling performance based on our sulfide electrolytes.

Experimental Assessment of the Practical Electrochemical Stability of Lithium Thiophosphate Solid Electrolytes in Li-S Cells Georg F. Dewald, Saneyuki Ohno, Juergen Janek and Wolfgang Zeier; Justus-Liebig-Universität Giessen, Germany

Lithium sulfur (Li-S) cells are promising candidates for high energy density battery systems. However, employing conventional liquid electrolytes leads to continuous degradation in Li-S batteries because of soluble reaction intermediates.[1] Today, ongoing developments in the field of solid electrolytes are drawing attention to all-solid-
state Li-S cells in which the so-called polysulfide shuttle is physically prevented by a solid separator.[2] Although modern thiophosphate electrolytes provide promising ionic conductivities, degradation reactions at the electrode interfaces due to their limited thermodynamic stability represent a major bottleneck for application. Experimentally, stabilities of thiophosphates up to 5 V vs. Li/Li⁺ are often claimed from cyclic voltammetry (CV) using planar working electrodes. Contradictorily, redox activity of electrolytes was observed at lower potentials in solid-state batteries.[4,5]

In this presentation, we will report how employing a high surface area carbon-electrolyte composite working electrode in a CV setup helps to visualize the practical stability limit of state-of-the-art solid electrolytes.[6] As carbon is a widely used additive in electrodes for solid-state batteries, this approach allows information on the practical stability of the electrolyte of interest. Furthermore, by combining CV and X-ray photoelectron spectroscopy, an insight into the underlying chemistry, i.e. the oxidation of thiophosphate building units, is given. Hereafter, we show the decomposition products to be redox active. Due to the partial reversible cyclability of the oxidized species, the decomposed electrolyte acts as pseudo-active material adding additional cell capacity while degrading the long term cell performance due to its highly resistive nature.

In a solid-state battery, the overall performance is governed by the evolving interphase between carbon and thiophosphate. By restricting the cycling window, the capacity retention can be increased significantly.

**Operando X-Ray Tomography of the Li/β-Li3PS4 Solid-State Electrolyte Interface at the Micro- and Nano-Scale**
Natalie Seitzman¹, Johanna N. Weker², Mowafak Al-Jassim³ and Svitlana Pylypenko¹; ¹Colorado School of Mines, United States; ²SLAC National Accelerator Laboratory, United States; ³National Renewable Energy Laboratory, United States

An optimally engineered lithium metal/solid electrolyte interface promises all-solid battery technologies that reap the capacitive benefits of Li metal anodes while mechanically resisting the Li interface evolution and thus prolonging lifetime. Additionally, such systems offer greater safety than chemistries that include flammable liquid electrolytes. However, detrimental interface evolution and short-circuit inducing Li protrusions are observed in solid state batteries despite theoretical mechanical resistance.¹,² There is debate as to whether these protrusions nucleate at the Li anode or within the ceramic electrolyte as well as the most crucial factors that affect these protrusions. These factors include electrolyte density, pre-existing defects, anode/electrolyte interfacial contact, and imperfect electronic insulation within the electrolyte.³ Understanding the influence of these variables is greatly enhanced by directly imaging the interior of the ceramic material at multiple scales in conjunction with electrochemical experiments and complementary chemical analyses.

In this talk, *operando* X-ray micro-tomography addresses the contribution of electrolyte density and defects, interfacial contact, and conductivity to structural changes at the interface between Li metal and β-Li3PS4 (LPS) ceramic electrolyte with sub-micron resolution. Cells of Li, LPS, and a blocking contact are constructed and studied during cycling at 200 psi and 70°C. Because electrolyte density and initial defects depend on the composition and synthesis of the ceramic conductor, two syntheses of LPS with different particle sizes are compared. Including pressure and temperature as variables addresses the remaining factors of interest as pressure is a key parameter in the quality and stability of interfacial contact while temperature affects both the ionic and electronic conductivity of the ceramic.

In our previous work, image analysis of micro-tomography data has identified sites of Li microstructure growth⁴ while the present work now isolates variable-dependent trends such as pressure-dependent void formation in the Li anode. Additionally, X-ray absorption spectroscopy at the phosphorus and sulfur K-edges tracks chemical changes in the LPS at the anode/electrolyte interface between pristine and cycled cells. Progress toward combining these data with *operando* transmission x-ray microscopy, which offers spatial resolution in the tens of nanometers, is also presented. Linking structural and chemical changes observed during cycling to the factors that contribute to Li evolution will guide the design of robust ceramic electrolytes with improved performance and safety.

**In Situ/Operando X-Ray Spectroscopy (XAS and RIXS) Characterization of the Interfacial Charge Transfer in Energy-Storage Materials**
Yi-Sheng Liu, Xuefei Feng and Jinghua Guo; Lawrence Berkeley National Lab, United States

X-ray spectroscopic techniques with operando capabilities offer the unique characterization in energy materials and catalysis in regards to the functionality, complexity of material architecture, chemical interactions. A particularly powerful soft x-ray technique is the resonant inelastic x-ray scattering (RIXS), which provides access to elementary excitations, such as d-d (f-f) excitations, vibrational excitations, and charge transfer effects that are critical for energy-related materials and chemical functions. Current in situ x-ray spectroscopy techniques (XAS and RIXS) have provided element-specific access to local chemical states in liquids and at solid/liquid interfaces during electrochemical reactions. The presentation will give a brief introduction on the XAS and RIXS and overview a number of the experimental studies that successfully revealed the electrochemical reactions at solid/liquid interfaces.
in real time, e.g. electrochemical interface of photocatalysis and batteries. The experimental results demonstrate that the operando soft x-ray characterization provides the unique information for understanding the real reaction mechanism. Also, an extension of this method toward simultaneous spatial- (100 nm) and time-dependent (ns and longer) RIXS probing of electronic and chemical dynamics is envisioned.

Electrochemical and Chemomechanical Effects of Charged Interfaces KSN Vikrant and Edwin Garcia; Purdue University, United States

Experimental studies aimed to understand the bottlenecks that control the transport and microstructural evolution in ionic ceramics indicate that grain boundary properties impact (positively or negatively) its macroscopic behavior. Scientific arguments to explain the ambiguous behavior in interfaces span a wide range of explanations that include the description of phenomena such as interfacial structural disorder, electrostatic phenomena, segregation of impurities and dopants, and even the appearance of glassy pockets. In this presentation, a thermodynamically consistent variational theory is presented to naturally include the effects of non-diluted segregation, dipolar and self-induced electric field effects, as well as long range, chemically induced (chemomechanical) elastic energy density contributions to the total free energy of the system. The developed model provides a rational basis to understand the stability of charge point defect distributions away from the interface and its effect on the properties and microstructural evolution of ionic polycrystalline ceramics. The theory is demonstrated on chemistries such as GDC, YSZ, and STO and validated against experimentally measured properties.

Multimodal X-Ray Characterization of Interfacial Chemistry in Li-Ion and Multi-Valent Batteries Johanna N. Weker1, Jesse Ko1 and Yang Ren1 2; 1SLAC National Accelerator Laboratory, United States; 2Weifang University, China

Solid-liquid interfaces play key roles in the degradation mechanisms of rechargeable batteries, yet they are notoriously difficult to study because they are buried and require in situ probes. Multimodal X-ray characterization spanning many relevant length scales during typical battery operation is vital in understand and overcoming the failure mechanisms of these complex and heterogenous interfaces. We will discuss our multimodal in situ approach combining information from high resolution X-ray microscopy and spectra-microscopy, micro- and nano-tomography, high resolution X-ray diffraction, and X-ray absorption spectroscopy to probe and ultimately understand the dynamics across buried interfaces in energy storage systems. Specifically, we will present our recent results in designing anode architectures to stabilize solid electrolyte interphase. We will also present recent work studying the interfacial and chemomechanical properties in multivalent ion systems.

Time-Dependent Interface Resistance between a Solid Electrolyte and an Electrode Ryo Nakayama1, Kazunori Nishio1, Daisuke Imazeki1, Naoto Nakamura1, Ryota Shimizu1 2 and Taro Hitosugi1; 1Tokyo Institute of Technology, Japan; 2PRESTO, Japan Science and Technology Agency, Japan

Solid-state lithium batteries (LBs) are promising next-generation energy storage devices due to high energy density, and long lifetime. However, in solid-state LBs, the high interface resistance (charge-transfer resistance $R_t$) between electrolyte and positive electrode hinders fast charging and discharging. Although the origin of the interface resistance is still controversial, considerable effects of the structural disorder and the space-charge layer near the interface have been pointed out.[1,2] Notably such structural disorder and space-charge layer are considered to be static factors, therefore the time-dependence of the interface resistance has never been discussed. In this study, we report time-dependent interface resistance between the solid electrolyte Li$_3$PO$_4$ (LPO) and 5 V-class positive electrode LiCo$_{0.5}$Mn$_{1.5}$O$_4$ (LCMO). To quantitatively evaluate $R_t$ of the electrolyte and electrode interface, model electrodes using (001)-oriented LCMO epitaxial thin films were fabricated, in which the electrode area, crystal structures and orientations are well-defined. The (001)-oriented LCMO epitaxial thin film on a LaNiO$_3$ epitaxial film was prepared on a Nb: SrTiO$_3$ (001) substrate by using pulsed laser deposition. Using this model electrode, we fabricated solid-state thin film LBs consisting of Li (negative electrode) on an LPO (solid electrolyte)/LCMO (positive electrode)/LaNiO$_3$ (current

Final Program 1/13/2020  607
collector) layered structure. All the processes including thin-film fabrication and electrochemical characterization were performed under high vacuum (In-vacuo process).[3]

In cyclic voltammetry, observed redox peaks at around 4.0 V and 5.3 V correspond to the Mn$^{3+}/4+$ and Co$^{3+}/4+$ redox reactions of spinel-structure LCMO. The interface resistance of the fabricated battery was quantitatively evaluated by electrochemical impedance spectroscopy, and the interface resistance at 4.0 V (13 $\Omega\text{cm}^2$) was comparable to that of the previously reported solid electrolyte electrode interface.[4] However, the interface resistance at 5.3 V was three orders of magnitude larger than that at 4.0 V, indicating that the interface resistance was rapidly increased with increase in voltage. Although the interface resistance showed hysteresis behavior during charge and discharge process, the interface resistance at 4.0 V was almost recovered from $7.4 \times 10^2 \Omega\text{cm}^2$ to its original value (12 $\Omega\text{cm}^2$) about 9.5 hours after discharge process (from 5.5 V to 3.5 V). Thus, the reversibility and time-dependence of the interfacial resistance at 4.0 V was observed after exposure to high voltage above 5 V. These results suggested that the origin of the interfacial resistance at high potential (> 5 V vs Li+/Li) was the formation of a Li depletion layer at the Li$_3$PO$_4$/LCMO interface and/or a reversible structural change at the interface.

4:45 PM EN05.07.07

*In Situ* Tracking of Chemo-Mechanical Transformations at Solid Electrolyte-Electrode Interfaces Using Advanced Synchrotron Techniques Marm Dixit and Kelsey B. Hatzell; Vanderbilt University, United States

While solid|liquid interfaces are the origin for degradation and transformation in liquid batteries, solid|solid interfaces govern transformations pathways in solid state batteries. The nature of anode|electrolyte and cathode|electrolyte effective interfacial properties (elastic, electrochemical, and morphological) govern transport, durability, and lifetime. Furthermore, the underlying electro-chemo-mechanical coupling that occurs during operation affect stability. During discharge, lithium metal is oxidized to Li$^+$ which transports through the electrolyte to the cathode. A vacancy forms at the anode surface and when the discharge rate exceeds the diffusion rate for lithium to fill this vacancy, interface morphology instabilities can occur and pores can form at the surface. Pores can lead ultimately to delamination of the anode, formation of dead lithium, and contribute to poor rate performance. At the cathode, there is a volume expansion upon discharge (i.e. intercalation). The active material in a lithium ion battery electrode undergoes volume changes during electrochemical cycling (i.e. charge and discharge) that can lead to local stress formation. This stress remains localized at the active material because the plastic binder and liquid electrolyte do not transfer stress. Herein, we demonstrate a technique that can probe both interfaces at the same time in-situ. By combining real and reciprocal space imaging and characterization techniques we can track strain at both interfaces and start to describe degradation pathways.

DFT Study on Mechanism of Oxygen Reduction Reaction on Hg-Au(111) in Acidic and Alkaline Solution **Ji Liu** and Michael Nolan; Tyndall National Institute, Ireland

Oxygen reduction reaction (ORR) is a topic of significant interest for the design of efficient and affordable catalysts for fuel cells. However, the sluggish kinetics of ORR has hindered the large-scale application of fuel cells. Platinum (Pt) is regarded as the best metal catalyst for ORR and Pt-based cathodic devices have been developed and researched for years to achieve high efficiency, long durability and stability. In recent years, Pt-free cathode materials such as palladium (Pd) have also attracted much attention and it is worth examining other metals that can promote ORR. In this contribution, we have investigated the mechanism of ORR on Hg doped Au(111) by first principles calculations and experimental work. We have considered the ORR reactions in both acid and alkaline solutions and calculated the adsorption energies of key intermediates including atomic O, O$_2$, OOH, OH. The possible reaction mechanisms are investigated by plotting the minimum energy pathway and computing the energy barriers for each elementary step. Both the associative mechanism and dissociative mechanism are considered. The
associative mechanism includes formation of OOH; and the dissociative mechanism includes the direct dissociation of O$_2$ into two atomic O. Along the pathway, the reactant and the product differ in acidic media and alkaline solution.

In addition to the bare surface, a H$_2$O-covered Hg-Au(111) surface is adopted to accurately simulate the mechanism of ORR. With the consideration of water interaction, a new mechanism called H$_2$O-mediated mechanism has been recently proposed by Liu and co-workers.\textsuperscript{1,2} Previous studies of ORR on Pt(111) in alkaline solution has proposed that the H$_2$O-mediated mechanism is more competitive than the dissociative and associative mechanisms. Here, based on previous experimental observation and DFT studies, one layer of ice-like bilayer structure of water layer is placed on top of Hg-Au(111) surface. This water layer is constructed by a honeycomb ($\sqrt{3}\times\sqrt{3}$) R30 pattern with 2/3ML of water coverage, where half of the water molecules are H$_2$O and the other half have an O-H bond pointing down (H-down). The H$_2$O-mediated mechanism is investigated by plotting the reaction pathway and calculating the energy barriers in each elementary step. Finally, the potential energy diagrams of the ORR via different mechanisms are plotted and the ORR activities of pure Au and Hg-Au are compared. This work sheds light on the ORR mechanism on gold and Hg modified gold.

WO$_3$ Hybrids Promoting Electrocatalytic Oxygen Reduction Reaction Jun-Hyeong Lee, DaBin Yim, Jung-Hyun Park, Jong-Min Ju, Chanhee Choi and Jong-Ho Kim; Hanyang University, Korea (the Republic of)

The growing global energy demand continues to derive the search for sustainable energy storage and conversion techniques such as metal-air batteries and fuel cells. In these next-generation energy storage and conversion systems, the electrocatalytic oxygen redox reactions are significantly sluggish in kinetics, limiting their performance. Hence, it is of great significance to develop electrocatalysts that can effectively promote the oxygen redox reactions. Here, we report a simple solution approach for the synthesis of thin WO$_3$ nanosheets bearing Pd nanoparticles as an electrocatalyst to promote the oxygen reduction reaction (ORR) effectively. Exfoliated WS$_2$ nanosheets were oxidized to WO$_3$ in H$_2$O along with deposition of Pd nanoparticles on the nanosheet surface. The coverage of Pd nanoparticles on the WO$_3$ surface was adjusted and found to influence the ORR kinetics. As-prepared WO$_3$/Pd hybrids exhibited excellent catalytic activity and durability in ORR at basic conditions.

EN05.08.04
Atomic Structure Variation at the Surface of Cathode-Oxide for Aqueous Lithium-Ion Batteries Pilgyu Byeon\textsuperscript{1}, Hyung Bin Bae\textsuperscript{2} and Sung-Yoon Chung\textsuperscript{1}; \textsuperscript{1}Korea Advanced Institute of Science and Technology, Korea (the Republic of); \textsuperscript{2}KAIST Analysis Center, Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Understanding the surface change of electrode materials in contact with an electrolyte, at the atomic-level, is a fundamental step toward achieving better electrochemical performance of rechargeable cells. Various type of water-based aqueous solutions have been proposed as alternative electrolytes to the currently used flammable organic solvents in Li-ion batteries. However, most research on aqueous rechargeable Li-ion cells has mainly focused on the synthetic processing of materials and resulting electrochemical properties rather than in-depth atomic-scale observation at the electrode surface where the initial charge transfer and the (de)intercalation reaction take place. By using LiCoO$_2$ single crystals with a (001) surface, in this article, we demonstrate the severe Co dissolution from LiCoO$_2$ surface into an aqueous solution under an O$_2$-flow environment without any electrochemical cycling. In addition, it is directly identified via atomic-scale scanning transmission electron microscopy that Co can occupy the tetrahedral interstices. Ab initio density functional theory calculations also reveal that this tetrahedral-site occupation is stabilized when cation vacancies are simultaneously present in both Li and Co sites. In addition to demonstrating the importance of controlling of oxygen content in an electrolyte to suppress Co dissolution, the findings in this study emphasize the significant role of vacancies in atomic structure variation and its local stability in Li-intercalation oxides.
Energy crisis has become one of the world's most serious challenges, as the rapid growth of the total energy consumption. The renewable energies have been intensively explored and converted into electricity to ensure the sustainable development. The inexhaustible blue energy from the ocean is independent of season, circadian rhythm and weather.\cite{1} At the same time, triboelectric nanogenerators (TENGs) are considered as one of the most promising approaches for harvesting blue energy.\cite{2,3} Previously, most of the blue-energy-harvesting TENGs are based on the friction between solids, but the contact/friction area is only a tiny portion of the total surface due to the roughness of the surface and the inefficient contact condition.\cite{4,5} In this work, a network of liquid-solid-contact triboelectric nanogenerator (LS TENG) is fabricated to efficiently harvest the huge quantities of blue energy from ocean. Due to the sufficient contact condition of the liquid-solid interface, the energy output per cycle of LS TENG is about 48.7 times bigger than that of the solid-solid-contact triboelectric nanogenerator (SS TENG) with the same area. The buoy LS TENG can generate several sequential damping signals just by one pulse of triggering, demonstrating the maximum utilization of the vibration energy. This characteristic merit renders it available for the buoy LS TENG to collect the low-frequency energy sufficiently. The output current, transferred charge and the output voltage of the network of 18 LS TENGs are 290 μA, 16725 nC and 300 V. Additionally, the buoy LS TENG can acquire energy from different types of movements, including the up-down, shaking and rotation movements. The last but not the least, the network of buoy LS TENGs could harvest large quantities of energy, including surface wave energy and submarine current energy, to power portable electric devices or navigation systems. In this work, the electricity energy generated from the LS TENGs is stored in the capacitor to drive a wireless SOS radio frequency (RF) transmitter for ocean emergencies. This work provides a more efficient method of capturing the blue energy and expands its applications.

Achieving widespread adoption of EVs requires higher energy density and safer, cheaper batteries. The development of solid-state electrolytes to enable Li metal solid-state batteries is one approach to achieve > 350 Wh/kg and > 1200 Wh/L. However, the underpinning mechanisms that control Li metal initiation and propagation in ceramic electrolytes remain unsolved. Most of the research has focused on solid Li-solid LLZO interfaces where researchers have demonstrated > 1 mA/cm² before Li penetration occurs. However, based on our recent study we have observed that the critical current density (CCD) of a molten Li-LLZTO-Li cell is significantly higher (hundreds of mA/cm²). Current densities of this magnitude may have applications for grid storage, but more importantly it elucidates the point that the CCD can increase over a hundred-fold simply by operating at higher temperatures. While the bulk properties of LLZO, such as electronic and ionic conductivity, increase with temperature along with an increasing CCD, there is still a large step increase in CCD across the melting point of Lithium at 180°C. Thus, it is possible to dramatically increase the CCD of a solid electrolyte without changing its intrinsic properties simply by making the interface liquid-solid rather than solid-solid. We coupled our CCD data with Operando cell cycling videos showing lithium dendrite propagation observable macroscopically. We believe the results of this study can help elucidate the vexing phenomenon that allows for a molten metal to penetrate a hard and dense ceramic electrolyte. These findings can establish deeper mechanistic insight into the factors that control the maximum Li plating density in Li metal batteries using ceramic electrolytes.
EN05.08.07
Synthesis and Evaluation of Zwitterion/Oligoether Copolymers (II)—Influence of Zwitterion on Thermal Properties and Conductivity Ryoma Ota, Yuko Takeoka, Masahiro Rikukawa and Masahiro Fujita; Sophia University, Japan

Mg-ion secondary batteries have been attracting attention as a next-generation rechargeable battery. Since Mg is a divalent ion and is abundant natural resource, Mg-ion secondary batteries can be expected to realize high capacity and low cost. Research on poly(ethylene oxide) (PEO) as a solid polymer electrolyte has been energetically conducted, but it is necessary to further improve their ionic conductivity. Therefore, we focus on zwitterions. Zwitterions are substances that have cation and anion fixed in the parent molecule. Zwitterions have a high polarity. Because of its high polarity, it can be expected to enhance Mg-salt dissociation and the ionic conductivity. In this study, diblock copolymers (PEGAm-b-SPBn) (m and n denote the unit numbers) were synthesized by RAFT polymerization of an oligoether monomer (PEGMA) and a zwitterionic monomer (SPB). The introduction of SPB block is expected to improve the electrochemical properties of PEGMA-based electrolytes. A given amount of Mg-salt (magnesium (II) bis(trifluoromethylsulfonyl)amide (Mg(TFSA)2) was added to the copolymers to prepare composites. Thermal and electrochemical measurements were performed. PEGMA44-b-SPB75/Mg(TFSA)2 exhibited an ionic conductivity value of 2.3 × 10⁻⁵ S cm⁻¹ at room temperature. On the other hand, the composites of the homopolymer PEGMA22 and Mg(TFSA)2 exhibited an ion conductivity value of 6.4 × 10⁻⁸ S cm⁻¹ at room temperature. The copolymerization of zwitterion improved the ionic conductivity. In phase AFM measurements, PEGMA44-b-SPB75, which showed the highest ionic conductivity, showed gyroid structure. It is suggested that there is a correlation between the microphase separation structure and the ion conductivity. When the unit ratio of PEGMA : SPB was 1: 1.7, a higher ionic conductivity was obtained as compared with those of other unit ratios. Raman spectroscopy was performed, and the results indicated that the dissociation of the Mg-salt was enhanced in PEGMA-b-SPB/Mg(TFSA)2 compared with PEGMA/Mg(TFSA)2.

EN05.08.08
Facile Synthesis of Palladium-Core@Carbon-Shell Catalysts for Proton Exchange Membrane Fuel Cells Hyo Eun Bae1, Youngkwang Kim2, Dohyeon Lee1, Mohanraj Karuppannan3 and Oh Joong Kwon1; 1Incheon National University, Korea (the Republic of); 2Seoul National University, Korea (the Republic of)

Proton exchange membrane fuel cell (PEMFC) has been attracting great attention as an alternative energy system to the energy conversion devices based on fossil fuels due to its high efficiency, high energy density, low operating temperature, and fast start-up and shut down. However, there is an obstacle in commercializing PEMFCization due to because it uses the high price of platinum (Pt) as a catalyst for boosting electrochemical reactions such as hydrogen oxidation and oxygen reduction. Therefore, huge studies have been conducted to develop cheaper catalysts such as non-precious metal catalyst and alloy catalyst. Palladium (Pd) is one of them. In this study, we investigated the Pd nanoparticles encapsulated by carbon shell (Pd@CS) and its electrochemical properties especially durability which is needed to be improved for Pd to be applied in PEMFC instead of Pt. Pd catalyst having a nitrogen doped carbon shell was synthesized by delicately controlling the synthesis order in this study. It is well known that Pd procures are reduced without a reducing agent when it is mixed with aniline monomers. Pd forms Pd nanoparticles while aniline monomers turn into polyaniline (PANI) through oxidative polymerization. The PANI becomes a nitrogen doped carbon shell when it is carbonized with Pd nanoparticles under specific condition. Actually, we optimized the specific condition. The structure of Pd@CS was characterized through XRD, HR-TEM, and TGA and it was revealed that Pd nanoparticle has well defined carbon shell. To demonstrate the electrochemical properties of Pd@CS, typical half cell and unit cell tests were conducted. Cyclic voltammetry and linear sweep voltammetry were studied for half cell, and current-potential and current-power curves were compared with those of Pt/C in the unit cell test. For durability, we have adopted the test protocol suggested by Department of Energy (DOE) in 2016. From the durability test, it was figured out that the carbon shell supplements the weakness of Pd.

EN05.08.09
Inversely Polarized Ferroelectric Polymer Contact Electrodes for Triboelectric Generators from Identical Materials Artis Linarts, Kaspars Malnieks, Linards Lapčinskis, Māris Knite, Juris Blums and Andris Šutka; Riga Technical University, Latvia
Triboelectric nanogenerators (TENG) are intriguing energy harvesting devices that convert mechanical energy into electricity and could power small portable devices, sensor networks or charge batteries [1;2]. Although it is known that (TENG) based on polarized ferroelectric polymer films show better performance, the origin of this enhancement is not fully clear. To date, it has been accepted that enhancement is observed due to shift of the effective work function of ferroelectric polymer insulator which in turn enhance electron transfer between TENG electrodes. The present study based on measurements in TENG and in piezo-regime reveals that the enhancement is observed due to induction driven by piezoelectric charges. Furthermore, a novel piezoelectric-electrostatic generator has been constructed from inversely polarized polyvinylidene films, which exhibit higher performance than TENG for mechanical energy conversion to electricity uncovering a promising avenue for further development of mechanical energy harvesting nanogenerators.

In Situ Visualization of Ion and Thermal Transport Behavior in Electrolytes During Battery Operation by Phase-Contrast X-Ray Imaging

Daiko Takamatsu, Akio Yoneyama, Shin Yabuuchi and Jun Hayakawa; Hitachi, Ltd., Japan

Optimal operation and design of batteries, particularly lithium-ion batteries (LIBs), in high-power applications such as electric vehicles, requires knowledge of transport properties (e.g., ion transport, thermal transport, etc.) in electrolytes during battery operation. As the electrolytes used in commercial LIBs exhibit large concentration polarization due to comparatively low lithium-ion transference number and salt diffusivity, the polarization is largely related to the transport properties. It is known that internal resistance of the LIBs temporarily rises by repeating high-rate charge/discharge cycles and that it decreases by stopping the battery operation and rest. Because such a reversible resistance rise occurs only during the battery operation, this phenomenon is speculated to be related to the ion concentration distributions in the electrolyte. However, there are few techniques that can be used to quantitatively characterize ion transport behavior in the electrolytes during the battery operation. Phase-contrast X-ray imaging is a technique that can be used to visualize density differences by detecting the X-ray phase shift caused by an X-ray passing through a sample. The sensitivity of the phase-contrast X-ray imaging is about 1000 times higher than that of conventional X-ray absorption imaging in a hard X-ray region for light elements. Since the electrolytes of batteries are also composed of light elements, the phase-contrast X-ray imaging is expected to be effective in visualizing small density differences in an electrolyte during battery operation. We demonstrated that in situ phase-contrast X-ray imaging technique can quantitatively visualize the salt concentration distributions that arise in electrolytes during battery operation [1].

Another crucial concern about batteries used in high-power applications is the thermal management of batteries. It is known that temperature of the batteries temporarily rises by repeating high-rate charge/discharge cycles and such a temperature distribution causes inhomogeneous reaction distribution of batteries. Therefore, a fundamental understanding of thermal transport properties in battery electrolytes during battery operation is also important. Although there are several conventional temperature measurement methods, such as thermistors, resistive temperature detectors, thermocouples, infrared thermography, etc., these methods detect the temperature directory through physical contact or using infrared and visible light from the object, and therefore, the detectable depth is limited to a few mm from its surface. So, its inner temperature distribution cannot be measured in principle. We have successfully demonstrated that nondestructive observations of inner temperature and thermal flow in heated water by using phase-contrast X-ray imaging [2].

In this presentation, we will show the quantitative evaluation of ion concentration distribution and thermal distribution (inner temperature gradient) in the electrolyte simultaneously during battery operation with high temporal (a few seconds) and spatial (a few microns) resolutions. We envisage that the phase-contrast X-ray imaging will become a versatile tool for evaluating electrolytes, both aqueous and non-aqueous, of many electrochemical systems, which will further our understanding of the dynamic behavior of electrolytes in actual applications.

EN05.08.11
Formation of Ion Conduction Pathway in Porous Electrodes for Proton Exchange Membrane Fuel Cells Jong-Hyeok Park, Seohhee Lim and Jin-Soo Park; Sangmyung Univ, Korea (the Republic of)

Pathway for ions is normally in an aqueous phase. Regardless, the introduction of any aqueous phase in energy conversion devices causes many problems during fabrication, operation, maintenance, and so on. Thus, much efforts have been devoted to develop quasi-solid electrolytes such as gel polymer, ion exchangeable polymers, impregnation of ions in porous matrix and so on. Among the candidates, ion exchangeable polymers are quite often chosen as ion conducting media for energy conversion devices. The technique to introduce ion exchangeable polymers within electrodes for oxidation and reduction reactions is to solidify catalyst inks consisting of electrocatalyst, dispersion of ion exchangeable polymers, controlling solvents and additives by evaporation of all solvents in catalyst inks. Ion exchangeable polymers could be dispersed in various solvents. It causes different shapes of ion exchangeable polymers in solvents, for instance, cylindrical rods, a less-defined large particles, coils and so on. Such different types of ion exchangeable polymers form distinguished structure catalyst layers. In this study, the effect of solvents dispersing ion exchangeable polymers on the performance and durability of catalyst layers was investigated. Electrochemical characterization such as I-V polarization, cyclic voltammetry, impedance and so on and microscopic characterization such as SEM and TEM were carried out to evaluate the performance and durability of catalyst layers.

Direct Measurement of Nano-Sized Li Dendrite Growth Stress by In Situ TEM Megan Aubin; University of Central Florida, United States

The all-solid-state Li-ion battery is attracting attention because it enables the use of a high capacity Li metal anode while easing safety concerns by employing a stable solid electrolyte. It is expected that the use of a solid electrolyte with a high shear modulus would prevent the growth and propagation of destructive lithium dendrites. However, there are several studies showing that dendrites can still penetrate solid electrolytes, causing the cell to short. The exact mechanism of the dendrite penetrations is still under debate. Additionally, a large compressive stress is generally applied to the cell to maintain good contact between the electrode and the solid electrolyte. This can affect the lithium deposition process. Therefore, understanding the relationship between the mechanical stress and lithium dendrite growth is a key factor in decoding the dendrite penetration process.

We developed a new in-situ transmission electron microscopy (TEM) technique to directly observe the lithium dendrite growth process and obtain the force on a Li dendrite to gain insight into the early stages of this destructive phenomenon. The in-situ TEM observation showed a nano-sized lithium pillar growing vertically causing increasing stress. It continued its vertical growth until the force reached a critical value of 13.5 nN, resulting in a maximum stress of 15.8 MPa. The pillar then changed its growth direction and started to expand horizontally. The measured critical stress is much higher than the yield stress of bulk lithium, which indicates that lithium can locally introduce high stresses on solid electrolytes without yielding. The information obtained in this work is useful for constructing a constitutive model of a lithium plating process in an all-solid-state system and understanding the mechanical stability of solid electrolytes particularly at the early stage of lithium deposition.

EN05.08.13
Durability Analysis of Size-Controlled Platinum Nanoparticle Synthesized Continuous Flow Method for Fuel Cells by Whole Powder Peak Fitting of Powder XRD Keiko Miyabayashi and Ankit Singh; Shizuoka University, Japan

Researches about the improvement of durability of fuel cell electrocatalysts have addressed for proliferate the fuel cell vehicle [1]. Electrochemical active surface area (ECSA) is one of characteristic parameters to measure durability of platinum based catalysts and is strongly correlated with the size of nanoparticles. Change of nanoparticle size during the potential cycle test is commonly evaluated by TEM observations [2]. The size and distribution of nanoparticles estimated by TEM, however, are originated from limited area of catalyst. To acquire the
size and size distribution from whole catalyst, powder X-ray diffraction (XRD) is a potential technique but only the crystal size is estimated from Scherrer equation in most cases.

In the present study, we prepared the size-controlled platinum nanoparticles by batch and continuous flow synthesis for catalyst coated glassy carbon GC electrode and MEA fabrication, respectively. After accelerated durability test, the crystal size and size distribution of nanoparticles were evaluated by whole powder peak fitting (WPPF) of powder XRD spectra.

As a model electrocatalyst, size-controlled platinum nanoparticles were prepared by batch and continuous flow synthesis. For batch synthesis, platinum nanoparticles were prepared using a previously reported method [3]. For continuous flow synthesis, platinum precursor (H₂PtCl₆) was dissolved in mixed solvent of water and ethylene glycol. Sodium hydroxide was added as additive to the solution. The precursor solution was then placed in an oven at 180 °C. The flow rate was controlled by micropump at 3ml min⁻¹. The synthesized nanoparticle solution was mixed with carbon black (Vulcan XC 72R) and stirred overnight. The platinum loading of catalyst was 30–35 wt% determined by ICP. Preparation of the catalyst coated GC electrodes and MEAs followed procedures reported in the literature [3, 4]. Electrochemical analyses were tested under start-stop potential cycling by the Fuel Cell Commercialization Conference of Japan’s (FCCJ) [4].

The average diameter of platinum nanoparticles (arithmetic mean) estimated by TEM observation was 2.3±0.4 nm. The nanoparticles dispersed well on the carbon support without aggregation irrespective of synthesis method. The distribution of arithmetic diameter was converted to that of volume mean diameter (2.4±0.4 nm) for comparison with XRD results. The WPPF of powder XRD analysis shows similar crystal size and distribution (2.3±0.6 nm) to those estimated by TEM. The result indicates that the WPPF analysis is useful for evaluation of size of nanoparticles from whole catalyst. After 2000 potential cycle test of GC electrode at 60 °C, the size of nanoparticle increased to 4.6±1.1 nm (TEM) and 5.1±1.1 nm (XRD). Evaluation of platinum nanoparticle size in degraded catalysts by TEM has some difficulty since the catalysts contains irregular shape nanoparticles and the contour of nanoparticle is unclear. This difficulty may cause underestimation of average size of nanoparticles. WPPF of powder XRD spectra is more or less structure independent analysis. We believe that WPPF of powder XRD provide more practical crystal size for degraded electrocatalyst.

This work has been financially supported by the New Energy and Industrial Technology Development Organization (NEDO), Japan.

EN05.08.14
Understanding Degradation Mechanism behind Degradation of the Garnet Solid Electrolyte Li₇La₃Zr₂O₁₂ and LiNi₀.₆Mn₀.₂Co₀.₂O₂ Cathode During Sintering Younggyu Kim and Bilge Yildiz; Massachusetts Institute of Technology, United States

Li-ion batteries which we use every day suffer from inherent safety issues due to low ignition point of liquid electrolytes. This problem can be solved by using solid electrolytes since they are non-flammable. LLZO (Li₇La₃Zr₂O₁₂) has been considered as a major candidate among the solid electrolytes because of its high conductivity and wide electrochemical window. Therefore, we can potentially develop all solid batteries with high stability and energy density using LLZO.

However, interfacial resistance of solid-state batteries remains too high for commercialization. The major problem comes from the sintering process which is necessary to gain good contact between electrodes and solid electrolyte. During the sintering, detrimental secondary phases form at the interface. These ruins the cell performance by blocking Li transport. There have been many works on the anode|electrolyte interface to improve the stability. However, works on the cathode side are relatively scarce. Considering the importance of cathode|electrolyte interface that has been recently demonstrated by our group (Vardar et al. 2018), we believe that unraveling the degradation mechanism at the cathode|electrolyte interface can be a major milestone in the development of successful solid Li-batteries.

We chose NMC622 (LiNi₀.₆Mn₀.₂Co₀.₂O₂) as the cathode and Al-doped LLZO (Al₀.₂₄-Li₆.₂₈La₃Zr₂O₁₂) as the solid electrolyte. We deposited thin film cathode (<100nm) on top of pre-prepared solid electrolyte pellets. Afterward, we annealed the samples in the air with different temperature conditions to simulate the sintering process.
process. In the samples with conventional geometry, it is difficult to characterize the cathode|electrolyte interface since they are buried deep inside the samples. In contrast, since we used thin film cathodes, we could characterize interfacial regions by using surface sensitive techniques such as XAS. By combining findings from those techniques with conventional characterization techniques such as XRD and EIS, we could clarify the degradation mechanism at the interface.

We could see major decomposition products at the interface of the sample which was annealed at 700°C. With XRD, we could see the formation of La2Zr2O7, Li2CO3 and a perovskite phase with La on A-site. The exact identification of the perovskite phase could be done by XANES analysis. We could detect drastic shape change of Co L-edge indicating the formation of Co4+(High Spin) (Merz et al. 2010) Based on this finding, we suggest that La(Ni,Co)O3 has formed at the interface. Due to the electronegativity difference between Ni and Co, Co4+(High Spin) could form in La(Ni,Co)O3. (Pérez et al. 1998) Effect of the secondary phase at the interface on the electrochemical property of the cell could be clearly seen in EIS analysis. We could identify additional arc which does not exist in the sample without further annealing. We attribute this feature to the interfacial resistance due to the detrimental secondary phase.

In conclusion, we claim that temperature for typical sintering condition(700°C) is too high for solid Li-batteries. This has been proven by multiple characterization techniques clarifying the formation of secondary phases and their detrimental effect on cell performance. As an alternative, we suggest a low-temperature annealing process(300°C) in order to inhibit degradation at the interface.

We acknowledge U.S. Army Research Office for funding the research through the Institute for Soldier Nanotechnologies. (Cooperative Agreement Number W911NF-18-2-0048)

EN05.08.15
Highly Active and Durable PtCo Nanocatalysts with Surface Structure Modification for Enhanced Oxygen Reduction Reaction Daeil Choi1, Docheon Ahn2, Kug-Seung Lee2, Namgee Jung2 and SungJong Yoo1; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Pohang Accelerator Laboratory, Korea (the Republic of); 3Chungnam National University, Korea (the Republic of)

Polymer electrolyte membrane fuel cells (PEMFCs) have gained attention as future power devices due to their high energy density and no pollutants such as carbonaceous materials during operation. However, the commercialization of PEMFCs is interrupted by several issues since their electrocatalysts should satisfy not only activity but also durability. Commonly, carbon-supported Pt nanoparticles are utilized as catalysts for PEMFCs owing to their excellent oxygen reduction reaction (ORR) activity at the cathode. However, the expensive cost of Pt according to low reserves impedes the commercialization of PEMFCs. In order to solve this practical problem, a great deal of effort has focused on the development of cost-effective and highly active electrocatalysts, as demonstrated by the widely investigated alloys of Pt with relatively cheap transition metals such as Ni, Co, and Fe. The above alloying optimizes d-band structure of Pt, which binding energy between Pt and oxygen species is more favorable than that of the pure Pt as well as decreases the cost of the catalyst thanks to the usage of inexpensive materials. However, it easily is dissolved under electrochemically stressful condition during PEMFC operation even though the alloyed electrocatalysts exhibit high enhanced ORR activity, which requires the development of durable bimetallic catalysts. A number of researches to improve the electrochemical durability have been introduced, for instance, core-shell structures, intermetallic structure, dealloyed surface structure, and additional surface functionalization with organic or inorganic materials. In spite of these efforts, the development of active, durable, and cost-effective ORR electrocatalysts has not been achieved yet. Herein, we propose several types of Pt skin structure PtCo nanocatalysts toward through various post-treatments such as acid treatment, thermal treatment, and additional Pt reduction. The physical and electrochemical properties were investigated and compared to commercial Pt/C. The Pt skin structure nanocatalysts showed enhanced catalytic activity approximately 2-fold compared with commercial Pt/C because of the tuning of d-band structure of Pt by alloying with Co. Furthermore, the Pt skin structure nanocatalysts exhibited the better ORR activity than initial performance of commercial Pt/C despite low loading amount of Pt even after accelerated degradation test (ADT) under harsh condition. Subsequently, the reason for improvement in long-term durability were analyzed via physical characterizations. Based on these results, the supplementary Pt-skin structure formation on the surface of PtCo nanocatalysts diminishes the amount of defect sites of Pt and prevents metal dissolution during electrochemical test. We expect that this study suggests a novel solution for designing active and
durable nanocatalysts for ORR and promotes the commercialization of PEMFCs.

Interfaces for Electrochemical Energy Conversion and Storage Vojislav Stamenkovic, Dusan Strmcnik, Pietro Papa Lopes, Nenad Markovic and Nigel Becknell; Argonne National Laboratory, United States

The development of new multi-functional electrochemical interfaces that can solve challenging problems of clean energy production, storage, and conversion is of paramount importance in the quest to find alternatives to fossil fuel use. Electrocatalysis – the study of electrode processes where the rate of reaction has a strong dependence on the nature of electrochemical interfaces – lies at the heart of the spectrum of electrochemical transformations relevant for resolving these challenges. Ability to tune physicochemical properties of electrochemical interfaces has evolved towards ability to define the nature, arrangement, and transformations of electrode surface atoms along with hydrated ions in the double layer, including the kinetics of electron transfer. Implementation of this approach will be presented for the development of non-precious and platinum-based nanoscale catalysts for the hydrogen evolution reaction, oxygen reduction and evolution reactions. The role of molecular species at the interface such as water, counter cations and anions, for both two and three phase interfaces, will be discussed in terms of ability to identify and understand their influence on reaction kinetics.

9:00 AM *EN05.09.02
Modeling Chemo-Mechanical Coupling in Ceramic Ion-Conducting and Phase-Transformation Electrolytes and Electrodes Robert J. Kee, Kasra Taghikhani, Huayang Zhu, Sandrine Ricote and John Berger; Colorado School of Mines, United States

Polycrystalline ceramic materials play central roles as electrolytes and electrodes within a wide range of electrochemical technologies, including fuel cells and batteries. Heterovalent doping within ceramic electrolytes (e.g., perovskites) produces mobile oxygen vacancies as well as facilitating the transport of other charged defects, including protons and small polarons. The lattice strain associated with lattice-scale defect concentrations induces mechanical stress. This paper is concerned with modeling thermo- and chemo-mechanical coupling, which can lead to potentially damaging stresses. The primary emphasis is on membrane-electrode assemblies (MEA) fabricated from proton-conducting ceramics. However, the paper will also incorporate recent efforts to extend the models to Li-ion battery electrodes.

9:30 AM EN05.09.03
Spontaneous Formation of Lithium Ion Conductor in Ultrathin Al2O3 Layer at the Interface of Solid Electrolyte and Anatase TiO2 Electrode Using Solid-State Li Thin-Film Batteries Daisuke Imazeki1, Kazunori Nishio1, Ryo Nakayama1, Ryota Shimizu1,2 and Taro Hitosugi1; 1Tokyo Institute of Technology, Japan; 2JST-PRESTO, Japan

All-solid-state lithium batteries are one of the candidates for next-generation energy storage devices due to high energy density and long cyclability. It is well known that the insertion of a thin electrical insulator, such as Al2O3, MgO, and ZrO2, between a solid electrolyte and an electrode is effective on improving battery performances.[1] However, the insulators do not contain lithium ions, and thus, the function of insulators remains unclear. Accordingly, it is crucial to understand the interfacial ionic transport properties across the solid electrolytes and electrodes through thin insulators.

Here, we present quantitative studies of the ionic transport through the thin insulators using thin-film batteries consisting of epitaxial films. This approach provides well-defined crystal orientations and interface structures. To verify the influence of the inserted thin insulator, we fabricated thin film lithium batteries using a very flat model electrode and covered the surface with a thin Al2O3 layer.
We prepared anatase Ti_{0.996}Nb_{0.004}O_2 (TNO) epitaxial thin films as a very flat model electrode (25 nm thickness, average surface roughness: \( R_a = 0.28 \) nm) on a (LaAlO_3)_{0.3}(SrAl_{0.5}Ta_{0.5}O_3)_{0.7} (LSAT) (100) substrate by employing pulsed laser deposition. Using this model electrode, we fabricated all-solid-state thin-film lithium batteries through \textit{in-vacuo} process that provides clean interfaces.[2] The thin film batteries consist of Li anode (800 nm), Li_3PO_4 solid electrolyte (450 nm), TNO thin film on LSAT substrate. Al_2O_3 thin layers with a variety of thicknesses ranging from 1 to 50 nm were inserted at the interface of a Li_3PO_4 and a TNO.

Cyclic voltammetry (CV) of the thin film battery without Al_2O_3 insertion showed redox peaks (Ti^{4+}/Ti^{3+}) in good agreement with those reported earlier using organic electrolytes.[3] As the thickness of the inserted Al_2O_3 layer was increased, the difference in the redox peak voltages was enlarged, indicating an increased overpotential. It is surprising to observe the battery redox cycling even though a Al_2O_3 layer completely covered the surface of a TNO electrode. In addition, we found that the overpotential decreased as the cycle number of CV was increased. These results suggest that a lithium ionic conductor has formed electrochemically in the Al_2O_3 layers.

9:45 AM EN05.09.04
\textbf{New Strategy for Fast Ionic Conduction in Nanostructured Ceria-Based Electrolytes} Mehmet E. Kilic\(^1\), Junsung Ahn\(^1,2\), Ho-II Ji\(^1\), Jong-Ho Lee\(^1\) and Kwang-Ryeol Lee\(^1\); \(^1\)Korea Institute of Science and Technology, Korea (the Republic of); \(^2\)Seoul National University, Korea (the Republic of)

Cerium oxide (CeO_2) or ceria is a known fast oxide ion conductor with an oxygen vacancy-mediated transport mechanism. The highest ionic conductivities are observed when it is doped with Gd_2O_3 and Sm_2O_3. For this reason, ceria-based materials are widely used electrolyte for solid oxide fuel cells (SOFCs). Over the past decade, many attempts have been made on the development of fast oxygen-ion conductors in SOFC. Strain engineering has been one of the most effective ways to enhance ionic conductivity. Many researchers have observed various strain-induced enhancements of ion conductivity in nanostructures such as ultrathin, multicoated, and free-standing layers.

In this study, using an atomistic model, we investigate the effects of biaxial extrinsic and local intrinsic lattice strain on oxygen-ion transport in doped ceria via performing molecular dynamics (MD) simulations with well tested interatomic potentials.

We have performed three main analyses to examine the structural integrity of doped ceria: (1) radial distribution function (RDF) analysis for the phase and bond informations, (2) the coordination number (CN) analysis for the vacancies, and (3) mean square displacement (MSD) analysis for the cations and anions.

We have focused on the oxygen ion diffusion of doped ceria by considering five main mechanisms contributing to accelerate oxygen-ion transport: (1) the influence of type of cations with respect to the ionic size, (2) the influence of cation concentration, (3) the influence of cation distribution, (4) the influence of local lattice intrinsic strain induced by co-doping and, (5) the influence of biaxial extrinsic strain.

\textbf{Garnet-Type Solid Electrolyte with Superior Electrochemical/Chemical Properties for Operating All-Solid-State Battery} Byoungwoo Kang; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

The demand for rechargeable Li batteries having more safety and higher energy density has been increased to meet the strong demand of novel applications such as electric vehicles and energy storage system. In this aspect, lithium ion batteries containing typical liquid electrolytes have fundamental limitations because liquid electrolytes can act as fuels in thermal runaway behavior leading to a fire or an explosion of battery and can be decomposed at high potential (> 4.5V) leading to the restricted use of high potential cathodes. Also, liquid electrolytes cause severe
safety problems with Li metal, which is the best anode material for high energy density with low potential and high capacity, because Li metal in liquid electrolytes easily leads to the formation of dendrite that can produce a short-circuit between cathode and anode. To address these problems, there are several approaches. One of promising approaches is to apply proper oxide-based solid electrolytes (SEs) instead of liquid electrolyte. Among oxide-based SEs, garnet-type SEs has been a lot of attraction because they can have several advantages over liquid electrolytes in terms of electrochemical window, chemical stability with Li metal, and safety.

In this talk, I will discuss about the newly developed garnet-type SE that has superior electrochemical/chemical properties with respect to the wettability with Li metal, ionic conductivity, and chemical stability with air. Also, I will talk about the efforts in our group to build up all solid-state battery by using the developed garnet-type SE.

Structure, Chemistry and Charge Transfer Resistance of the Interface between Garnet Solid Electrolyte and Oxide Cathodes  
Bilge Yildiz; Massachusetts Institute of Technology, United States

All-solid-state batteries promise significant safety and energy density advantages over liquid-electrolyte batteries. The interface between the cathode and the solid electrolyte is an important contributor to charge transfer resistance. Strong bonding of solid oxide electrolytes and cathodes requires sintering at elevated temperatures. Knowledge of the temperature dependence of the composition and charge transfer properties of this interface is important for determining the ideal sintering conditions. To understand the interfacial decomposition processes and their onset temperatures, model cathode systems of LiCoO$_2$ (LCO) and LiNi$_{0.6}$Mn$_{0.2}$Co$_{0.2}$O$_2$ (NMC622) thin films deposited on cubic Al-doped Li$_7$La$_3$Zr$_2$O$_{12}$ (LLZO) pellets were studied as a function of temperature, gas composition and electrochemical conditions. The methods combine interface-sensitive techniques, including X-ray photoelectron spectroscopy (XPS), synchrotron X-ray absorption spectroscopy, hard X-ray photoemission (HAXPES), and synchrotron X-ray diffraction. In this talk, we will present the found precipitation products at the interface as a function of synthesis and electrochemical conditions, their role in altering the interface resistance to Li transfer, and compare the LCO and NMC related cathodes in terms of their instability onset conditions. We will also present the role of protective coatings such as LiNbO$_3$ in interfering with the detrimental interface reactions.

11:30 AM  EN05.09.07

Miara$^1$, Tan Shi$^{1,2}$, Mary Scott$^{1,2}$ and Gerbrand Ceder$^{1,2}$; $^1$University of California Berkeley, United States; $^2$Lawrence Berkeley National Laboratory, United States; $^3$Advanced Materials Lab, Samsung Research America, United States

Solid-state batteries (SSB) have been considered as promising next-generation energy storage device with improved safety and potentially increased energy density. Among all the inorganic solid electrolytes (SE), thiophosphates offer competitive advantages in terms of the low cost, high ionic conductivity, low Young’s modulus and yield strength, which makes them a strong candidate for room temperature application in SSB.$^1$

Despite providing high bulk conductivity and good processability, both theoretical calculations and experimental results suggest that thiophosphates will experience oxidation/decomposition upon charging when being in direct contact with commonly used oxide cathode materials.$^{2,3}$ This interfacial instability results in increased interfacial resistance during cycling and highlights the necessity of interfacial protection at the cathode/SE interface. Searching for promising cathode coatings and understand the mechanism of the coating functionality and validity is critical for improving the SSB cycle life. In this work, we predict potential coatings materials for thiophosphate Li$_3$PS$_4$ (LPS) system through ab-initio computational calculation, and we experimentally verify the performances of the selected coating materials through direct observation using advanced (scanning) transmission electron microscopy ((S)TEM) analysis with air-free sample preparation. By combining different modes of microscopy techniques (image, diffraction, and spectroscopy), we were able to probe the chemical composition and interface structure in SSB at a resolution of nanoscale. Our work elucidates the correlation between calculated chemical /electrochemical stability and the observed coating integrity during cycling, and provides a powerful method for predicting and probing the interfacial stability issue of the cathode/SE.

Strain Effect on Li-Ion Migration in $\beta$-Li$_3$PS$_4$

Pjotrs Zguns and Bilge Yildiz; Massachusetts Institute of Technology, United States

$\beta$-Li$_3$PS$_4$ is a promising Li-ion conductor (0.2 mS/cm at room temperature). Recently, its air-stability and ionic conductivity were improved by a small amount of ZnO doping (1 mS/cm), making it even more appealing study case. Here, we investigate the influence of interfacial cathode/electrolyte strain on $\beta$-Li$_3$PS$_4$ ionic conductivity by studying the effect of uniaxial and biaxial strains on Li-ion migrations by means of DFT calculations. Interestingly, migration energies show non-linear response to strain indicating that strain accommodation in lithium-phosphorus-sulfide family is different from that in conventional oxide-ion conductors, and, overall, the effect of strain is smaller. The structural response to strain and atomistic mechanisms behind migration barrier reduction are discussed.

Computation Accelerated Design of Materials and Interfaces for Solid-State Batteries

Yifei Mo; University of Maryland, United States

All-solid-state Li-ion battery based on solid electrolytes is a promising next-generation battery technology with high energy density, intrinsic safety, long cycle life, and wide operational temperatures. However, multiple materials challenges, such as low ionic conductivity of solid electrolytes and poor interfacial compatibility at the solid electrolyte-electrode interfaces, are impeding the development of this new battery technology. To resolve these materials challenges, we develop and leverage an array of ab initio computation techniques to provide unique insights into the fundamental materials limitations and to establish general design principles of materials and solid interfaces. Our first-principles atomistic modeling studies reveal the origin of ultra-fast Li-ion diffusion in lithium super-ionic conductors. Based on the newly gained understanding, we establish design principles for fast ion-conductor materials, and demonstrate these design principles for the computation discovery and design of new lithium super-ionic conductors. In addition, we develop thermodynamic calculations based on the materials-genome database for investigating the compatibility of heterogeneous interfaces between solid electrolytes and electrodes. Key factors affecting the compatibility of the solid electrolyte-electrode interfaces are identified, and interfacial design strategies are proposed from our thermodynamic computation. The demonstrated computation capabilities represent a transferable model in designing new materials and interfaces for emerging technologies.

Accelerated Materials Design for Solid-State Batteries with In Situ Characterizations

Shan Xiong, Zhantao Liu, Lufeng Yang and Hailong Chen; Georgia Institute of Technology, United States

In the past, advanced characterization methods, no matter in situ or ex situ, are majorly considered as means for understanding the functioning mechanisms of materials. However, they can also be powerful tools for accelerating the materials design loops, especially in the cases where computational designs nowadays can quickly provide dozens and hundreds of promising candidate materials for synthesis trials. High-throughput synthesis is a straightforward approach to accelerate the synthesis trials. However, in the cases where high-throughput synthesis is difficult or too expensive, in situ characterizations on the synthesis process represent a more economical and even more information-rich route for the quick synthesis of target materials.

Here we report multiple case studies where in situ characterizations for a variety of synthesis methods were used to advance our understanding on the thermodynamics and phase diagrams of novel battery materials, including
electrodes and solid electrolytes. The discovery of a sodium cathode P2-Na0.66Li0.12Fe0.18Mn0.70O2 with very high capacity and outstanding capacity retention will be discussed. In situ XRD and solid state NMR characterizations were used to understand the formation and functioning mechanisms. Novel sulfide based Li+ and Na+ ionic conductors identified with using in situ XRD will also be presented with their structure resolution, ionic conductivity measurement and full-cell battery tests.

2:30 PM EN05.10.03
Computational Screening of Cathode Coatings for Solid-State Batteries Yihan Xiao1,2, Lincoln J. Miara3, Yan Wang4 and Gerbrand Ceder1,2; 1University of California, Berkeley, United States; 2Lawrence Berkeley National Laboratory, United States; 3Samsung Research America, United States

Solid-state batteries (SSBs) are considered as the next-generation batteries due to their potential for improved safety, power density, and energy density compared with conventional Li-ion batteries. However, the interfacial reactivity and resulting resistance increase between the cathode and solid-state electrolyte (SSE) can significantly deteriorate the cell performance. Since virtually none of the SSEs are intrinsically stable against both electrodes, coatings are needed that are chemically and electrochemically stable with the SSE and the electrode.

We employ a high-throughput (HT) computational framework to screen Li-containing materials for cathode coating application, focusing on their phase stability, electrochemical and chemical stability, and ionic conductivity. The HT results show that there are clear chemical rules to explain reactivity between electrodes and SSEs and that the optimal coating materials need to be selected for each specific SSE/cathode combination.

We identified polyanionic oxides as promising cathode coating candidates to protect sulfide electrolytes against oxide cathodes, with LiH2PO4, LiTi2(PO4)3, and LiPO3 being particularly appealing choices. Some lithium borates exhibiting excellent (electro)chemical stability at various interfaces are also highlighted. Lastly, factors affecting the stability of coating materials such as Li content and oxygen bonding covalency are also discussed.

Characterizing Chemo-Mechanical Degradation at Solid-State Battery Interfaces John Lewis, Jared Tippens, Francisco J. Cortes and Matthew T. McDowell; Georgia Institute of Technology, United States

The solid-state lithium metal battery is a promising next-generation technology due to the high energy density of the lithium metal anode and the potential for solid-state electrolytes (SSEs) to prevent failure modes seen in liquid electrolyte lithium metal batteries. However, the interfaces between many SSEs and lithium metal are (electro)chemically unstable, and we lack a detailed understanding of how interfacial transformations relate to electrochemical degradation. Using the NASICON-type Li1.4Al0.4Ge1.6(PO4)3 (LAGP) as a reactive SSE, we study the reaction processes that occur at the lithium metal/SSE interface and develop a chemo-mechanical understanding of degradation in LAGP. In situ transmission electron microscopy reveals that lithium insertion into LAGP at the interface drives the transformation to form an amorphous phase with expanded volume [1]. In symmetric Li/LAGP/Li cells, the evolution of mechanical stress due to this transformation ultimately causes fracture of the SSE and complete cell failure. Ex situ characterization of LAGP after cycling shows that the morphology of the interphase layer is highly dependent on the applied current density, and the interphase morphology significantly influences mechanical stability. In situ X-ray tomography during electrochemical cycling of symmetric cells reveals the onset of fracture and growth of the crack network throughout cycling [2]. Our results show that the impedance begins to increase when fracture first initiates, indicating that the ionic conductivity of the interphase is comparable to pristine LAGP and is not responsible for the significant increase in impedance. This work highlights that the nature of the reaction at the Li/SSE interface plays a crucial role in determining chemo-mechanical degradation mechanisms, with implications for understanding degradation in a wide range of practical SSEs.

References:
Formation and migration of point defects underlie nearly all materials for energy transformation, such as electrodes and solid electrolytes for lithium-ion batteries and solid oxide fuel cells. The distribution of point defects such as lithium and oxygen vacancies reflect electro-chemo-mechanical equilibria. In this talk, I will present two such examples. First, we show that anisotropic and polycrystalline lithium layered oxide can exhibit extremely non-uniform lithium concentration due to mechanical effect due to orientation distribution of crystallites. Second, we present a general theory framework for understanding how mechanical contribution plays a key role in determining the space-charge effect at interfaces.

Na-ion batteries (SIB) as one of the battery technologies for grid-scale energy storage has attracted great attention recently. SIBs, like Li-ion counterparts, usually have solid electrolyte interphase (SEI) at the anode side and cathode electrolyte interphase (CEI) on cathode surface, which determine the reversibility and rate of the cell reactions for the rest of the cell life. The electrode/electrolyte interphases have not been thoroughly investigated despite the progress in SIB development. Here, we reported our work on the development of advanced electrolyte systems for 1) controlled SEI on hard carbon anodes and hence fast Na-ion transfer; and 2) mitigated cathode surface phase transition and significantly improved cyclability. Hard carbon anodes demonstrated high rate and good low temperature performance in TEGDME based electrolyte. The specific capacity of hard carbon anode is ~180 mAh/g at the current density of ~250 mA/g at room temperature. The specific capacity is ~200 mAh/g at -20oC/ discharge at the current density of ~25 mA/g. The O3-type metal oxide cathode in localized high concentration electrolyte delivers a high specific capacity of ~190 mAh/g between 2-4.2V. The capacity retention is >80% over 1000 cycles between 2-4V with a specific capacity of ~150 mAh/g.

The solid-electrolyte-interphase (SEI) is probably the least understood component in Li-ion batteries. Considerable effort has been put in the understanding of its formation and electrochemistry under realistic battery conditions, but mechanistic insights have been inferred mostly indirectly. Here we show the formation of the SEI between a graphite anode and a carbonate electrolyte using combined atomic scale microscopy and in-situ and operando techniques. In particular, we weigh the graphic anode during its initial lithiation process with electrochemical quartz crystal microbalance, which unequivocally identifies lithium fluoride (LiF) and lithium alkylcarbonates as the main chemical components at different potentials. In-situ gas analysis confirmed the preferential reduction of cyclic over acyclic carbonate molecules, making its reduction product the major component in SEI. We find that SEI formation starts at graphite edge-sites with dimerization of solvated Li+-intercalation between graphite-layers. We also show that this lithium salt, at least in its nascent form, is re-oxidizable, despite the general belief that an SEI is electrochemically inert and its formation irreversible.
Degradation of Nominally Ionic Solid Electrolytes—A Thermodynamic Perspective Yanhao Dong¹, I-Wei Chen² and Ju Li¹; ¹MIT, United States; ²University of Pennsylvania, United States

Electrochemical devices such as solid oxide fuel/electrolyzer cells (SOFC/SOEC) and all-solid-state batteries employ an ion-conducting and electron-blocking solid electrolyte and can be operated reversibly between charge and discharge. Yet reversing operation modes from SOFC to SOEC, or from battery discharge to charge often lead to more severe degradations, as evidenced by oxygen bubble formation at the grain boundaries in the zirconia electrolyte, Na metal islands in the Na-beta-alumina solid electrolytes of Na-S batteries and similar Li metal islands inside the Li/La₃Zr₂O₁₂ electrolyte in lithium ion batteries. While conventional wisdoms rationalized such observations by electrode overpotential and thought internal phase formation can be kinetically suppressed by sluggish electron transport through electron-blocking electrolytes, our thermodynamic analysis show (i) possible overpotential at transport bottlenecks inside solid electrolytes, leading to (ii) potential overshoot/undershoot beyond two boundary values at electrode/electrolyte interfaces, thus setting (iii) largest chemical driving forces to precipitate damaging internal phases, and (iv) electrons/holes can be readily transported to form such phases with ionic transference number >0.999 under typical operation conditions of such electrochemical devices. To the end, our work calls for better understanding of materials theory and better characterizations of transport properties for solid electrolytes, in order to achieve higher-energy-density and safer electrochemical devices.

An Artificial Solid Interface for Dendrite-Free Lithium Deposition Rajesh Pathak, Ke Chen, Jyotshna Pokharel, Wei He, Abiral Baniya, Qiquan Qiao and Yue Zhou; South Dakota State University, United States

Lithium (Li)-metal based anode is of particular interest owing to their high energy density, and specific capacity more than ten times to that of LiC₆ anodes. However, the highly reactive Li-metal inhibit further practical applications due to the growth of undesired Li dendrites and the formation of unstable solid electrolyte interphase (SEI) formation. This Li dendrites growth and continuous formation of SEI consume much electrolyte leading to low CE and capacity fading. In addition, the notorious Li dendrites can pierce the separator causing the short circuit and fire explosion. To improve the cycling performances and safety concerns, herein, we consider a rational approach for designing an artificial Li-metal/electrolyte interface. Facile and cost-effective mechanism of engineering ex situ artificial SEI layer was introduced by using WS₂. The chemical and mechanical stable artificial layer provides both high Li-ion conductivity that facilitates fast Li-ion diffusion and high Young’s modulus enough to suppress the Li dendrite growth. The ability to store Li by the conversion reaction and plating underneath the SEI layer induces a homogenous Li deposition. Such an artificial protected Li symmetrical cell showed significantly long hours plating/stripping cycles and reduced overpotential compared to the bare Li. The full cell configuration with high-loading (11.88 mg.cm⁻²) of NMC111 showed astonishing results such as longer stable cycling, higher capacity at higher rates and higher rate capability compared to the bare Li anode. This approach could lead to the development of high energy density and safe Li-metal based batteries.

Engineering Solid Electrolyte Interphase Composition by Assessing Decomposition Pathways of Fluorinated Organic Solvents for Lithium Metal Batteries Yumin Zhang, Dilip Krishnamurthy and Venkatasubramanian Viswanathan; Carnegie Mellon University, United States

The development of lithium metal batteries (LMB) is hauled by uncontrollable dendrite growth and short cycling life, which restrained its potential to replace lithium ion batteries (LIB) or bring revolutionary advances to energy storage systems. Engineering solid electrolyte interphase (SEI) by modifying electrolyte recipe is considered the most effective way to improve the performance of LMB. Despite the general acceptance of potential improvements by substituting more Fluorine to organic electrolytes, it is still unclear what differences in decomposition mechanisms or derived SEI components between Fluoroethylene Carbonate (FEC) and Difluoroethylene Carbonate
(DFEC) can lead to contradictory results with respect to the general expectation. In this study, using Density Functional Theory (DFT) and the developed "two lithiums" method, we have observed distinctive spontaneous initial bond-breaking mechanisms for FEC and DFEC. FEC breaks by forming CO and LiF, or Li$_2$CO$_3$ and CHFCH$_2$; while DFEC breaks by forming CO, 2LiF and C$_2$H$_2$O$_2$, or Vinylene Carbonate (VC) and 2LiF. DFT confidence measurement C-value indicates absolute energetic favorability of CO forming mechanism for FEC, while approximately equal competence of both mechanisms for DFEC. On the basis of initial bond breaking mechanisms, we provide and discuss the detailed step-by-step energetic pathways and identify the full sets of FEC and DFEC decomposition products. The final SEI components from our analysis are carefully compared to X-ray photoelectron spectroscopy (XPS) results from literature and found good agreements. The results from this study provide the evidence of contrasts in bond breaking mechanisms and final decomposition products between FEC and DFEC, which offer sound explanation of the variations in cell performances and enhanced fundamental understanding of SEI formation. At last, we suggest electrolyte additive with more Fluorine substitution does not necessarily contribute to cell performance upgrade, and a rigorous study using the demonstrated methodology in this work should be performed beforehand to assist electrolyte selection and SEI engineering.

Simulation of Depositional and Morphological Stability at Li Metal/Solid Electrolyte Interface in Solid-State Batteries Qingsong Tu, Luis Barroso-Luque and Gerbrand Ceder; University of California, Berkeley, United States

Theoretical investigations are important for understanding the depositional and morphological evolutions at the interface of Li metal and solid electrolyte (SE) in Li-metal solid state batteries (LMSSBs), especially when direct experimental measurements are hard because of the buried nature of the interface between two solids. In this work, we provide theoretical illustrations of the evolution of the Li metal/SE interface under the relevant boundary conditions (BCs) of LMSSBs. We first prove that the effect of mechanical pressure on the interfacial electrochemistry is negligible compared with other factors, such as the charge-transfer and the mass-transfer of Li-ions. We then investigate the Li electrodeposition and Li plastic deformation for a wide range of BCs, including the initial surface irregularity, kinetics of charge transfer and mass transfer of Li-ions, yield strength of Li metal, and applied stack pressure at boundaries. We conclude that the interfacial contact loss and surface overpotential at Li metal/SE can be well controlled by optimizing the electrochemical and mechanical conditions, such as the applied stack pressure and applied current density.

EN05.11.05
High Active Material Loading in All-Solid-State Battery Electrode via Particle Size Optimization Tan Shi$^1$, Qingsong Tu$^1$, Yaosen Tian$^1$, Yihan Xiao$^1$, Lincoln J. Miara$^2$, Olga Kononova$^1$ and Gerbrand Ceder$^1$; $^1$University of California, Berkeley, United States; $^2$Samsung Research America, United States

The rapid expansion of electrical vehicle market raises the demand for batteries with improved safety and higher energy density. All-solid-state batteries (SSBs) are widely considered as the next-generation energy storage device that can meet both requirements. They improve safety by removing organic carbonate-based liquid electrolytes and can potentially increase energy density by utilizing a Li-metal anode. However, because of the large solid-electrolyte fraction (30 wt%–50 wt%) typically required in cathode composites to provide sufficient ionic diffusion, the volume fraction of cathode (cathode loading) of current SSBs is low, resulting in low energy density. Using experiments and modeling, we demonstrate in this work that very high volume fractions of cathode can be fully utilized in a composite cathode as long as the ratio of the solid electrolyte to cathode particle size is controlled in a cold-pressed composite cathode. This conclusion is experimentally verified, and a composite cathode with > 50 vol% cathode loading is demonstrated using Li$_2$O–ZrO$_2$ (LZO)-coated LiNi$_{0.5}$Mn$_{0.3}$Co$_{0.2}$O$_2$ (NMC) as the active material and amorphous 75Li$_2$S–25P$_2$S$_5$ (LPS) as the solid electrolyte. Our model is applicable to various active materials and solid conductors and provides a generalized guideline for increasing active material loading via particle size optimization.

EN05.11.06
Design of Double-Layer Coatings in All-Solid-State Lithium-Ion Batteries for Enhanced Mobility and Stability Chuhong Wang, Koutarou Aoyagi and Tim Mueller; Johns Hopkins University, United States

All-solid-state lithium-ion batteries have attracted significant interest as candidates for the next generation of
rechargeable batteries. However, commonly observed interfacial reactions between sulfide electrolytes and oxide electrode materials can increase interfacial impedance, thus degrading the battery performance. Interposing an ionic conductor as an interface coating can suppress any unanticipated reactions while maintaining lithium ion diffusion through the battery. However, known lithium-ion-conducting sulfides are usually unstable against cathode materials while the stable oxides are typically poor lithium ion conductors. To increase the space of potential interfacial coatings, we propose that a double-layer coating design could potentially stabilize the electrolyte-electrode interfaces and facilitate the lithium ion transfer. We present the results of a search for stable double-layer coatings with high ionic conductivity. Mobility of lithium ions in the double layer coatings is characterized with a recently developed class of machine learning interatomic potentials, which accesses nanosecond-long molecular dynamics with nearly \textit{ab initio} accuracy. The identified coating strategies highlight opportunities for creating stable solid-state lithium-ion batteries with fast charge and discharge rates.

\textit{In Operando} KPFM—Interfacial Potentials in a Thin-Film All-Solid-State Li-Ion Battery Evgeni Sirek1,2, Elliot J. Fuller2, Michael Swift4, William McGreevey1, Nikolay Zhitelev3, Yue Qi3, Jabez McClelland1 and Alec Talin2; 1NIST, United States; 2University of Maryland, United States; 3Sandia National Laboratories, United States; 4Michigan State University, United States

The continuing search for methods to engineer safer, smaller, lighter, cheaper, and more stable batteries requires comprehensive understanding of the processes governing their operation at multiple length scales. All-solid-state power sources do not contain flammable organic electrolytes, and therefore, are safer. However, they suffer from high internal impedances, arising at the interfaces between the solid electrolyte and electrodes. The nanoscopic thickness of these interfaces calls for microscopic tools to study their behavior. Here, using in operando Kelvin Probe Force Microscopy (KPFM), we measure the potential distribution in a solid-state Li-ion battery as a function of its state of charge. The battery was fabricated by sequentially depositing thin layers of Pt (110-130 nm), LiCoO2 (280-420 nm), LIPON (1100-1200 nm), Si (50-240 nm) Cu or Pt (150-200 nm) onto a Si/SiO2 wafer (oxide thickness 100 nm). The fabricated battery was cleaved in an Ar atmosphere to expose the stacked layers, mounted on a holder, wired, and safely transferred without exposing to air into a dual-beam instrument that combines a scanning electron microscope (SEM), a Ga-ion focused ion beam (FIB) and an atomic force microscope (AFM) in one vacuum chamber (residual pressure of 10^{-4} Pa). The stacked battery was milled to expose a cross-section of the layers, and imaged using SEM and KPFM, while cycling the battery. The acquired potential maps reveal a highly non-uniform interelectrode potential distribution, with most of the potential drop occurring at the electrolyte-Si anode interface in the pristine battery. During the first charge, the potential distribution gradually changes, revealing complex polarization within the LIPON layer due to Li-ion redistribution. Cycling the battery at high rate significantly decreased its capacity, although the capacity loss can be recovered. KPFM imaging allowed the detection of the interface responsible for this capacity loss. The acquired data was compared to first principles calculations shedding light onto the interfacial Li-ion transport in the battery and its reversibility.

Insight into the Compatibility of Lithium Lanthanum Zirconium Oxide (LLZO) and Conventional Liquid Electrolytes Arushi Gupta1, Michael Wang2 and Jeff Sakamoto2,1; 1University of Michigan-Ann Arbor, United States; 2University of Michigan–Ann Arbor, United States

Lithium lanthanum zirconium oxide (LLZO), a ceramic oxide is a promising solid electrolyte candidate to enable Li metal anodes due to its high ionic conductivity (1 mS/cm), stability and low interfacial impedance against Li. However, in a full cell configuration, how LLZO is integrated into cathode constructs requires further development. Recently, bilaminar cell configurations consisting of discrete LLZO membranes to protect Li metal anodes, coupled with conventional liquid electrolyte permeated cathodes, has been suggested as a viable approach. In this electrolyte configuration, LLZO would act to stabilize the Li anode and the liquid electrolyte provides facile transport between LLZO and the cathode. However, we have shown that there may be an incompatibility between typical liquid electrolyte (1M LiPF6 in Ethylene carbonate/Dimethyl carbonate) and LLZO. For example, in hybrid cell configurations, the interfacial impedance increases with time. This work was focused on first developing a mechanistic understanding of the interactions between LLZO and carbonate-based liquid electrolytes. Understanding the reaction pathways between LLZO and liquid electrolytes provided us insight to develop approaches to enable a stable interface between LLZO and the catholyte. In this work, we propose a candidate for the catholyte which is compatible with LLZO and would enable a low interfacial impedance and stable cycling in a
full cell configuration. The results of this work provide an insight into the limitations of using liquid electrolytes with LLZO. We also provide a solution which would help in enabling Li metal anodes using a bilaminar electrolyte configuration.

EN05.11.09
New Insights into How Ultra-Thin Coatings Improve Battery Performance Yaqi Zhu, Yufang He, Hiep Pham and Jonghyun Park; Missouri University of Science and Technology, United States

Atomic layer deposition (ALD) coating technique is proved to be an effective and efficient strategy to improve the capacity and cycle capability of lithium-ion batteries. One of the key roles of the ALD coating layer is to facilitate the species transfer and diffusion in electrode particles. It has been generally believed that this enhancement has resulted from the higher conductivity of the coating layer itself. However, there is a concern about this idea because the proportion of ALD coating layer is very small. Here, we propose a new hypothesis about the role of ALD coating layer in ion transportation. Due to the agglomeration of particles, the surfaces of electrode particles are partially blocked, and, as a result, Li-ion intercalation is not uniform over the surfaces. On the other hand, ALD coating could provide a path to quickly distribute Li-ions over the whole particle surface, leading to enhanced diffusivity of Li-ions through the particles. This hypothesis is validated by both continuum simulation and experiment in this work. In addition, an investigation is conducted to study the ALD coating thickness impact on Li-ion diffusivity via first-principles calculations, which shows that the Li-ion diffusion increases to the maximum value and then decrease as the coating thickness increases. We find that this is related to the higher diffusivity of the ALD coating than that of the active material, and higher diffusivity through the surface than through the bulk. This combined work reveals the influence of ALD coating layer on Li-ion diffusion and provides us a clue why there is an optimal ALD coating thickness for the best battery performance.

EN05.11.10
Features of Mechanical Behavior of LiPON Sergiy Kalnaus, Andrew S. Westover and Nancy J. Dudney; Oak Ridge National Laboratory, United States

Ability to resist penetration of metallic lithium is the major requirement for the electrolyte membrane in an all solid-state lithium cell. In this regard, the lithium phosphorus oxynitride (LiPON) electrolyte has been demonstrated to successfully block Li metal propagation (often termed lithium dendrites) in thin-film cell configuration. It is therefore important to understand which properties of LiPON are critical for such stable performance with Li metal so that other electrolytes could be designed following similar metric. Here we concentrate on mechanical properties of LiPON, specifically its resistance to cracking, i.e. fracture toughness. This property appears to be rather important, since metallic lithium penetration has been demonstrated from artificially introduced defects even in the absence of grain boundaries.

By using instrumented nano-indentation we observed unusually high resistance of LiPON to crack initiation and propagation. We compare this behavior to fracture in typical glass materials and other Li-ion conducting glass-ceramic electrolytes. In addition to resistance to cracking LiPON apparently exhibits time-dependent behavior and is capable of partial recovery upon unloading. We discuss these features in relation to LiPON functionality in all solid state cell with metallic lithium anode.

Improving the Durability of Pt-Alloy Nanoparticles for the Oxygen Reduction Reaction in Acidic Media via
Encapsulation Qiang Sun, Sanjeev Mukerjee and Qingying Jia; Northeastern University, United States

The Oxygen Reduction Reaction (ORR) is the desired cathode reaction in Proton Exchange Membrane Fuel Cells (PEMFCs). Carbon-supported platinum alloy (PtM/C) nanoparticles are by far the most effective ORR catalysts in PEMFCs. However, the durability of PtM/C is not satisfying. Efforts to improve their durability have been impeded by the poor understandings of their degradation mechanisms. In this study, by conducting accelerated stress tests (ASTs) on a commercial PtCo/C catalyst in both a rotating disk electrode and a PEMFC, we identified that a significant fraction of the electrochemical surface area (ECSA) loss of the PtCo/C upon the AST was recoverable. This recoverable ECSA loss was tentatively ascribed to the poisoning of the Pt surface by the sulfate ions either from the H2SO4 electrolyte in a RDE or the Nafion in a PEMFC. We further demonstrated that this poisoning effect can be largely suppressed without compromising the activity by encapsulating PtCo/C into thin functionalized carbon overlayers that were tuned to be permeable to H+, O2, and H2O, but not to sulfate ions.

EN05.11.12
Nanomechanical Studies of Ultrathin ALD and MLD Films Applied as Protective Layers for Metallic Li Anodes Using AFM Maedeh D. Amirmaleki1, Yang Zhao2, Teng Cui1, Xueliang A. Sun2 and Tobin Filleter1; 1University of Toronto, Canada; 2University of Western Ontario, Canada

Solid-state batteries (SSBs) have been considered as one of the most promising next-generation energy storage systems. However, interfacial issues such as mechanical instability between electrodes and solid-electrolytes are critical factors affecting the cyclic performances of SSBs. Ultrathin Al2O3 and polyurea thin film prepared by atomic layer deposition (ALD) and molecular layer deposition (MLD) techniques have been used as a coating layer for Li metal anode and solid-electrolyte materials in SSBs, which helped to boost the cycling performance and mechanical stability by protecting the interface of electrode/electrolyte. However, the static and dynamic mechanical response of ALD and MLD films is still unclear. We studied the elastic, fracture, and fatigue behavior of ALD Al2O3 and MLD aglucone as well as hybrid MLD/ALD films on a thickness range of 2 nm to 20nm. The static and dynamic mechanical behavior of suspended ALD and MLD films over supporting monolayer graphene was studied using atomic force microscope (AFM) film deflection technique. All ALD films at all thicknesses failed by brittle failure and showed higher stiffness than MLD films. The overall stiffness of ALD and MLD films affected by graphene to a greater extent below the critical thickness of 2 nm and 9 nm, respectively. Remarkable fatigue life was obtained for all Al2O3 films from million to several billion cycles under force range of 50% to 80% of static failure forces, while the fatigue cycle numbers increased by decreasing the thickness. Higher stiffness and failure forces of “15nmMLD/5nmALD” hybrid film in compare to “5nmALD/15nmMLD” films were shown to be the reason behind their better electrochemical performances in contact with Li metal anodes.

EN05.11.13
Understanding Organic Electrolyte Interactions in Calcium Ion Batteries from First Principles Joshua Young1, Peter Kulick2, Taylor Juran3 and Manuel Smeu2; 1New Jersey Institute of Technology, United States; 2Binghamton University, United States

Batteries utilizing multivalent species (e.g., Mg, Ca, Zn, or Al) as the working ion are gaining increasing attention for use in applications where large numbers of inexpensive cells are needed, such as grid storage. Ca in particular offers several advantages, including a reduction potential close to that of Li, high volumetric capacity, and fast solid state diffusion. However, the breakdown of commonly used organic electrolytes causes an ionically insulating passivating layer (the solid electrolyte interphase, or SEI) to form on the electrode surface, preventing reversible plating and stripping of the Ca metal anode. In this work we use density functional theory (DFT) and ab initio molecular dynamics (AIMD) calculations to study the interaction of Ca ions with various organic solvents used in typical electrolytes and investigate their breakdown on Ca metal surfaces. We find that Ca2+ forms a large first solvation shell in ethylene carbonate (EC) and propylene carbonate (PC) and a slightly smaller one in tetrahydrofuran (THF). We then use AIMD to compute the diffusion coefficient of Ca in each solvent using ClO4 as...
a counterion, and find that it diffuses fastest in THF, and slower in EC and PC. Finally, we used AIMD to identify the principle components of the SEI by studying the decomposition of EC on Li, Ca, and Al surfaces. We believe that these results have generated an increased understanding of Ca-based electrolytes and can help in the design of new ones in the future.

EN05.11.14
Revealing Electrolyte Oxidation via Carbonate Dehydrogenation on Ni-Based Oxides in Li-Ion Batteries by In Situ Fourier Transform Infrared Spectroscopy
Yirui Zhang, Yu Katayama and Yang Shao-Horn; Massachusetts Institute of Technology, United States

Understanding (electro-)chemical reactions at the electrode-electrolyte interface (EEI) is crucial to promote the cycle life of lithium-ion batteries. In this study, we developed an in situ Fourier-transform infrared spectroscopy (FT-IR) method, which provided unprecedented information on the oxidation of carbonate solvents via dehydrogenation on LiNi0.5Mn0.2Co0.3O2 (NMC). While ethylene carbonate (EC) was stable against oxidation on Pt up to 4.8 VLi, unique evidence for dehydrogenation of EC on LiNi0.8Co0.1Mn0.1O2 (NMC811) at voltages as low as 3.8 VLi was revealed by in situ FT-IR measurements, which was supported by density functional theory (DFT) results. Unique dehydrogenated species from EC were observed on NMC811 surface, including dehydrogenated EC anchored on oxides, vinylene carbonate (VC) and dehydrogenated oligomers which could diffuse away from the surface. Similar dehydrogenation on NMC811 was noted for EMC-based and LP57 (1 M LiPF6 in 3:7 EC/EMC) electrolytes. In contrast, no dehydrogenation was found for NMC111 or surface-modified NMC by coatings such as Al2O3. In addition, while the dehydrogenation of solvents was observed in 1 M electrolytes with different anions, they were not observed on NMC811 in the concentrated electrolyte (EC/EMC with 3.1 M LiPF6), indicating lithium coordination could suppress dehydrogenation. Dehydrogenation of carbonates on NMC811 accompanied with rapid growth of interfacial impedance with increasing voltage revealed by electrochemical impedance spectroscopy (EIS), while the electrode-electrolyte combinations without dehydrogenation did not show significant impedance growth. Therefore, minimizing carbonate dehydrogenation on the NMC surface by tuning electrode reactivity and electrolyte reactivity is critical to develop high-energy Li-ion batteries with long cycle life.

EN05.11.15
Oxide Ion Vacancies and Covalency Difference to Understand Chemical Expansion by Hydration Reaction between Yttrium-Doped SrCeO3 and SrZrO3
Takaya Fujisaki1, Aleksandar T. Stayko1, Kwati Leonard1, Yuhang Jing2,3, Narayana R. Aluru2,3 and Hiroshige Matsumoto1; 1Kyushu University, Japan; 2Beckman Institute, United States; 3University of Illinois at Urbana-Champaign, United States

It is necessary to reduce operating temperature below 600 °C for solid oxide fuel cell (SOFC) and solid oxide electrolysis cell (SOEC) toward cost reduction. High temperature proton conducting oxides have gained widespread interest as an electrolyte materials which are alternative to oxygen ion conductors. For typical high temperature proton conducting oxides, aliovalent cation-doped perovskite-type oxides (ABO3) exhibit proton conductivity originating from the hydration of oxide ion vacancies [1]. The hydration reaction is accompanied by structural deformation, i.e. chemical expansion. The chemical expansion lead to mechanical failure in electrochemical devices, and thus it is necessary to understand the causes of this process at the atomic scale. In this study, the chemical expansion behaviors of Y-doped strontium cerate (SCY) and Y-doped strontium zirconate (SZY) were comparatively investigated. High temperature X-ray diffraction and thermogravimetric analysis revealed that the cerate exhibits higher chemical expansion. To understand the reason why cerate has experimentally higher chemical expansion than zirconate, density functional theory (DFT) calculations revealed that size of oxide ion vacancies, and covalency between B-site and oxygen played important roles to understand the chemical expansion difference [2]. DFT shows the chemical expansion of SZY is larger than that of SCY when two dopant Y atoms are close each other. However, the reverse is also true for the case in which two dopant Y atoms are distant from each other. The former Y clustering case is energetically more stable in comparison with the latter of Y distant case. When it comes to sintering process of SZY and SCY, it seems that Y atoms are not experimentally diffused on the most stable atomic positions. Moreover, DFT revealed that the size of oxide ion vacancies in SZY is much smaller than that in
SCY in the case of Y-clustering; this is the reason why the chemical expansion of SZY is large than that of SCY. However, in case of the Y atoms are distant, oxide ion vacancies’ size is similar between SZY and SCY. Ionic and covalent bonding nature support the trend that SCY experimentally shows larger chemical expansion than SZY.

Rigidity of Interlayer Structural Water in Tungsten Oxide Leads to High-Rate, Pseudocapacitive Electrochemical Proton Intercalation
Veronica Augustyn; North Carolina State University, United States

In order to understand proton transport during a faradaic reaction in an oxide whose structural water content and structure was well-known, we have been investigating the electrochemical de/intercalation of protons in hydrated tungsten oxides, WO₃●nH₂O (n = 1, 2). Recently, we found that the presence of structural water leads to a transition in the energy storage mechanism from solid-state diffusion limited in WO₃ to surface-limited (or pseudocapacitive) in WO₃●2H₂O. We also found that WO₃●2H₂O exhibits much smaller and more reversible mechanical deformation during proton intercalation than WO₃, suggesting that the presence of structural water minimized the electrochemically-driven structural transformations (electrochemomechanics). Surface-limited energy storage in WO₃●2H₂O would suggest that a facile solid-state proton diffusion mechanism, such as Grotthuss transport, was present in this material. However, the fact that the energy storage process was closely related to the mechanical deformation of the material led us to consider an alternate explanation for the observed kinetic behavior. We investigated the role of structural water on the observed kinetic and electrochemomechanical differences between WO₃●nH₂O and WO₃ by coupling electrochemical characterization with fundamental studies of the structure and dynamics of both the solid state structure and confined water network. Operando X-ray diffraction (XRD), ex situ quasielastic and inelastic neutron scattering (QENS and INS, respectively), and density functional theory (DFT) calculations as a function of potential and proton content reveal that structural water in WO₃●nH₂O is extremely stable, which allows for rapid and facile structural transformation during electrochemical proton intercalation. We demonstrate that the facile electrochemomechanics of WO₃●nH₂O allow for reversible proton intercalation at a scan rate of 2 V s⁻¹, corresponding to a charge/discharge time of only ~ 500 ms. We hypothesize that it is the structural rigidity of the water network and not the presence of a Grotthuss mechanism, that leads to pseudocapacitive proton storage in the WO₃●nH₂O. This leads us to propose a new materials design strategy for high power, high energy density storage via the presence of structurally rigid fluids confined in the interlayer of 2D materials that stabilize the solid state structure at high rates.

In Situ GISAXS Investigation of Asymmetric Ostwald Ripening into PtNi Bimetallic Alloy under Operational Conditions of PEM Fuel Cells
Marco Bogar1,2, Ivan Khalakhan3, Josef Mysliveček3, Vladimir Matolin3 and Heinz Amenitsch2; 1CERIC-ERIC, Italy; 2Technical University of Graz, Austria; 3Charles University, Czechia
In the last years, several Platinum-based bimetallic alloys have been studied as possible substituents of pure Platinum catalysts in Proton Exchange Membrane Fuel Cells (PEMFCs) to strongly reduce production cost. In particular, PtNi alloy was found to be a promising alternative to pure Pt due to its very good mass activity and its competitive catalytic activity. The main drawback is related to the acid-based environment in which catalyst has to operate, which causes the dissolution of the less noble metal and the consequent degradation of the whole catalyst layer. In this framework, in situ Grazing Incidence Small Angle X-ray Scattering combined with electrochemistry is used to investigate the real-time kinetics of the surface degradation of PtNi alloy during electrochemical cycling voltammetry. In order to simulate the realistic fuel cell operation conditions, the study has been performed by applying different upper potentials and using different alloy compositions. Obtained results, have been complemented with in situ Electro-Chemical AFM and with Inductively Coupled Plasma Mass Spectrometry. Data revealed in depth the degradation of the aforementioned catalyst, the structural / compositional changes during fuel cell operation, and the asymmetric Ostwald ripening process, here described in electrochemistry the first time.

The authors acknowledge the financial support from project CEROP, which is a CERIC-ERIC internal research project.

Nitro Oxidized Cellulose Nano Paper for Proton Exchange Membrane Fuel Cells Sunil K. Sharma, Priyanka Sharma, Miriam Rafailovich, Benjamin S. Hsiao and Likun Wang; Stony Brook University, The State University of New York, United States

Nanocellulose is a renewable, inexpensive and biocompatible nanomaterial with high strength and tunable surface chemistry. Due to high global energy demand and environmental concerns it is vital to find alternative of fossil fuel; in this aspect Polymer electrolyte membrane fuel cells are highly effective and environmental friendly energy source. But higher cost for fabrication of proton exchange membrane in the fuel cell is major factor which makes it expensive. In this regards we have used novel, simple, cost effective and less chemical oriented Nitro-oxidation method to prepare high strength Cellulose nanopore having -COONa and -COOH functionalities with high proton conductivity at (80 °C with various RH%), good gas barrier properties and efficient fuel cell performance (37 mS2). Further we have characterized NO-CNF Nanopaper with morphological, spectroscopic and analytical techniques which includes IR, elemental anlysis, SEM, TEM, WXRD, 13CPNMR, BET surface area analysis, DMA etc.

9:30 AM EN05.12.04
Development of Nanocrystalline/Amorphous (La,Sr)CoO3-(La,Sr)2CoO4 Composite Cathodes for IT-SOFCs D. Sari1,2, B. Yasar1,2, F. Piskin1,2,3, Y.E. Kalay1,2 and Tayfur Ozturk1,2; 1Middle East Technical University, Turkey; 2Middle Eastern Technical University, Turkey; 3Mugla Sitki Kocman University, Turkey

A new class of amorphous/nanocrystalline (La,Sr)CoO3-(La,Sr)2CoO4 composite cathodes were developed for IT-SOFCs via co-sputtering of the respective oxides. The cathodes as deposited were amorphous at mid-compositions and could remain so when used at reduced temperatures. They could crystallize into two phase structures at temperatures close to 700 °C, with grains no more than 10 nm in size yielding a structure with extremely high density of hetero-interfaces[1]. EIS responses measured on symmetric cells imply satisfactory ORR performance at temperatures as low as 575°C especially when the volume fractions are in the range 0.40 < (La,Sr)2CoO4 < 0.60. Moreover it was found that co-sputtered (La,Sr)CoO3-(La,Sr)2CoO4 cathodes, followed in terms of area specific resistance (ASR), had highly stable cathode performance in prolonged testing. Cathodes were resistant to Sr segregation due probably to the high stability of extremely fine two-phase structure.

Flexible and Wearable All-Solid-State Al-Air Battery Based on Iron Carbide Encapsulated in Electrospun Porous Carbon Nanofibers Yuanyuan Ma1,2, Afriyanti Sumboja3, Xu Li3 and John Wang1; 1National University of Singapore, Singapore; 2Institute of Materials Research and Engineering, A*STAR, Singapore; 3Institut Teknologi Bandung, Indonesia

The growing demand for wearable and flexible energy storage devices requires batteries with high capacity and low cost. A rationally designed air cathode with high catalytic activity and robust mechanical properties is the key
requirement to realize flexible metal-air batteries for wearable applications. In this work, electrospinning N-doped carbon nanofibers containing iron carbide (Fe$_3$C@N-CFs) are synthesized and employed as the cathode in the flexible Al-air battery. Benefiting from the excellent catalytic activity of the iron carbide which are uniformly encapsulated in the N-doped carbon matrix, as well as the large specific surface area of the cross-linked network nanostructure, the as-prepared Fe$_3$C@N-CFs show outstanding catalytic activity and stability during oxygen reduction reaction. The as-fabricated all-solid-state Al-air batteries with Fe$_3$C@N-CFs catalyst show a stable discharge voltage (≈1.7 V) for 8 hours, giving a capacity of 1287.3 mAh g$^{-1}$. They are also demonstrated to power a LED watch continuously for over 22 hours, indicating their promising application as energy storage device for flexible electronics.

**In Situ X-Ray Absorption Spectroscopy of Synergistic Co–Mn Spinel Oxides as ORR Electrocatalysts in Alkaline Fuel Cells**  
Yao Yang, Yin Xiong, Rui Zeng, Francis J. DiSalvo and Héctor Abreuña; Cornell University, United States

As high-efficiency energy conversion devices, proton exchange membrane fuel cells (PEMFCs) have been recognized as crucial technologies for electric vehicles. However, PEMFCs still rely on expensive platinum-based electrocatalysts for the sluggish oxygen reduction reaction (ORR). As an emerging alternative, alkaline polymer electrolyte fuel cells (APEFCs) have drawn increasing attention because they can enable the use of non-precious metal electrocatalysts, in particular 3d metals, due to their low cost and high activity. Here, we report on a novel family of Co-Mn spinel oxide nanoparticle catalysts, that exhibit significantly enhanced ORR activity when compared to both Co$_3$O$_4$/C and Mn$_3$O$_4$/C and which rival Pt/C catalysts in alkaline fuel cells. Co-Mn spinels achieved a benchmark peak power density of 1.2 W/cm$^2$ at 2.6 A/cm$^2$ in membrane electrode assembly (MEA) tests at an optimal loading of 80 wt.% metal oxide on carbon supports. However, the origin of such electrocatalytic activity remains elusive, and necessitates the use of *in situ* techniques to identify the catalytically active (and relevant) sites under real-time electrochemical conditions.

Synchrotron-based *in situ* X-ray absorption spectroscopy (XAS) is a powerful nondestructive technique to study electrocatalytic mechanisms because it can provide atomic-level information on electrochemical reactions under operating conditions. The high penetration depth of high-energy X-rays, combined with a home-made electrochemical cell, have enabled the operando study of Co-Mn oxide catalysts. *In situ* X-ray absorption near-edge structure (XANES) was employed to track/monitor the oxidation state changes of Co and Mn, not only under steady state (constant applied potential), but also under non-steady state (potentiodynamic cyclic voltammetry) conditions. The periodic conversion between Mn(III, IV), Co(III) and Mn(II, III), Co(II) during the CV scans suggested that Co and Mn redox couples serve as co-active sites (co-catalyst) for the ORR. Rapid X-ray data acquisition, combined with a slow sweep rate in CV, enabled a 3 mV resolution in the applied potential and X-ray measurements, approaching a non-steady (potentiodynamic) state. Changes in the Co and Mn valence states were simultaneous and exhibited periodic patterns that tracked the cyclic potential sweeps. These observations strongly suggest a potential (and very likely) synergistic effect between Co and Mn, which may explain the superior activity of the Co$_{1.5}$Mn$_{1.5}$O$_4$/C electrocatalyst over the monometallic oxide counterparts. Aiming for a practical Pt-free cathode for AEMFCs for automotive applications, non-precious ORR electrocatalysts need to not only fulfill the requirements of high initial ORR activity, but also address durability concerns. We designed a family of Mn-Co-Fe trimetallic oxides to effectively improve the durability of our first-generation Mn-Co catalysts. The periodic conversion between Mn(III, IV)/Co(III) and Mn(II, III)/Co(II) as well as the essentially constant oxidation state of Fe during the CV suggested collaborative efforts among Mn, Co, and Fe. Mn and Co served as the synergistic coactive sites to catalyze the oxygen reduction, resulting in the observed high activity, while Fe worked to maintain the integrity of the spinel structure, likely contributing to the remarkable durability of the catalyst.

In summary, *in situ* XAS studies of electrocatalytic systems for the ORR in alkaline media have dramatically advanced our understanding of catalytic systems with various-valence multi-metallic active sites, in general, and for fuel cells, in particular.

Extremely Stable Platinum Core/Carbon Shell Electrocatalyst for Oxygen Reduction Reaction Youngkwang Kim1, Sujin Gok2, Mohanraju Karuppannan2, Eunjik Lee3, Jee Youn Hwang3, Ji-Hoon Jang3 and Oh Joong Kwon3; 1Seoul National University, Korea (the Republic of); 2Incheon National University, Korea (the Republic of); 3Hyundai Motor Group, Korea (the Republic of)

Polymer electrolyte membrane fuel cell (PEMFC) is considered as a promising energy source due to high energy efficiency and environment friendly characteristics. However, its commercialization is hampered by platinum catalysts requiring high cost and having low stability originating from an aggregation and a dissolution. To prevent particle agglomeration and dissolution, some researchers have introduced shells on platinum particles. For example, Chung et al. [“Highly Durable and Active PtFe Nanocatalyst for Electrochemical Oxygen Reduction Reaction” J. Am. Chem. Soc. 2015, 137, 15478−15485] reported PtFe electro-catalysts coated by carbon shell by adopting polydopamine layer and a carbonization. The carbon shell hinders the aggregation of alloy particles during the pyrolysis step carried out to transform the crystal structure of PtFe from fcc to fct. In addition, this shell protects platinum from dissolution during electrochemical reaction, thus enhances the durability at both half cell and unit cell tests. Chen et al. [“Nanostructured Polyaniline-Decorated Pt/C@PANI Core−Shell Catalyst with Enhanced Durability and Activity” J. Am. Chem. Soc. 2012, 134, 13252−13255] reported that the polymer coated commercial Pt / C had better durability than the uncoated Pt/C. They coated Pt/C with polyaniline and confirmed the carbon shell using a transmission electron microscope. PANI coated Pt/C exhibits improved activity and stability in half-cell test.

In this study, we are going to propose a new method for synthesizing platinum electro-catalyst encapsulated with a carbon shell and prove its improved durability in unit cell performance test. Typically, the carbon shell can be prepared by heating the polymer or carbon source coated on metal particle. However, this method requires extra processes which are generally difficult and tricky. Typical methods for synthesizing platinum core/carbon shell catalyst are comprised of 1) platinum reduction (electrochemical catalyst synthesis), 2) polymer or carbon source coating and 3) pyrolysis (carbon shell formation). In contrast, we have simplified the process to two steps of 1) synthesis of platinum and carbon source complexes and 2) pyrolysis (platinum reduction + carbon shell formation). Platinum-aniline complex made the reduction of synthesis step possible. The structural characteristics were investigated through XRD and HR-TEM and it was revealed that the Pt particles are encapsulated by 2~3 layers of graphitic carbon shells. From the Pt particle size of 5 nm, it could be inferred that aniline prevents the aggregation of Pt while it is decomposing to carbon.

In order to verify that carbon shell is perfectly covering Pt particle and this could contribute to the enhancement of durability of Pt catalyst, as-synthesized catalysts were electrochemically studied following the AST protocol suggested by DOE in 2016. The catalyst showed a similar activity but an enhanced stability in half cell test compared to the result obtained with a commercial Pt/C. Unit cell test had proved the real value of carbon shell. No loss in current density at 0.6 V was observed after 30 K AST cycles carried out following DOE 2016. The analysis of MEA performed after AST revealed that carbon shell still encapsulates the Pt particle and no aggregation and dissolution happen.

11:00 AM EN05.12.08
Reducing Degradation of PEM Fuel Cells Using HOR-Selective Anode Catalysts Leiming Hu1, Bharothy Parimalam1, Bo Ki Hong2, Jong-Gil Oh2 and Shawn Litster1; 1Carnegie Mellon University, United States; 2Hyundai Motor Company, Korea (the Republic of)

Polymer electrolyte membrane (PEM) fuel cells are promising power systems for future automotive applications, due to their low emissions and high efficiency. However, the lifetime of PEM fuel cells can be strongly affected by their various operation modes and transitional states. One such case is start-up/shutdown cycles, during which the air/hydrogen gas boundary will form in the anode gas flow channel and elevate the catalyst-electrolyte interfacial potential difference in the cathode. This increased interfacial potential causes carbon corrosion and Pt dissolution inside the cathode catalyst layer, leading to a loss of active catalyst area and performance degradation. One mitigation strategy is to use a selective catalyst at the anode that inhibits the anode half-cell reaction, which in turn reduces the corresponding corrosion current at the cathode. In this case, the selective anode uses a catalyst with high hydrogen oxidation reaction (HOR) activity and low oxygen reduction reaction (ORR) activity.
In this current work, we investigate the effectiveness of different selective anode catalysts, including iridium (Ir) and platinum (Pt) alloys of alloy composition on the PEM fuel cell’s start-up/shutdown durability. Results show that the anode with Ir on carbon (Ir/C) catalyst has the highest start-up/shutdown durability, with less than 20% of electrochemically active surface area (ECSA) lost after 1100 start-up/shutdown gas purging cycles. In comparison, conventional Pt/C anode causes more than 60% of ECSA loss after the same amount of cycles. Among Pt_xIr_y alloy catalysts, the Ir_3Pt_1/C shows the highest improvement on the start-up/shutdown durability, but not comparable with the Ir/C catalyst. Differences in the HOR and ORR activity of these anode catalysts are compared, and the degradation patterns are analyzed for better understanding of cause of the differences in start-up/shutdown durability.

Chemomechanical Response of Defective MnO_2 Nanosheet Pseudocapacitor Electrodes Scott T. Misture, Madeleine N. Flint, Peter Metz, Robert Koch, Peng Gao and Alec Ladonis; Alfred University, United States

X-ray total scattering was teamed with Raman and X-ray spectroscopy and related tools to probe the atomic-scale defects and chemomechanical response of MnO_2 nanosheet assemblies. The data reveal a direct link between surface Mn_3+ defects and charge storage, where intentionally introducing ~25% Mn_3+ defects increases the gravimetric capacitance by a factor of 3. An operando measurement cell was developed for X-ray PDF and XAS studies, and new PDF modeling approaches were developed that yield accurate quantification of the interatomic spacings and defect content vs. charge state. The data demonstrate that the nanosheets breathe in 2-D; in other words, the interlayer spacing between nanosheets remains invariant while the nanosheets expand and contract in the plane of the nanosheets by as much as 1% during charging. X-ray spectroscopy provides the Mn oxidation state which completes the picture of Mn redox. Overall, the study demonstrates that adding ~25% Mn_3+ defects increases charge storage by 3X with improvement in charge transfer resistance and dramatically improved cycle stability.

11:30 AM EN05.12.10
Modeling of PEM Fuel Cell Aging Due to Platinum Catalyst Degradation Giovanna Bucci1,2, Nathan Craig1 and W. Craig Carter2; 1Bosch Research Center, United States; 2Massachusetts Institute of Technology, United States

Ongoing development of proton exchange membrane (PEM) fuel cells focuses around the durability and the precious metal content of the membrane electrode assembly (MEA) of the fuel cell stack [1, 2]. The loss of the electrochemical surface area (ECSA) of the platinum (Pt) catalyst in the cathode electrode, particularly induced by voltage cycling, is a very important factor governing the performance degradation of the MEA [3, 4]. Thus, understanding the performance loss mechanism of voltage cycling is crucial for the successful commercialization of the PEM fuel cell for automotive applications.

We present a physics-based Pt catalyst degradation model that predicts ECSA loss via Pt particle coarsening and the formation of electronically disconnected Pt particles in the ionomer phase. The continuum electrochemical model includes: dissolution of Pt and subsequent electrochemical deposition on Pt nanoparticles; platinum-oxide coverage that forms a passivating layer, decreasing dissolution of the metal underneath; diffusion of Pt ions in the membrane electrode assembly; and Pt ion chemical reduction in membrane by hydrogen permeating through the membrane from the anode electrode [5-8]. Coarsening of Pt nanoparticles follows the mechanism of source-limited Oswald ripening, and it is investigated by tracking the evolution of the particle size distribution upon cycling. In the model, the Gibbs-Thompson effect drives the redistribution of mass from small to large particles, therefore decreasing the Pt active surface area. Diffusion of dissolved Pt at the micrometer scale leads to permanent mass loss and the formation of Pt bands in the membrane.

Comparing with literature experimental data [3, 4], the analysis provides further understanding of catalyst degradation mechanisms under voltage cycling and accelerated stress test conditions.

Role of Buffering Anions and Proton Donors in Carbon Dioxide Reduction at Immobilized Cobalt Phthalocyanine
Joy Zeng, Nathan S. Corbin, Kindle S. Williams and Karthish Manthiram; Massachusetts Institute of Technology, United States

Immobilized molecular complexes are an atomically precise platform on which to systematically interrogate and design electrocatalysts. This is a particularly exciting prospect because in electrocatalysis, the interplay between electrode, solvent, electrolyte, and reactants is often complex, and well-defined active sites could be leveraged to clarify some of that complexity. Cobalt tetrapyroles, such as cobalt phthalocyanine (CoPc), are well known to be active and selective for the reduction of carbon dioxide (CO₂) into carbon monoxide (CO) when immobilized on carbonaceous supports. To date, many studies of CoPc have focused on achieving performance, and indeed, current densities upward of 100 mA/cm² with near unity Faradaic efficiencies to CO have been reported. However, in order to take deeper lessons from this successful catalyst, and use them to guide rational design of future catalysts, it is important to understand intrinsic catalytic properties of CoPc. Towards this more fundamental goal, we measured the influence of bicarbonate buffer concentration on CO₂ reduction to CO at well-dispersed, immobilized CoPc. We found that the apparent bicarbonate order dependence shifted from negative to positive as the applied potential became more reductive. Tafel slopes were also found to vary depending on bicarbonate concentration. Coupled reaction-diffusion models suggested that transport limitations do not account for these observations. We propose a
mechanism in which CoPc is deactivated either via coordination to bicarbonate anions or partial reduction, which is able to explain the measured bicarbonate order dependencies and Tafel data. This work provides evidence that the rate determining step in the CoPc catalytic cycle is in fact an initial proton coupled electron transfer and that the presence of various “spectating” ionic species affect intrinsic activity. Such a complete set of mechanistic measurements on immobilized CoPc has not been reported before, and these surprising results have important fundamental implications for elucidating reaction mechanism and practical implications for designing and evaluating high-performance devices.

Haber–Bosch Reaction Mechanism and Kinetics on Highly Reactive Iron Surface and Hierarchical High-Throughput In Silico Screening Catalyst Design Qi An1, Alessandro Fortunelli2 and William A. Goddard3; 1University of Nevada, Reno, United States; 2Consiglio Nazionale delle Ricerche, Italy; 3Caltech, United States

To discover new alloy catalysts that might dramatically improve the efficiency of the Haber–Bosch (HB) process for ammonia synthesis from hydrogen and nitrogen, we employed quantum mechanics (QM) to determine the reaction mechanism and free energy reaction barriers for the two most highly reactive Fe surfaces (Fe(211)R and Fe(111)) under experimental single crystal reaction conditions (400°C and 20 atm). We determined the rates for all 10 important surface reactions on both surfaces. Then we used this information in a full kinetic Monte Carlo (kMC) simulation (60 minutes) to determine the kinetics. We predict that the Turn Over Frequency (TOF) for Fe(111) surface is TOF =18.7 s⁻¹ per 2 x 2 surface site for 1.5 Torr NH₃ pressure in excellent agreement with experiment (9.7 NH₃/sec for (111) and 7.3 NH₃/sec for (211)R) which is consistent with experiment (~1:0.75). The excellent agreement between theory and experiment on two very different surfaces and reaction mechanisms is a testament to the completeness and accuracy of our QM and kMC modelling. To dramatically improve the efficiency of HB reactions on these highly reactive surfaces, we applied hierarchical high throughput screening approach to sift the promising doping elements on these two highly reactive surfaces. We found several promising dopants that can significantly improve the TOF.

9:30 AM  EN06.01.03
Unraveling Mechanistic Reaction Pathways of the Electrochemical CO₂ Reduction on Fe-N-C Single Site Catalysts Wen Ju1, Peter Strasser1, Alexander Bagger2, Jan Rossmeisl2 and Ana Sofia Varela3; 1Technische Universität Berlin, Germany; 2University of Copenhagen, Denmark; 3National Autonomous University of Mexico, Mexico

We report an experimental-computational study of mechanistic reaction pathways during the electrochemical reduction of CO₂ to CH₄, catalyzed by solid-state, single-site Fe-N-C catalysts. Fe-N-C catalysts feature molecularly dispersed catalytically active Fe-N motifs and represent a type of non-Cu-based catalysts that yield “beyond CO” hydrocarbon products. The various multi-step mechanistic pathways toward hydrocarbons with these catalysts has never been studied before and is the focus of this study. A number of different reactant molecules with varying formal carbon redox states, more specifically CO₂, CO, CH₂O, CH₃OH and formate were electrochemically converted at the Fe-N sites, yet only CO₂, CO and CH₂O could be protonated into methane. Also, we observed a distinctly different pH dependence of the catalytic CH₄ evolution from CO and CH₂O, suggesting differences in the proton participation of rate determining steps. In comparing the experimental observations with Density Functional Theory (DFT) -derived Free Energy Diagrams of reactive intermediates along the reaction coordinates, we unraveled the distinctly different dominant mechanistic pathways and roles of CO and CH₂O along the catalytic CO₂-to-CH₄ cascade and their rate-determine-steps (RDS). We close with the first comprehensive reaction network of the CO₂ electroreduction on a M-N-C catalyst. Our findings offer valuable insights in the catalysis of the CO₂RR on single site Fe-N-C catalysts that may prove useful in developing efficient, non-Cu-based catalysts for direct electrochemical hydrocarbons production.

9:45 AM  BREAK

Cooperative and Reversible Photoactivation of Single-Atom Cu/TiO₂ Photocatalysts Taeghwan Hyeon1,2 and Byoung-Hoon Lee1, 2; 1Seoul National University, Korea (the Republic of); 2Institute for Basic Science (IBS), Korea (the Republic of)
I present the design and synthesis of highly active TiO₂ photocatalysts incorporated with site-specific single copper atoms (Cu/TiO₂) that exhibit reversible and cooperative photoactivation process.¹ I believe that this study represents one of the important breakthroughs in atomically defined photocatalysts that share the similar mechanism with metalloenzymes. The reversible and cooperative activation process is one of the most important characteristics of biological enzymes, and has been frequently used in designing homogeneous catalysts. However, there is nearly no report on industrially important heterogeneous catalysts with these enzyme-like characteristics. Herein we designed single atom catalysts (SACs) with well-dispersed copper atoms exclusively occupied in the most stable Ti vacancies in the hollow TiO₂ nanoparticles, and identified atomic-level reversible and cooperative photoactivation process during dynamic photocatalysis. Furthermore, we demonstrate that in single-atom Cu/TiO₂, the dynamic cooperation between site-exclusive Cu atoms and TiO₂ can trigger the unprecedented reversible photo-activation process that includes valence state change of Cu atom and reversible modulation of surface electronic structure of the local TiO₂ environment. This unique photo-activation process has led to the extremely strong light absorption in the whole visible range and resulting highly enhanced H₂ generation activity that far exceeds state-of-the-art TiO₂-based photocatalysts incorporated with earth-abundant transition metal-based cocatalysts. This first demonstration of heterogeneous catalysts with the enzyme-like characteristics is a monumental discovery in realizing the reversible electronic structure modulation in heterogeneous catalysts. I will also report various catalytic applications of SACs based on nanomaterials of CeO₂, TiO₂, and graphene oxide.

11:00 AM EN06.01.06
Ultrafast, Controllable Synthesis of Sub-Nano Metallic Clusters and Single Atoms through Defect Engineering Yonggang Yao and Liangbing Hu; Univ of Maryland, United States

Supported metallic nanoclusters (NCs, < 2 nm) are of great interests in various catalytic reactions with enhanced activities and selectivity, yet it is still challenging to efficiently and controllably synthesize ultra-small NCs with a high-dispersal density. Herein, we report the in situ synthesis of surfactant-free, ultra-small, and uniform NCs via a rapid thermal shock on defective substrates. This is achieved by using high temperature synthesis with extremely fast kinetics while limiting the synthesis time down to milliseconds (e.g. ~1800 K for 55 ms) to avoid aggregation. Through defect engineering and optimized loading, the particle size can be robustly tuned from > 50 nm particles to < 1 nm uniform NCs with a high-dispersal density. We can also achieve high-density single atom dispersion using a similar high-temperature method. We demonstrate that the ultra-small NCs exhibit drastically improved activities for catalytic CO oxidation as compared to their nanoparticulated counterparts. In addition, the reported method shows generality in synthesizing most metallic NCs (e.g. Pt, Ru, Ir, Ni) in an extremely facile and efficient manner. The ultrafast and robust synthesis of uniform, high-density, and size-controllable NCs paves the way for the utilization and nanomanufacturing of NCs for a range of catalytic reactions.

11:15 AM EN06.01.07
Stabilization of Dinuclear Rhodium Clusters on a Layered Titanate Support Ritesh Uppuluri, Jennifer Gray and Thomas E. Mallouk; The Pennsylvania State University, United States

Atomically dispersed clusters comprising single and pairs of atoms are gaining increasing attention for heterogeneous catalysis as they are structurally different from bulk metal and metal nanoparticles. The different catalytic activity stems from both surface effects, where the number of unsaturated bonds increase with decreasing cluster size, and electronic effects that result in discrete energy levels of the electrons thus enabling greater orbital overlap with substrate molecules. In recent years, the structure and catalytic activity of single atom catalysts has been extended to selectively investigate the stability of dimers on different supports by wet chemical deposition.¹,² In this study, we present that dinuclear rhodium complexes could be well-dispersed on layered titanate supports (H₀.₁₃Ti₀.₈₇O₂ and H₂TiO₃ nanosheets). Nanosheets derived from layered metal oxides represent a unique class of catalyst supports as they can be imaged by electron microscopy and were previously shown to resist sintering of late transition metal oxide nanoparticles.³ The stability of dinuclear clusters on layered titanate supports are elucidated by a combination of aberration-corrected transmission electron microscopy, DRIFT spectroscopy, and X-ray absorption (EXAFS and XANES) spectroscopy.

*Elucidate Atomistic Mechanisms of Single Atom Catalysis on Graphene for CO2 Reduction* Yuanyue Liu; The University of Texas at Austin, United States

Single metal atoms anchored on N doped graphene (M-N4-G) have attracted extensive interest as catalysts for carbon dioxide reduction. Although DFT calculations based on computational hydrogen electrode mode have been performed to understand the atomistic mechanisms, several important questions remain unexplained. For example, the DFT calculations show that the formation free energy of *COOH, a critical intermediate during CO2R, is rather high (> 1 eV), contradicting with the experimental report of high activity. Here, using ab initio molecular dynamics (AIMD) simulations with explicit water molecules and surface charge (which are neglected in conventional DFT calculations), we are able to elucidate the atomistic mechanisms, and explain the difference in catalytic activity of different metal atoms.

*Electrochemical Reduction of Carbon Dioxide on Copper MOFs—Effect of Ligand Functional Groups on Efficiency and Selectivity* Nusrat Rashid and Pravin P. Ingole; Indian Institute of Technology Delhi, India

The current rate of energy consumption has shifted the balance of environment especially owing to the exponentially increasing concentration of carbon dioxide. Reduction of carbon dioxide into fuels or useful chemicals is probed as a new way to clean the air, lessen the release of carbon dioxide in the atmosphere (especially from point sources) and store renewable energy like electricity as chemical energy. Different approaches have been used to reduce carbon dioxide, like electrochemical, photochemical, thermochemical, biological or combination of any of these approaches. The electrochemical route is attractive given many renewable energies are stored in electric form and hence are readily available. Copper metal has been found unique pertaining to its ability to reduce carbon dioxide into hydrocarbons which can be used as fuels or industrial feedstock. Given the affinity of MOFs to absorb gases like carbon dioxide many groups developed different MOFs to study ERC (electrochemical reduction of carbon dioxide). Copper variants of MOFs have shown promising activity for ERC. Taking cues from the gas absorbing capability of MOFs and promising performance of copper towards ERC, we synthesized different copper MOFs like CuBDC (copper benzyl-di-carboxylic acid) and CuBTC (copper benzyl-tri-carboxylic acid) to study ERC. The materials were characterized by XRD, FESEM, TEM, IR, Raman, XPS and TGA. All analysis confirmed the formation of impurity-free successful synthesis of CuMOFs. We found that both MOFs are active for ERC but CuBDC is more selective for hydrocarbons than CuBTC. Further, it was found and thoroughly analyzed that the active site for ERC is actually *in situ* formed metastable copper and copper (I) oxides which are formed over negative potentials applied. Structural changes were also found on the application of negative potentials, metal and metal oxides were embossed in the carbon backbone. Earlier reports suggest that MOFs are proven to convert CO2 into alcohols while we found they convert CO2 considerably into ethylene and some methane. Recent studies have proved that associated organic groups with metal catalysts as ligands or stabilizers are also
involved in the alteration of catalytic activity of the materials, especially in nano-domain. We altered the free -COOH groups in terephthalate groups of an organic framework with amine groups to check the effect of functional groups on ERC associated with the metal centers. It was found that -NH2 groups aid in catalyzing the ERC with greater selectivity towards hydrocarbons and higher cumulative faradaic efficiencies towards ERC. Also, the stability of the catalyst increased with keeping hydrogen evolution limited under 30%.

Use of Functionalization on Bimetallic MOFs for Enhanced ORR and OER Performance Simranjit K. Grewal and Min-Hwan Lee; University of California, Merced, United States

Oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) is the most studied reactions for clean energy devices for energy conversion devices such as fuel cells as result of slow kinetics. Transmission metal oxides (TMO) such as Co3O4, Fe3O4, and MnOx [1] have been extensively researched as way to replace platinum and its alloys for both sustainability and cost effectiveness. To combat the intrinsic low conductivity of TMOs, they are often incorporated into a highly conductive carbon nanostructure such as metal organic frameworks (MOFs). MOFs have garnered wide attention for their ability to efficiently and effectively improve adsorption of reactants, stability, and conductivity.

In this study a bimetallic MOF was synthesized via a solvothermal method and pyrolysis using both cerium and cobalt nitrate salts with a ligand called 1,3,5-Benezenetricarboxylic acid to create MOF-Co-Ce with extreme surface area and excellent electronic conductivity. Though this structure is conductive, this can be enhanced with the functionalization of cerium particles. Specifically, the Ce(IV) complexes has shown superior rates of phosphonate ester bond cleavage compared to other metal oxides. This unprecedented activity of the Ce(IV) complex has been attributed to it’s 4f orbital being able to “mix” with the orbitals of the P=O bond to form hybrid orbitals[2]. To functionalize cerium, phosphoric acid is employed to induce the binding of phosphate groups onto cerium oxide. This gives rise to the pentacoordinate intermediate being susceptible to a nucleophilic attack [2]. The functionalized MOF-Co-Ce is subjected to the solvothermal method at 160°C for 24 h with the precursor P25, thus creating MOF-Co-Ce with TiO2 attached (MOF-Co-Ce-Ti).

Results have shown an enhanced performance in terms of current density and onset/halfwave potential for both CV and LSV data as result of phosphate groups absorbing cerium nanoparticles. FTIR data indicates the absorption of 1040 cm⁻¹ (phosphate group peak) appeared after MOF-Ce-Co treatment of phosphoric acid. X-ray analysis indicated that both samples (MOF-Co-Ce and MOF-Co-Ce-Ti) had cerium and cobalt particles, with MOF-Co-Ce-Ti having an additional peak at 56°. Thus, indicating the presence of TiO2 (anatase). Therefore, the improved performance of the treated MOF is the result of its functionalization.

This project was funded by NASA Advanced STEM Training and Research (ASTAR) Fellowship.

Tuning Catalytic Activity by Confinement: Aluminum Metal Organic Framework Triggers Selectivity for Carbon Dioxide Reduction Michelle Lee1,2, Alberto De Riccardis1, Roman Kazantsev1, Jason K. Cooper1, Aya K. Buckley1, Paul Burroughs1, David M. Larson1, Giuseppe Mele3 and Francesca Maria Toma1; 1Lawrence Berkeley National Laboratory, United States; 2Cornell University, United States; 3Università del Santo, Italy

Confinement of metal centres is a powerful tool to manipulate reactivity of catalytic centres and tune selectivity in chemical transformations. While aluminum as a foil is inactive for CO2 reduction and shows high selectivity for hydrogen evolution reaction, here we show that aluminum centres confined in a metal organic framework, MIL-53(Al), suppress hydrogen evolution reaction activity and interestingly enhance carbon dioxide reduction.
Aluminum confined in MIL-53 can electrochemically reduce CO₂ to both carbon monoxide and formic acid, as valuable carbon-based products. Control experiments support that the catalytic activity is related to the presence of aluminum and that the confinement effect promoted by the organic ligands is key to obtaining carbon dioxide reduction behaviour. The observation of Al⁰ after electrochemical CO₂ reduction supports that the active form of the catalyst may involve the presence of aluminium in this oxidation state. This aluminum MOFs can produce up to 40% faradaic efficiency for carbon monoxide and formic acid, and with a turnover frequency of 174 h⁻¹. This study demonstrates that the confined reaction space enables changes in reaction selectivity and can impart atypical catalytic capabilities to metals.

AIM-ing for Single Atom Precision for High-Density Supported Arrays of Hetroegeneous Catalysts Joseph T. Hupp, Jian Liu, Hyunho Noh and Subhadip Goswami; Northwestern University, United States

A frontier challenge in the materials chemistry of heterogeneous catalysis is to obtain designed, stable arrays of desired catalysts that are uniform in structure and composition. Catalyst organization in high-density, yet reactant accessible, form enables catalysts to out-perform lower density structures simply because rates of chemical transformations generally scale as the quantity of accessible catalyst employed. Thus, heterogeneous electrocatalysts that are perhaps marginal in sub-monolayer amounts can yield kinetic overpotentials that are hundreds of millivolts smaller when the same catalysts are presented as hundreds or thousands of redox-addressable, and reactant- and product-permeable monolayers at electrode/solution interfaces.¹,² Related arguments are relevant to heterogeneous catalysis of gas phase chemical reactions.

Uniformity of catalyst structure and composition, while standard for molecular catalysts, can be difficult to achieve - or, once achieved, difficult to sustain -- for non-molecular, heterogeneous catalysts. To the extent that uniformity can be achieved, however, hypothesis-driven approaches to advancing Catalysis Science can be pursued. For heterogeneous catalysis, pertinent hypotheses may include the dependence of catalyst activity, selectivity, and long-term stability on, for example: a) catalyst-catalyst site-isolation versus reactant accessibility, b) the nature of the environment beyond the catalyst active-site,³ c) cluster-type-catalyst metal nuclearity, d) the nature and extent of catalyst/support interactions, e) the chemical basis for conversion of synthesized precatalysts to functional catalysts, and f) the ability of the surrounding infrastructure, for example the porous MOF, to supply or sustain essential ancillary properties or components such as local pH, reaction-space confinement, suitably reactive oxidizing or reducing equivalents, charge-compensating ions, or reactive photo-generated molecular excitons.

This presentation will focus on synthesis, characterization, and chemical/photochemical/electrochemical application of cluster-based catalysts that are constructed in automated, atom-by-atom fashion and supported on crystallographically well-defined metal-oxide nodes within high porosity, metal-organic frameworks.⁴,⁵ By way of illustration, two or three case studies will be presented.

Single Atom Alloys—Novel Catalysts for Selective Catalytic Reactions Georgios Giannakis, Ryan T. Hannagan, Mengyao Ouyang, Charles H. Sykes and Maria Flytzani-Stephanopoulos; Tufts University, United States
Novel catalyst designs aiming at the development of energy-efficient, low-cost and sustainable processes are of great interest for applications to fuels and chemicals production, and to environmental pollution abatement. Identification of the active catalytic site and design of catalysts with 100% atom efficiency has been a long-standing goal in heterogeneous catalysis. For catalytic metals, atomic dispersion affords better utilization, different (often better) selectivity than the extended metal, and new prospects for low-cost and green process development. It is crucial to understand the mechanisms behind catalysis by supported single metal atoms, as this will guide new, improved catalyst designs.

A new class of single-atom heterogeneous catalysts will be presented, namely Single-Atom Alloys that comprises catalytically active elements like Pt, Pd and Ni alloyed in a more inert host metal like Cu, Au or Ag at the single-atom limit. Single-atom alloys offer a unique approach towards rational catalyst design, one that combines surface science, catalysis and theory in a most efficient way. Model surfaces and nanoparticles that can host isolated atoms in the surface layers behave similarly in escaping the linear scaling relationships and allowing for the rational fine-tuning of activity and selectivity. Good stability is imparted by the strong metal-metal bonds between the host and the minority metal, and atomic dispersion can be maintained at high temperatures. Resistance to CO poisoning and to coking are additional advantages of these promising materials, as will be shown in the presentation drawing examples from alkyne and alkadiene hydrogenation and alkane dehydrogenation. Novel synthesis methods and the stability of single-atom metal catalysts in various supports and reaction environments will be discussed.

Diverse Effects of Metal-Oxide Interfaces in Catalysis Sergey Kozlov; National University of Singapore, Singapore

Numerous global challenges, such as the development of environmentally friendly energy and fuel technologies, can be addressed by the development of advanced heterogeneous catalysts. Increasingly often, such catalysts are developed by designing metal-oxide interactions that can boost the catalytic activity by several orders of magnitude. However, such interactions are notoriously challenging to characterize experimentally, which puts electronic structure simulations to the forefront of research on complex nanostructured catalysts.

In this contribution, first I will discuss pioneering density functional simulations of Pd and/or Pt nanocrystallites up to 1.5 nm in size supported on MgO(100), cubic ZrO2(111) and/or CeO2(111) supports. The electron transfer from Pt nanoparticles to reducible CeO2(111) support was quantified by experiments and simulations, which showed that it can reach up to 0.1 electrons per Pt atom and significantly change the reactivity of Pt particles.[1] In turn, the effect of irreducible oxide supports on the nanoparticle reactivity is more complicated. On the one hand, MgO(100) support was calculated to insignificantly affect H adsorption and absorption in supported Pd and Pt nanoparticles.[2] On the other hand, perimeters sites on MgO(100) and ZrO2(111) interfaces with Pd particles were calculated to have increased resistance to CO poisoning, which was observed to significantly increase overall CO tolerance of μm-large Pd aggregates in societally important CO oxidation reaction.[3]

At the same time, interactions with metallic supports also affect the structure and the catalytic properties of the oxides. For example, indium oxide films on Co supports are calculated to contain more O vacancies, which are active sites for CO2 reduction, and have higher methanol selectivity compared to pristine indium oxide surfaces, which is also shown experimentally.[4] In another study, we show how MoOxHy clusters interacting with Ni support adopt the structure and the degree of oxidation that makes them highly active in electrochemical hydrogen evolution reaction (HER) at neutral pH, which is in line with the experimental characterization of Ni-Mo catalysts.[5]

The discussed studies shed light on the electronic aspects of metal-oxide interactions and offer strategies for using such interactions to improve the activity and the selectivity of catalysts.

Enhanced Ethylene Yields in the Electroreduction of CO2/CO Co-Feeds on Cu and Cu-Tandem Electro catalysts Xingli Wang1, Jorge Ferreira de Araújo1, Jan Rossmeisl2 and Peter Strasser1; 1Technical University Berlin, Germany; 2University of Copenhagen, Denmark

The electrochemical CO2 reduction reaction (CO2RR) valorizes CO2 directly into chemicals and fuels. In addition to energy efficiency and selectivity challenges, the supply of CO2 in sufficiently high purity is of great concern. Industrial CO2 feeds are often contaminated with CO, which calls for an investigation of the catalytic CO2RR under CO2/CO co-feed (“dirty CO2”) conditions. In this talk, we present new mechanistic insights into the electroreduction of external (mixed) CO2/CO co-feeds on Cu-based nanocatalysts, which exhibits significantly promoted ethylene production rate over a wide range of electrode potentials and co-feeding ratios. Kinetic isotope labelling experiments using 12CO2 and 13CO – performed in a novel operando differential electrochemical mass spectrometry (DEMS) capillary flow cell with milli-second time-resolution – showed that in both cathodic and anodic scan direction the enhanced C2H4 production originated to almost 50% from the C-C coupling of a 12CO with a 13CO molecule, that is from a cross-coupled “12CO2-13CO” reactive pathway, and to a lower degree from the 12CO2-12CO2 or 13CO -13CO pathways. These transit results with DEMS setup identify the stationary results with gas chromatography and further evidence the absence of a kinetic competition between CO2 and CO molecules for surface adsorption sites, implying distinct surface sites for CO2 and CO adsorption/reduction and suppressed surface adsorbate scrambling. Based on these fundamental mechanistic insights, the practical significance of sustained local interfacial CO partial pressures under local CO2 depletion is then demonstrated using the family of non-metallic/metallic and metallic/metallic tandem CO2RR catalysts with improved and stable ethylene yields. Together, our findings uncover the mechanistic origin of improved C-C product selectivities under co-feeding, but also highlight technological opportunities of impure CO2/CO process feeds for use in the electrochemical CO2 reduction process.

Impact of the Metal Support on the Catalytic Activity of Nanoclusters Mira Todorova, Su-Hyun Yoo and Jörg Neugebauer; Max-Planck-Institut fuer Eisenforschung, Germany

Strategies to enhance catalytic activity are manifold and often rely on exploiting features of seemingly disjoint system. Examples are electrochemistry based catalytic approaches (e.g. electro-catalysis or photo-catalytic electrochemistry processes), nano-catalyst, supported catalyst and others. We will discuss two examples, in which density-theory calculations provide insight into features relevant for catalysis, thereby suggesting routes to tailor catalytic activities. The first example is concerned with ZnO surfaces, where the contact with an aqueous environment leads to the stabilization of catalytically active step and kink sites [1]. The second example, focuses on gold nanocatalysts supported on reduced TiO2 surfaces, for which we discuss the alignment of the respective band structures and its consequences for the catalytic activity of the overall system [2].

Rational Design of Alloy Catalysts by Simultaneously Addressing Strain and Ensemble Effects Tim Mueller and Liang Cao; Johns Hopkins University, United States

The activity, selectivity, and stability of alloy catalysts can be optimized by tailoring their bulk lattice parameters (the strain effect) and near-surface atomic order (the ensemble effect). However this same compositional and structural flexibility makes it difficult to predict the structure and catalytic properties of alloys from first principles. We will present an approach for simultaneously accounting for the strain and ensemble effects in alloy surfaces that enables the rapid prediction of the surface structure and catalytic properties of stable and metastable alloy materials.
We use our approach to introduce complete maps of catalytic activity for thermodynamically stable phases across compositions and temperatures, making it possible to identify the synthesis conditions likely to produce the most active catalysts. By analyzing these maps, we will discuss in particular the roles of intermetallic phases, nanoparticle sizes, and atomic ensembles in determining the catalytic activity of alloy surfaces. We will present examples from Pt-based alloys for the oxygen reduction reaction, but the approach we present is applicable to a wide range of reactions on alloy surfaces.

**Automated Detection and Characterization of Surface Restructuring Events in Bimetallic Catalysts** Jin Soo Lim¹, Nicola Molinari¹, Kaining Duanmu², Philippe Sautet²,³ and Boris Kozinsky¹; ¹Harvard University, United States; ²University of California, Los Angeles, United States

Surface segregation in bimetallic systems plays a crucial role in heterogeneous catalysis. However, mechanistic studies of such restructuring phenomena remain scarce due to the large configurational space that makes it challenging to establish the most relevant set of mechanisms. To this end, we develop an automated method to discover elementary surface restructuring processes in an unbiased fashion, and apply it to Pd/Ag single-atom alloy as an example.

We employ high-temperature classical molecular dynamics (MD) to rapidly detect restructuring events, isolate them, and optimize using density functional theory (DFT). Our approach, combining MD and ab initio calculations, has two main advantages over conventional static transition state modeling methods. First, our approach is unbiased and does not rely on human intuition, instead discovering the relevant transition state pathways from the real-time surface dynamics. Second, the process is streamlined, quickly and automatically detecting restructuring events from MD and optimizing every event with DFT.

In addition to finding the previously proposed mechanism of exchange descent, our approach has revealed three new general classes of concerted restructuring events, dominant at step edges of close-packed surfaces: (1) vacancy insertion; (2) direct exchange; (3) interlayer exchange. Our results highlight the importance of vacancies at steps and kinks in facilitating Pd-Ag exchange processes, an insight that could not be established from previous DFT calculations on model terraces. The restructuring events discovered through our automated scheme enable us to go beyond thermodynamics and construct a complete set of mechanisms by which Pd is incorporated into the Ag host in vacuum at the single-atom limit. Furthermore, the approach establishes an important foundation to investigate more complex restructuring phenomena, such as Pd/Ag heteroepitaxy and adsorbate-induced reverse segregation. Our automated method is transferable to other alloy systems of interest and allows the dynamic nature of surfaces to be studied at the microscopic level with ab initio level of accuracy. The atomistic insights presented in our work provide a step toward systematic understanding and engineering of surface segregation dynamics in bimetallic catalysts.

**Paving the Way to Greener Chemistry with Nanocatalyst Control—Stable AuPd for On-Site Hydrogen Production and Use** Michelle Muzzio and Shouheng Sun; Brown University, United States

Catalysis is one of the main tenants of green chemistry and the optimization of catalytic processes to improve the stability and reusability of the catalyst is an important research endeavor. Nanocatalysts in particular have been widely used and can uniquely catalyze more than one reaction on their large amounts of surface area – potentially minimizing solvent, substrate, and catalyst waste if reactions are engineered properly. In this work, we report the synthesis of a series of AuPd alloy nanoparticles with careful control of nanoparticle size and composition. We
highlight AuPd’s high activity for ammonia borane (a green alternative hydrogen source) dehydrogenation. With a TOF of 160 min\(^{-1}\) for AB methanolysis, Au\(_{66}\)Pd\(_{34}\) has the highest activity of all Pd-based catalysts reported for H\(_2\) production with a very low activation energy, 22.4 kJ/mol. Not only is the AuPd active for the formation of hydrogen (H\(_2\)), but, we can then use this generated H\(_2\) in-situ for the dehalogenation of polychlorinated phenols (tough to degrade chemicals that have been used as pesticides in the past). Beyond this, ambient pressure H\(_2\) formed can also be used for the mild reductive amination of levulinic acid/ethyl levulinate, biomass derivatives, to value-added pyrrolidones, over the same AuPd catalyst, simply recycled and used for both reactions, over ten times with no change in catalyst activity.

Solar-Driven Asymmetric Reduction of C=C Bonds via Light-Harvesting Alginate Hydrogel for Sustainable Photobiocatalysis
Yoon Jaeho\(^1\), Sahng Ha Lee\(^1\), Tieves Florian\(^2\), Rauch Marine\(^2\), Hollmann Frank\(^3\) and Chan Beum Park\(^4\); \(^1\)Korea Advanced Institute of Science and Technology, Korea (the Republic of); \(^2\)Delft University of Technology, Netherlands

Here, we report a robust platform for sustainable photobiocatalysis using an ene-reductase from *Thermus scotoductus* SA-01 (*TsOYE*) and a light-harvesting dye (rose bengal, RB) co-immobilized alginate hydrogel. *TsOYE*-encapsulated alginate hydrogel was prepared by simple mixing and gelling with high efficiency. Highly efficient encapsulation of RB in alginate hydrogel was followed using the intrinsic affinity between *TsOYE* and RB, which allowed for the construction of robust RB-*TsOYE*-loaded alginate capsules. A series of spectroscopic and electrochemical assays verified spontaneous binding of RB molecules to the flavin prosthetic group of *TsOYE* with a higher affinity than NADH, and direct electron transfer and co-reduction of *TsOYE* and RB in alginate hydrogel. In the absence of NADH, the photobiocatalytic system facilitated asymmetric hydrogenation of 2-methylcyclohexenone to an enantiopure (R)-2-methylcyclohexanone (max. conversion: 70.4%, turnover number: 300.2, turnover frequency: 1.54 min\(^{-1}\)) under illumination of a white light-emitting diode (LED) (power: 5.22 mW/cm\(^2\)). While the limited mobility of immobilized *TsOYE* and substrate accessibility reduced the overall catalytic performances, we revealed a significant enhancement of *TsOYE*'s robustness against heat and chemical denaturants and reusability while immobilized in alginate hydrogel. This study provides insight into a greener and sustainable approach of cofactor-free OYE biocatalysis for solar-driven synthesis of value-added chemicals.

EN06.03.03
Selective Oxidation of Methane to Methanol Using Bioinspired Metal–Organic Framework Catalysts
Jayeon Baek\(^1\), Bunyarat Rungtaweeworani\(^2\), Gabor A. Somorjai\(^3\) and Omar M. Yaghi\(^3\); \(^1\)Korea Institute of Industrial Technology, Korea (the Republic of); \(^2\)National Science and Technology Development Agency, Thailand; \(^3\)University of California, Berkeley, United States

Selective methane oxidation to methanol represents an important challenge in catalysis due to the difficulty in activating the strong C–H bond of methane (bond dissociation energy = 104 kcal mol\(^{-1}\)), giving rise to selectivity and activity problems. Finding a solution to this impediment is a key toward the direct synthesis of methanol from methane.

In nature, particulate methane monooxygenase (pMMO) is known as an effective catalyst for the oxidation of methane to methanol. Inspired by pMMO, molecular complexes have been developed utilizing the tunability of ligand design in pursuit of duplicating the structure and reactivity in a synthetic system. However, it has been a challenge to incorporate copper active sites bound to imidazole units in the pore of heterogeneous catalysts for methane oxidation.

We envisaged that metal–organic framework (MOF) can serve as a scaffold akin to the polypeptide chains in enzymes whose arrangement of secondary and tertiary structures can be achieved by judicious choice of structure and topology of MOFs. From structural analysis of various MOFs, MOF-808 was used to postsynthetically install ligands bearing imidazole units for subsequent metalation with Cu(I) in the presence of dioxygen. The catalysts show high selectivity for methane oxidation to methanol under isothermal conditions at 150 °C. We identified the structure of the active sites using solid-state UV–vis, resonance Raman, and X-ray absorption spectroscopies complemented by density functional theory (DFT) calculations. The results led us to conclude the most probable active site as bis(μ-oxo) dicopper species. We also demonstrated the modularity of our system by incorporating three different ligands bearing imidazole groups with different levels of rigidity and studied their effects on the catalytic
EN06.03.04
Interfacial Study of First Row Transitional Metal Ferrites as Oxygen Reduction Reaction (ORR) Electrocatalysts
Joselyn C. Del Pilar; Universidad de Puerto Rico-Rio Pied, Puerto Rico

Proton exchange membrane fuel cells (PEMFC) are a promising power technology for vehicles. However, their commercialization has been hindered due to high-cost platinum and platinum-based electrocatalyst which accounts for approximately 20% of the PEMFC total cost. Alkaline membrane fuel cells (AMFC) have emerged as an alternative to PEMFC as ORR kinetics are greatly improved in alkaline conditions. Alkaline media also enables the use of first row transition metal thus allowing for more cost-effective catalysts to be develop. Here we present the use of first row transition metal ferrites as ORR electrocatalyst in alkaline media and study their electrocatalytic mechanism using synchrotron-based X-ray absorption (XAS) techniques. We use a facile co-precipitation method to prepare zinc, cobalt and manganese ferrites. X-ray diffraction patterns suggest a spinel crystal phase is formed for cobalt and manganese ferrites. However, when zinc is used, two crystal phases are observed; zinc oxide and zinc ferrite. Electrocatalytic activity toward ORR was performed in 1.0 M NaOH using a glassy carbon rotary disk electrode (RDE). The highest onset potential was observed for MnFe2O4 followed by CoFe2O4 and ZnFe2O4. Beyond just evaluating the ORR activity of the materials, our work seeks to gain an understanding of the in situ electrocatalytic reactions taking place during ORR. To this end, efforts to conduct in situ XAS electrochemical characterization at are underway. ACKNOWLEDGMENTS: This work was supported by the National Science Foundation NSF-PREM: Center for Interfacial Electrochemistry of Energy Materials (CiE²M) grant number DMR-1827622.

EN06.03.05
Pt-Au Solid-Solution Alloy Nanoparticles with Remarkable Catalytic Performances for H2O2 Direct Synthesis
Hong Woo Lee1,2, Kwan-Young Lee2 and Sang Soo Han1; 1Korea Institute of Science and Technology, Korea (the Republic of); 2Korea University, Korea (the Republic of)

Hydrogen peroxide (H2O2) has been mainly produced by the sequential hydrogenation and oxidation process of anthraquinone molecules, which is called as an indirect synthesis method. However, this process requires large volume facilities and a large quantity of energy. So, a direct synthesis method from H2 and O2 molecules in the presence of Pd catalyst has been considered for small-scale and on-site H2O2 production. However, the disadvantages of the prototypical Pd is that water is easily generated during the synthesis process. In order to improve the catalytic performance, many researchers have focused on Pd-based bimetallic alloys that can be easily formed thermodynamically such as Pd-Pt, Pd-Au, and Pd-Sn. In other words, the combinations of immiscible elements have been thoroughly ignored so far. Therefore, it has been a big challenge to broaden the scope of catalyst research into a wider area.

In this study, we report solid-solution alloy nanoparticles (NPs) of Pt and Au with a face-centered cubic (fcc) structure, although they are completely immiscible in the bulk phase. X-ray diffraction, transmission electron microscopy (TEM), energy-dispersive X-ray measurements, and density functional theory (DFT) calculations revealed that Pt and Au atoms were homogeneously distributed in a wide composition range of the Pt$_x$Au$_{100-x}$ NPs (7≤x≤82). Out of all tested compositions, Pt$_7$Au$_{93}$ NPs exhibited superior catalytic performances both in productivity (2,327 mmol /gcat h) and H2O2 selectivity (99.2%) and even under ambient conditions (20 °C, 1 atm) and without halide-ion additives. This exceptional catalytic property of the solid-solution Pt-Au alloys was clearly proved with the reaction mechanism obtained from the DFT calculation. In addition, we have checked that the introduction of inactive Au atoms likely suppresses dissociations of O$_2^*$ and OOH*, which leads to enhance the H2O2 selectivity. To our knowledge, this study is the first demonstration of stabilizing non-equilibrium solid-solution NPs as H2O2 direct synthesis catalysts. In addition, this work suggests that active utilization of other bulk-immiscible elements is highly desirable for catalyst development.

EN06.03.06
Facile Norbornadiene—Quadricyclane Interconversion Mediated by a Magnetic Catalyst
Patrick Lorenz, Tobias Luchs and Andreas Hirsch; University of Erlangen-Nuremberg, Germany

One problem that most solar based devices have in common is the discontinuous energy production and the concomitant mismatch between energy production and energy demand. This problem can be circumvented by using
molecular solar thermal (MOST) energy storage and release systems. These systems are capable of harvesting the energy and transforming it into a storable form on a molecular level. When needed the stored energy can then be released as thermal energy.[1] The valence isomerization of norbornadiene (NBD) to its metastable and energy rich isomer quadricyclane (QC) is regarded a promising candidate for MOST applications.[2]

Within the scope of this project, we designed and synthesized NBD and QC interconversion couples with red-shifted absorption profiles. These NBD derivatives can undergo photoisomerization to their metastable QC isomers upon direct irradiation without the need for a triplet photosensitizer. We investigated each interconversion couple regarding their photophysical properties, stability of the energy rich isomer (t₁/₂ ranging from hours to over a year at room temperature) and their potential energy storage capacity. Finally, the most promising derivatives were treated with a magnetic nanoparticle catalyst, designed in our group, to facilitate strain energy release via back-conversion of QC to NBD followed by straightforward purification by the action of an external magnetic field.

Role of Oxygen Vacancies in CuO/In₂O₃ Nanocomposite for Selective Electrochemical Reduction of CO₂ to CO

Pinki Devi, Karan Malik, Ekta Arora, Saswata Bhattacharya, Anil Verma and Jitendra P. Singh; Indian Institute of Technology Delhi, India

Abstract: Sequestration of carbon dioxide (CO₂) through electrocatalytic reduction to produce high-value industrial precursors, such as, CO is a promising avenue for sustainable development. However, the choice of an energy efficient and stable electrocatalysts for the selective reduction of CO₂ is a major challenge. Here, we prepare highly active, stable and cost effective CuO/In₂O₃ nanocomposites. We demonstrate a novel approach that utilizes oxygen vacancy (Vₒ), in CuO/In₂O₃ nanocomposites for the reduction of CO₂ to CO. Here, we control the concentration of Vₒ by varying the calcination environment during synthesis of the CuO/In₂O₃ nanocomposites. Photoluminescence, X-ray photoelectron and electron paramagnetic resonance spectroscopy measurements indicate that CuO/In₂O₃ nanocomposites prepared in an argon environment exhibit higher concentrations of Vₒ defects in comparison with samples that are prepared in air ambient. Moreover, CuO/In₂O₃ nanocomposites with less Vₒ defects exhibit 63% faradaic efficiency at -0.645V, while, CuO/In₂O₃ nanocomposites that are rich in Vₒ defects yield CO with 85% faradaic efficiency at -0.895V w.r.t. RHE suggesting that Vₒ serves as the active site for CO₂ adsorption. Through a combination of electrochemical measurements, physical characterization and density functional theory (DFT) calculations, we establish that the enhancement in CO yield is directly correlated to the concentration of Vₒ defects in the CuO/In₂O₃ nanocomposites and propose a plausible mechanism for electrocatalytic CO₂ reduction.

Photocatalytic Stereoselective C-C Oxidative Coupling Reactions with Semiconductor Quantum Dots

Yucheng Yuan, Hua Zhu and Ou Chen; Brown University, United States

Semiconductor quantum dots have emerged in diverse practical applications including bioimaging and labeling, solar energy harvesting, light-emitting diodes, and next-generation displays. Most recently semiconductor quantum dots have attracted more and more attention in the field of photocatalysis, owing to their suitable optoelectronic properties for photocatalytic reactions, including high absorption coefficient and long carrier lifetime. Herein, we report the visible-light-mediated stereoselective C-C oxidative coupling reactions photocatalyzed by semiconductor quantum dots. High quality of halide perovskite and CdSe-based quantum dots have been synthesized and characterized, and then been applied to the model reaction to afford optimized reaction conditions. The desired product can be generated exhibiting high yield with high stereoselectivity. The reaction can be generalized to...
different starting materials with various substituents on the phenyl ring and varied functional moieties. Furthermore, we study the reaction pathway by using radical trapping agent and electron paramagnetic resonance (EPR) spectroscopy. We propose our stereoselectivity is caused by steric hindered radical reactions. Our study shows semiconductor quantum dots are expected to bring new insights in photochemical synthesis.

EN06.03.10
Efficient Electrochemical Nitrogen Reduction Reaction on Nickel Single Atom Catalyst Yeeji Baek, Ying Chuan Tan and Jihun Oh; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Ammonia is used in various industries as an essential chemical in the modern industrial economy. Haber-Bosch process has been widely used to produce ammonia, which involves extremely high temperature and pressure, and hydrogen gas produced from steam reforming. As a result, this process emits more than 1.9 ton CO₂ per ton NH₃. Due to the high global demand of ammonia, 2% of the world’s total energy supply is used for ammonia production, and thus is responsible for more than 400 Mt of emitted CO₂, which is 1.6 % of total CO₂ emissions. Therefore, electrochemical nitrogen reduction reaction (NRR) is attracting attention as an alternative to this process, because electrochemical NRR could serve as an environmentally friendly approach to synthesize ammonia with lower or potentially zero CO₂ emission depending on the electrical source. However, it has many drawbacks. One of them is the low activity for NRR, because nitrogen is a very stable compound due to its triple bond. Catalysts are critical to achieve better activity and selectivity. Single atom catalyst is one of the attractive materials not only for electrochemical ammonia production, but also for various electrocatalysis where high product selectivity could be achieved.

Here, we present the use of nickel single atom catalyst (Ni-SAC) as an efficient electrocatalyst for NRR. Ni-SAC is derived from Ni²⁺-exchanged ZIF-8 (Ni-ZIF), which involved the ionic exchange between Zn²⁺ and Ni²⁺. Pyrolysis of Ni-ZIF at 950°C yielded Ni-SAC, in which the Ni-atom in this material bonds with 3 nitrogen atoms and 1 carbon atom. The as-prepared Ni-SAC shows high ammonia production rate (3.9 µg h⁻¹ mg⁻¹) and faradaic efficiency (0.27 %) at -1.2 vs. RHE in a flow cell. These values are independent on ambient ammonia which are obtained by subtracting the amount of ammonia present during NRR in Ar atmosphere. The high performance can be attributed to the ensemble effect and electronic effect of the isolated Ni²⁺ ion in Ni-SAC. Also, it has high surface area and porosity, which translates to more catalytic sites being accessible for NRR. In this conference, we will present a more holistic evaluation of the high performance observed for NRR and discuss the differences of NRR performances using Ni-SAC in H-cell and in flow cell.

EN06.03.11
Fe-Doped Lanthanum Nickelate Deposited on Pyrolytic Graphite Sheet as Potential Electrode for Oxygen Evolution Reaction Cipriano B. Gozzo¹, Mario R. Soares¹,², Júlio C. Sczancoski¹, Fabricio B. Destro¹ and Edson R. Leite²,¹; ¹Federal University of São Carlos, Brazil; ²Brazilian Nanotechnology National Laboratory (LNNano), Brazilian Center for Research in Energy and Materials (CNPEM), Brazil

In recent years, there is an unprecedented interest of worldwide organizations in replacing fossil fuel-based energies with other renewable energy sources to reduce the emissions of greenhouse gases released into the atmosphere and to overcome the serious problem of climate change. A viable alternative for this purpose is the use of electrocatalysts for the production of hydrogen (Hydrogen Evolution Reaction - HER) and oxygen (Oxygen Evolution Reaction - OER). In general, the main attributes of efficient electrocatalysts for practical applications include use of low cost and non-toxic materials, high chemical and mechanical stability, durability and low overpotential. Particularly, the lanthanum nickelate (LaNiO₃) is a promising candidate as electrocatalyst because of its high conductivity, low charge transfer resistance, and interesting electrocatalytic properties for OER. The intrinsic OER activity of LaNiO₃ has been attributed to the existence of a single electron in the eg orbital belonging to Ni³⁺. However, Ni³⁺ is easily reduced to Ni²⁺, leading the eg orbital to exhibit more than a single electron. The commonly employed strategy to solve this, it’s the partial replacement of crystallographic sites occupied by Ni³⁺ with other transition metals. Therefore, the main aim of our study was to investigate the electrocatalytic properties of LaNiₓ₋ₓFeₓO₃ (x = 0.0, 0.3, 0.6, and 0.9 mol%) for OER, mainly analyzing the influences provoked by Fe³⁺ ions in the lattice and the use of pyrolytic graphite sheet (PGS) as a potential substrate for electrocatalysis. LaNiₓ₋ₓFeₓO₃ powders were synthesized by the co-precipitation method followed by post-heats treatment (900 °C for 4 h). The thin film electrodes were prepared depositing the obtained powders on PGS substrates via drop-casting. In relation to the powders, X-ray diffraction patterns revealed that the Fe³⁺ level was responsible for a structural phase transition from
rhombohedral \((x = 0.0 \text{ to } x = 0.3 \text{ mol%})\) to orthorhombic \((x = 0.6 \text{ to } x = 0.9 \text{ mol%})\). The substitution of \(\text{Ni}^{2+}\) by \(\text{Fe}^{3+}\) in the crystalline structure favored a morphological change from irregular cube- to spherical-like microparticles. A superior electrocatalytic activity for OER was detected for Fe-doped electrodes in relation to phase pure \((\text{LaNiO}_3)\), so that the \(\text{LaNi}_{0.4}\text{Fe}_{0.6}\text{O}_3\) was the most efficient for this purpose. Besides the low charge transfer resistance, \(\text{LaNi}_{0.4}\text{Fe}_{0.6}\text{O}_3\) demonstrated a lower overpotential (439 mV) and a smaller Tafel slope (52 mV dec\(^{-1}\)) than the \(\text{LaNiO}_3\) (465 mV and 76 mV dec\(^{-1}\)). In addition, a current density above 10 mA cm\(^{-2}\) was registered for this electrocatalyst in chronoamperometry tests, confirming its effectiveness over long times. The potentiality of PGS substrate for our electrocatalysts was confirmed by comparing with other electrocatalytic tests performed on glassy carbon substrate.

**EN06.03.12**

**Understanding the Heterogeneous Nucleation of Pt Single-Atoms and sub-Nanometer Clusters** Pavithra B\(^1\), Dipanwita Chatterjee\(^2\) and Ravishankar Narayanan\(^1\); \(^1\)Indian Institute of Science, India; \(^2\)Norwegian University of Science and Technology, Norway

Supported precious metal catalysts are extensively employed in industries for several chemical processes. Size of the metal species is a decisive factor in controlling the performance of such catalysts. Smaller the size, higher is the activity. So, huge interest has been directed towards the formation, stabilization and characterization of single atom catalysts and sub-nanometer clusters in the past few years. However, Supersaturation controlled, wet chemical methods have been hardly explored to synthesize such catalysts on various supports. We describe a robust wet chemical method to synthesize catalyst that consists of stable, isolated single atoms and sub-nanometer clusters of Pt anchored to the surfaces of \(\text{ZnO}\) nanorods. The thermodynamic and kinetic aspects of reduction of Pt salt under microwave heating conditions and heterogeneous nucleation of Pt atoms/clusters on \(\text{ZnO}\) have been understood. Driving force of the reaction has been optimized to obtain as small nuclei as possible with no post-nucleation growth and to have only heterogeneously nucleated ones. Heterogeneous nucleation also helps in further reduction of the cluster size by truncating the clusters. Facets on the \(\text{ZnO}\) rods having highest surface energy possess the lowest kinetic barrier for nucleation and thus such sites are always the most favored for nucleation. Having a very low driving force for nucleation, all the observed Pt clusters sit preferentially on the basal planes of the nanorods. Also, it is desired to produce catalysts that are resistant to sintering. These Pt clusters are stable under elevated temperatures both in air and CO atmosphere at least till 220°C. So, these can be efficiently utilized for CO oxidation which happens below 200°C. Electron microscopy HAADF-STEM technique, which is the only viable tool to visualize atomically distributed species, has been exploited extensively to characterize the \(\text{ZnO}/\text{Pt}\) hybrid structures. Having the finer size of Pt nucleated on \(\text{ZnO}\), we expect to achieve higher catalytic activity as compared to Pt nanoparticles on \(\text{ZnO}\).

**EN06.03.13**

**Synthesis of Fibers with Zeolite/Lignin by Electrospinning for the Deoxygenation of Bio-Oil from Soybean Hulls** Jose L. Toro Trochez, Eileen S. Carrillo Pedraza, Héctor M. Leija Gutierrez, Diana Bustos Matínez and Eduardo Soto Regalado; Universidad Autónoma de Nuevo León, Mexico

Catalytic upgrading of biomass derived pyrolysis vapors, by passing them over a zeolite catalyst has been explore in the last years. In the fibers incorporated zeolite HZSM-5 as a catalyst, have shown that the Zeolite HZSM-5 has the best yields in the deoxygenation of pyrolytic oil. The synthesis of a catalyst using fibers could increase the accessibility to the active sites and improving the deoxygenation of the pyrolytic oil and to promote green chemistry practice using biopolymers instead of traditional polymers derived from fuel. The use of fibers with zeolite/lignin is proposed in this work to promote de-oxygenation reactions, improving the characteristics of pyrolytic oil such as pH, calorific value, among other properties in the soybean hulls pyrolytic bio-oils. The aim is the fabrication of fibers using lignin as polymer, reducing the use of traditional polymers such as polyvinylpyrrolidone (PVP) and polyacrylonitrile (bread), polymers of high economic value and harmful to environment, compared to lignin. The fibers and zeolite will be characterized by the techniques of XRD, SEM, and ATP. Pyrolytic oils are characterized by GC/MS. This research will contribute to the synthesis of a new catalyst, as well as to use in obtaining biofuels.

The characterization of HZSM zeolite and the thermal characterization of the polymers has been carried out. the XRD Analysis is obtained the crystalline phases of the HZSM-5 zeolite, with sharp reflections corresponding to the MFI structure, the results of nitrogen physisorption Analysis was obtained TYPE IV isotherm and hysteresis characteristic from Mesopores, according to the IUPAC. The analysis BET obtained a surface area of 289.2 m\(^2\)/g,
was obtained with a promised pore diameter of 36.1 nm, characteristic of structures mesoporous, these structures promote the obtaining of bio-oil and the reduction of biochar. The obtained the different signals from the acid sites, the desorption signals of ammonia less than 200 °C correspond to sites with weak superficial acidity, while desorption signals exhibited between 200-400 °C are associated with medium-strength acid sites, and the signals found to temperatures higher than 400 °C, correspond to sites with strong acidity, weak acid sites are in greater proportion, the results are similar to those obtained by Jia Lui et al. 2015 (Liu et al. 2015). The next step is to manufacture fibers with zeolite HZSM-5 to favor accessibility to acid sites and to increase the deoxygenation of pyrolytic oil, which until now was obtained 18% of deoxygenation using a zeolite catalyst.

EN06.03.14
Pd and Cu Single-atom Doped Two-Dimensional Ti3C2Tx Nanosheets as Efficient Catalysts for Electrochemical CO2 Reduction Essraa A. Hussein, Yasseen S. Ibrahim, Samah Dib, Zainab Abdul-Rahman, Kamel Eid, Aboubakr M. Abdullah and Ahmed Elzatahry; Qatar University, Qatar

Recently, single atom catalysts (SACs) have gained a great deal of attention as heterogeneous electro-catalysts, owing to their high surface area, abundant active sites, stability, and selectivity. Here, we report the fabrication of Pd and Cu single atom co-doped two-dimensional 2D Ti3C2Tx, MXene nanosheets (Pd/Cu/Ti3C2Tx). This is achieved by the selective chemical etching of Ti3AlC2 (MAX phase) followed by ultrasonic irradiation at room temperature and then co-doping with Pd and Cu. This drove the formation of well-defined, ordered, and exfoliated Ti3C2Tx nanosheets with average dimensions of 300nm in length and 150nm in width as well as homogeneously co-doped with Pd and Cu as single atom (nearly 1 wt. % each). The catalytic activity and durability of the typically prepared Pd/Cu/Ti3C2Tx were investigated relative to metal-free Ti3C2Tx nanosheets. The results displayed the significant activity of Pd/Cu/Ti3C2Tx as reflected in its earlier onset potential, lower reduction potential, and higher reduction current density. This is in addition to the high tolerance to the intermediate poisonings owing to the combination between the unique properties of MXene and impressive electro-catalytic properties of Pd/Cu single atom. Intriguingly, Pd-Cu/Ti3C2Tx nanosheets showed a high propensity to reduce CO2 into formic acid with a great faradaic efficiency. We believe that the results obtained from this work may open the door for new efficient and well-designated SACs/MXenes catalysts for further electrochemical applications.

EN06.03.15
Tailored the Fabrication of Cu and Zn Single Atom Doped Two-Dimensional MXene Nanosheets for the Efficient Electrochemical Reduction of CO2 at Room Temperature Ghada G. Abdo, Yasseen S. Ibrahim, Samah Dib, Zainab Abdul-Rahman, Kamel Eid, Aboubakr M. Abdullah and Ahmed Elzatahry; Qatar University, Qatar

Accumulation and excessive release of CO2 into the atmosphere resulting from the consumption of fossil fuels are considered as serious debate on harmful environmental changes, such as global warming, desertification, and ocean acidification. To tackle these problems, electrochemical reduction of CO2 has been regarded as a paramount demand in order to enable the recycling and conversion of CO2 to useful fuels. Herein, we controlled fabrication of Cu and Zn single atom doped MXene denoted as (Cu/Zn/Ti3C2Tx). The typically prepared Cu/Zn/Ti3C2Tx were obtained in a high yield of uniform and exfoliated two-dimensional nanosheets with average diameters of (400 nm) in the length and (200 nm) in the width and coherently doped with Cu (1 Wt. %) and Zn (1 Wt. %) in the form of single atom. Cu/Zn/Ti3C2Tx showed a significant higher electrochemical CO2 reduction activity and stability compared to Ti3C2Tx at room temperature. The obtained current density on Cu/Zn/Ti3C2Tx was around 3 times higher than that of Ti3C2Tx as well as faster reduction kinetics. Intestinally enough, Cu/Zn/Ti3C2Tx revealed higher selectivity and tendency to reduce CO2 into ethanol. The insights gained from this work would shed the light on designing novel bimetallic systems with MXene support for the electrochemical reduction of CO2.

EN06.03.16
Utilization of Nb2O5/g-C3N4 heterostructure as Catalyst to CO2 Heterogeneous Photoelectroreduction Eduardo H. Dias; USP, Brazil

Pollution caused by CO2 emissions in the atmosphere causes a number of environmental damages, such as the so-
called greenhouse effect. Thus, in recent years the search for technologies capable of bringing environmental and economic benefits has been intensified, converting CO2 into value-added molecules, such as ethanol, ethane and formic acid. Among the efficient ways of promoting this conversion of CO2, we highlight the electrocatalytic and photocatalytic processes, mainly using semiconductors. Niobium pentoxide (Nb2O5) and graphite carbon nitride (g-C3N4) demonstrate good catalytic performances for degradation of organic pollutants and water splitting. However, these catalysts have as limitation their high recombination of the photogenerated charge carriers. One way to overcome this negative effect in photocatalytic processes is the formation of heterojunctions between the two materials (Nb2O5 and g-C3N4). Therefore, in this work the photo and electrocatalytic efficiency of the Nb2O5/g-C3N4 heterostructures was verified for conversion of CO2 into CH4. In addition, we investigated the electrical properties of the synthesized materials, such as flatband values. Thus, this properties change the selectivity of the formed products, obtaining highly efficient processes. In the electrochemical and photoelectrochemical tests, the Nafion and PEDOT: PSS5 was used with binder to increase the contact between the synthesized samples (Nb2O5, g-C3N4, and Nb2O5/g-C3N4) and de substrate (Fluorine doped Tin Oxide Glass). The photoelectrocatalytic tests shown that the electrode with the heterostructure Nb2O5/g-C3N4 and PEDOT:PSS has 10 times higher current values than the value obtained to the electrode without PEDOT: PSS (12 μA cm2 and 1.5 μA cm2) to 0.4V under irradiation. However, both samples showed increase of current in the presence of light, double for samples with nafion and triple for samples with PEDOT. The flatband values obtained were -0.55V and -0.77V, for the Nb2O5/g-C3N4 samples with and without PEDOT through the Motty-Schottky analyzes using the frequency of 100 Hz, showing that PEDOT decreased the flat band value. It was possible to verify that the synthesized samples are photoactive and that they have great chances of being possible catalysts for photoelectroreduction of CO2 and will be tested later with quantification of the products through GC and HPLC measurements, and the studies in different potential will be performed to analyse the effect of the potential in the selectivity.

EN06.03.17
Electrochemical Reduction of CO2 over O3-Pretreated Ag Cathode Masaatsu Ishida, Soichi Kikkawa, Kentaro Teramura, Hiroyuki Asakura, Saburo Hosokawa and Tsunehiro Tanaka; Kyoto University, Japan

In electrochemical reduction of CO2 in aqueous media, it is well-known that CO is generated as a main product over Ag cathodes. Several research groups reported that anodic oxidation (anodization) improves the current density and faradaic efficiency toward CO evolution due to the crystal orientation and the valence of Ag cathode. On the other hand, ozone (O3) is generally used for chemical oxidation. In this study, we investigated the current density and faradaic efficiency toward CO evolution for the electrochemical reduction of CO2 by using the O3-pretreated Ag cathode.

Ag foil (Nilaco Co., 99.98%, 6 cm2) electrodes were sonicated in hexane, ethanol, and Milli-Q water, prior to the electrochemical measurements. The O3 pretreatment of Ag electrodes were performed in an O3 generator (ASM401N, Asumi Giken Ltd.). Front and back sides of Ag foil were exposed to O3 atmosphere for 10 hours each. The electrochemical CO2 reduction experiments were conducted in a H-type two-glass chamber with using Pt wire and Ag/AgCl as a counter electrode and a reference electrode, respectively. The electrolyte was 0.1 M KHCO3 aqueous solution under flowing of CO2 gas (99.999 %) at a flow rate of 20 mL min-1. The CO2 reduction activity was evaluated at constant potential (~1.6 V vs. Ag/AgCl). The electrochemical surface area (ECSA) of Ag electrodes were determined by using underpotentially deposition of lead (Pb UPD) in an aqueous solution containing 0.1 M HClO4, 0.1 M NaClO4, 1 mM Pb(ClO4)2. The crystal structure was confirmed by X-ray diffraction (XRD) analysis.

The XRD patterns of O3-pretreated Ag electrode were assigned to the typical diffraction pattern of AgO. This electrode exhibited the current density of 3.9 mA cm-2 and faradaic efficiency of 95%, although these were 1.2 mA cm-2 and 68% over Ag foil, respectively. After the electrochemical reduction of CO2 only the diffraction patterns of fcc structure of Ag metal were observed, suggesting that AgO species on O3-pretreated Ag electrode were reduced to Ag metal during the reaction. The amount of underpotentially deposited Pb atoms on O3-pretreated Ag electrode
(13 nmol) was almost two times larger than that on Ag foil (6.2 nmol). The current density and faradaic efficiency toward CO evolution were not dependent on only ECSA. After the reaction, the ratio of (111) to (200) facets of O$_3$-pretreated Ag electrode was much higher than that of Ag foil in the XRD pattern. We concluded that the high current density and faradaic efficiency toward CO evolution were attributed to not only the high ECSA but also the face orientation of O$_3$-pretreated Ag electrode.

**Nanostructured Amalgams with Tuneable Silver-Mercury Bonding Sites for Selective Electroreduction of Carbon Dioxide into Formate and Carbon Monoxide** Wanfeng Yang, Sheng Chen, Wenhao Ren, Yong Zhao, Xianjue Chen, Chen Jia, Junnan Liu and Chuan Zhao; UNSW Sydney, Australia

Realizing highly efficient and selective electrochemical CO$_2$ reduction by using cost-effective catalysts is key to large-scale commercialization of this technology. In this work, a nanoporous amalgam catalyst with tuneable amount of Ag-Hg bonding sites has been developed for selective CO$_2$ electroreduction to formate or CO via a one-step wet-chemistry method. This catalyst is composed of Ag(Hg) solid solution phase and Ag-Hg intermetallic compound, exhibiting a loosened nanorod-channel networks morphology. Ag$_{70}$Hg$_{30}$ alloy drives efficient formate generation with a high Faradaic efficiency of 85% at a moderate overpotential of 790 mV while Ag$_{91}$Hg$_9$ alloy promotes CO$_2$ reduction to CO with a Faradaic efficiency of 58% at a low overpotential of 590 mV. The switchable product selectivity has been correlated to a preferable formation of HCOO* or *COOH intermediates at Ag-Hg and Ag-Ag bonding sites. This work highlights amalgams as novel electrocatalysts for CO$_2$ reduction to valuable products on demand.

**EN06.03.19**

**Active Site Engineering by Surface Sulfurization for a Highly Efficient Oxygen Evolution Reaction—A Case Study of Co$_3$O$_4$ Electrocatalysts** Ying Pan$^1$, Hangjuan Ren$^1$, Haiwei Du$^2$, Fuyang Cao$^1$, Yifeng Jiang$^1$, Haojin Du$^1$ and Dewei Chu$^1$; $^1$University of New South Wales, Australia; $^2$Anhui University, China

Surface sulfurization strategy is utilized to construct Co$_3$O$_4$@CoS$_x$ heterogeneous catalysts with a highly efficient activity towards the oxygen evolution reaction (OER), and the enhanced catalytic activity is dependent on the degree of surface sulfurization. It is found that forming amorphous CoS$_x$ on the Co$_3$O$_4$ surface through surface anion exchange can effectively generate more Co$^{2+}$ ions and oxygen vacancies in the lattice structure, not only inducing the production of more CoOOH but also facilitating water adsorption during the water oxidation process.

**EN06.03.20**

**Controllable Local Electronic Migration Induced Charge Separation and Red-Shift Emission in Carbon Nitride for Enhanced Photocatalysis and Potential Phototherapy** Zongzhao Sun and Limin Huang; Southern University of Science and Technology, China

Since the performance is highly dependent on the electronic structure of the material, it is crucial to adjust electron distribution to achieve various improved properties for the utilization of the material in cross-functional applications. Here, precise control of the local electronic migration of carbon nitride via molecular grafting has been successfully developed. The electronic structure could be carefully tailored by the incorporation of π-conjugated molecules and electronwithdrawing groups. Experimental results and theoretical calculation reveal the possible electronic migration path to reset the local electronic configuration, leading to charge separation and red-shift emission. As a result, H$_2$ evolution of 5 mmol h$^{-1}$ g$^{-1}$ with a high AQY of 20.98 % at 420 nm and in vitro phototherapy for the anti-cancer effect can be realized. These findings provide a new opportunity for modifying the properties of emerging materials for extended applications through careful control of the electronic structure process.

**EN06.03.21**

**Bioinspired Fabrication of ZnS/Polydopamine Nanorods for Solar-Light-Driven Photocatalytic Hydrogen Production** Yeonho Kim and Hae Jin Kim; Korea Basic Science Inst, Korea (the Republic of)

Photocatalytic hydrogen (H$_2$) production of ZnS catalysts still remains unsatisfactory because of the fast charge carrier recombination originated from the inherent characteristics of the direct-bandgap semiconductor as well as the photocorrosion by the oxidative holes in the valence band. In this study, we developed the strongly coupled
ZnS/polydopamine (ZnS/PDA) photocatalysts via a facile in-situ polymerization method with the precisely controlled thickness of PDA layer onto the ZnS nanorods. The introducing of thin PDA shell on the surface of ZnS nanorods exhibits enhanced photocatalytic H₂ production activity and stability than a single component of pristine ZnS or PDA itself. The synergistic effect responsible for the enhancement of catalytic performance can be attributed to the favored effective charge separation/transport at the ZnS/PDA heterojunction interface as well as extended light absorption of photocatalysts due to the origin of partially formed ZnO. Moreover, the higher surface wettability of ZnS/PDA nanocomposites could be desired properties for photocatalytic water splitting H₂ production than that of the pristine one. The density functional theory (DFT) calculation reveals advantageous type-II band alignment of ZnS/PDA, hole accepter levels of PDA can facilitate the charge-carrier separation and long-periods stability of ZnS via lowering the oxidative capacity of holes in the valence band state. The optimized catalyst of ZnS/PDA hybrid nanorods with PDA shell thickness of 1.2 nm, exhibits excellent photocatalytic H₂ production rate of 2162.5 mmol h⁻¹ g⁻¹ (10 mg catalysts) without using a Pt cocatalyst as well as enhanced photostability over long periods.

EN06.03.22
Cobalt-Iron-Phosphorus Catalysts for an Efficient Hydrogen Generation from the Hydrolysis of Ammonia Borane Solution
SeKwon Oh; Korea Institute of Industrial Technology, Korea (the Republic of)

Co-Fe-P catalysts for fast hydrogen generation from hydrolysis of NH₃BH₃ were fabricated by an electro-deposition. Effects of cathodic current density and plating time on the microstructures of the Co-Fe-P catalysts and their catalytic activities for hydrolysis of NH₃BH₃ were explored. The microstructure, surface morphologies, and composition of the Co-Fe-P catalysts were analyzed by X-ray diffraction (XRD), scanning electron microscope (SEM), energy dispersive spectroscopy (EDS), respectively. Their hydrogen generation kinetics were measured using mass flow meter (MFM). The particle sizes and composition of Co-Fe-P catalysts were depended significantly on the current densities and deposition times during an electro-deposition. As a current density increase, the particle sizes of the Co-Fe-P catalysts increased. With an increase in deposition time, the particles of the Co-Fe-P catalyst get agglomerated densely. The hydrogen generation kinetics of the catalysts was depended largely on their microstructures, which was affected by the electro-deposition conditions such as current density and deposition time. In particular, the Co-Fe-P catalysts, which was deposited at 50 mA for 5min, exhibits the best hydrogen generation rate of 2858. min⁻¹ g⁻¹-catalyst in 1 wt% NH₃BH₃ solution at 30 °C. With an increase in a solution temperature from 10 to 60 °C, the hydrogen generation rate increases dramatically. Specially, at 60 °C, which is the optimal temperature for the best PEMFC operation, the hydrogen generation rate was 8915 ml min⁻¹ g⁻¹-catalyst in 1 wt% NH₃BH₃ solution at 60 °C. With increasing the concentration of NH₃BH₃ from 0.5wt% to 3wt%, the hydrogen generation rate of the Co-Fe-P catalyst increased gradually from 1900 ml min⁻¹ g⁻¹-catalyst to 8105 ml min⁻¹ g⁻¹-catalyst. This behavior of the Co-Fe-P catalyst was in contrast with that of noble metals such as Ru and Pt. Since it is necessary to increase the concentration of NH₃BH₃ in the solution for high hydrogen storage density, it is considered that the Co-Fe-P catalyst is more suitable than noble metal catalysts for a practical use.

EN06.03.23
Electrochemical CO₂ Reduction to C₂ or C₃ Alcohols over Cu-Supported N-Doped Porous Carbon Catalysts
Hyunsu Han, Seongmin Park, Wongeun Yoon, Junil Choi, Dahee Jang, Hyunwoo Ahn and Won Bae Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Electrocatalytic conversion of carbon dioxide (CO₂) to multicrocarbon alcohols (C₂H₅OH and C₃H₇OH) in a selective and efficient manner remains a great challenge in renewable and sustainable energy research. Herein, we report a series of hybrid catalysts of Cu nanoparticles supported on N-doped porous carbon with different contents of pyridinic N and demonstrate that the selectivity to the multicarbon alcohols could be tuned by introducing the cocatalyst of N-doped porous carbon materials. By varying the contents of pyridinic N in hybrid catalysts, the highly selective production of multicarbon alcohols is achieved with notable total Faradaic efficiencies of multicarbon alcohols up to the value of 73.3 % at – 1.05 V (vs RHE) for both C₂H₅OH and C₃H₇OH products. We hypothesize in this work that pyridinic N as a CO-producing site together with Cu catalytic sites can act cooperatively to produce C₂H₅OH and C₃H₇OH. Furthermore, a two-site mechanism to rationalize the efficient CO₂ reduction to multicarbon alcohols on the hybrid catalysts is proposed and discussed. These findings provide a new guideline for the rational design of electrocatalysts for tuning catalytic activity and selectivity toward multicarbon alcohols.

EN06.03.24
Z-Scheme Electron Transfer of ZnS/ZnIn₂S₄ Heterostructure as a High Efficiency Photocatalyst for CO₂
Utilization of carbon dioxide conversion to chemical fuels using an artificial photocatalyst under solar irradiation is an ideal goal in renewable energy studies. To date, a variety of strategies have been demonstrated to boost the quantum efficiency of CO₂ photoreduction. Coupling of semiconductors considered one of the key challenges to designing a good photocatalyst that can activate the CO₂ molecule with smallest possible activation energy and produce selective fuels. Since the activity and selectivity are mainly determined by the suitable band structures and surface states of photocatalysts as well as the photoreaction conditions. In this study, we fabricate ZnS/ZnIn₂S₄ composite for CO₂ reduction under visible light irradiation. When the mass ratio between Zinc and Indium is varied, the composite catalyst shows dramatically increasing of acetaldehyde and methanol formation as major products of CO₂ conversion. The optimum ratio exhibits a 200 times enhancement over a single phase of ZnS. The as synthesized samples were characterized by XRD, SEM, TEM, Photoluminescence, UV-Visible diffuse reflectance spectroscopy, XPS, UPS, surface area and CO₂ adsorption measurements. Based on the experimental evidence, the interface between both phases is the crucial role of interfacial charge transfer and subsequent enhancing of catalytic activity. In-situ FTIR study has been done to get a deeper insight into the product formation and gain a detailed comprehension of the fundamental reaction steps during the photocatalysis. In conclusion, my presentation will focus on how to efficiently manage the photo-generated charge carriers and surface reactions of semiconductor photocatalysts to boost the photoreduction activity.

**EN06.03.25**

**Determining Rate Dominant Steps and Synergistic Effects in Heterogeneous Catalytic Reactions Using Nano-Porous Supports**

Hongyu Li, Anatoly Frenkel and Dilip Gersappe; State University of New York at Stony Brook, United States

Catalysts embedded in porous structures are widely used in materials research and industry. Understanding the dominant step of catalytic chemical reaction rate is crucial for the development of such catalysts. However, the coupling of mass transport and kinetic effects with reactions presents a significant computational challenge. Here, we show that by using a Lattice Boltzmann approach we can develop a model that will allow us to include kinetic effects such as adsorption and desorption of reactants/products, mass transport bottlenecks in the support, and possible pore blocking effects. Further, we show that our model can be used to determine possible synergistic interactions when bi-metallic catalysts are used. We use a model system composed of Ni-Pt bimetallic catalysts, that are used to catalyze the reverse water gas shift reaction and methanation through a nanostructured support as an case study for our approach. We compare our results to experimental results and show that our model can be used to explain synergistic effects in this system.

**EN06.03.26**

**Interfacial Electron Transfer of Metal/Nitrogen Carbon Composite Prompts Efficient Green Chemical Transformation**

Hui Su; Shanghai Jiao Tong University, China

The transition-metal/nitrogen carbon hybrids with the features of low-cost and high-stability are emerging candidates to homogeneous catalysts used to efficiently catalyse novel sustainable chemical transformation process. The relatively low activity of active metal sites has been an insurmountable dilemma to inhibit development of heterogeneous metal/nitrogen carbon catalyst for their practical application. Attractively, the electron transfer effect of metal/nitrogen carbon interface was wide available to enhance reactivity towards thermal and electrochemical conversions. However, the exact relationship between electron population of metal/carbonic support boundary and specific catalytic performance still remains elusive. We initially used nanoscale assembly of metal-organic complexes to realize the construction of high-loading Co/carbon interfaces. The as-obtained Co nanoparticles embedded into carbon nanofibers with high conductivity exhibited superior activity for electrochemical hydrogen evolution reaction (Nano Energy, 2016, 16, 79). To further enhance the catalytic activity of Co nanoparticles, the Mott-Schottky catalyst of nitrogen-rich carbon-coated cobalt nanoparticles (Co@NC) was prepared through direct polycondensation of simple organic molecules and inorganic metal salts in the presence of polymeric carbon nitride powder. The presented electron-deficiency Co particles induced Mott-Schottky effect can trigger the synthesis of a series of alkyl esters and even diesters in high yields via base-free aerobic of alcohol (J. Am. Chem. Soc., 2017, 139, 811). More importantly, high electron density of single Ni-N₄ sites anchored into nitrogen-doped carbon was
fabricated via ligand-stabilized polycondensation method. The experiment and theoretical calculation results elucidates that the enhanced electron density at each single Ni-N4 site by a collective grouping effect substantially decreases the binding energy of H radicals to Ni, promoting a highly efficient hydrogen transfer coupling of benzyl alcohol and aniline into N-benzyl aniline (*Angew. Chem. Int. Ed.* 2018, 57, 15194).

**EN06.03.28**

**Facile Underwater Plasma Discharge Process for the Synthesis of the Nitrogen-Functionalized Onion-Like Carbons and Their Enhanced Electrocatalytic Activities** SangYul Lee1, Jung-Wan Kim2 and Hoe-Kun Kim1; 1Korea Aerospace University, Korea (the Republic of); 2InCheon National University, Korea (the Republic of)

Nitrogen-functionalized onion-like carbon (N-OLC) was synthesized using an arc discharge in a liquid phase (a so-called Solution Plasma Process) in the presence of different ammonia concentrations. The N-OLC was investigated as a catalyst support material for a catalytic oxygen reduction reaction (ORR). With increasing ammonia concentrations up to 5 M, the nitrogen doping degree increased to 1.7 at.%, which created a highly defective onion-like structure. The edge and defective sites induced from nitrogen atoms effectively facilitated the nucleation of Pt clusters, which led to the stable dispersion and size-reduction of Pt nanoparticles (PtNPs), as revealed via XPS, XRD, Raman spectroscopy and electron microscopy. From the results of the electrochemical characterization, the PtNPs supported on the N-OLC with a nitrogen content of 1.7 at.% exhibited the highest electrochemically active surface area (ECSA), specific current density and half-wave potential. The enhanced (ORR) could be ascribed to the defective outermost layers and the electronic modification. Moreover, even after an accelerated durability test (ADT) with 5,000 cycles, the N-OLC with a nitrogen of 1.7 at.% exhibited less degradation, indicating the excellent ORR durability.

**Mesoporous CuOx-Derived Nanostructured Copper Catalysts for CO2 Reduction** Giorgio Giuffredi1,2, Federica Arena1,2 and Fabio Di Fonzo1; 1Istituto Italiano di Tecnologia, Italy; 2Politecnico di Milano, Italy

Electrochemical reduction of emitted CO2 to fuels and complex hydrocarbons represents a promising solution to efficiently store intermittent, renewable energies-generated electricity in the form of chemical energy of carbon-based fuels. Copper is one of the most interesting CO2 reduction electrocatalysts, thanks to its ability to reduce carbon dioxide to complex hydrocarbons with good efficiency, however when in bulk polycrystalline form it has low activity and requires a high overpotential for the reduction reaction. Obtaining Cu catalysts by the in-situ reduction of a copper oxide precursor at CO2 reduction potentials - with the so-called Oxide-derived Cu catalysts - is considered one of the most efficient way to increase the intrinsic activity of Cu: this class of materials have higher selectivity for complex hydrocarbons and longer stability. Moreover, their CO2 reduction activity and selectivity are strongly affected by the morphology, which controls the mass transport of the reactants to the active sites and the residence time of the reaction intermediates near the CO2 reduction active sites.

In this contribution, the CO2 reduction activity and selectivity of Cu catalysts derived from the reduction of Copper Oxide (CuOx) hierarchical nanostructures with different structural features are investigated. We firstly employ a nanocrystalline CuOx material, which presents a higher availability of undercoordinated surface sites which, coupled with the high surface area, increases the activity. We synthesize nanostructures for this highly-active material by Pulsed Laser Deposition (PLD), a synthesis method that allows us to control the morphology of the deposited nanostructures down to the nanoscale: this technique, in fact, allows for a fine control over the deposit morphology by finely tuning the deposition parameters. In this way, the chemical composition and thickness of the hierarchical quasi-1D nanostructures are kept constant and it is possible to modify their aspect ratios, their nanostructuring and their micro- and nanopores diameters. Characterization of the PLD-synthesized nanostructures shows an amorphous matrix with embedded crystalline seeds of CuO and Cu2O, differently from other reported oxide-derived Cu catalysts. CO2 reduction performance of the oxide-derived Cu nanostructures is assessed through chronocoulometric measurements in aqueous electrolyte, showing good current densities and a good stability for at least one hour of prolonged operation. Liquid products
analysis, performed via 1H NMR spectroscopy, shows a high productivity of ethanol at limited potentials applied (V = -0.4 VRHE). Overall, the CuOx-derived nanostructures show a good faradaic efficiency at low overpotentials applied, with an FE for CH4 of 40% and an FE for liquids of 55% at -0.4 VRHE.

This contribution shows how coupling an amorphous, oxide-derived Cu catalyst with a fine control over morphology can be an efficient way to increase the activity of CO2 reduction catalysts.

**EN06.03.31**

**In Situ Characterization of MOx/CeO2 (M=Fe, Co, Ni and Cu) Catalysts for the Methane Activation and Methane Dry Reforming Reaction**

Feng Zhang¹, Zongyuan Liu², Sanjaya D. Senanayake³ and Jose A. Rodriguez²,³; ¹Stony Brook University, The State University of New York, United States; ²Brookhaven National Lab, United States

Based on the concept of electronic effect used in the development of homogeneous catalysts, we have prepared the heterogeneous systems, in which metal-support interaction leads to methane activation at room temperature, enabling the conversion of this hydrocarbon into value-added chemicals. *In-situ* characterization techniques, such as Time-Resolved X-ray Diffraction (TR-XRD), X-ray Absorption Fine Structure(XAFS) and Ambient Pressure X-ray Photoelectron Spectroscopy (AP-XPS) were employed to investigate changes in chemical state and structural transformations occurring in a series of MOx/CeO2 (M = Fe, Co, Ni and Cu) powder catalysts upon reaction with methane and under the methane dry reforming condition. XPS shows the presence of adsorbed CHx and COx species after exposing the powder catalysts to methane at room temperature. Temperature-programmed reduction (TPR) measurements point to the reaction of the samples with methane and formation of CO, CO2, and H2O gas at temperatures as low as 100 °C. The TR-XRD results show that all of the transition-metal oxides in the as-prepared catalysts can be reduced to their metallic phase during the CH4-TPR process with the ceria support undergoing significant reduction from the surface to bulk, yet the reduction temperature varies for different MOx/CeO2 samples. Among these samples, CuOx/CeO2 shows the lowest reduction temperature (below 260 °C) for both the oxide overlayer and the ceria support. The NiOx/CeO2 and CoOx/CeO2 powder catalysts also activate CH4 at relatively low temperatures (below 350 °C), and the oxide overlayers undergo NiO → Ni and Co3O4 → CoO → Co transformations. In the case of FeOx/CeO2, a series of complex changes in the chemical state is observed for the oxide overlayer, Fe2O3 → Fe3O4 → FeO → Fe → Fe3C. The ceria support of all of the three MOx/CeO2 (M = Cu, Ni, and Fe) samples undergoes severe reduction and form Ce2O3 at high temperature (> 650 °C) during the CH4-TPR reaction. The *in-situ* TR-XRD results highlight rich and complex chemistry for methane on these MOx/CeO2 mixed oxide systems. The strong metal-support interactions seen in the Ni and Co/CeO2(111) model catalysts also determine the good performance of the MOx/CeO2 (M = Ni, Co) powders for the methane dry reforming reaction.

**EN06.03.32**

**Catalyst-Free Coproduction of Hydrogen and Activated Alumina as Value-Added Byproduct from Hydrolysis of Nanoporous Aluminum with Pure Water**

Timothy Lee¹, Jintao Fu¹, Victoria Basile², John Corsi¹ and Eric Detsi¹,¹; ¹University of Pennsylvania, United States; ²University of California Los Angeles, United States

The sale of value-added byproducts from hydrogen-generating reactions is a strategic approach to lower the costs of hydrogen fuel in realizing a truly-sustainable hydrogen economy. Metal hydrolysis is a chemical process that produces hydrogen together with a metal hydroxide species; however, this reaction is rarely observed without addition of chemical catalysts or extreme reaction conditions. In this talk, I will demonstrate the use ultra-fine nanoporous aluminum to create hydrogen at standard conditions for temperature and pressure via hydrolysis without any catalyst additives.[1] The advantage of this method is the co-production of pure aluminum hydroxide (Al(OH)3) during the process. I will demonstrate the transformation of this hydrolysis byproduct into valuable materials to elucidate measures in reducing the overall cost of hydrogen. Our results show that (i) the synthesis of nanoporous aluminum is scalable to meet the needs of large scale production for a hydrogen gas economy, and (ii) the transformation of the hydrolysis byproduct Al(OH)3 to create high surface-area “activated alumina” (Al2O3) as a commercially viable product.

ACS Sustainable Chemistry & Engineering 2019; https://doi.org/10.1021/acssuschemeng.9b00481

**EN06.03.33**
Optimal nanodesign of catalysts can surely be obtained benefitting from the functionalization of carbon based materials. By this approach various functionalities can be strategically anchored on the backbone of these materials, aiming at specific applications such as catalytic. In the context of catalysis, the development of heterogeneous nanocatalysts allies not only the interesting intrinsic properties of nanomaterials but also the facile separation and reuse of the catalysts. The main challenges involve how to design the desired functionalities on heterogeneous surfaces, which many times is inspired on homogenous reactions. Herein, we pursued various functionalization of graphene oxide (GO) and carbon nanotube (NTC) with functional groups and metallic nanoparticles (NPs) towards several application, highlighting the efficient production of hydrogen. In this sense, we obtained nanocatalysts derived from GO, NTC filled with Co, Ag NPs and Ni NPs obtained as thin films, which were employed in the hydrogen production from the hydrolysis reaction of NaBH₄. The maximum rate of hydrogen production reached over 50 x10³ mL⁻¹ min⁻¹ g⁻¹, among the highest reported. Hence, high volumes of hydrogen could be produced using low amounts of catalysts (~0.1–0.8 mg) and could be reused for 10 consecutive cycles without losing activity. The facile use of the nanocatalyst thin film is the most promising aspect towards such an important field: sustainable energy. We can produce high amounts of hydrogen, in a controlled system (ceasing the production is easy) and easily remove the thin film (deposited on glass substrate), wash and reuse it again. Furthermore, another catalytic application is regarding the monitoring and destruction of toxic agrochemical in the field or our food and also chemical warfare in terrorist attacks or war zones, mainly concerned in promoting worldwide chemical security. We have been using the functionalization GO and NTC with various moieties covalently (imidazole, thiol, hydroxamate) and non-covalently (Ni and Ag NPs) linked, obtained as powder and thin film. An innovative interfacial functionalization method is proposed for obtaining the thin films. Bifunctionalization has also been carried out by anchoring two different neighbouring groups. Expressive rate enhancements up to 10⁸-fold were obtained in the presence of the nanocatalysts compared to the spontaneous reaction. The nanocatalysts also showed a dual function: could be used as sensors for detecting these toxic agents. These results can be further extended for alerting pesticide contamination and chemical attacks. In summary, indeed the nanodesign of heterogeneous catalysts opens a myriad of possibilities for achieving prominent catalysis.

EN06.03.34
Adsorption/Oxidation Performance of Hybrid Co3O4/ZSM-5 Monolithic Catalysts under Low Temperature Combustion of Diesel Condition Junfei Weng and Pu-Xian Gao; University of Connecticut, United States

Abstract

Cobalt oxide nano-arrays structured catalysts had been demonstrated to exhibit high NO oxidation performance with porous nature of nanowires and relative amount of Co³⁺ on the surface ¹, and ZSM-5 was studied as a porous catalytic material for trapping hydrocarbon during the cold-start process ². In this work, hybrid Co₃O₄/ZSM-5 monolithic catalysts were synthesized on honeycomb cordierite substrate by hydrothermal methods. Two configurations were adopted: Co₃O₄ nanoarray was grown on substrate first followed by the growth of ZSM-5 (CZ), and ZSM-5 layer was grown first followed by the growth of Co₃O₄ nanoarray (ZC). The adsorption/oxidation performance was evaluated under low temperature combustion of diesel (LTC-D) condition with feed gas of CO, C₂H₄, C₃H₆, C₃H₈, and NO. The results showed that within the tested temperature range (up to 300 °C), although the adsorption/oxidation behavior for CO, C₂H₄ and C₃H₈ were similar, ZC configuration exhibited higher adsorption capacity for C₃H₈ and NO than those of CZ. In ZC, C₃H₈ was not released and oxidized directly below 300 °C while NO was desorbed at 280 °C, which was higher than that in CZ.

**Preparation of Gold-Platinum Bimetallic Nanoparticles via Pulsed Laser Dewetting** Stephanie Bonvicini, Annie Hoang, Viola Birss and Yujun Shi; University of Calgary, Canada

Platinum is an important catalyst for many fuel cell applications. Due to the high cost of platinum, there is continuing research interest in developing nanostructures to reduce the amount of platinum used while maintaining performance. Bimetallic nanoparticles containing platinum are a promising approach to improve the efficiency of fuel cells at a reduced cost. In this work, we report on the formation of gold-platinum nanoparticles through pulsed laser dewetting of metal thin films. Important parameters in laser dewetting, such as laser fluence and irradiation time, were explored. The sputtering order and thickness of the gold and platinum thin films were also investigated. Elemental analysis confirms that both gold and platinum are found within the nanoparticles after dewetting. The results from cyclic voltammetry of the produced bimetallic gold-platinum nanoparticles will also be presented.

**Electrochemical Desulfurization of Molybdenum Disulfide Nanocatalysts Supported on Reduced Graphene Oxide for Efficient Hydrogen Evolution Reaction** Sanju Gupta, Taylor Robinson and Jacob Dobler; Western Kentucky University, United States

Recent development of two-dimensional layered materials including graphene-family and related nanomaterials have arisen as potential game changer for energy, water and sensing applications. While graphene is a form of carbon arranged hexagonally within atomic thin sheet, MoS2 is becoming a popular, efficient, and cost-effective catalyst for electrochemical energy devices, in contrast to expensive platinum and palladium catalysts. In this work, we electrochemically desulfurize few-layer molybdenum disulfide (MoS2) and aerogels with reduced graphene oxide (rGO) prepared under hydrothermal conditions ((P< 20 bar, T< 200 oC), for improving hydrogen evolution reaction (HER) activity via point defects (S-vacancy). Moreover, the interactions between rGO and MoS2 components create emergent heterostructures with desirable physicochemical properties (specific surface area, mechanical strength, faster diffusion, facile electron and ion transport) enabled by chemically bridged (covalently) tailored interfaces. We demonstrate that with an optimized number defect density, particularly by exposing the edges of MoS2 layers and nanowalls in graphene-MoS2 hybrid aerogels, interfacial processes during catalytic reactions are accelerated. To understand the effects of defects on HER activity, we varied the applied potential and operating duration for optimized defect density. This study offers a unique method for tuning the properties of layered MoS2 and hybrids as promising, cost-effective and efficient nanocatalysts. In addition, it establishes the structure–catalytic activity relationships via scanning electrochemical microscopy at electrode/electrolyte interface besides mapping electrochemical (re)activity and electro-active site distribution.

**Self-Assembled Iridium Cobalt Hollow Structure on Activated MXene for Efficient Overall Water Splitting** Thi Anh Le1,2, Ngoc Quang Tran1,2, Ye sul Hong2, Meeree Kim1,2 and Hyo young Lee1,2, 1Centre for Integrated Nanostructure Physics Institute for Basic Science (IBS), Korea (the Republic of); 2Sungkyunkwan University, Korea (the Republic of)

Electrochemical water splitting has been recognized as a promising route for hydrogen fuel generation at the
industrial scale. However, due to the sluggish kinetics of both half cathodic and anodic reactions of the electrolyzer (hydrogen/oxygen evolution reactions-HER/OER), the water electrolysis usually requires large input energy that strongly inhibits its application in practice. Therefore, facile and scalable construction of catalytic active, durable and low-cost electrocatalysts to largely boost the sluggish kinetics during electrocatalytic process remains a huge challenge.

Hybridization of a catalytic active material with a large surface area and good electrical conductivity with a hydrophilic substrate is a wise strategy to enhance the electrocatalytic performance by achieving the synergistic effects. Recently, two-dimensional (2D) titanium carbide MXene-based composites applied for energy conversion applications have widely attracted researches due to their unique electronic structure and surface properties over other carbonaceous materials such as reduced graphene oxide (rGO), carbon nanotubes (CNTs), etc. However, MXenes suffer from sluggish ionic accessibility and mass transport due to the strong van der Waals attraction and hydrogen bonding between inter-sheets, which seriously inhibits the realization of the full potential for these materials.

In this work, we develop an advanced electrocatalyst system composed of iridium cobalt (IrCo) hollow structure homogeneously distributed on the highly porous activated titanium carbide MXene (ac-Ti₃C₂) matrix via a wet chemical method at room temperature. We exploit the OER performance of the as-prepared catalyst (IrCo@ac-Ti₃C₂), which shows significantly enhanced catalytic activity with a low overpotential of 220 mV at a current density of 10 mA cm⁻², surpassing the benchmark IrO₂ and stability for 30 h of continuous testing in alkaline media. We also demonstrate the effectiveness of the electrode architecture through the rapid charge/mass transport in the internal electrode by tripling the mass loading on the rotating disk electrode. As expected, the novel catalyst displays a negligible dependence of the current density on the mass loading. Finally, when employed as a bifunctional catalyst in overall water splitting reaction, the optimal IrCo@ac-Ti₃C₂ also shows superior activity with the low voltage cell and excellent long-term durability, standing among the best catalytic activity of the reported electrocatalysts.

The outstanding performance can be attributed to the synergistic effects below: (1) the excellent electrical conductivity of the substrate and the smooth metal-support electronic interaction can ensure fast electron conductance; and (2) the hierarchically porous nanoarchitecture of the obtained compound with abundant of macro/meso/micropores and edges/defects sites not only benefits the ionic accessibility, increases the electrode wettability, boosts the migration of reactant-related species, and fastens gas evolution/evacuation by shortened mass-transport pathways, but also assures uniform distribution and maximization of the number of active sites exposed to the electrolyte, preventing the aggregation of active materials during electrochemical process.

Promoting the Oxygen Evolution Reaction through the Incorporation of V and Se in Amorphous Nickel-Cobalt Based Electro catalysts Jehad Abed, Aoni Xu, Edward H. Sargent and Steven Thorpe; University of Toronto, Canada

Stable and affordable electrocatalysts are urgently needed to accelerate the transition from conventional fossil fuels to sustainable energy resources such as hydrogen derived from renewable energy sources such as solar and wind. Converting said harvested energy electrochemically into chemical fuels and feed stocks is also highly desirable. Over the last two decades, the electrocatalytic splitting of water, and carbon dioxide reduction to hydrocarbons have received great attention, however approximately 90% of the electricity input is consumed in the anodic oxygen evolution reaction (OER) due to poor reaction kinetics. Precious metal based catalysts (Pt, Ir, Ru) are commonly used as OER catalysts, but prove uneconomic for large scale industrial deployment. New low cost, stable, earth-abundant catalysts such as those based on transition-metal alloys (Ni,Co) offer great promise to overcome these kinetic limitations.

In this work, we used a two-step novel milling process to produce NiCo-based amorphous nano-electrocatalysts. Cryo-milling (mechanical milling of precursors at cryogenic temperatures to achieve alloying) followed by surfactant-assisted ball milling (SABM for particle size reduction) create stable amorphous alloys with high surface areas and coordinatively unsaturated active sites for the reaction of OER intermediates. The improved stability of the amorphous alloys is yet another exciting feature that can significantly enhance the overall catalytic performance of the catalyst.

Using density functional theory (DFT) calculations, two potential elements V and Se were predicted to reduce the overpotential of the catalyst when incorporated in these structure. Alloys of NiCoV and NiCoSe were milled under
various conditions and the structural evolution of the system monitored using x-ray diffraction (XRD) and electron microscopy. Our results confirm the production of two fully alloyed ternary systems after 6 hours of milling time. Furthermore, a wide composition range could be investigated using this synthesis technique to accordingly tailor the activity of the catalyst. The electrocatalytic activity and stability of the catalysts was evaluated by Tafel measurements obtained from linear sweep voltammetry (LSV) and cyclic voltammetry (CV) experiments. We found that V in NiCo-based alloys helped the amorphous structures to stabilize by forming non-transitional clusters\(^2\) while Se significantly reduced the size of the produced particles. Operando X-ray Absorption Spectroscopy (XAS) was conducted to reveal the role of adding V and Se on the chemical-structural transformation and bonding environment of surface species during the reaction. This work suggests that milling can potentially be used to produce OER catalysts for industrial applications.

**Guiding Principles for Designing Metal-Coordinated Frameworks as Electrocatalysts for Clean Energy Conversion**

Chun-Yu Lin and Zhenhai Xia; University of North Texas, United States

We are facing energy crisis because of the limitation of the fossil fuel and the pollution caused by burning it. Clean energy technologies, such as fuel cells and metal-air batteries, are studied extensively because of their high efficiency and less pollution. Oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) are essential in the process of energy storage and conversion, and noble metals (e.g. Pt) are needed to catalyze the critical chemical reactions in these devices. Functionalized metal coordinated frameworks such as metal organic frameworks, covalent organic frameworks, and zeolitic imidazolate frameworks can be used as efficient catalysts to replace expensive and scarce platinum-based catalysts for energy storage and conversion. Traditionally, experimental studies on the catalytic performance of metal coordinated frameworks have been conducted extensively, however, there is lack of computational studies to guide the experiments for rapid search for the best catalysts. In addition, catalytic mechanism and rational design principles towards ORR and OER also needed to be fully understood.

Density functional theory calculations are performed to calculate the thermodynamic and electrochemical properties of metal coordinated frameworks for ORR and OER. Gibb’s free energy, overpotential, charge transfer and ligands effect are evaluated. The charge transfer analysis shows the positive charges on the metal coordinated frameworks play an essential role in improving the electrochemical properties of the metal coordinated frameworks. Based on the calculations, design principles are introduced to rationally design and predict the electrochemical properties of metal coordinated frameworks as efficient catalysts for ORR and OER. An intrinsic descriptor is discovered for the first time, which can be used as a materials parameter for rational design of the metal coordinated frameworks for energy storage and conversion. The success of the design principles provides a better understanding of the mechanism behind ORR and OER and a screening approach for the best catalyst for energy storage and conversion.

**9:00 AM EN06.04.04**

**Nonradical Activation of Peroxydisulfate Promoted by Oxygen Vacancy-Laden NiO for Catalytic Phenol Oxidative Polymerization**

Nian Liu; Georgia Institute of Technology, United States

Engineering the electronic properties of catalysts to facilitate electron transfer and activation of dynamically stable peroxydisulfate (PDS) offers a promising strategy for efficient remediation of recalcitrant organic pollutants through heterogeneous Fenton-like processes, but it also presents challenges due to a lack of facile methods. In this presentation, we report a simple defect engineering strategy that significantly increases the efficiency of PDS adsorption and activation by introducing oxygen vacancies (VO) into NiO to produce an electron-rich surface. Experimental studies and density functional theory (DFT) calculations confirmed that VO confined in NiO could successfully cause synergetic effects of lower adsorption energy and more exposed active sites, thus facilitating the bonding with PDS molecules and promoting the reactivity of PDS-NiO complex, giving rise to dramatic enhancement of catalytic performance with removal rate as high as 3.978 mmol(phenol) min\(^{-1}\) g(NiO)\(^{-1}\). Mechanistic studies further reveal that the surface-activated PDS-NiO complex mediate oxidative polymerization of phenol (a model pollutant) involved in the generation of phenoxy radicals and subsequent coupling reactions,
providing the potential to convert recalcitrant organic pollutants into value-added products. We believe this work pave the way toward practical fabrication of highly efficient “defect-type” Fenton-like catalysts, and the present method also provides new opportunities to achieve sustainable wastewater treatment through reuse of organic pollutants.

This presentation is based on our recent publication:  
*Applied Catalysis B: Environmental*, 2019, 254, 166-173  
https://doi.org/10.1016/j.apcatb.2019.04.094
evolution, thus validating the applicability of single crystal surfaces to understand the OER mechanism on polycrystalline surfaces.

In order to understand the kinetic behavior of oxygen evolution of RuO$_2$ surfaces, electrochemical activity measurements were combined with highly sensitive electrochemical mass spectrometry to quantify the amount of evolved oxygen at low overpotentials. The combined electrochemical and mass spectrometry results indicate that the current-potential dependence goes through three distinct Tafel regimes, where the Tafel slope increases with electrochemical potential from 30 mV/decade at low potentials to 120 mV/decade at high potentials. We rationalize this kinetic behavior by modeling the coverage of the reaction intermediates as a function of potential, based on their energetics proposed on the (110) surface. Finally, using oriented RuO$_2$ surfaces, which have different binding energetics for oxygenated species, we highlight differences in Tafel behavior as a function of potential. Thus, by using different experimental and theoretical techniques as well as model surfaces, this study identifies the active sites and reaction mechanism for oxygen electrocatalysis. We also highlight the importance of understanding and controlling kinetics of OER on highly active catalysts, in order to achieve higher current densities at low overpotentials.

11:00 AM EN06.04.09
Symmetry Breaking of Atom Configurations as an Efficient Tool for Oxygen Evolution Electro catalysis in Perovskite Oxides Sung-Yoon Chung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

As metal-oxygen octahedra in $ABO_3$-type perovskite oxides are regarded as active sites for notable oxygen electrocatalysis, many studies have been carried out seeking higher catalytic activity by experimenting with various transition metals and their combinations on the $B$ site, as well as the influence of oxygen vacancies. In contrast to the substantial amount of research on different compositions and their impact on overall catalytic performance, the correlation between the structure of the oxygen octahedra in perovskites and electrocatalysis performance has been overlooked, resulting in a limited understanding of the effect of structural variation. From a structural viewpoint, the $ABO_3$ perovskite framework consists of corner-shared $[BO_6]$ octahedral units, which are catalytically active sites, together with $A$-centered dodecahedra. Consequently, identifying variations in the shape of the $[BO_6]$ octahedra and understanding under what circumstances structural change takes place remain as key issues for the accurate prediction of electronic structure and subsequent oxygen evolution reaction (OER) activity. In particular, since the shape of the $[BO_6]$ octahedra is determined largely by the location of oxygen anions in the lattice, visualization of the oxygen positions is an essential part of that direct observation of structure (J. Bak et al., Nano Lett. 17, 3126 (2017)), despite being very challenging.

In the first part, by using both sintered polycrystals with various grain sizes and thin films on bicrystal substrates, we directly verify that surface-terminating grain boundaries in LaCoO$_3$ and LaMnO$_3$ are exceptional in oxygen evolution electrocatalysis, showing more than an order of magnitude higher activity. A combination of atomic-scale structure observation and density functional theory calculations demonstrates that the displacement of atoms in metal-oxygen octahedra correlates with significant splitting of the degenerate transition-metal $3d$ orbitals, and subsequently higher covalency for rapid charge transfer between metals and oxygen is attained (Y. Heo et al., Adv. Energy Mater. 8, 1802481 (2018)). In the second part, by utilizing epitaxial LnNiO$_3$ ($Ln =$ La, Pr, Nd) thin films, we also demonstrate that order-of magnitude higher catalytic activity for the OER can be achieved by selective electrochemical exchange of Fe in the surface region. In addition, we directly establish that strong distortion of oxygen octahedra is induced during the Fe exchange, and that this structural perturbation correlates with the high density of Ni/Fe $3d$ and O $2p$ states near the Fermi level, permitting easier charge transfer (J. Bak et al., Nature Commun. (in press)). By demonstrating the remarkable structure-property relationship in oxygen electrocatalysis, our findings suggest that symmetry breaking by atom displacements in metal-oxygen octahedra can be a new and
Combining Theory and Experiment to Engineer \( \text{Ba(Fe, Co, Zr)}O_{3-d} \) (BFCZ) as a Family of Stable, Highly Active Oxygen Reduction Catalysts

Ryan Jacobs\(^1\), Jian Liu\(^2\), Boem-tak Na\(^2\), Shiwoo Lee\(^2\), Gregory Hackett\(^2\), Harry Abernathy\(^2\) and Dane Morgan\(^1\); \(^1\)University of Wisconsin–Madison, United States; \(^2\)National Energy Technology Lab (NETL), United States

The discovery of new materials with high oxygen reduction reaction (ORR) catalytic activity and high thermodynamic stability under typical cathode operating conditions are crucial for the development of improved solid oxide fuel cell (SOFC) and related technologies. To aid in this discovery we have performed high-throughput Density Functional Theory (DFT) calculations of \( \sim 2150 \) perovskite materials,\(^1\) assessed bulk thermodynamic stability via multicomponent phase stability analysis using the Python Materials Genomics (Pymatgen) package\(^2\), and predicted oxygen reduction reaction (ORR) catalytic activity with the \( O_p \)-band center. We found that \( \text{BaCo}_x\text{Fe}_y\text{Zr}_z\text{O}_{3-d} \) (BFCZ) \((x+y+z=1)\) was a promising family of highly active and stable ORR cathode materials.\(^1\)

Here, perovskite-type oxides with compositions \( \text{BaCo}_x\text{Fe}_y\text{Zr}_z\text{O}_{3-d} \) (BFCZ) \((x+y+z=1, z=0.2, 0.4, 0.6 \text{ and } 0.75 \text{ Zr fraction})\) were synthesized and characterized via X-ray diffraction (XRD) analysis and electrical conductivity relaxation (ECR) measurements. The bulk stability of BFCZ was analyzed with XRD and atomic force microscopy (AFM) after accelerated high temperature testing. The performance of BFCZ as an electrode was characterized by monitoring the impedance over time of dense spin-coated BFCZ films on a Sm-doped ceria (SDC) protected YSZ electrolyte.

All of the synthesized BFCZ compositions exhibit the cubic perovskite structure. ECR measurements indicate exceptionally high oxygen surface exchange rates and bulk oxygen diffusivity values, on par or better than other state-of-the-art high surface exchange materials like \( \text{Ba}_0.5\text{Sr}_0.5\text{Co}_0.8\text{Fe}_0.2\text{O}_3 \) (BSCF).\(^3,4\) Comparisons between the experimentally measured activities and the model predicted activity results in good qualitative agreement. Chemical trends of activity and stability as a function of Zr content are also in agreement between the computational model and the experimental results. These results collectively demonstrate (1) the power of the developed modeling scheme in predicting and rationalizing the stability and activity of BFCZ and perovskite catalysts more broadly and (2) experimental confirmation of the promise of BFCZ with high Zr content as both a highly active and stable ORR catalyst material.

Parallelization of Multi-Step Electrocatalytic Reactions

Heechae Choi and Minyeong Je; University of Cologne, Germany

In general, ‘Task Parallelization’ is the simplest and ultimate solution for bottle-neck problems of serial multi-step tasks. Catalytic reactions for energy conversion and storage are in many cases, serial multi-step reactions having bottle-neck steps. In this work, we first suggest the concept of ‘Task Parallelization’ in multi-step catalytic reactions. As the prototype study, we applied this concept to oxygen evolution reaction (OER) on electrocatalytic materials. Since the catalytic activity of a material is the result of moderate adsorption energies of reactants and intermediates, mixture of multiple phases having different bottle-neck reaction steps can lead to excellent catalytic material composite, even though each phase is not much good. In this study, we used first-principles calculations and thermodynamic modeling to predict reaction pathways and facile synthesis of multiphase nanostructure. Our well-designed experiments prove this concept very well for OER electrocatalysis.
SESSION EN06.05: Catalysis of and with Oxygen II

Sheraton, 2nd Floor, Independence West

1:30 PM EN06.05.01
Surface Restructuring of Phosphides Catalyzing Water Electrolysis Zishan Wu1,2, Ling Huang1,3, Huan Liu1,4 and Hailiang Wang1,2; 1Yale Energy Science Institute, United States; 2Yale University, United States; 3Sichuan University, China; 4Harbin Institute of Technology, China

Transition metal phosphides (TMPs) are a well-known category of catalysts with good activity and durability for both hydrogen evolution reaction (HER) and oxygen evolution reaction (OER). Most TMPs are found to possess a naturally oxidized surface under ambient condition. However, how the oxidized surface adapts to the electrochemical conditions and leads to the observed catalytic properties are poorly understood. To gain insights into their structure-properties correlations, quasi-in-situ X-ray Photoelectron Spectroscopy (XPS) is employed to study the surface restructuring of TMPs under electrochemical conditions. It is found that the naturally oxidized and phosphorus-rich surface of cobalt phosphide (CoP) will be removed in acidic electrolyte under HER conditions, exposing a fresh CoP surface. Under HER conditions in alkaline electrolyte, electrochemical reduction of the oxidized species and dissolution of the oxidized P species will together render a Co-rich phosphide surface. Under OER conditions in alkaline electrolyte, a cobalt hydroxide/oxide surface will be formed as a result of combined oxidation and anion substitution. In order to explore the dependence of catalytic reactivity on substitutional doping, cation- and anion- substituted CoP nanoparticles are also investigated. For Fe0.5Co0.5P, the Fe substituents are more easily oxidized than Co in the air; they are also more difficult to be reduced under HER conditions in alkaline electrolyte and the remaining Fe-OH species on the surface hampers the activity for HER. For CoP0.5S0.5, the S substituents are less oxidized than P in the air; they are also more difficult to be oxidized under OER conditions in alkaline electrolyte, and the remaining sulfate like species enhance the activity for OER.

1:45 PM EN06.05.02
Oxygen Evolution Activity and Stability of Amorphous Ni-Based Nanoparticles Produced through Surfactant-Assisted Ball Milling Kevin Cole, Donald Kirk and Steven Thorpe; University of Toronto, Canada

The use of novel anion exchange membranes (AEM) in alkaline water electrolysers is now of particular interest since it eliminates the aqueous KOH electrolyte and can provide improved form factors and much higher current densities that rival proton exchange membrane (PEM) electrolysers.1 The use of AEM water electrolysis also enables the use of less expensive, earth-abundant, non-platinum group metals (PGM) materials such as nickel-based alloys as electrocatalysts.1 Conventional Ni electrocatalysts for the oxygen evolution reaction (OER) still display large overpotentials and slow reaction kinetics. The addition of Co to Ni-based alloys has been noted to increase the activity by stabilizing the β-NiOOH phase over γ-NiOOH, but this often leads to an increase in the oxygen overpotential.2,3 The issue of increased overpotential can be mitigated with the use of amorphous structures to reduce oxygen overpotentials with the addition of Co.3,4 This prior research has been limited to structures not ideal for catalysts in AEM water electrolysis.4

In this work, amorphous Ni79.2-xCoxNb12.5Y8.3 (x = 0 and 5 at.% Co) nanoparticles were synthesized using cryogenic mechanical alloying followed by surfactant-assisted high energy ball milling (SA-HEBM).5 This two-stage ball milling process provided a novel processing route for the production of nanostructured / amorphous materials with a wide range of possible compositions not achievable through rapid solidification, electrodeposition, or chemical reduction techniques. The effect of milling temperature and time on the resulting powder microstructure was characterized using a combination of x-ray diffraction and electron microscopy. The electrocatalytic activity and stability of amorphous nanoparticles on the alkaline oxygen evolution reaction were investigated through cyclic voltammetry and Tafel measurements. Cyclic voltammograms demonstrated stable and reproducible curves for amorphous alloys up to 10000 cycles while crystalline Ni and Ni50Co50 showed signs of deactivation with cycling. Initially the addition of Co to crystalline Ni resulted in enhanced OER catalytic performance, but the performance drastically reduced beyond 500 cycles. A similar increase in performance was observed when adding Co to amorphous Ni79.2Nb12.5Y8.3, except the activity and stability was maintained throughout the 10000 cycles. The presence of Co in Ni-based materials is shown to enhance the OER activity with amorphous
structure providing excellent long-term cycling stability. These features, along with the high surface area achieved through SA-HEBM, provide a cost-effective and simple method for producing stable and active amorphous electrocatalysts for the oxygen evolution reaction in AEM water electrolysis.

Boron Decorated Nickel Electrodes for Efficient Oxygen Evolution Reaction
Viridiana L. Perez, Audrey K. Taylor, Michael T. Paul, Jeffrey Ovens, Alexi Pauls, Mehrtoos Eslamibidgoli, Michael Eikerling and Byron D. Gates; Simon Fraser University, Canada

Clean energy sources such as hydro, wind and solar energy represent some of the alternatives to diminish our dependency on fossil fuels. Fluctuations in their availability due to geographical features and seasonal weather limit their use. Finding reliable ways to store the energy produced by these clean energy sources will help mitigate these issues.

Chemical energy storage and energy conversion are two ways to approach this problematic. Hydrogen is a clean fuel source, but currently it is mostly obtained from fossil fuels. Water splitting for the production of hydrogen in alkaline water electrolyzers arise as a viable option. However, commercial electrolysers perform at efficiencies of 60 to 70%, which is insufficient to supply for the demand of the fast-growing hydrogen economy. Hydrogen production by electrochemical water splitting is limited by the oxygen evolution reaction (OER). This reaction takes place at the anode, sluggish kinetics and accumulation of oxygen bubbles can block active sites on the surface of the electrode. Electrodes are typically made of expensive precious metals, however nickel-based metal oxides are a promising and robust alternative. Nickel electrodes have shown high activity and reduced activation energies for alkaline OER. However, the surface wettability and the accumulation of oxygen bubbles blocking active sites remain as an issue.

Our work explored the inclusion of boron containing species that are conductive, improve wettability, are stable under alkaline conditions and are inert at OER potentials. The decorated nickel surfaces showed improved OER activity. The electrodes were characterized using electron microscopy, electrochemical testing and X-ray diffraction measurements. The study was complemented with theoretical calculations of the electronic effects of the boron species and reaction intermediaries at the interface of the electrode and the electrolyte.

Tracking Structures in Solar Fuels Catalysis—In Situ X-Ray Structure Characterization of Heterogenized Molecular and Thin-Film Metal-Oxide Water-Splitting Catalysts
David M. Tiede1, Gihan Kwon2, Emily Sprague-Klein1, Tae Wu Kim1, Karen Mulfort1 and Alex B. Martinson1; 1Argonne National Laboratory, United States; 2Brookhaven National Laboratory, United States

A key challenge for the design of efficient photoelectrochemical devices that employ nanoscaled interfacial designs for solar energy-to-fuels conversion lies in resolving atomic structures and dynamics at the active interfaces, and relating these to the complex cascade of events which includes excited-state charge separation, charge-accumulation, and multi-step energy conversion and catalysis. Our research programs have been developing in-situ, time-resolved X-ray techniques aimed at the resolution of atomic-scale structures that underlie interfacial charge transfer and photo-driven water-splitting catalysis under conditions relevant to photoelectrochemical function for both interfacial thin-films and molecular photosensitizers and catalysts bound to semiconductor surfaces.

This presentation will show how high energy (>50 keV) X-ray scattering and pair distribution function (PDF) analysis provides atomic structure characterization that usefully complements electronic structure characterization derived from a combination of soft X-ray absorption (XAS), resonant X-ray emission (RXES), resonant inelastic X-ray scattering (RIXS) techniques for structure-function analysis of transition metal semi-conductor and catalyst thin films. Microporous high surface area electrodes were designed that allowed PDF analysis to be accomplished 0.2 Å spatial resolution for amorphous transition metal oxide thin films having thickness of down to 60 nm. The combined
electronic and structural analyses demonstrate that hole transfer to catalytic sites in amorphous cobalt oxide thin films is the rate-limiting step for electrochemical water-splitting rather than the multi-step catalytic events themselves. The macroscopic catalytic properties of the thin films were found to be correlated to the electronic structures measured at the atomic scale for the metal-oxo cluster domains. These results show the interplay between intrinsic catalytic activity and charge transport properties of semiconductor thin-film catalysts.

We have extended this approach by the development of nanoporous electrode architectures which enable the use of combined PDF and X-ray spectroscopy analyses to resolve differences in coordination structures for molecular photosensitizers and catalysts in solution and when bound to semiconductor oxide surfaces. Measurements on ruthenium photosensitizer complexes bound to the TiO₂ surface resolve distortions in the surface-coordinating ligand structures. On-going work is investigating the correlation between ligand structural distortion and the metal-to-ligand charge-transfer (MLCT) states with ultrafast interfacial charge injection function.

Tracking Structural Transformations by Operando X-Ray Scattering for the Oxygen/Water Electrocatalysis
Fabio Dionigi and Peter Strasser; Technische Universität Berlin, Germany

The intermittent nature of renewable energy sources, i.e. wind and solar radiation, requires storage solutions to match the energy demand of human activities. Among the chemical fuels, hydrogen is an interesting energy vector due to its high gravimetric energy density. Energy can be stored in the chemical bonds of hydrogen by water electrolysis and electric energy can be obtained with the related back reaction by using a fuel cell. The oxygen evolution reaction (OER) and the oxygen reduction reaction (ORR), involved respectively in the forward and backward reaction, are associated with higher conversion efficiency losses in comparison with their half-reaction counterparts. Therefore, catalysts with superior activity for these reactions are of high interest. Understanding the reaction mechanism and identifying the catalytically active sites is important in order to improve the performance of the state-of-the-art catalysts. However, the atomic structure under reaction condition can be different than in the as synthesized phase. In this contribution, we will present operando wide angle X-ray scattering (WAXS) results providing insights into important structural changes leading to formation of catalytic active phases or associated to degradation mechanisms.

For the OER, NiFe layered double hydroxides (LDHs) are recognized among the most active catalysts in alkaline electrolytes [1]. Their crystal structure is known and is composed of layers of edge sharing metal oxygen octahedra that are intercalated with water molecules and charge balancing anions. Despite their structure is well characterized, there are evidences that the OER active structure of LDH catalysts during OER is different than the one of the as prepared materials [1]. Using operando WAXS we identified the structure of the catalytically active catalyst state and observed that both the interlayer and in-plane distances contract under operating conditions [2]. We further proved that this structure is also exhibited by other Fe containing LDHs under OER conditions. These results are important to validate the structures used in theoretical models to predict the OER mechanism and ultimately to develop strategies to improve the OER activity of NiFe LDH catalysts.

In a second study, we show that operando WAXS can also be applied to study degradation mechanisms. For ORR, octahedral PtNi alloy based nanoparticles shows very high activities in thin film rotating disk electrode measurements in acid [3]. However, the prevention of Ni loss and morphological stability under operation are still challenging. Using a combination of operando WAXS and ex situ X-ray fluorescence spectroscopy (XRF) we found that a structural transformation is involved in the degradation mechanism occurring while cycling the applied potential. The catalyst crystalline structure was modeled using multiple metal phases and the dealloying of the Ni richer phase with associated Ni loss is proposed as the main degradation mechanism [4]. The sensitivity of this process to operating conditions such as the upper potential limit of the cycling protocol was investigated. The binary PtNi alloy based nanoparticles were also compared with surface doped ternary compositions as potential method to prevent structural changes.

Fundamental Understanding of Activity-Stability Issues on Electrocatalysis for Oxygen Evolution Reaction

Dong Young Chung, Pietro Papa Lopes, Dusan Strmcnik, Vojislav Stamenkovic and Nenad Markovic; Argonne National Laboratory, United States

Water electrolysis has been accentuated important building blocks for energy conversion and storage concepts in aqueous system. In particular, oxygen evolution reaction (OER) is important counter reaction for not only hydrogen evolution reaction but also various electrochemical synthetic reaction including CO2 and N2 process. Durable electrocatalyst designs are an urgent problem in both acid and alkaline media because even noble metal based Ru and Ir materials suffer significant activity loss due to the highly corrosive thermodynamic potential window. In order to obtain highly durable electrocatalyst with high activity, it is urgent to link the activity-stability relationship during reaction. Here, we will discuss activity-stability relationship in water electrolysis reaction using our well-defined model system from simple monometallic system to bimetallic and complicated system. In the model system approach, we will discuss the general relationship between activity and stability what we observed and suggest which concept appeal to the future direction for achieving high activity and stability in OER electrocatalysis.

Engineering Dopant Position in Core-Shell CeO2-ZrO2 Nanoparticles to Control Catalytic Activity

Behnam Safavinia1, Pragathi Darapaneni1, Orhan Kizilkaya1, David Cullen2, Kerry M. Dooley1 and James A. Dorman1; 1Louisiana State University, United States; 2Oak Ridge National Laboratory, United States

Tailoring active sites position and concentration on the catalyst surface has been shown to effect activity and stability of a catalyst. Specifically, the surface coverage of transition metals on CeO2-ZrO2 (CZO) nanoparticles (NPs) is known to directly affect the redox property and ability to utilize lattice oxygens. Recently, Ni incorporation in the core of a CZO NPs has caused a two-fold increase in catalytic activity per surface area due an increased oxygen storage capacity. However, the activity of the particle is dependent on the Ni surface concentration and is traditionally deposited via the insipid wetness impregnation technique, forming Ni on the surface of the particle. In this work, the role of Ni position on catalytic activity is probed to develop a two-step synthesis process which allows for spatially controlled dopant distribution for improved catalytic activity.

A two-step process, co-precipitation/molten salt synthesis (MSS), has been explored for the catalyst core, and urea deposition synthesis for the shell of CZO:Ni NPs. The concentration of oxygen vacancies in these NPs was studied using Raman spectroscopy, which shows an order of magnitude increase in oxygen vacancies based on the change in intensity of defect-induced (D) band at 600 cm⁻¹ as the position of the active site is modified. High resolution transmission electron microscopy (HRTEM) and energy dispersive x-ray spectroscopy (EDX) identify that a core-shell structure is obtained with spatially controlled Ni concentrations To further correlate the dopant position and oxygen vacancies, local bond structure and geometry of the active site (Ni) were studied by performing L edge X-ray Absorption Spectroscopy (XAS) measurements. Geometric distortions due to the eg and t2g orbitals is dependent on the distribution of Ni within the NPs. The change in the geometric structure of Ni was observed via in situ CO chemisorption XAS measurements and correlated to the orbital structures. These preliminary results on the spatially controlled CZO core-shell NPs demonstrate that controlling the position of the active site (Ni) modifies the oxygen vacancies of the NPs which is the first step to understand the diffusion of the active site during a reaction and deactivation pattern of the catalyst.

Engineer Metal Oxide–Metal–Carbon Interface for Highly Efficient Oxygen Reduction

Jun Chen
jun.chen@ucla.edu
Assistant Professor in Department of Bioengineering,
University of California, Los Angeles, CA 90095, United States

Abstract:
Oxygen is the most abundant element in the Earth’s crust. The oxygen reduction reaction (ORR) is also the most
important reaction in life processes and energy converting/storage systems. Developing techniques toward high-
efficiency ORR remains highly desired and a challenge. Here, we report a N-doped carbon (NC) encapsulated
CeO2/Co interfacial hollow structure (CeO2–Co–NC) via a generalized strategy for largely increased oxygen
species adsorption and improved ORR activities. First, the metallic Co nanoparticles not only provide high
conductivity but also serve as electron donors to largely create oxygen vacancies in CeO2. Second, the outer carbon
layer can effectively protect cobalt from oxidation and dissociation in alkaline media and as well imparts its higher
ORR activity. In the meanwhile, the electronic interactions between CeO2 and Co in the CeO2/Co interface are
unveiled theoretically by density functional theory calculations to justify the increased oxygen absorption for ORR
activity improvement. The reported CeO2–Co–NC hollow nanospheres not only exhibit decent ORR performance
with a high onset potential (922 mV vs RHE), half-wave potential (797 mV vs RHE), and small Tafel slope (60 mV
dec–1) comparable to those of the state-of-the-art Pt/C catalysts but also possess long-term stability with a negative
shift of only 7 mV of the half-wave potential after 2000 cycles and strong tolerance against methanol. This work
represents a solid step toward high-efficient oxygen reduction.

Exploring the Low-Temperature Carbon Monoxide Oxidation and Thermochemical Water Splitting
Capabilities of High Entropy Oxides James E. Park1, Elizabeth Paisley1, Eric N. Coker1, Abhaya Datye2 and
Stanley S. Chou1; 1Sandia National Laboratories, United States; 2The University of New Mexico, United States

High entropy oxides (HEOs) have been a recently emerging class of materials with promising catalytic activities
and electrochemical energy storage capabilities.1 By incorporating five or more cations, an entropy-stabilized single-
phase crystal structure can be formed with various combinations of atomic elements. However, there have been a
limited number of reports of HEOs being utilized for catalytic reactions. Here, HEOs with fluorite and rock-salt
structures were synthesized via solid state synthesis, and their catalytic activities for low-temperature carbon
monoxide (CO) oxidation and thermochemical water splitting (TWS) were explored. HEOs allow incorporation of
different elements while maintaining the same crystal structure. Thus, unprecedented chemical combinations can be
synthesized to engineer chemical and defect structure of oxides for improved catalysis. Moreover, the phase stability
at different temperatures and atmospheres will be investigated to provide insight into the extent of entropy
stabilization in HEOs. Current research focuses on HEOs with fluorite-type and rock-salt-type structures but will
expand to perovskite-type and spinel-type structures with multiple cation sites.

Comparison between Thermochemical and Electrochemical Exsolution of Catalysts from Perovskite Oxides
for Efficient Hydrogen Production through Steam Electrolysis Georgios Dimitrakopoulos1, Jia Yue Wang1,
Rachael Rothman2 and Bilge Yildiz1; 1Massachusetts Institute of Technology, United States; 2The University of
Sheffield, United Kingdom
Increasing the performance of Solid Oxide Electrolysis Cells for the production of hydrogen (H₂) from water (H₂O) splitting requires the use of electrodes with low polarization resistance. To effectively enhance their splitting rate, catalysts are infiltrated into the porous electrodes. Traditional catalyst deposition methods such as wet impregnation or atomic layer deposition are expensive and the resulting catalysts suffer from agglomeration due to operation at high temperature that reduces the long-term performance. To improve upon the aforementioned methods and reduce the catalyst deposition cost, the in-situ growth of catalysts from perovskite oxides (termed catalyst exsolution) has been proposed as a means to decorate the porous electrode with highly dispersed, nanometer-sized catalytic particles [1-3]. These particles are highly active towards reactions of interest and show increased resistance to agglomeration due to their socketed nature [4].

Exsolution occurs when the oxygen chemical potential is reduced significantly and hence can be triggered either thermochemically (i.e. reduction of a perovskite oxide at elevated temperatures in the presence of fuel, usually H₂) or electrochemically (i.e. application of a voltage/current at elevated temperatures with/without the presence of fuel) [5]. In this work, we study the dependency of the exsolution mode (thermochemical vs. electrochemical) on the particle morphology, distribution, dispersion and activity towards H₂O-splitting to H₂. To investigate this dependency, exsolution of metallic Iron (Fe⁰) from an A-site deficient La₀.₇₅Sr₀.₂Cr₀.₉₅Fe₀.⁰₅O₃₋δ (LSCF) electrode was examined. Exsolution was triggered at different temperatures (in the 700C-900C temperature range) either thermochemically using 3%H₂-N₂ or electrochemically under an applied bias ranging between 0-2V in a 3% H₂O – 3% H₂ – N₂ environment. The polarization resistance before and after exsolution is measured using Electrochemical Impedance Spectroscopy (EIS) on asymmetric cells employing La₀.₈Sr₀.₂CrO₃₋δ as the counter electrode. Electrode polarization resistances under Open Circuit Voltage (OCV) in 3% H₂O – 3% H₂ – N₂ show that the exsolution mode plays a significant role in the particle growth and electrode activity. We demonstrate that, under the same environment, applying a bias to trigger exsolution generates more particles on the surface of the electrode compared to thermochemical exsolution. Characterization of the samples using X-Ray Diffraction (XRD), X-Ray Photoelectron Spectroscopy (XPS), Scanning Electron Microscopy (SEM) and Energy Dispersive X-Ray Spectroscopy (EDS) confirm the presence of Fe⁰ nanoparticles on the surface of the LSCF electrode and their existence decreases the polarization resistance as observed from EIS data.

Scalable Photoelectrochemical Perovskite-BiVO₄ Tandem Devices for Solar Fuel Synthesis Virgil Andrei,
Haijiao Lu, Sebastian D. Pike, Robert L. Hoye, Bertrand Reuillard, Shahab Ahmad, Dominic S. Wright, Michael De
Volder, Richard H. Friend and Erwin Reisner; University of Cambridge, United Kingdom

As the energetic demands of our society keep rising, any emerging technology faces the challenge of matching the commercial benefits presented by fossil fuels in terms of energy storage and mobility. Since a vast part of the modern energetic infrastructure already relies on fuels, their production in a sustainable manner stands out as an obvious solution. Therefore, the light-driven conversion of small molecules such as water and CO₂ into so-called solar fuels (e.g. H₂, CO) represents an attractive alternative for simultaneous energy harvesting and storage.[1,2] While great progress has been made in the development of light absorbers maximizing the solar spectrum coverage, their integration with catalysts into photoelectrochemical (PEC) devices for fuel production still poses challenges. Beside the performance and stability of common PEC prototypes, their scalability and choice of catalyst are also
major factors which must be considered for commercial applications. In this work, we address those issues by developing approaches to synthesize and characterize up-scaled PEC devices, which are able to produce fuels autonomously in the absence of external bias. To overcome the overpotential losses of electroreduction, we introduce state-of-the-art photocathodes obtained by protecting triple cation mixed halide perovskite solar cells with a Field’s metal encapsulant. Their PEC performance is benchmarked using a platinum nanoparticle catalyst for proton reduction, reaching photocurrents as high as -14 mA cm\(^{-2}\) at 0 V against the reversible hydrogen electrode (RHE) under 1 Sun irradiation.\[^{[3,4,5]}\] By combining the perovskite photocathodes with robust BiVO\(_4\) photoanodes, tandem PEC devices can be obtained which sustain unassisted water splitting at a solar-to-hydrogen conversion of approximately 0.3%. The PEC devices present remarkable stabilities of up to 20 h under operation in an aqueous medium,\[^{[4,5]}\] revealing key general insights for the encapsulation of perovskite optoelectronic devices.

To investigate the scalability of our “artificial leaves”, we prepare devices of sizes up to 10 cm\(^2\) which reveal a similar performance to their 0.25 cm\(^2\) counterparts. The PEC tandems are characterized in a versatile 3D-printed PEC cell, which can accommodate a wide array of samples due to its modular design.\[^{[5]}\] The potential for further device up-scaling is revealed by fabricating 25 and 300 cm\(^2\) doped BiVO\(_4\) panels from bismuth (transition metal) polyoxovanadate single-source precursors.\[^{[6]}\] The overall findings are applicable to a wide range of photoelectrochemical systems employing various photoabsorbers.\[^{[7]}\] Looking beyond water splitting, we will also discuss our recent progress on the development of PEC devices that can couple the more challenging CO\(_2\) reduction to water oxidation, with the ultimate goal of contributing towards a circular carbon economy via photoelectrocatalysis.

Nanosurface Engineering of Oxide Based Semiconductor towards Full Solar Spectrum Harvesting—A Combined Experimental and Theoretical Investigation Tuhin K. Maji\(^1\), Debjani Karmakar\(^2\) and Samir Kumar Pal\(^2\); \(^1\)SN Bose National Centre for Basic Sciences, India; \(^2\)Bhabha Atomic Research Centre, India

That there is an environmental and energy crisis due to civilization is beyond question. Utilization of full solar light spectrum to harvest energy is considered to be one of the most efficient techniques to overcome the energy crisis. The photothermal effect and photocatalytic effect are considered to be two of the most suitable strategies for solar light energy conversion. Metal oxide semiconductors are extensively used in photocatalysis because of their ability to absorb light from different part of the solar spectrum (depends on their band gap). Besides they also have other beneficial properties like high surface area, morphology, stability, non-toxic nature etc. We have tailored the surface defect state of ZnO nanoparticle (NP) using halide ion to enhance the charge separation property of ZnO. Particular halide ion (namely chloride) shows enhance photocatalytic activity in presence of UV light as well as room temperature magnetic activity. In our other work, we have prepared a new nanohybrid heterojunction using one low band gap semiconductor (CuS) with a wide bandgap semiconductor (ZnO) to form an efficient NIR harvesting photocatalyst. This newly prepared nanohybrid exhibit efficient photocatalytic performance using the NIR fraction of the solar light spectrum. An increment of significant charge separation from the conduction bands of CuS to those of ZnO is the key mechanism behind the enhanced photocatalysis. To utilize visible light for photocatalytic activity, we have prepared porphyrin dye sensitized metal oxide nanohybrid. Porphyrin dye is very much advantageous for visible light based photocatalytic activity due to their additional absorption band that resembles with the visible range of the solar spectrum. Here we have functionalized protoporphyrin IX with copper (II) ion and sensitized a
porous metal oxide microsphere TiO$_2$ (~1.5 µm diameter) in order to prepare a unique functional nanohybrid for visible light photocatalysis application. We have applied the nanohybrid for an efficient reduction of a toxic metal ion Cr (VI) to non-toxic Cr (III) in water under visible light illumination. For a prototype application, we have developed an active filter (having physical and chemical filtering capability) by depositing the nanohybrid on an extended surface of a stainless-steel metal mesh. The prototype active filter exhibits significant potential for chemical filtering of toxic Cr (VI) ions along with physical cleaning of suspended particulates present in water. Various microscopic and spectroscopic characterizations have been carried out to confirm the heterojunction formation. We have utilized first principles investigations to understand the modulation of electronic properties and obtain the insight to the photocatalytic process.

9:00 AM EN06.06.03
Photobase Effect in Photocatalytic Activity of Carbon Dots Jiawen Fang, Jacek K. Stolarczyk and Jochen Feldmann; Ludwig-Maximilians-Universität München, Germany

Carbon dots (CDs) are a versatile nanomaterial with attractive photoluminescent and photocatalytic properties. Their complex internal structure, considered to comprise sp$^2$-hybridized domains embedded in an amorphous sp$^3$-hybridized matrix, results in an intricate interplay between the constituent parts with multiple charge and energy transfer pathways determining the photocatalytic properties.[1,2] In effect, the mechanism of the photocatalytic hydrogen generation with CDs remains the subject of a debate. Here we demonstrate that the mode of nitrogen inclusion in the CDs within the aromatic domains controls the charge transfer and separation and thereby the photocatalytic activity for water reduction. [3,4] Furthermore, we propose that the photobasic effect, that is the abstraction of a proton from water upon excitation of CDs by light, facilitates the photoexcited electron transfer to the proton. In this context, we studied the effect of controlled inclusion in CDs of photobasic molecules which resemble the molecular moieties found in photocatalytically active CDs. We show that such addition strongly increases the hydrogen generation. Ultrafast spectroscopy measurements corroborated these findings, revealing the dynamics of the relevant electron and excited state proton transfer processes. The study demonstrates the critical role of understanding the structure and dynamics of the CDs in designing the materials with improved photocatalytic efficiency.

Heterogenized Molecular Catalysts for Water Oxidation Gary Brudvig; Yale University, United States

Devising cost effective methods for efficiently capturing and storing solar energy is among the grand challenges of science. We are using insights from studies of natural photosynthetic systems to develop bioinspired molecular catalysts for photo- and electrochemical water oxidation necessary for solar fuel production. Molecular catalysts are known for their high activity and tunability, but their solubility and limited stability often restrict their use in practical applications. We are developing anchoring chemistry to attach molecular water-oxidation catalysts to metal oxide surfaces, which not only greatly increases the stability of the molecular catalyst but also improves the catalytic performance of the oxide material. Our progress on the development and characterization of molecular iridium, copper and manganese water-oxidation catalysts, along with their application for photoelectrochemical water oxidation and solar fuel production, will be discussed.

Solar-Driven Synthesis of Fuels and Chemicals with Semiconductor Powders Erwin Reisner; University of
The synthesis of solar fuels and chemicals through artificial photosynthesis allows the direct pairing of light absorption to drive chemical redox processes. This approach is a one-step and versatile alternative to the more indirect coupling of a photovoltaic cell with electrolysis and enables potentially the synthesis of a wide range of fuels and feedstock chemicals. A common drawback in most artificial photosynthetic systems and organic photocatalysis is their reliance on expensive materials and device architectures, which challenges the development of ultimately scalable devices. Another limitation in many approaches is their inefficiency and reliance on sacrificial redox reagents, which may be system damaging and often prevent truly energy-storing chemistry to proceed. This presentation will give an overview about our recent progress in developing molecular-semiconductor hybrid systems to perform efficient full redox cycle solar fuel catalysis with inexpensive components, and our steps in extending this approach for sustainable waste polymer photoreforming and fine chemical synthesis.

Plasmonic Ruthenium (II) Nanopigments for Field-Enhanced Photocatalysis of Urea Oxidation and Visible Light Fuel Cells Xingda An and Björn M. Reinhard; Boston University, United States

The localized surface plasmon resonance (LSPR) of noble metal nanostructures provides appealing strategies to enhance photoinduced charge transfer in photocatalysis. While the plasmonic hot charge carrier production mechanism is well-characterized for initiating direct catalysis by plasmonic metals or heterostructures, the intense but evanescent Electric (E-) field generated by the nanoantennas provides a powerful alternative pathway to magnify resonant intramolecular transition processes in plasmonic catalysis. Harnessing plasmonic E-fields for photocatalysis, however, is fundamentally challenged by the trade-off between distance-dependent local field intensity enhancement and excited state quenching through the metal. Here, we explore quantitative optimization of photocatalysis mediated by an E-field enhanced metal-to-ligand charge transfer (MLCT) process. We present a hierarchical nanopigment architecture that localizes a transition metal photocatalyst, [Ru(bpy)₃]²⁺, in an electromagnetic “sweet spot” for efficient plasmonic enhancement of photocatalysis. A phospholipid membrane self-assembled around a Ag nanoparticle (NP) binds [Ru(bpy)₃]²⁺ as well as serves as a spacer between the transition metal complex and the NP, whose LSPR overlaps with the [Ru(bpy)₃]²⁺ MLCT. The nanopigments allow for substantial absorption enhancement but avoid quenching of photoexcited Ru*(II). We demonstrate direct photocatalytic urea oxidation with the nanopigments, and implement a visible light-driven Direct Urea Fuel Cell (LDUFC) to achieve simultaneous solar energy harvesting and waste water treatment. Our approach provides great promise as an effective and broadly applicable strategy to enhance intramolecular charge or energy transfer processes with metal plasmon resonances, and it depicts a blueprint for designs of bio-mimetic efficient and specific nanoreactors.

11:30 AM EN06.06.09
Magnetic Nanoparticles for the Facile Release of Photochemically Stored Energy Tobias Luchs, Patrick Lorenz and Andreas Hirsch; University of Erlangen-Nuremberg, Germany

With record high emissions of greenhouse gases, the global demand for renewable energies increases. Therefore, also the need for efficient and flexible energy storage systems arises. On the molecular level photoswitches that can undergo reversible transformation to a high energy isomer display a promising class of storage systems. We report on a novel, inexpensive and effective process for the repeatable photoisomerization of norbornadiene (NBD) to its metastable isomer quadricyclane (QC), followed by catalytically induced strain energy release via back-conversion of QC to NBD. By implementing a quasi homogeneous catalyst system based on magnetic iron oxide (Fe₃O₄) nanoparticles that were covalently functionalized with a Cobalt (II) complex, tedious purification steps can be avoided. These core-shell nanoparticles combine a high active surface area with the intrinsic magnetic properties of the iron oxide core to enable facile separation by the action of an external magnetic field. Together with the interconversion couple NBD1-QC1 that provides an extraordinary stability of the high energy isomer QC1 (t₁/₂ = 450 days at room temperature), as well as a high energy storage capacity (88.3 kJ/mol) these core-shell nanoparticles present a promising system for photochemical energy storage.

11:45 AM EN06.06.10
BiFeO Thin Films as a New Visible-Light Active Photoanode Material for Solar Water Splitting Joe Briscoe¹, Yaqiong Wang², Matyas Dabóczi³, Camilo Mesa³, Sinclair R. Ratnasingham³, Ji-Seon Kim³, James R. Durrant², Steve Dunn³ and Haixue Yan¹; ¹Queen Mary University of London, United Kingdom; ²Imperial College London, United Kingdom; ³London South Bank University, United Kingdom
BiFeO$_3$ is a material that is of interest for many applications due to its combination of visible bandgap (2.3-2.7 eV) with multiferalic properties (ferroelectricity combined with antiferromagnetism). Bi$_2$Fe$_4$O$_9$ is normally considered as an unwanted secondary phase in the synthesis of BiFeO$_3$ and therefore has received little attention. However, modelling has shown that it should also possess a bandgap in the visible range [1], and one report has shown that powders of the material are active for photocatalysis, showing degradation of organic pollutants [2].

Here we report the synthesis of Bi$_2$Fe$_4$O$_9$ thin films via simple sol-gel deposition with, for the first time, photoelectrochemical (PEC) properties of the films demonstrating their suitability for use as photoanodes for solar water splitting. UV-Vis absorption show a highly suitable bandgap (2.05 eV) with strong absorption from 600 nm. Phase and composition are also confirmed using XRD and XPS. Furthermore, measurement of the energetics of the material show that this band gap straddles the water reduction and oxidation potentials, with the material displaying slightly n-type behavior.

PEC measurements in the 0 V to 1.5 V range (vs Ag/AgCl) show almost twice the photocurrent compared to BiFeO$_3$. Further insight is achieved by testing using a hole scavenger (H$_2$O$_2$), which leads to an increased photocurrent from 0.05 mA/cm$^2$ to 0.1 mA/cm$^2$ at 1.2 V (vs NHE), a shift in onset potential from 0.5 V to 0 V (vs Ag/AgCl), and the disappearance of positive/negative photocurrent transients upon light chopping. These results indicate that hole injection barriers leading to slow kinetics and surface recombination limit the photocatalytic performance of this material, thus combination with appropriate water oxidation catalysts may lead to further improved performance. To test this, Co-Pi was deposited on the surface of the thin-film photocatalyst, leading to a 5-fold increase in photocurrent. To confirm water splitting was taking place, oxygen evolution was successfully measured from the photocatalyst, and by comparing to the measured photocurrent a Faradaic efficiency of 82.1% was calculated – over 10% higher than BiFeO$_3$ photocatalysts.

Overall these results indicate that Bi$_2$Fe$_4$O$_9$ may be a promising new material for PEC water oxidation, with the potential for significant improvements to be made in the future through routes such as nanostructuring and reduction of surface defects. Also, the measured band positions indicate that PEC water reduction may also be possible with this visible-bandgap oxide material via suitable p-type doping and stabilization at cathodic potentials.

Solar Driven CO₂ Reduction to CO with 19 % Efficiency in a PV-GDE Flow Cell under Outdoor Solar Illumination

Wen-Hui Cheng¹, Matthias H. Richter¹, Ian Sullivan¹, David M. Larson², Bruce S. Brunschwig¹, Chengxiang Xiang¹ and Harry A. Atwater¹; ¹California Institute of Technology, United States; ²Lawrence Berkeley National Laboratory, United States

Producing sustainable fuels from sunlight is an important objective for mitigating climate changes. We report here results for a solar-driven CO₂ reduction device for CO generation using a flow-by type gas diffusion electrode (GDE), employing a Ag nanoparticle catalyst layer and a GaInP/GaInAs/Ge triple junction solar cell. The GDE is designed to utilize high CO₂ concentration and low overpotential catalysts for the CO₂ reduction reaction. Near-unity Faradic efficiency is obtained for CO₂-to-CO conversion and a solar-to-CO efficiency of 19.5 % can be realized with AM 1.5G illumination at 3.25 Suns. The device was shown to be stable for >20 h with no loss in efficiency, suggesting that high efficiency GDEs are a promising path to producing a chemical fuel from CO₂. Outdoor measurements were performed under ambient solar illumination in Pasadena, CA, resulting in a solar-to-CO conversion efficiency of 18.9 % during noontime, a diurnal-averaged solar-to-CO conversion efficiency of 6.1 %, and yielded a CO production rate of 50 mg/cm² per day. This work gives an outlook for the potential of solar driven carbon dioxide reduction. Pathways to further improvements beyond this record efficiency will be discussed, including the optimization of band gaps and further catalyst engineering. The system opens a new avenue for research into very high efficiency and stable devices for solar CO₂ conversion.

Developing Nanostructured Photoelectrochemical Electrodes and Electrocatalysts for Efficient Solar Energy Conversion

Shihe Yang; Peking University Shenzhen Graduate School, China

Photoelectrochemical (PEC) water splitting is a promising technique to directly convert solar energy into hydrogen energy for storage and transportation. PEC devices need to efficiently absorb sunlight and separate and collect the photocarriers. Herein we will present our recent work on the development of photonic structures for light trapping, PEC electrodes and electrocatalysts for water splitting. The importance of understanding both the light harvesting and the charge collection characteristics will be highlighted for the light trapping structural design. For electrocatalysts, we will focus on two-dimensional (2D) materials, and combine experimental and theoretical techniques to reveal the importance of the specific nanostructures for hydrogen evolution reaction and oxygen evolution reaction in electrolytes of different pH values. Our overall goal is to develop cost-efficient and robust photocatalysts and electrocatalyst to efficiently convert the abundant solar energy to clean, storable and transportable chemical fuels.

4:00 PM Enhanced Catalytic Activity of Dye-Sensitized Photoelectrosynthesis Cells by Characterizing and Passivating NiO Surface Defect Sites

Aaron Taggart, Jake Evans and James Cahoon; University of North Carolina at Chapel Hill, United States

Tandem water splitting with wide-bandgap metal oxides functionalized with chromophore-catalyst assemblies is a potential low-cost solution to synthesize solar fuels. In recent years, high performing molecular catalysts have been developed for reducing protons to H₂ and reducing CO₂ to CO, CH₄, and other useful carbon derivatives. However, many of these dye-sensitized photocathodes are based on NiO scaffolds which exhibit poor performance and limit the catalytic efficiency in aqueous conditions and at potentials needed for tandem water splitting. Here, we elucidate that in the presence of water, intra-bandgap surface states exist that are associated with hydroxyl and oxygen moieties adjacent to Ni vacancies. Through a combination of electrochemical measurements and First-principles calculations, we show that these trap states give rise to a surface capacitance which can be almost completely eliminated by targeted atomic deposition (TAD) of Al treatment. TAD-treated electrodes functionalized with chromophore-catalyst assemblies sustain cathodic photocurrent at positive electrochemical potentials and yield a champion Faradaic efficiency of 46.0 ± 5.9% for H₂ evolution compared to 3.1 ± 0.4% for untreated films at +0.83
V vs. RHE. To the best of our knowledge, these results are the most positive potentials at which H₂ evolution has been observed for a dye-sensitized photoelectrosynthesis cell to date, and they represent an important step toward designing tandem water splitting devices with high efficiencies. This work demonstrates the utility of TAD passivation in suppressing recombination and side reactions that impede aqueous photocatalytic performance, especially at the positive electrochemical potentials needed for wireless operation of tandem solar fuel devices.

Energy Level Alignment and Charge Transport at the Semiconductor-Protoporphyrin IX-Interface Felix Eckmann, Jennifer Padberg and Martin Stutzmann; Technische Universität München, Germany

Efficient photocatalytic conversion of carbon dioxide to solar fuels presents an attractive option to reduce the problem of energy storage present in today’s renewable energy technology. Until today, most effort has been put into either homogeneous or heterogeneous approaches, working separately on molecular catalysts in solution or metal and semiconductor surfaces, respectively. By anchoring molecular catalysts on semiconductor surfaces and therefore combining approaches of heterogeneous and homogeneous catalysis, one might be able to profit from advantages of both, leading to enhanced efficiency and stability. A major challenge of this idea is the lack of fundamental knowledge about the interaction of the molecular catalyst with the semiconductor.

In order to gain more information specifically on the energy level alignment and charge transport between catalytically active molecules and semiconductor surfaces, a simple model system containing a protoporphyrin IX (PPIX) monolayer deposited on different semiconductor substrates via Langmuir-Blodgett deposition is investigated. Monolayer morphology as well as molecular packing density are studied using atomic force microscopy and surface pressure isotherms, indicating a closely packed monolayer with a slightly tilted orientation on Silicon and Gallium Nitride surfaces. The potential landscape at the interfaces of Silicon and Aluminum Gallium Nitride surfaces with varying Aluminum to Gallium ratio and PPIX are investigated by surface photovoltage analysis, showing indications of a surface potential shift due to an interface dipole. Photoluminescence (PL) studies of these PPIX monolayers reveal a strong dependence of the PL intensity on the band gap of the underlying substrate and excitation wavelength. Shorter excitation wavelengths and higher electron affinities of AlGaN substrates yield lower PL intensity, giving rise to the assumption that electrons in excited molecular states are transferred to the substrate’s conduction band, if the excited electron has sufficient energy compared to the conduction band minimum. This leads to a quenching of the luminescence in this model system and would lead to a decrease in efficiency for a photocatalytically reducing device, highlighting the necessity of matching the choice of the semiconductor support to the specific catalytic molecule in order to ensure beneficial interaction.

4:30 PM EN06.07.07
Bimetallic Plasmonic Catalysts—Effect of Nanostructure on Thermal and Non-Thermal Light Enhancement Peter Novello¹, Siyuan Zhu¹, Leah Zachary¹, Pani Varanasi²¹ and Jie Liu¹; ¹Duke University, United States; ²U.S. Army Research Office—Materials Science Division, United States

Plasmonic catalysts where a single material combines plasmonic and catalytic functionalities can improve reaction rates, improve catalyst lifetimes, and alter product selectivity. These catalytic processes are largely affected by energy transfer between a plasmonically excited active-site and reactants. To access a broader range of reactions, catalysts with weak or no plasmonic properties have been utilized and coupled to a plasmonic absorber. This work addresses the more complex nature of the interaction between a plasmonic absorber, a catalyst, and reactant molecules. Specifically, though alteration of the nanostructure of bimetallic plasmonic-catalytic particles, we analyze the light enhanced reaction rates and separate out thermal and hot-electron transfer effects. Alloy, co-impregnated, and core-frame Pt-Rh catalysts were examined with findings suggest a guiding set of nanostructure design principles which can be used to maximize the efficiency of bimetallic plasmonic catalysts.

Balancing Light Absorption and Charge Transport in Vertical SnS₂ Nanoflake Photoanodes with Stepped Layers and Large Intrinsic Mobility Binod Giri¹, Maryam Masroor Shalmani¹, Tao Yan¹, Kateryna Kushnir¹, Alexander D. Carl¹, Curtis W. Doiron¹, Haochuan Zhang², Yanyan Zhao², Arthur McClelland³, Geoffrey A. Tompsett², Dunwei Wang², Ronald L. Grimm¹, Lyubov V. Titova¹ and Pratap M. Rao¹; ¹Worcester Polytechnic Institute, United States; ²Boston College, United States; ³Harvard University, United States

Significant optical absorption in the blue-green spectral range, high intralayer carrier mobility, and band alignment
suitable for water splitting suggest tin disulfide (SnS\textsubscript{2}) as a candidate material for photoelectrochemical applications. In this work, vertically aligned SnS\textsubscript{2} nanoflakes are synthesized directly on transparent conductive substrates using a scalable close space sublimation (CSS) method. Detailed characterization by time-resolved terahertz and time-resolved photoluminescence spectroscopies reveals high intrinsic carrier mobility of 330 cm\textsuperscript{2}V\textsuperscript{-1}s\textsuperscript{-1} and photoexcited carrier lifetimes of 1.3 ns in these nanoflakes, resulting in a long vertical diffusion length of \(~1\) \textmu m. The highest photoelectrochemical performance is achieved by growing SnS\textsubscript{2} nanoflakes with heights that are between this diffusion length and the optical absorption depth of \(~2\) \textmu m, which balances the competing requirements of charge transport and light absorption. Moreover, the unique stepped morphology of these CSS-grown nanoflakes improves photocurrent by exposing multiple edge sites in every nanoflake. The optimized vertical SnS\textsubscript{2} nanoflake photoanodes produce record photocurrents of 4.5 mAcm\textsuperscript{-2} for oxidation of a sulfite hole scavenger and 2.6 mAcm\textsuperscript{-2} for water oxidation without any hole scavenger, both at 1.23 V\textsubscript{RHE} in neutral electrolyte under simulated AM1.5G sunlight, and stable photocurrents for iodide oxidation in acidic electrolyte.

EN06.08.02
Soft-Template Synthesis of Mesoporous Metal Sulfide Nanoparticle Networks for Efficient Photocatalytic Hydrogen Evolution
Ioannis Vamvasakis and Gerasimos S. Armatas; University of Crete, Greece

Photocatalytic hydrogen production through water splitting has recently gained significant attention for efficient solar-to-chemical energy conversion.\(^1\) However, despite immense research efforts on semiconductor materials, key challenges of obtaining catalysts with high activity and long-term stability still remain. Recently, the synthesis of highly crystalline mesoporous semiconductors has been the focus in the field of electro- and photocatalysis. These materials combine the high reactivity of semiconductor nanoparticles with mesoporosity, offering new perspectives in designing novel catalysts with improved efficiency and reliability. Unlike to bulk-like microstructures and individual nanoparticles, 3D mesoporous networks of connected nanoparticles can benefit from the large and accessible surface area within the assembled structure and enhanced light-harvesting efficiency arising from multiple scattering of light inside the pores.

Herein, we present the synthesis of chemically stable and robust mesoporous networks of β-Ni(OH)\textsubscript{2} and ZnS decorated CdS nanoparticles (ca. 4–5 nm) that show high photocatalytic activity for hydrogen evolution under visible light irradiation.\(^2\) We utilize polymer-assisted self-assembly of colloidal nanoparticles to assemble mesoporous CdS nanoparticle-linked frameworks with high interstitial porosity. This method utilizes the nanoparticles as building block units and based on the coassembly of these nanoscopic units with organic structure-directing agents to construct 3D structures with open-pore morphology.\(^3\) The resulting materials feature a nanometer-sized framework perforated by uniform pores, which allows rapid mass transport and provides plenty of exposed surface-active sites available for reaction. In addition, using a combination of photocatalytic experiments and optical absorption, luminescence and electrochemical impedance spectroscopy studies, we highlight the effect of β-Ni(OH)\textsubscript{2} and ZnS additives on the electronic structure and photochemical performance of CdS. For instance, our results indicate that the p-type β-Ni(OH)\textsubscript{2} acts as hole collector, favoring efficient charge transfer and separation across the β-Ni(OH)\textsubscript{2}/CdS nano-heterojunctions. As thus, the β-Ni(OH)\textsubscript{2}/CdS catalyst containing 10 wt% Ni reached a photocatalytic H\textsubscript{2}-evolution rate of 1.4 mmol/h with an apparent QY of 72% at 420 nm, while demonstrating excellent stability in alkaline (5M NaOH) ethanol solution (10% v/v). The results of these studies can offer new insights into the design and development of efficient photocatalysts for energy conversion and environmental remediation applications.

Electrocatalytic carbon dioxide (CO$_2$) reduction is an attractive approach to provide renewable energy from atmospheric CO$_2$. For achieving efficient CO$_2$ reduction reaction, electrocatalysts are required to have high selectivity to target gas product, and their enormous conversion rate. The developments of nanostructures achieved high energy efficiency and selectivity for reusable carbon-containing chemicals. However, the complicated nanostructures have restricted the CO$_2$ conversion rates because of poor mass transport of reactants. Herein, we propose a three-dimensional (3D) hierarchically porous Au consisting of continuous macroporous channels (200-300 nm) and nanopores (<10 nm) fabricated by Proximity-field nanoPatterning (PnP). This hierarchically porous nanostructures could be fabricated involving three sequential processes: i) fabrication of 3D epoxy-based periodic nanostructures using PnP technique on an electrically-conductive substrate, ii) electroplating the Au-Ag alloy into the 3D nanostructured template, and iii) selective removal of Ag components and 3D epoxy template using dealloying and plasma etching machine, respectively. The fabricated macroporous channels have well-ordered pores with the periodicity is approximately 600 nm along the x, y-axis and 1 µm along the z-axis. The roles of each pore network are investigated using reliable 3D nanostructures possessing controlled pore distribution and size: nanoporous Au (N-Au), macroporous Au (M-Au), and hierarchically porous Au (N/M-Au). The continuous, perfectly periodic macropores and nanopores enable efficient mass transport and large active areas, respectively. Numerous nanopores in N/M-Au produce a large electrochemical surface area that is 66.1 times larger than that of electroplated Au film, and high index facet results in high CO selectivity of 85.5 % at a low overpotential of 264 mV. For analysis of the structural effect on CO$_2$ conversion rates, the specific $j_{CO}$ is measured using nanostructured electrodes with various thickness at a different applied potential of -0.274 VRHE and -0.574 VRHE. The Au nanostructures having macroporous channels show a noteworthy tendency that has higher specific $j_{CO}$ at the relatively high applied potential of -0.574 VRHE. The 3D hierarchically porous electrodes consequent allow efficient mass transport during vigorous electrolysis resulting in maximum 3.96 times higher $j_{CO}$ per mass than that of dealloyed nanoporous Au film. Thus, the systematic model study shows the proposed hierarchical nanostructured electrodes have critical value in increasing the efficiency of expensive Au. These investigations are also useful for other electrochemical applications in an aqueous base solution including batteries, flow cell, and electrocatalysts.
Then, using the low-dimensional model developed by Joshi et al., we quantified the relative contributions of the chemical kinetics, internal mass transfer and external mass transfer as functions of various catalyst design and operating parameters. The analysis indicates that the nanoarray-based monolithic catalysts show decreased internal mass transfer resistance compared to the washcoat-based catalysts, which originates from the ordered nanoarray configuration and decreased catalyst layer thickness, which facilitate the diffusion of the reactant gas molecules through the nanoarray layers. Furthermore, the mesoporous TiO₂ nanoarrays provide sufficient specific surface area and catalytically active sites for reactions, and the adherent interface between the in-situ grown nanoarrays and substrate channel surfaces promoted the mechanical robustness of the monolithic catalysts. This study sheds light on the design of novel monolithic catalysts for various gas phase reactions.

**ZnS Nanoparticle Embedded N, S-Codoped Mesoporous Carbon for Efficient Oxygen Reduction Reaction**

Dongjun Kim¹, Geonho Kim¹, Seoyeob Oh¹, Jiheyon Park¹, Seokhee Lee¹, Wonsik Lee¹, Seoyoung Yoon¹, Eunkyoung Cho², Kwonnam Sohn², Doo-kyung Yang² and Jiwon Kim¹,¹; ¹Yonsei University, Korea (the Republic of); ²LG Chem., Korea (the Republic of)

As demand for energy increases, it is inevitable to develop more efficient, stable, and long-life energy conversion/storage systems. Accordingly, devising highly active and stable electrodes for oxygen reduction reaction (ORR) has attracted a great attention. Heteroatom doped mesoporous carbon is one of the most promising substitutes for Pt-based ORR electrocatalysts with outstanding stability, activity, and electric conductivity. Furthermore, hybridization with transition metal is known to be one of the most efficient ways to improve ORR catalytic activity of mesoporous carbon (MC). Herein, we demonstrate a novel synthetic method of ZnS nanoparticle embedded N, S-codoped mesoporous carbon (NSMC) and its enhanced electrochemical property compared to the commercial Pt/C catalyst. NSMC was synthesized by one-step pyrolysis of a novel metal-organic framework (MOF), S-modified Zn-MOF-74, which was additionally doped with thiourea. The as-prepared NSMC exhibited high catalytic activity (limiting current density \( J_L = -5.19 \) mA cm\(^{-2}\)), superior stability (91.7% of \( J_L \) retention after 25000 s), and a great methanol tolerance in ORR. The enhanced ORR properties might be attributed to the ZnS nanoparticles as catalytic active sites and well-defined structure of N, S-codoped mesoporous carbon. Our results suggest that the introduction of ZnS nanoparticle and N, S-codoping could be a promising strategy for enhancing ORR in basic medium.

**A Duable, Inexpensive Oxygen Reduction Reaction Electrocatalyst**

Sung Beom Cho¹,², Cheng He¹, Arashdeep S. Thind¹, Shrihari Sankarasubramanian¹, Jordan Hachtel¹, Albina Borisiević³, Juan-Carlos Idrobo², Vijay Ramani¹ and Rohan Mishra¹; ¹Washington University in St. Louis, United States; ²Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); ³Oak Ridge National Laboratory, United States

The current proton exchange fuel cells (PEFC) employ platinum group metal (PGM) catalysts in their electrode for oxygen reduction reaction (ORR). However, the excessive cost of PGM catalysts is a major hurdle for realizing the potential of PEFCs, thus necessitating the development of inexpensive non-PGM catalysts. Amongst the different PGM-free catalysts, a complex mixture of carbon (C), nitrogen (N), and transition metals (M) forming M-N-C clusters (M=Co, Fe, Ni, Mn, etc.) are currently the leading candidates due to their comparable activity to PGM catalysts and cost-effectiveness [1]. This complex is generally synthesized by the pyrolysis of carbon-based support
with metal and nitrogen precursors [2]; however, the carbon-based support suffers from catastrophic failure during repeated start-up/shut-down events wherein the high cathode interfacial potential results in the irreversible corrosion of carbon and hence to the loss of active centers [3]. More distressingly, the reactions typically yield a complex structure, where the active site and reaction mechanism is still under the debate.

To overcome this issue, we employed an approach based on first-principles calculations to rapidly screen through a large set of TMN clusters (TM = Mn, Fe, Co, Ni, Zn, Zr, and Mo) on corrosion-resistant TiC supports that have a good combination of stability, surface area and conductivity. We predict FeN₄ clusters on TiC support to be an inexpensive and durable catalyst having better performance than TMN clusters on carbon (graphene) supports. This catalyst formulation was obtained by developing a scaling relation based on the electrostatic interactions between the TiC support and the TMN clusters. To validate our theoretical predictions, we synthesized various TMN catalysts on TiC supports. We characterized their structure and composition using a suite of techniques including XPS, SEM, STEM-EELS to show successful incorporation of the catalytically active clusters onto the TiC support. The measured ORR activity of these catalysts precisely confirmed our electrostatics-based scaling relation.

Moreover, upon comparing an electrocatalyst comprising FeN₄ clusters on TiC with a baseline carbon-supported FeN₄ cluster electrocatalyst synthesized using the same method, we found that FeN₄/TiC exhibited an ORR activity (2.3mA.cm⁻² at the half-wave potential E₁/₂) that was 20% greater than FeN₄/C (1.85mA.cm⁻² at E₁/₂) and comparable to the state-of-the-art [4, 5]. Furthermore, it showed high stability under 1000 cycles of the stringent accelerated start-up/shut-down stability protocol [6] adopted by the US Department of Energy and most major automotive companies.

EN06.08.08
Understanding the Origin of Products Selectivity on Copper Catalysts During Electrochemical CO₂ Reduction Tsu-Chin Chou¹, Chiao-Chun Chang²,¹ and Heng-Liang Wu¹; ¹National Taiwan Univ, Taiwan; ²National Taiwan Normal University, Taiwan

Electrochemical CO₂ reduction has been considered as a potential route to convert harmful CO₂ to valuable hydrocarbons for sustainable carbon cycles. Since late 1980s, copper catalyst has been recognized as one and the only catalyst which produced hydrocarbons as primary products;¹ however, the poor selectivity obstructs the applications. According to DFT calculations, surface CO is the most common and important intermediate during CO₂ reduction reaction,² but further reaction mechanisms are still unclear, e.g. protonation and dimerization of CO. Cu(I) oxide was correlated to the formation of C₂ products during reactions,³ yet there is lack of solid intermediate evidence to distinguish different reaction routes.

In this talk, we used in situ surface enhanced infrared absorption spectroscopy, in situ X-ray absorption spectroscopy (Cu L-edge) and on-line GC to study the electrochemical CO₂ reduction mechanism occurred in different copper catalysts. We observed various CO intermediates such as CO₅ atop and CO₅ bridge on copper surface during electrochemical CO₂ reduction and the formation of CO₅ atop/CO₅ bridge can be correlated to the existence of surface Cu(I) and Cu(0) sites, respectively. Our results suggested that the existence of CO₅ atop can result in the formation of methane during further reduction. In addition, ethylene can be produced in the presence of CO₅ atop and CO₅ bridge. Our results both prove theoretical predictions ⁴ and meet the gap to illustrate the detail reaction mechanisms from CO₂ to hydrocarbons. We next propose a method to create Cu(I) sites efficiently on copper catalysts.

The Magnetic Field Tunability of the Photocatalytic System Based on Spintronic Materials  
Jie He; Tianjin University of Technology, China

In recent years, many achievements have been made in improving photocatalytic activity, but the solar conversion efficiency of photocatalysts is still far below the expected value. According to the reaction mechanism of photocatalysis, the factors affecting the conversion efficiency of photocatalyst can be summarized as follows: the band gap, the position of conduction band and valence band, the efficiency of carrier separation and transfer. The magnetic field can be introduced into the photocatalytic process and enhance the solar conversion efficiency: on the one hand, in some molecular catalytic reactions, the ferromagnetic arrangement of catalyst materials will align the spin orientation of the electrons accumulated on the surface, effectively promoting the occurrence of oxygen evolution reaction, on the other hand, magnetic field can change the conductivity of some materials with specific properties, and increase the carrier transport and separation. In addition, the external magnetic field does not require direct contact with the reactor vessel, and does not affect the morphology and own characteristics of photocatalysts, therefore the magnetic field will not cause secondary pollution.

In this work, the composite photocatalysts ZnFe₂O₄/Ag and ZnFe₂O₄/AgBr based on spintronic material ZnFe₂O₄ are constructed. The interface between ZnFe₂O₄ and Ag or AgBr can induce the magnetic moments in Ag or AgBr due to the magnetic proximity effect, emerging negative magnetoresistance (MR) effect in composite photocatalysts. Under the magnetic field, the organic dyes can be removed more efficiently compared to that without magnetic field. The measurement results demonstrate that the magnetic field plays two kinds of roles during the photocatalytic process, firstly, the magnetic field promote the transfer and separation of electrons and holes to enhance the photocatalytic activity because of the negative MR of the composite photocatalysts. Secondly, the magnetic field can replace the function of electron transmission medium in Z-scheme structure, which can simply the structure of the Z-scheme photocatalyst ZnFe₂O₄/AgBr. The combination of spintronics and photocatalysis is of great scientific significance in understanding charge transfer, physical mechanism of photocatalysis, mutual promotion between spin characteristics and photocatalytic performance, meanwhile, this combination provides an important reference for the development of multifunctional electronic devices.

**Shaped Controlled Synthesis of Core Shell Ir-Ni Nanostructures toward Efficient Oxygen Evolution Electrocatalysis**

Seongeun Park¹, Meital Shviro¹, Marcelo Carmo¹ and Detlef Stolten¹,²; ¹Forschungszentrum Jülich GmbH, Germany; ²RWTH Aachen University, Germany

Electrocatalytic water splitting is a highly efficient and sustainable way for hydrogen production.¹ For the development of electrocatalysts there have been countless studies, however, the choice of electrocatalysts for oxygen evolution reaction (OER) in acidic condition is quite limited by harsh working condition given by the low pH and high overvoltage.² Iridium oxide is by far the most durable and active performance anode catalyst, but its restricted reserves and increasing price requires a decrease in the usage of Iridium. Many approaches have been done, for example, synthesis of multi-metallic catalysts,³ designing of hollow structures, and more. Herein, we developed a facile, in one-pot preparation core-shell Ir-Ni nanoparticles which further etched to form a defined nanoframe structure.

The Ir-Ni nanostructures growth mechanism was studied to control the Ir layer. The as prepared Ir-Ni, and the nanoframe structure were tested as electrocatalysts for OER in acidic conditions. The nanoframe structure showed better activity than the pristine structure with lower onset potential compared with commercial IrO₂.

This work provides a deep insight into the design of bimetallic electrocatalysts with controlled shape and shape dependent catalytic performance.

EN06.08.12

**Size Effect of Pt Decorations on Oxygen Reduction Reaction Performance for Co@Pd Core-Shell Nanocatalyst—A First-Principles Study**

Haolin Li¹,²², Jyh-Pin Chou¹, Alice Hu¹,¹ and Tsan-Yao Chen²,²; ¹City University of Hong Kong, Hong Kong; ²National Tsing Hua University, Taiwan

The sluggish kinetics of the oxygen reduction reaction (ORR), insufficient durability and the use of high-cost Pt-based catalyst restrict the comprehensive performance as well as the widespread commercialization of fuel cells (FC). For the development of cost-effective catalyst possessing low noble-metal loading, outstanding ORR activity and long-term stability, we propose novel model nanocatalysts with size-variable Pt clusters decorated Co@Pd core-shell configurations use for the fuel cells cathode. In this work, the effects of Pt-cluster size on ORR catalytic activity for Co@Pd core-shell structure were studied via tuning the number of Pt atoms from 3 to 9 (in size of 0.3-1 nm), 16 and 32 (regard as 1 cover layer and 2 cover layers), based on density functional theory (DFT) calculations. Our results show that the size of Ptn (n=3-9, 16 and 32) decoration significantly effects the ORR catalytic activity, the active sites selectivity and the stability of Co@Pd model nanocatalyst, which are attributed to their modified electronic structures giving rise to the strong electronic coupling and unique charge transfer process. The moderate ORR-species (O, O₂, H₂O and OH) adsorption energies on different stable active sites and moderate O₂ dissociation barriers corresponding to the Ptn-cluster model catalysts exhibit the better ORR activity compare to the pure Pt and Pd models. The influence of d-band center shift, strain and ligand effects on the adsorption energies on different surfaces are also discussed. In particular, small platinum-trimer (Pt₃) decorated Co@Pd model nanocatalyst exhibits the most significant enhancement in the ORR kinetics and the predicted structural stability, due to the electron transfer from Pd shell to Pt₃ cluster and then to the adsorbates giving the Pt-trimer a role as ‘charge transfer station’ during the whole ORR process. As a consequence, the ‘charge transfer station’ avoids the valence electrons transfer of adsorption-site Pt atoms to the direct-contact ORR-species, but proceeding the indirect charge transfer between the Pt-neighboring Pd atoms and ORR-species atoms instead, so that reducing the risks of the noble metals oxidation and poisoning. Therefore, the Pt-associated sites are selected spontaneously as the preferred stable active sites, and meanwhile the atomic scale Pt-trimer provides the most number of the optimal active sites. These results are consistent with our latest experimental results.[1] The effect on the ORR performance of our size-tunable clusters from atomic scale to thin film scale decorated on the core-shell models, can be further extented to other ternary or multi-metallic systems with most types of 3d-5d transition metals in the three (core-shell-cluster) regions. This conclusion can be applied to guide the selection of candidate systems and predict the performance of the ORR in studies for the catalyst development toward low cost, excellent activity, high durability and environment-friendly designs.

Development of New Solid-Solution Alloy Nanoparticles for Three-Way Catalytic Applications Kohei Kusada\textsuperscript{1} and Hiroshi Kitagawa\textsuperscript{2}; \textsuperscript{1}Kyushu University, Japan; \textsuperscript{2}Kyoto University, Japan

The properties of elements are correlated directly with their electronic states. If we can realize a concept of “density-of-states (DOS) engineering”\textsuperscript{1} for the design of materials having the most suitable electronic structure for the target properties, we will be able to make full use of available elements and relieve the resource problems. To freely control an electronic state of a material, the solid-solution alloy is advantageous because its electronic state can be continuously controlled by tuning the compositions and/or combinations of the constituent elements. However, the majority of bulk alloy systems are the phase-separated type under ambient conditions. Recently, we demonstrated that the nanosize effect offers a chance to find a way out of this metallurgical difficulty; that is, we can obtain metal nanoparticles (NPs) having new phases that do not exist in bulk states\textsuperscript{2-9}. As one of the examples, we found that Pd\textsubscript{0.5}Ru\textsubscript{0.5} NPs having a similar electronic structure to Rh exhibit comparable NO\textsubscript{x} reduction activity, even though monometallic Ru or Pd NPs do not show high activity.\textsuperscript{5, 10} However, this alloy structure is destroyed after the reaction due to the nature of the alloy system, resulting in the degradation of catalytic activity. In this work, we designed and synthesized ternary PdRuM alloy systems to develop a stable and highly active NO\textsubscript{x} reduction property. DFT calculations predicted suitable third metal candidates to improve PdRu systems. The designed ternary solid-solution alloy NPs were successfully synthesized and characterized structures by synchrotron X-ray powder diffraction technique and scanning transmission electron microscopy coupled with energy dispersive X-ray spectroscopy. The designed ternary PdRuM exhibited higher NO\textsubscript{x} reduction than Rh or PdRu NPs and maintained its structure after the reaction.

Distinctive Functionality of Carbon Shells Coated on Metal Nanoparticles for Fuel Cell Applications Namgee Jung\textsuperscript{1}, SungJong Yoo\textsuperscript{2}, Monika Sharma\textsuperscript{1}, Hukwang Sung\textsuperscript{1}, Jeonghee Jang\textsuperscript{1}, Jiho Min\textsuperscript{1} and Youngjin Kim\textsuperscript{1}; \textsuperscript{1}Chungnam National University, Korea (the Republic of); \textsuperscript{2}Korea Institute of Science and Technology, Korea (the Republic of)

Recently, carbon shell-encapsulated metal nanoparticles have been widely studied to enhance the durability of metal catalysts in proton exchange membrane fuel cells (PEMFCs) and anion exchange membrane fuel cells (AEMFCs). However, through the interfacial interaction between the carbon shells and the core metal nanoparticles, the carbon shells can also serve as the main and exclusive active sites to boost electrochemical catalytic activity instead of the core metal nanoparticles. Therefore, we propose the distinctive functionality of carbon shells coated on metal nanoparticles for oxygen reduction reaction (ORR) in AEMFCs. As a model study to prove the application feasibility of the ideal carbon-coated metal system for the ORR, the physical and electrochemical properties of Pd nanoparticles encapsulated with carbon shells are investigated. Furthermore, to practically apply the carbon shell-encapsulated metal nanoparticles to the AEMFC system, less expensive Co nanoparticles coated with carbon shells are intensively studied. From the experimental results, it is concluded that the transition metal core materials can boost the ORR activity of carbon shells and the catalyst durability can be also enhanced due to the protection of the core metal nanoparticles. The present work will provide an interesting strategy for designing new types of carbon-based catalysts for the ORR in AEMFCs.

Mechanochemical Synthesis of Copper Sulfide (Cu\textsubscript{2}S) Impregnated Bi-Functional Organic Polymer and Its Integration with the Flow Reactor for the Production of Dimethylcarbonate from Carbon Dioxide Subodh Kumar; Regional Centre of Advanced Technologies and Materials, Palacky University, Czechia

Continuous accumulation of carbon dioxide in the atmosphere is a threat to the environment and its symptoms are increasingly visible every passing year in the form of impulsive whether changes. Therefore, converting carbon dioxide has turned out to be promising to produce fuel and chemicals. Among the various chemicals synthesized...
from CO₂, dimethylcarbonate (DMC), a simplest organic carbonate, has attracted considerable attention due to its applications as green solvent, fuel additive for octane booster, electrolyte in lithium-ion batteries, and monomer for polycarbonate synthesis etc. Conventionally, DMC is produced either by the reaction of phosgene with methanol or oxidative carbonylation of methanol using CO. The use of phosgene and Co, which are highly toxic and corrosive in nature; makes these processes undesirable. Therefore, much importance has been given to the DMC synthesis from CO₂. In this context, various catalytic systems (homogeneous and heterogeneous) have been reported. However, most of the catalyst afford lower yield of the DMC because of the water generation during the reaction as side product, which shifts reaction equilibrium backwards providing lower yield of DMC. Therefore, the use of dehydrating agent is needed for better conversion. However, these dehydrating agents are difficult to separate from the reaction mixture after the reaction and further increase the cost of the process. Moreover, most of the methods are batch process, which restricts their direct application in industries.

Hence, it is desirable to synthesize DMC directly from the methanol and carbon dioxide in a continuous flow without using any external dehydrating agent. In the present paper, we have synthesized copper sulfide (Cu₂S) impregnated two-dimensional organic polymer (Cu-OP) by simple mechanical mixing of CuCl₂·H₂O, 1, 3, 5-trybenzenecarboxydehyde and 2, 5-diaminobenzene sulfonic acid. Synthesized catalyst was then used to perform the reaction of methanol and carbon dioxide on the high-pressure fixed bed flow reactor without using any dehydrating agent and exhibited excellent catalytic activity, selectivity reusability affording up to 43% yield of DMC. Moreover, we also investigated the effect of various reaction parameters including flow rate, pressure, temperature and catalyst amount on the DMC yield. It was observed that the high pressure and lower flow rate facilitates the reaction at desired temperature. In addition, the presence of -SO₃H and -C=N functional groups on the catalyst surface was found to be crucial, which not only helps in trapping the water formed during the reaction, shifting reaction equilibrium forward direction, but also activate the carbon dioxide, respectively.

EN06.08.16 Coverage, Size and Stability Phenomena of Well-Defined Nanoparticle Model Catalysts Synthesized by Mass-Selected Magnetron Sputtering Niklas Secher, Jakob Kibsgaard and I.B. Chorkendorff; Technical University of Denmark, Denmark

Clusters and nanoparticles of late transition group metals have shown promising catalytic properties for reactions for sustainable fuels and chemicals (Seh et al., “Combining Theory and Experiment in Electrocatalysis: Insights into Materials Design”, Science 2017). Entities in this size range (<10 nm) display an increased number of under-coordinated sites and yield a higher surface area per volume. This is advantageous since under-coordinated sites of these materials have been shown to be highly active towards certain reactions e.g. Au for CO oxidation (Janssens et al., “Insights into the Reactivity of Supported Au Nanoparticles: Combining Theory and Experiments”. Topics in Catalysis, 2007). Furthermore, the increase in surface area allows for a lower volumetric loading of these expensive elements. Altogether, this decreases the cost of using non-abundant materials as catalysts in industrial processes.

However, these small entities are prone to deactivation due to their high surface energy and increased reactivity. Deactivation can be due to particle agglomeration via sintering or due to particle oxidation via the reactive sites (Wallace et al., “The Stabilization of Gold Particles by Surface Defects”, Journal of Molecular Catalysis A, 2005). These deactivation phenomena are known to depend on several catalyst properties such as particle size, coverage and the support material. Therefore, it is vital to control these parameters when studying deactivation phenomena of small entities. However, it is worth considering other factors that might influence catalyst deactivation, recently the edge-edge interparticle distance has received growing attention (Nesselberger et al., “The Effect of Particle Proximity on the Oxygen Reduction Rate of Size-Selected Platinum Clusters”, Nature Materials, 2013). Additionally, one might consider new design strategies to counteract deactivation; it is well known that some supports have anchoring sites that stabilize small entities, but perhaps it is possible to design self-anchoring particles with increased stability.

Using a mass-selected magnetron sputter source it is possible to create well-defined model systems of clusters and nanoparticles, where particle size and coverage are controlled in detail (Roy et al., “Impact of Nanoparticle Size and Lattice Oxygen on Water Oxidation in NiFeOxHy”, Nature Catalysis 2018). Furthermore, a suitable substrate can be chosen to allow a variety of characterization techniques including ISS, XPS and electron microscopy followed by catalytic testing either electrochemically or using micro-reactors for gas phase catalysis.

I will present the results of studying how catalyst design, size, coverage or even the edge-edge inter-particle distance
affects relevant catalytic properties of small entities of Au or Pt for different reactions such as CO oxidation or the Oxygen Reduction Reaction. The well-defined model systems are thoroughly characterized before probing their activity/stability leading to a novel insight into the deactivation that typically occurs when using these materials in commercial catalysts.

EN06.08.17
**Hydrogen Evolution Reaction Electrocatalysis—Electrodeposited Electrodes Based on MoS<sub>2</sub>:** Ramunas Levinas<sup>1</sup>, Natalia Tsyntsaru<sup>1,2</sup> and Henrikas Cesulis<sup>1</sup>; <sup>1</sup>Vilnius University, Faculty of Chemistry and Geosciences, Lithuania; <sup>2</sup>Institute of Applied Physics of ASM, Moldova (the Republic of)

Platinum exhibits the best currently known HER catalytic properties, but its sparsity and price prevent widespread use. Transition metal chalcogenides, especially MoS<sub>2</sub>, have been shown also to catalyze the hydrogen evolution reaction. Sulfur vacancies in the crystal lattice have a low free hydrogen adsorption energy and therefore easily bind to H<sup>+</sup> in the solution. This results in the catalysis of the adsorption (Volmer) step of the hydrogen evolution reaction, and these materials generally exhibit Tafel slopes similar to those of platinum (~ 40 mV/dec). Therefore, transitional metal chalcogenides are currently an area of active research.

Although there are several different methods to obtain MoS<sub>2</sub> materials of various crystallographic structures, in this study, we focused on electrodeposition, which results in amorphous MoS<sub>2</sub>. Previous research has shown that amorphous MoS<sub>2</sub> has excellent HER catalytic activity due to the number of defect sites, which act as active sites for cathodic hydrogen evolution. MoS<sub>2</sub> films were electrodeposited cathodically onto copper wire substrates from a solution of tetrathiomolybdate (MoS<sub>4</sub><sup>2-</sup>) which acts as a common Mo and S ion precursor. EDX compositional measurements have shown that the films have a varying stoichiometry, but are deficient in sulfur – MoS<sub>2-x</sub>. Polarization experiments in acidic media (0.5 M H<sub>2</sub>SO<sub>4</sub>) showed that the deposited films have excellent HER activity, and could reach 10 mA/cm<sup>2</sup> at -0.18 V overpotential.

As a further modification of the process, we attempted to incorporate W (as a substitute to Mo) and Se (as a substitute to S) into the films during electrodeposition. Due to the difference in their atomic radii and electronegativity, this could have an effect on the electrodes’ electrocatalytic properties. This was realized by mixing a small amount of the respective material into the precursor solution during synthesis. Subsequent electrodepositions were carried out in the same way. Compositional analysis showed that a small amount of the heteroatoms were incorporated into the material; stoichiometry, such as MoS<sub>1.91</sub>Se<sub>0.03</sub>, or Mo<sub>0.97</sub>W<sub>0.03</sub>S<sub>1.74</sub>, were obtained. The modified electrodes have Tafel slopes of ~ 40 mV/dec, which shows good HER catalytic activity. Electrochemical impedance spectroscopy was also used to characterize the catalyst-solution interface.

**Controlled Modification of Pt-Ni Nanoalloy Surfaces through a Facile Thermal Annealing Process with Carbon Monoxide** Yiliang Luan<sup>1</sup>, Amar Kumbhar<sup>2</sup>, Can Li<sup>1</sup>, Shaohui Yan<sup>1</sup>, Lihua Zhang<sup>2</sup>, Xiaobo Chen<sup>1</sup>, Bo Zhao<sup>1</sup>, Fan Zhang<sup>1</sup>, Guangwen Zhou<sup>1</sup> and Jiye Fang<sup>1</sup>; <sup>1</sup>SUNY Binghamton, United States; <sup>2</sup>University of North Carolina at Chapel Hill, United States; <sup>3</sup>Brookhaven National Laboratory, United States; <sup>4</sup>Texas Tech University, United States

Heterogeneous catalysts have been used in all fields of chemical processes, such as the petrochemical industry, pharmaceutical fabrication, energy conversion, etc. Among these catalysts, Pt and its alloys play important roles due to their unique electronic structures and resultant special catalytic properties. However, the low abundance of Pt poses a grand challenge on the scalability of Pt-based catalysts. As a catalytic process only occurs on the surface of a catalyst, the surface and sub-surface atomic structures greatly impact the catalytic activity and stability. As a result, surface structure modification is expected as one of the significant routes that can improve the catalytic performance. Herein, we report a facile method of Pt-Ni catalyst surface modification through a thermal annealing process with carbon monoxide (CO). Literally, the Ni atoms on the catalyst surface can be etched with CO by forming a gaseous intermediate, Ni(CO)<sub>4</sub>, at an elevated temperature. This method is utilized to modify the Pt-Ni octahedral and plane-tetrahexahedral (p-THH) catalysts towards oxygen reduction reaction (ORR). EDS mapping and ICP elemental analysis are used to identify the structure evolution. Catalytic results indicate that the ORR activity of Pt-Ni octahedra is improved (E<sub>1/2</sub> increased from 0.8 V to 0.88 V vs. RHE) due to a d-band center shift when Ni is removed from the surface lattice. Simultaneously, it is further determined that the electrocatalytic stability is enhanced (only a 10% decrease in mass activity after 3000 electrochemical potential cycles in HClO<sub>4</sub>)
since most of the vacancy defects formed after removing the Ni atoms are diminished due to the thermal annealing effect. In addition, it is observed that this gaseous manipulation can alter the reaction environments from Ni-dominated ORR to Pt-dominated ORR on the Pt-Ni p-THH catalyst, resulting in a change of onset potential from 0.86 V to 1.0 V vs. RHE.

EN06.08.19
Facet-Dependent Enhanced Catalytic Performance Toward 4-Nitrophenol Reduction Reaction by Shape-Controlled CuNi Octahedral and Cubic Nanocatalysts Can Li1, Bo Zhao2, Yiliang Luan1, Amar Kumbhar3 and Jiye Fang1; 1SUNY Binghamton, United States; 2Texas Tech University, United States; 3University of North Carolina at Chapel Hill, United States

Compared with noble metals, the transition metal nanocatalysts including Cu, Fe, Co, and Ni have received considerable attention in a number of catalytic reactions such as hydrogenation and organic reductions, due to their low cost and high earth-abundance. Like the behavior of noble metals, it is believed that their surface structure heavily governs the catalytic process. However, only a few studies reported the crystal facet-dependent catalytic performance of these transition metal nanocatalysts. In this work, we report a facile colloidal method to fabricate shape-controlled CuNi nanocatalysts. The {111}-terminated CuNi nano-octahedra and {100}-bounded CuNi nanocubes were prepared using a group of synergetic capping ligands in a hot organic solvent system. Borane morpholine was adopted as a reducing agent in both syntheses. It was determined that the {100} surfaces of CuNi nanocrystals could be stabilized by chloride ions released from the precursors, leading to the formation of nanocubes; whereas the CuNi nano-octahedra could be achieved through a thermodynamic control. The resultant CuNi nano-octahedra and nanocubes were further loaded on carbon black, respectively, and reduction of 4-nitrophenol (4-NP) using sodium borohydride (NaBH4) as a reducing reagent on these nanocatalysts at room temperature was investigated. Both the CuNi nano-octahedra and nanocubes exhibited remarkable catalytic activities with high rate constants over mass (k/m). Specifically, the CuNi nanocubes (k/m = 235 s⁻¹●g⁻¹) showed better catalytic performance than CuNi nano-octahedra (k/m = 160 s⁻¹●g⁻¹). Results suggest that 4-NP molecules are adsorbed on the {100} facets of CuNi much easier than on the {111}, indicating a strong facet-dependence due to different surface energies.

EN06.08.20
Ab Initio Mechanism Study and Material Screening of Transition-Metal Dichalcogenides for CO2 Reduction Catalysis Sungwoo Kang1, Suyeon Ju1, Youngho Kang2 and Seungwu Han1; 1Seoul National University, Korea (the Republic of); 2Korea Institute of Materials Science, Korea (the Republic of)

The electrochemical CO2 reduction (CO2R) has received great attention in converting CO2 into valuable chemical products. Recently, it was found experimentally that MoS2 converts CO2 to 1-propanol as a major product. It is also reported that the current density decreases when increasing the portion of edge sites, which indicates that the active sites locate on the basal plane rather than the edges. However, the practical utilization of MoS2 is limited because Faradaic efficiency of CO2R is only about 5% because of the poor selectivity compared to hydrogen evolution reaction (HER).

In this study, we first investigate the mechanism of CO2R at sulfur vacancy (VS) of MoS2 by calculating free energies through ab initio calculations and computational hydrogen electrode model.[1] We identify favorable C1, C2, C3, and C4 pathways starting from *OCHO. HCHO is found to be a key intermediate for CN pathways by coupling of sp² carbons. The predicted products and corresponding onset potentials are in good agreement with the experiment. To discover novel materials with better selectivity than MoS2, we perform computational screening of the catalytic activity of CO2R at atomic defects of various transition-metal dichalcogenides (TMDs). As a result of screening, several TMDs are suggested as promising candidates for CO2R catalysts with good selectivity.

EN06.08.21
Calculation of Catalytic Activity for Alloy Nanoparticles with Experimentally Relevant Sizes by Explicitly Predicting Adsorbate Binding Energy Liang Cao and Tim Mueller; Johns Hopkins University, United States

We present the use of ab-initio calculations to calculate the catalytic activity of alloy nanoparticles with
experimentally relevant sizes (5 nm-10 nm) by explicitly predicting atomic-scale structures and adsorbrates binding energies. We demonstrate our approach using PtNi nanoparticles as catalysts for the oxygen reduction reaction (ORR). We achieve our results by constructing a quaternary Pt-Ni-OH-Vacancy cluster expansion model to explicitly predict OH adsorption energies on nanoparticles of varying shape, size, and atomic structure. These adsorption energies are then used to predict ORR activity through a volcano plot. This model enables us to accurately investigate the catalytic activity of various surface sites with different coordination numbers and local atomic environments. Using this model, we evaluate how different parameters affect the ORR activity of Pt-Ni nanoparticles, including size (2 nm-10 nm), Pt composition (50%-100%), and shape. Through the use of kinetic Monte Carlo simulations we evaluate how the activities of the particles change due to Ni dissolution. Our approach provides theoretical insights into how to tune the structures of alloy nanoparticles to optimize catalytic activity.

EN06.08.22
The Reaction Mechanism for Electrooxidation of CH₄ at the β-NiOOH Surface Hyoseok Kim, Seungjae Kwak and Won Bo Lee; Seoul National University, Korea (the Republic of)

The direct conversion of methane at room temperature is a great challenge to replace the existing Fisher-Tropsch process. However, thermodynamic and kinetic mechanisms have hardly been proposed for the electrochemical reactions of methane. In this study, first-principles calculations were performed on the electrochemical oxidation of methane at β-NiOOH electrode surface. An active oxygen species on the surface play an important role in the CH₄ activation reaction. The effect of the implicit solvation model at constant potential was considered in this calculation. The partial charge of the active oxygen is calculated at each onset potential, and how this change influences on the reaction pathways was investigated. Possible reaction paths were suggested and the reaction rates of the anticipated products were calculated based on the microkinetic models.

EN06.08.23
Rapid and Scalable Synthesis of Cuprous Halide-Derived Copper Nano-Architectures for Selective Electrochemical Reduction of Carbon Dioxide Huan Wang, Edward Matios, Chuanlong Wang and Weiyang Li; Dartmouth College, United States

Electrochemical reduction of carbon dioxide (CO₂) into value-added chemicals and fuels provides a promising pathway for environmental and energy sustainability. Copper (Cu) demonstrates a unique ability to catalyze the electrochemical conversion of CO₂ into valuable multicarbon products. However, developing a rapid, scalable and cost-effective method to synthesize efficient and stable Cu catalysts with high selectivity towards multicarbon products at a low overpotential is still hard to achieve and highly desirable. In this work, we present a facile wet chemistry approach to yield well-defined cuprous halide (CuX, X=Cl, Br or I) microcrystals with different degrees of truncations at edges/vertices, which can be ascribed to the oxidative etching mechanism of halide ions. More importantly, the as-obtained cuprous halides can be electrochemically transformed into varied Cu nano-architectures, thus exhibiting distinct CO₂ reduction behaviors. The Cul-derived Cu nanofibers composed of self-assembled nanoparticles are reported for the first time, which favor the formation of C₂+₃ products at a low overpotential with a particular selectivity towards ethane. In comparison, the Cu nanocubes evolved from CuCl are highly selective towards C₁ products. For CuBr-derived Cu nanodendrites, C₁ products are subject to form at a low overpotential, while C₂+₃ products gradually become dominant with a favorable formation of ethylene when the potential turns more negative. This work explicitly reveals the critical morphology effect of halide-derived Cu nanostructures on the CO₂ product selectivity, and also provides an ideal platform to investigate the structure-property relationship for CO₂ electroreduction.

EN06.08.24
Surface Functionalized Graphene Monolayers—Fabrication, Properties and Chemical Catalysis Devika Mudusu, Koteeswara Reddy Nandanapalli, Han Hee Jung, Jiwon Yoon, Sungwon Lee and Kyung-In Jang; Daegu Gyeongbuk Institute of Science & Technology (DGIST), Korea (the Republic of)

Today, one of the focusing issues in graphene technology is the development of functionalized (doped) graphene monolayers since the pristine graphene is chemically inert, hydrophobic and zero band gap material [1]. As a result, the potential applications of graphene are limited to a few fields of science and technology. Recently, functionalization of graphene layers with different materials has received great attention as an alternative route to tailor the physical properties of graphene layers [2, 3]. The surface functionalized graphene layers find applications
in various fields including the development of paints, corrosion resistive tools, plastics, electronics, flexible devices, LEDs, sensors, energy harvesting devices, wearable devices, bio-imaging, drug-delivery systems [4]. In order to adopt these unique 2-dimensional structures for energy harvesting applications, we have developed surface functionalized graphene monolayers, transferred on to SiO2/Si substrates, by covalent attachment of metal-oxide particles. Influence of covalently attached metal-oxide particles on the surface morphology, carbon hybridization, and electrical properties of graphene monolayers was investigated. Further, the surface functionalized structures were adopted for the development of electrocatalytic devices and then, their water-splitting performance in different electrolyte solutions was studied.

**Solution-Based Synthesis of Nanostructured Barium Titanate Thin Films for Enhancement of Photocatalytic Activity**
Adriana Augurio, Qian Guo, Ana Belen Jorge Sobrido and Joe Briscoe; Queen Mary University of London, United Kingdom

Today, the study of novel photocatalyst and photo-electrocatalysts (PEC) for solar energy has gained great attention, aiming to use solar energy to directly split water into hydrogen and oxygen to produce solar fuels. To achieve unassisted water splitting, there is a need for low-cost, stable and high-efficiency PEC systems. Therefore, recent research works have focused on a wide range of materials such as Fe2O3, BiVO4, CuWO4, with bandgaps in the range of 2-2.5 eV, which allow visible light absorption compared to the traditional photocatalyst, TiO2. However, these materials generally present high level of surface or bulk recombination and low carrier mobility. Recently, polarization has emerged as novel strategy in photocatalysis to facilitate charge migration towards different sites, promoting selective redox reactions in the respective locations. Thus, in the present work, we develop and investigate a nanostructured, composite thin film, obtained by combining ferroelectric BaTiO3 with the photocatalyst Fe2O3 in parallel at the nanoscale to improve the photocatalytic performance. The polarization of ferroelectrics can aid effective charge separation while narrow bandgaps and good charge transport properties of the photocatalyst are needed for light absorption and carrier extraction. The BaTiO3 thin films are synthesized by solution-based synthesis, which has been optimized in order to obtain suitable thin films for photocatalyst integration. The morphology of BaTiO3 is investigated by SEM, which confirms the successfully preparation of nanostructured thin films. The crystalline properties of BaTiO3 thin films are analysed by X-ray diffraction (XRD) and Raman spectroscopy, in order to verify the transition to the tetragonal phase, which is responsible to the ferroelectric polarization. In addition, the switching of spontaneous polarization of BaTiO3 thin films by an electric field is investigated by piezoresponse force microscopy (PFM). The optical properties of BaTiO3 thin film, Fe2O3 thin film and BaTiO3/Fe2O3 composite photocatalyst thin film are analysed by UV-vis spectroscopy, which allow the estimation of the optical bandgap. The PEC water splitting performance was measured by using the BaTiO3/Fe2O3 composite photocatalyst thin film as working electrode in a 3-electrode half cell configuration and illuminating with AM 1.5 simulated solar light. The BaTiO3/Fe2O3 composite photocatalyst thin film shows an enhancement of the photocurrent density compared to either the bare BaTiO3 or Fe2O3 thin films, which indicates a promising performance of the ferroelectric/photocatalyst composite thin film in solar energy conversion systems.

**Electrocatalytic Reduction of Gaseous CO2 to CO on Sn/Cu-Nanofiber-Based Gas Diffusion Electrodes**
Wenbo Jun and Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Earth-abundant Sn/Cu catalysts are highly selective for the electrocatalytic reduction of CO2 to CO in aqueous electrolyte. However, CO2 mass transport limitations, resulting from the low solubility of CO2 in water, so far limit
the CO partial current density to about 10 mA cm\(^{-2}\).[1-2] To enhance CO\(_2\) mass transport, we developed a process to fabricate Sn/Cu-coated polymer nanofiber networks, and demonstrate the materials as gas diffusion electrodes (GDEs) for electrochemically converting gaseous CO\(_2\) to CO.[3] The Sn/Cu-coated PVDF (Sn/Cu-PVDF) nanofiber GDEs achieve CO faradaic efficiencies (FEs) above 80%, and maintain high CO partial current densities of up to 104 mA cm\(^{-2}\). The Sn/Cu-PVDF GDE remains highly stable during extended operation at -1.0 V for 135 hours, with an average FE for CO of > 85%. These results represent an important step towards an economically viable pathway to CO\(_2\)RR.

Role of CuFeO\(_2\) Surface Oxygen Vacancies in the Catalytic Activation of CO\(_2\)—A First-Principles Study
Eduardo Schiavo\(^1\), Carmen Baiano\(^1,2\), Ana B. Munoz-Garcia\(^1\) and Michele Pavone\(^1\); \(^1\)University of Naples "Federico II", Italy; \(^2\)Scuola Normale Superiore, Italy

Carbon dioxide is the most abundant greenhouse gas produced as byproduct of fossil fuels exploitation and it is the main responsible for the global climate crisis of current days. The recycling of CO\(_2\) back into chemicals via photo-electrochemical cells represents a viable route to mitigate such problem and great research efforts have been focusing on finding and optimizing functional materials able to catalyze the CO\(_2\) reduction reaction [1, 2]. Here we focus on the copper-iron delafossite oxide, CuFeO\(_2\), which has been proven to have suitable physico-chemical properties to photo-catalyze the carbon dioxide reduction to formic acid [3]. We address the specific electronic and structural features that allow activating the highly stable CO\(_2\) molecule. In particular, by exploiting state-of-the art first principles methods, we dissect the effects of surface oxygen vacancies as well as the different roles of copper and iron on the adsorption and the activation of carbon dioxide at the CuFeO\(_2\) most stable surface. Our results highlight the key role of oxygen defects to allow the CO\(_2\) adsorption and to promote the formation of a radical anion or a carbonate-like adsorbate. While the formation of both intermediates is found to be a downhill process, our data show the second one to be the most probable, paving the route to further mechanistic and kinetic studies on the full pathway for the CO\(_2\) reduction reaction.

Direct Evidence of Isolated Single Metal Atoms Incorporated on Laser Ablated Defective Graphene Support for Electrocatalysis
Kishwar Khan and Zhengtang Luo; Hong Kong University of Science & Technology, Hong Kong

2D nanomaterials decorated with single atom catalyst (SACs) are efficient and low-cost electrocatalyst candidate for clean energy technologies. The 2D supports and coordination environments play an important role in optimizing the catalytic activity and reaction mechanism of single atom centers. Here we summarize the suitable synthetic strategies of single atom on graphene supports. We used recently different methods that facilitate the formation of homogeneous structure and enabled the regulation of surrounding atomic of environment center. We recently used new laser ablation techniques for making defects in 2D nanomaterials, and then used it as supporting material to grow SAC for catalytic applications. Here, we elucidate our latest results about SAC on laser ablated 2D defective nanomaterials for different electrochemical reactions, including HER, ORR and OER. Uniting advanced experimental and theoretical approaches including aberration-corrected scanning transmission electron microscopy
EN06.08.29
Unraveling the Mechanistic Link between the Carburization Process and Catalytic Active Sites in the Performance of Mo/HZSM-5 Catalysts for Methane Dehydroaromatization
Sonit Balyan, Manish Kumar, Tuhin S. Khan, Saswata Bhattacharya, Kamal K. Pant and M. Ali Haider; Indian Institute of Technology Delhi, India

Structural evolution of catalytic active sites in methane dehydroaromatization (MDA) reaction in non-oxidative conditions over the Mo/HZSM-5 catalyst is a critical factor in deciding the reactivity and stability of the catalyst as discussed by Khan et al. [J. Phys. Chem. C 2018, 122, 11754-11764]. Molybdenum oxide species, which are anchored on the zeolite framework are transformed into oxycarbide and carbide clusters during the carburization process. The molybdenum carbide clusters anchored on the zeolite framework are considered to be the active sites for MDA. On prolong operation, the clusters tend to migrate and agglomerate at the external zeolite surface, leading to catalyst deactivation. Therefore, a diligent and realistic choice of carburization conditions to control the formation and anchoring of the carbide cluster on the zeolite framework essentially holds the key for obtaining high stability and activity of the catalyst in the MDA process. This thoughtful pretreatment of as-synthesized Mo/HZSM-5 catalyst is demonstrated in two different carburization conditions; using pure methane and a mixture of hydrocarbons representing the natural gas. The effect of carburization process under the two different carburization conditions is monitored with catalyst characterization using the X-ray photoelectron spectroscopy (XPS), which is specifically pointing towards the formation of active molybdenum carbide species under natural gas. In contrast, under pure methane, molybdenum species are observed to transform into an oxycarbide phase. This significant change in the structural evolution of active molybdenum species in the two different carburization conditions reflected into a significant change in the reactivity and deactivation behavior of the Mo/HZSM-5 catalyst. The catalyst treated in natural gas showed a higher benzene formation rate of 3199 nmol/gcat.s as compared to the one treated in pure methane (2280 nmol/gcat.s) after 2 hours time-on-stream. This is correlated with high level of BrØnsted acidity measured for natural gas carburized Mo/HZSM-5 catalyst (1.22 mmol/gcat) as compared to the methane-carburized Mo/HZSM-5 catalyst (0.37 mmol/gcat). TPO, TGA, XPS and Raman analysis of the carburized and spent catalysts further pointed towards lesser coke formation for the catalyst pretreated under natural gas environments as compared to pure methane environment. Experimental results are correlated with ab-initio thermodynamic phase diagrams constructed under reaction conditions to understand the stability of different phases of molybdenum in different hydrocarbon environments. Overall the results are elucidating a microscopic level control on active sites in the MDA reaction by macroscopic process conditions.

EN06.08.30
Oxidation Catalysis with LaFe\(_{x}\)Co\(_{1-x}\)O\(_3\) Perovskites Made by Spray Flame Synthesis
Steven Angel\(^1\), Baris Alkan\(^1\), Chakrapani Kalapu\(^1\), Malte Behrens\(^1,2\), Christof Schulz\(^1,2\) and Hartmut Wiggers\(^1,2\); \(^1\)University of Duisburg-Essen, Germany; \(^2\)CENIDE, Germany

The versatile properties of cobalt based perovskites such as chemical stability in alkaline media and high electron mobility have led to detailed investigations of LaFe\(_{x}\)Co\(_{1-x}\)O\(_3\) concerning their utilization as potential catalysts for replacing costly and low-abundant materials (e.g. RuO\(_2\), IrO\(_2\) and Pt). A specific interest is in electrochemical water splitting / anodic oxygen evolution reaction (OER) in alkaline electrolytes. Typically, the synthesis of the perovskite materials is done in time-consuming wet-chemical batch processes followed by a calcination step. Thus, the particle size of the raw materials increases, affecting the effective number of active sites and hence, the catalytic performance.

We utilized the scalable spray-flame synthesis (SFS) method to directly synthesize high surface area LaFe\(_{x}\)Co\(_{1-x}\)O\(_3\) perovskites. Typically, high surface area nanoparticles with sizes below 10 nm could be produced. Their catalytic activity can be tuned by adjusting the Fe-to-Co ratio. Materials containing 20% Fe performed best for the oxygen evolution reaction (OER) than the samples with lower (10%) and higher (30%) iron substitution concentrations. A potential of 1.53 V vs. RHE was achieved for the OER in alkaline at 10 mA/cm\(^2\), which is lower than the commercial IrO\(_2\) reference material (1.59 V vs. RHE at 10 mA/cm\(^2\)). To the best of our knowledge, our high surface area spray-flame made LaFe\(_{0.2}\)Co\(_{0.8}\)O\(_3\) perovskites belong to the best materials for OER and are comparable to the top reported materials for this reaction (e.g. Ba\(_{0.5}\)Sr\(_{0.5}\)Co\(_{0.8}\)Fe\(_{0.2}\)O\(_{3-q}\)).
EN06.08.31
Atomic Structure of Isolated Single Pt Atoms Anchored on Nanographene Kenji Yamazaki, Yosuke Maehara and Kazutoshi Gohara; Hokkaido University, Japan

In single-atom catalysis, the atomic structure of single metal atoms on a supporting material is one of fundamental questions[1]. We experimentally solved these problems for single Pt atoms dispersed on free-standing graphene using aberration-corrected transmission electron microscopy (TEM) [2]. Graphene was synthesized by the chemical vapor deposition (CVD) method on a copper substrate (purity 99.8%; thickness 25 μm; Alfa Aesar #46365)[3]. We dipped the H₂SO₄ and H₂O₂ mixed solution (H₂SO₄ : H₂O₂ = 3 : 1) to remove the misplaced graphene grown on the back of the Cu substrate. After etching the Cu substrate with 100-mM ammonium peroxodisulfate solution for 4 h, the specimen was rinsed thoroughly with distilled water, and then transferred onto a carbon-supported Cu TEM grid. The graphene was verified as a single layer by electron diffraction. Single Pt atoms were uniformly dispersed on graphene by plasma sputtering method. Sputtering in plasma is well established to form thin films, but this method has also been used to synthesize nanoparticles. Several studies have also attempted to downsize the resulting nanoparticles. In this study, we used this method to disperse single atoms on a substrate. We used an aberration-corrected TEM/STEM (Titan Cubed 60-300, FEI) to verify that the graphene was a single layer and to clarify the atomic arrangements of single Pt atoms. Dispersed single atoms with a size less than 2 Å are clearly discernible in the image of a sputtering time of 1 s. The atom was identified as Pt by energy-dispersive X-ray spectroscopy (EDX), and separation of Pt atoms of 99% was confirmed by measuring the nearest-neighbor distance between Pt atoms. High-resolution imaging using TEM was performed in order to clarify the atomic arrangement of Pt atoms adsorbed on graphene. Although the atomic arrangement above the third layers was hardly realized due to the complicated contrast and atomic migration, typical examples could be clarified. Single Pt atom anchored at the step edge of graphene. The first layer showed a pristine hexagonal lattice, whereas the second layer had a polycrystalline structure, e.g., five- and seven-membered rings. Although this polycrystalline graphene has previously been considered to represent amorphous-like hydrocarbons or contaminations, we revealed the contamination was identified as the aggregation of small islands consisting of several layers of nanographene flakes stacked on a single layer of graphene[4]. The nanographene has a rich area of step edges that serve as anchors and active sites for chemical reactions such as adsorption and catalysis. We reported dense and highly selective formation of single Pt atoms on graphene using nitrogen gas atmosphere during plasma sputtering[5]. We also conducted XPS measurements using the same sample, and observed a large core-level shift for single Pt atoms.

Modulating the Catalytic Efficiency of Pt-Ni Alloy Nanoparticles and Their Role in Mediating the Oxime Reaction Sarah S. Albalawi¹, Sher Bahadar Khan², Esraa M. Bakhsh² and Sherine O. Obare³; ¹Western Michigan University, United States; ²King Abdulaziz University, Saudi Arabia; ³University of North Carolina at Greensboro, United States

Well-defined catalytic nanoparticles consisting of bimetallic Pt-Ni alloys were prepared with homogeneity and characterized by high-resolution transmission electron microscopy (HRTEM), x-ray photoelectron spectroscopy (XPS), and energy dispersive x-ray spectroscopy (EDS). The effect of the support material on the catalytic activity of the nanoparticles was investigated with the aim of optimizing the catalyst activity. Nickel and platinum supported on silica (SiO₂), graphene oxide (GO), and molybdenum sulfide (MoS₂) with the ratio of the Pt:Ni being 1:1, 1:2, and 2:1 were prepared and their catalytic efficiency was evaluated using a model oxime reaction. The catalysts were optimized to allow the reaction to proceed at ambient temperature and in the aqueous phase. The concentration of each metal ion was determined by employing inductively coupled plasma–optical emission spectroscopy (ICP-OES). The turnover frequency (TOF) was calculated to evaluate the catalytic performance of Pt/Ni@SiO₂, Pt/Ni@GO, and Pt/Ni@MoS₂ toward oximation reactions at 50% and 90% conversion. The TOF of Pt/Ni@MoS₂ was found to be higher than that of Pt@SiO₂ and Pt/Ni@GO.

EN06.08.34
Comparing the Electrochemical Performance of Au and Sn Catalysts on Gas Diffusion Electrodes and Aqueous H-Cells
Sanjana Chandrashekar and Wilson Smith; TU Delft, Netherlands

Carbon dioxide can be electrochemically converted into feedstocks for many industrial processes such as the manufacturing of synthetic fuels and chemicals. In order for this technology to be capable of matching and ultimately supplanting any industrial process, it needs the capability to convert CO₂ at an industrial scale. This means the reaction needs to happen at a fast rate for long periods of time and make products with high selectivity and high energy efficiency. In order to achieve these objectives, the electrocatalysts and electrochemical systems need to be studied while operating at high current densities.
This talk will focus on the structure-functionality relationship between Au, Sn, and bimetallic AuSn catalysts, and their CO₂ reduction performance at high current densities.
X-Ray diffraction (XRD), X-ray photoemission spectroscopy (XPS), and atomic force microscopy (AFM) were used to determine the crystal structure, surface topography and composition of compositionally variant alloy thin films of Au-Sn before and after electrolysis. The electrochemical activity for each bimetallic film was measured in terms of electrode potential/current and product selectivity as a function of applied current density/potential and catalyst composition. To achieve high current density operation (>100mA/cm²), gas diffusion electrode’s (GDE’s) were used as the working electrode in a gas-fed electrolyser.
Finally, the reaction’s activity and selectivity were examined in an aqueous H-cell reactor to compare the performance of the bimetallic catalyst’s with liquid and gas-phase feedstock.
The results of this work provide fundamental insights to reaction mechanisms in aqueous and gas-fed CO₂ electrolyser’s, while also providing a template for assessing electrochemical performance across these two reactor configurations. Electrochemical trends at low current density were found to not always translate to high current density operation, and therefore future work is needed to understand the differences in these two architectures.

EN06.08.35
Structural study on the chemical reactivity of GO regarding oxidative amine coupling reaction
Kazuyuki Takai, Ryutaro Suzuki, Takuya Isaka, Kentaro Tajima and Tomoki Yamashina; Hosei University, Japan

Graphene oxide (GO) having oxygen-containing groups is expected as metal-free and environment-compatible catalyst. The research on GO catalyst progressed [1 - 3], although the detail mechanism for GO catalytic activity is not clear yet. Investigating Graphene Oxide (GO) properties before / after the catalytic reaction is a promising strategy for clarification of the mechanism for GO catalytic activity. Additionally, it is known that removing oxidative debris on GO by base-treatment is important factor to get the higher yield for the following catalytic reaction [1]. In this study, the principle for reactivity of GO is investigated by conducting the oxidative amine coupling reaction of benzylamine (1) to N-benzylidenebenzylamine (2) using baGO and thermally reduced one (rbaGO) as catalysts. baGO-Pristine was obtained by washing GO, synthesized by Hummers method, with NaOH. rbaGO was prepared by reducing baGO at 450°C under Ar gas flow. After the reaction, the reaction media filtered for removing the catalyst was characterized by GC-MS. After the 1st cycle reaction, the recovered catalyst was used as that for the 2nd cycle (baGO-1st cycle, rbaGO-1st cycle). The chemical structure of each catalyst after the reaction was evaluated by XPS (Al Ka), where it was washed with ethanol after the reaction. The atomic ratio O/C of catalyst much decreases after the reduction or 1st cycle reaction and rbaGO shows poor yield, suggesting roles of baGO / rbaGO not as catalyst but as oxidant. However, baGO-1st cycle exhibits the highest yield in spite of C1s spectrum and O/C similar to that of rbaGO and rbaGO-1st cycle, which also indicates no more reduction for rbaGO in the 1st cycle reaction. Taking these results and appearance of nitrogen content after the 1st cycle reaction into consideration, a different mechanism in the 2nd cycle reaction is suggested, where nitrogen incorporated into rbaGO / baGO in the 1st cycle reaction plays an important role for the reactivity. To clarify the most responsible functional groups in rbaGO / baGO for the higher catalytic reactivity in the 2nd cycle reaction, we have derived the amount of nitrogen-containing functional group per 100 mg in each GO sample for the 2nd cycle reaction. By plotting the amount of nitrogen-containing functional group and the GC-yield of the product, the correlation coefficient r is calculated for each functional groups. In particular, the GC-yield tends to increase as Graphitic N (correlation coefficient r = 0.94) and Oxidized N (correlation coefficient r = 0.87) increase. The important roles of those functional groups in the oxidation amine coupling reaction could be explained by the enhancement in the oxygen adsorption ability, which is important to produce O2*- species from ambient oxygen molecules for proceeding the oxidative coupling reaction.

Meatl Phthalocyanine Precursors to Construct Single Metal Site Electrocatalysts Yang Wang and Yongye Liang; Southern University of Science and Technology, China

Single metal sites embedded in nitrogen doped carbon materials have recently demonstrated superior performance as electrocatalysts for oxygen reduction reaction (ORR), carbon dioxide reduction reaction (CO2RR) and so on. However, it's still a challenge to construct abundant single metal atoms during the high temperature processing due to easy aggregation of metal species. Herein, we present a facile method to construct N-doped carbon with prevalent single metal sites by employing metal phthalocyanine derivatives as metal precursors. First, iron phthalocyanine (FePc) molecules are encapsulated during the synthesis of zeolitic imidazolate frameworks (ZIFs), and the subsequent pyrolysis yields the Fe-N/C materials. Cyano substitution on FePc can facilitate the introduction of phthalocyanine molecules into ZIFs and formation of more active sites in the carbene network, thus affording higher activity for oxygen reduction reaction (ORR) than the FePc counterpart. It is also found that the ORR activities in acidic conditions are closely correlated with the surface Fe-Nx contents. Adding iron salt with cyano substituted FePc can afford a better catalyst with enhanced surface Fe-Nx content, which exhibits high activities with a half-wave potential of 0.910 and 0.811 V versus reversible hydrogen electrode in alkaline and acidic conditions, respectively. Moreover, the catalyst derived from cyano substituted FePc exhibits good activities with a reduction current density of 5.0 mA/cm^2 and a turnover frequency of 0.13 s^-1 and high selectivities with Faradaic efficiency for CO production of around 94% at -0.46 V for carbon dioxide reduction (CO2RR). DFT calculations are conducted that the bulk Fe-Nx sites are superior to the surface Fe-Nx sites with better catalytic stability in CO2RR.

EN06.08.38
Hybridization with Carbon Nanotubes to Enhance CO2 Electroreduction Performance of Metal Phthalocyanines Zhan Jiang and Yongye Liang; Southern University of Science and Technology of China, China

Metal phthalocyanines (MePcs) are interesting molecular catalysts for CO2 electroreduction due to well-defined structural and high turnover frequency (TOF). However, MePcs are semiconducting and have strong intramolecular interactions due to the large \( \pi \) system, which often lead to molecular aggregation on electrodes. As a result, their catalytic performance of MePcs reported in literature could vary significantly and often limited by low current density. Here, we report a carbon nanotube (CNT) hybridization approach and prepare MePcs(Me = Co, Fe and Mn)/CNT hybrids to study the CO2 reduce electrocatalytic performance of MePcs molecular catalyst. MePc/CNT hybrids are synthesized with MePc molecules anchored on the surface of CNTs without noticeable molecular aggregations. Both activities and stabilities of MePc are significantly enhanced by hybridization with carbon nanotubes. The activity of FePc/CNT is slightly less than CoPc/CNT, but it could deliver higher Faradaic efficiencies for CO production over 98% at low overpotentials. In contrast, among the neat molecules, only CoPc shows appreciable activities for CO2 electroreduction. Further, the TOF results indicate that CNTs hybridization is helpful to reveal the intrinsic activities of MePc molecules and deliver higher current densities.

EN06.08.39
Operando Atomic Force Microscopy of Gas Diffusion Electrodes to Understand the Gas/Liquid/Electrode Interface Nathan T. Nesbitt, Thomas Burdyny, Divya Bohra, Sanjana Chandrashekar, Recep Kas and Wilson Smith; Delft University of Technology, Netherlands

Electrochemical conversion of carbon dioxide (CO2) to renewable chemical feedstocks and fuels could play an important role for ending the use of fossil fuels. To amortize equipment costs over large product volumes, commercial applications will require high current density devices. Due to solubility and diffusion limitations of CO2 in liquid electrolytes, this requires electrodes to be near the liquid/gas interface, which is accomplished by the gas diffusion electrode (GDE) cell architecture. In designing such electrodes, the question of where the gas/liquid layer is positioned within the GDE becomes important. For example, it has been suggested that the CO2 reduction reaction occurs at a triple-phase-point, where the gaseous CO2, aqueous protons, and electrons from a solid metal
Electrocatalyst can interact. However, from various literature, it seems more likely that the metal is fully wetted and a two-phase reaction occurs with the CO₂ dissolved in the electrolyte. Likewise, it is unclear whether product gas forms nanobubbles on the electrocatalyst surface, or dissolves into the electrolyte.

Here, we use an electrochemical atomic force microscope (EC-AFM) to make operando measurements of the electrocatalyst surface in a GDE CO₂ reduction cell, while operating at 1, 10, and 100 mA/cm². Using peak-force tapping, we map the topography and nanomechanical information. No nanobubbles or macroscopic bubbles are observed. Comparison with a solid metal foil shows bubble formation on only the macroscopic scale, supporting the idea that gaseous reactants and products interacting with the electrocatalyst are primarily, dissolved in the electrolyte.

Understanding the Role of Electrolyte in Electrochemical CO₂ Reduction Reactions Qi Dong, Da He, Chaochao Lang and Dunwei Wang; Boston College, United States

Electrochemical CO₂ reduction has attracted significant attention not only for its technological implications but also for the scientific knowledge it holds. One critical challenge is to suppress the kinetically favored hydrogen evolution reaction in an aqueous electrolyte while achieving high selectivities toward carbonaceous products. Here we report a new way to realize such a goal. Our strategy involves a unique system where the hydrogen formation can be controlled. Such a platform offers the opportunity to study the role of electrolyte component in electrochemical CO₂ reduction, which is critical to the understanding of the reaction mechanisms and the performance matrix. Using Au as a prototypical catalyst, we revealed that the selectivity toward CO can be greatly improved by manipulating the electrolyte properties. It was also found that the overall performance can be significantly influenced by mass transport. The results shed new light on the mechanistic understanding of electrochemical CO₂ reduction, and offered a new way to achieve high selectivities for practical applications.

8:45 AM EN06.09.03
Host-Guest Chemistry Meets Electrocatalysis—Cucurbit[6]uril on a Au Surface as Hybrid System in CO₂ Reduction Andreas Wagner¹, Khoa Ly¹,², Nina Heidary¹,³, István Szabó⁴, Tamás Földes⁴, Khaleel Assaf⁵, Steven Barrow¹,⁶, Kamil Sokolowski¹,⁻, Nikolay Kornienko¹,⁻, Moritz Kuehnel¹,⁶, Edina Rosta¹, Ingo Zebger¹, Werner Nau⁵, Oren A. Scherman¹ and Erwin Reisner¹; ¹University of Cambridge, Department of Chemistry, United Kingdom; ²Technische Universität Dresden, Germany; ³Université de Montréal, Canada; ⁴King's College London, United Kingdom; ⁵Jacobs University Bremen, Germany; ⁶RMIT University, Australia; ⁷Polish Academy of Sciences, Poland; ⁸Swansea University, United Kingdom; ⁹Technische Universität Berlin, Germany

A major challenge in electrocatalysis is the rational control of forming and stabilizing reaction intermediates to guide specific reaction pathways. In this work, we present a model system introducing the concept of surface-bound host-guest chemistry in CO₂ electrocatalysis. The functionalization of pristine gold (Au) with cucurbit[6]uril (CB[6]) nanocavities was studied as a hybrid organic-inorganic model system that utilizes host-guest chemistry to influence heterogeneous electrocatalytic reactions.

The combination of surface-enhanced infrared absorption (SEIRA) spectroscopy and electrocatalytic experiments in conjunction with theoretical calculations support capture and reduction of CO₂ inside the hydrophobic cavity of CB[6] on the gold surface in aqueous KHCO₃ at negative potentials. SEIRA spectroscopic experiments show that the decoration of gold with the supramolecular host CB[6] leads to an increased local CO₂ concentration close to the gold interface. Electrocatalytic CO₂ reduction on a CB[6]-coated gold electrode indicates differences in the specific interactions between CO₂ reduction intermediates within and outside the CB[6] molecular cavity, illustrated by a decrease in CO current density, but almost invariant H₂ production.
Based on the obtained results, design criteria of molecular cavities that allow to overcome current limitations in heterogeneous CO\textsubscript{2} electrocatalysis are discussed. We believe that the methodology and molecular insights in the presented work will provide fruitful basis for future design concepts of molecularly engineered catalytic environments through interfacial host-guest chemistry.

9:00 AM EN06.09.04
Beyond Adsorption in Heterogeneous Electrocatalytic Water Splitting Maureen Tang; Drexel University, United States

It has long been recognized that the reaction rates of the hydrogen oxidation and hydrogen evolution reactions (HOR /HER) are up to 200 times slower in basic than acidic electrolytes, even though the surface intermediate of adsorbed hydrogen is independent of solution pH [1]. One explanation for this difference is a proposed `bifunctional mechanism’, in which slow water dissociation is overcome by mediation of adsorbed hydroxide [2]. We have completed detailed microkinetic models of this pathway for single- and two-site catalysts, and compared these models to single-crystal voltammetry on Pt(110) and transition-metal-doped Pt(111) [3-4]. We find that any chemical dissociation steps result in anomalous trends with potential, and that oxophilicity has no effect on hydrogen coverage or HER/HOR rates. Comparison with experiment strongly indicates that the observed bifunctional mechanism is unrelated to hydroxide binding strength [4].

Our work resolves a long-standing paradox in electrocatalysis and surface science by determining that oxophilicity is not an accurate descriptor for alkaline hydrogen electrocatalysts. Other parameters, such as water orientation and non-covalent interactions, must play a greater role in overall activity. In efforts to identify and measure these parameters, we combine a series of techniques from catalysis, classical electrochemistry, and colloid science. These experiments yield new understanding how the solution-phase double-layer interacts with solid-phase surface structure to govern electrocatalytic activity, thus enabling rational design of next-generation catalytic interfaces [5].

Activity and Selectivity Control in CO\textsubscript{2} Electroreduction—Catalyst Structure, Composition and Electrolyte Effect Beatriz Roldan Cuenya; Fritz Haber Institute of Max Planck Society, Germany

The utilization of fossil fuels as the main energy source gives rise to serious environmental issues, including global warming caused by the continuously increasing level of atmospheric CO\textsubscript{2}. Recently, the electrochemical conversion of CO\textsubscript{2} (CO\textsubscript{2}RR) to chemicals and fuels driven by electricity derived from renewable energy has been recognized as a promising strategy towards sustainable energy.

I will provide examples of recent advances in the development of highly active plasma-modified single crystals, nanostructured thin films and nanoparticle (NP) electrocatalysts (Cu, Ag, Zn, Ag-Sn and Cu-M with M = Co, Zn, Ag, Pd) and how their structure, oxidation state and composition influence their selectivity in CO\textsubscript{2}RR. Additionally, the determining role of the electrolyte in the reaction activity and selectivity will be illustrated by considering the role of different cations and anions (Cs\textsuperscript{+}, Li\textsuperscript{+}, Na\textsuperscript{+}, K\textsuperscript{+}, I\textsuperscript{−}, Br\textsuperscript{−}, Cl\textsuperscript{−}) in aqueous electrolytes. Finally, the importance of in situ and operando characterization methods (e.g. EC-AFM, Liquid-TEM, XAS, XPS) to gain in depth understanding on the structure- and electrolyte-sensitivity of real CO\textsubscript{2}RR catalysts under working conditions will be demonstrated. Our results are expected to open up new routes for the reutilization of CO\textsubscript{2} through its direct selective conversion into higher value products.

9:45 AM BREAK

10:15 AM *EN06.09.06
CO\textsubscript{2} Reduction Electrocatalysis Edward H. Sargent; University of Toronto, Canada

I will discuss advances in increasing the selectivity, improving the energetic efficiency, and improve the rate (current density) of heterogeneous CO\textsubscript{2} electrocatalysts and systems.
A key challenge in heterogeneous catalysis has been developing technologies that can selectively convert CO$_2$ or CO into short-chain multi-carbon oxygenates. Here, I will show how to improve selectivity to multi-carbon oxygenates by rationally controlling a variety of properties that are intrinsic and extrinsic to the catalyst. First, I will discuss how extrinsic properties such as the electrochemical potential and electrolyte pH impact reactivity on polycrystalline Cu electrodes. By comparing CO and CO$_2$ reduction from similar reactors, we demonstrate that alkaline reaction conditions increase the energy efficiency towards multi-carbon products. Furthermore, we reveal selectivity trends that are common to both CO and CO$_2$ reduction, indicating both the production of oxygenates and the growth of longer carbon chains are favored at lower overpotentials. Next, I will show how proper control of these extrinsic properties combined with increasing the electrode surface area of polycrystalline Cu leads to high selectivity for multi-carbon oxygenates. We demonstrate that by increasing the electrode surface area, nearly 100% selectivity for CO electroreduction to multi-carbon oxygenates is achieved at a very low overpotential of ~200 mV, from a concomitant suppression of the competing hydrogen evolution reaction. Furthermore, we reveal the generalizability of this surface area effect by using a variety of methods to synthesize polycrystalline Cu electrodes of many different morphologies and roughness factors, and comparing their electrocatalytic performance. Finally, I will show how combining all of these design principles with controlling the surface composition, an intrinsic property of the catalyst, leads to improved selectivity for a single multi-carbon oxygenate. Under alkaline reaction conditions, we observed high selectivity for CO reduction to acetaldehyde on CuAg bimetallic electrodes at low overpotentials, reaching a maximum total Faradaic efficiency of >70% and selectivity of >90% on a carbon basis.

It is of both scientific and societal importance to advance the sustainable energy technology that enables the conversion of CO$_2$ into fuels and value-added chemicals *via* cost-effective electrocatalysis. At present, precious metals (*e.g.* Au, Ag, and Pd) exhibit the best catalytic activity for the electrochemical reduction reaction of CO$_2$ (CO$_2$RR) to fuels. However, their high cost and lack of selectivity hamper the wide implementation of the technology. Development of alternative catalysts based on earth-abundant elements (*i.e.*, free of precious group metals (PGM-free)) is therefore highly demanded. In recent years, transition metal (TM=Fe, Co, or Ni) and/or nitrogen (N) doped carbon (denoted as TM-N-C) catalysts have been demonstrated to be capable of catalyzing CO$_2$ reduction to CO with a reasonable activity and amazingly high selectivity. However, knowledge about how the activity and selectivity of TM-N-C electrocatalysts for CO$_2$RR are dependent on their chemical composition, structure, morphology, and synthetic chemistry is seriously lacking. For a rational design of these TM-N-C catalysts, we have performed density functional theory (DFT) calculations to investigate CO$_2$RR on various TM-N$_4$ active sites (TM = Fe, Co, Ni) with different moieties. Specifically, three different TM-N$_4$ moieties are studied, such as the TM-N$_4$ moiety embedded in the graphene basal plane, the porphyrin-like moiety and/or the TM-N$_4$ moiety bridging the edges of two adjacent graphene layers. We calculated the adsorption energies of all the possible chemical species and the activation energies for C-O bond dissociation reactions involved in CO$_2$RR on the active sites. Our DFT calculations predicted that the CO$_2$RR could happen at the proposed active sites under an electrode potential more positive than that for competing hydrogen evolution reaction (HER). Consequently, these TM-N-C catalysts exhibit good selectivity by diminishing parasitic HER. Moreover, the TM-N$_4$ moiety bridging the edges of two adjacent graphene layers was predicted to be capable of breaking the C-O bond efficiently. These theoretical results are in agreement with experimental observations. Furthermore, we investigated how the doping of S would affect the CO$_2$RR on Fe-N-C catalysts. Our DFT calculation reveals that the adjacent S atoms engineering increases the charge density of centered Fe in a Fe-N$_4$ site, and thus predicts that endowing S-modified Fe$^{~}$N$_4$ with lower formation energy barriers for the key COOH* intermediate in CO$_2$RR. These results suggest that adding S into the TM-N-C catalysts is an effective approach to enhance their catalytic activity for CO$_2$RR.
The quest for the design of active and stable (electro)catalysts hinges on the ability to unequivocally identify the reaction mechanism under realistic operating conditions. The past few decades of research have focused on developing a range of spectroscopic and imagining tools to enable the study of the chemical and structural changes at the solid/liquid interface.

In this talk, we will bring the most recent understanding of the surface (electro)chemistry of CO2 on Pt surface. The molecular-level understanding of the interfacial (electro)chemical processes on Pt surfaces under CO2-contained aqueous system by *in situ* surface enhanced infrared spectroscopy (SEIRAS) will be particularly discussed. We will also show the integration of those experimental approaches and density functional theory (DFT) calculation further strengthen the understanding of the reaction mechanism. It will be also demonstrated that the holistic information about the nature of the adsorbed species can provide additional knobs to tune the kinetics of electrochemical reaction, leading further improvements in performance for energy conversion and storage devices.

**11:30 AM EN06.09.10**

*Elucidating the Effects of N-Arylpyridiniums on CO2 Reduction at the Cu/Electrolyte Interface*  
*Vincent J. Ovalle* and *Matthias Waegele,* Boston College, United States

Increasing the selectivity of the electroreduction of carbon dioxide on Cu electrodes for valuable hydrocarbons is a great challenge. A promising approach for improving the product selectivity is through modification of the Cu/electrolyte interface with organic additives. For example, it has been shown that the decoration of the Cu electrode surface with amino acids or polyamide films can enhance the selectivity of ethylene by approximately a factor of two. Recently, it has been reported that addition of N-substituted arylpyridinium salts can greatly alter the product selectivity of the electroreduction of CO2 on Cu electrodes [Han *et al.* *ACS Cent. Sci.* (2017) **3**, 853-859]. Han *et al.* found that the product spectrum sensitively depends on the structure of the added pyridinium cation. For example, 1-(4-tolyl)pyridinium (T-Pyr) increases the Faradaic efficiency of C≥2 products to ≈80% (compared to ≈25% observed for unmodified Cu/electrolyte interface). By contrast, in the presence of 1-(4-pyridyl)pyridinium (P-Pyr), hydrogen is the major product. Although it has been shown that thin films derived from the reduced cation species form on the surface of Cu electrode, the mechanisms of how product selectivity is altered remain poorly understood. To further improve the selectivity of CO2 reduction, mechanistic insights are essential. Herein, using surface enhanced infrared spectroscopy (SEIRS) during the electroreduction of CO2, we reveal the differential impact of T-Pyr and P-Pyr on the properties of the Cu/electrolyte contact. We find that under reduction conditions both cations form thin films that are composed of the reduced dimers of the respective cation. In the presence of T-Pyr, we observe a substantial build-up of solution-phase carbonate at the interface. By contrast, no such increase is observed at the bare Cu and P-Pyr-modified interfaces. These observations demonstrate that, in the presence of T-Pyr, the local pH in the vicinity of the electrode measurably increases. Because a high local pH is known to change the selectivity towards C≥2 products, our measurements suggest that the higher local pH in the presence of T-Pyr is the underlying mechanism of the selectivity changes (compared to bare Cu). We propose that the T-Pyr films impose mass transport limitations that give rise to the observed high local pH. In addition, we find that in the presence of P-Pyr, the CO stretch frequency of surface adsorbed CO is significantly red-shifted by several tens of wavenumbers (with respect to the frequencies observed at the unmodified and T-Pyr-modified electrodes). This observation suggests that that the CO adsorption on Cu is negatively impacted by the presence of this additive, explaining the poor selectivity for hydrocarbons in its presence. We will discuss the implications of these findings for the design of catalytic interfaces with organic thin films.

**11:45 AM EN06.09.11**

*Continuous Production of Pure Liquid Fuel Solutions via Electrocatalytic CO2 Reduction Using Solid-Electrolyte Devices*  
*Haotian Wang,* Rice University, United States

Electrocatalytic CO2 reduction is often carried out in a solution electrolyte such as KHCO3 (aq) for ion conduction. Therefore, liquid products that form are in a mixture with the dissolved salts, requiring energy-intensive downstream separation. Here we report continuous electrocatalytic conversion of CO2 to pure liquid fuel solutions in cells that utilize solid electrolytes, where electrochemically generated cations and anions are combined to form pure product solutions without mixing with other ions. Using a HCOOH-selective (Faradaic efficiencies > 90%) and easily-scaled catalyst at the cathode, we demonstrate production of pure HCOOH solutions with concentrations up to 12 M. We
also show 100-hour continuous and stable generation of 0.1 M HCOOH with negligible degradation in selectivity and activity.

**SESSION EN06.10: Electrocatalysis II**

**PdPt Alloys for Synergistic CO2 Reduction with Microorganisms—Lessons for Catalyst Development and Integration of Electrochemical and Biological Catalysts**
Andrew B. Wong1,2, Frauke Kracke1, Joseph Gauthier3, Alan Landers1,2, Drew Higgins1,2, Antaeres Antoniuk-Pablant1, Christopher Hahn2, Karen Chan1, Alfred Spormann1,1 and Thomas F. Jaramillo1,2; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States; 3Technical University of Denmark, Denmark

The development of the next generation technologies for CO2 reductions benefits from investigating a wide range of approaches in order to move catalytic CO2 reduction towards a path to commercialization. This presentation focuses on lessons learned from the development of a novel PdPt bimetallic catalyst with a ‘nanoclam’ morphology for electrocatalytic CO2 reduction. This presentation will be divided into two parts: study of the electrochemical properties of this catalysts and efforts to use this catalyst synergistically with microorganisms to achieve high selectivity to a single multi-electron reduction product.

In terms of catalyst development, the PdPt nanoclams have a unique tapered morphology that combines high surface area with exposure of numerous undercoordinated sites for CO2 reduction with activity exceeding that of either Pd or Pt for CO2 reduction to formate at - 0.2 V vs RHE. In comparison with bulk Pd, PdPt, and Pt systems, we find that the interplay of multiple trends affects the activity:

1. The PdPt alloy composition offers improved activity by disfavoring hydride intercalation into the lattice
2. The incorporation of Pt affects increases the faradaic efficiency for HER over formate production
3. The nanostructured morphology appears to increase the faradaic efficiency for formate production over HER

This PdPt nanoclam catalyst is uniquely suited to integration with microorganisms owing to its high activity for the formation of 2-electron products from CO2 reduction at a mild overpotential of ~ 0.2 V vs RHE as well as reduced deactivation from CO poisoning. Thus, we have developed a hybrid electrochemical-biological CO2 reduction system in which formate and hydrogen are produced through electrochemical CO2 reduction by PdPt nanoclams. These products are metabolized by methanogens in combination with CO2 to yield ~100% faradaic efficiency to methane. The integration of microbial communities with these nanostructured PdPt catalysts has the potential to combine the best-of-both-worlds from electrochemical and biological systems to achieve a regenerative catalytic system with high-selectivity, high activity, and low overpotential.

**Single-Source Molecular Precursor Route to Metal Phosphide Nanoparticles and Their Evaluation as Electrocatalysts for Energy Conversion Reactions**
Courtney A. Downes, Kurt M. Van Allsburg, Anne E. Harman-Ware, Renee Happs, Frederick G. Baddour, Daniel A. Ruddy, Susan E. Habas, Jack R. Ferrell and Joshua A. Schaidle; National Renewable Energy Laboratory, United States

The utilization of renewable energy sources to drive electrochemical transformations that allow for the storage of energy in chemical bonds is important for the realization of a more sustainable energy infrastructure. The conversion of abundant small molecules into fuels and/or high-value chemicals driven by renewable electrons is a promising strategy to reduce the reliance on traditional fossil fuels in the transportation and industrial sectors, provide liquid energy carriers for energy storage, and improve grid management. To selectively promote these difficult conversions, electrocatalysts that operate at high rates and efficiencies and low overpotentials are needed. Nanoparticle metal phosphides have emerged as a promising class of electrocatalysts for a variety of energy
conversion reactions. Significant advances in the solution phase synthesis of nanomaterials for energy conversion applications have enabled a high level of control over the size, shape, and composition of nanostructured catalysts, which has revealed the importance of these properties on the observed electrocatalytic performance. In this work, we present a novel and facile approach utilizing air-stable and inexpensive metal triphenylphosphine complexes as single-source molecular precursors to access phase-pure metal phosphide nanoparticles that have controlled stoichiometry, size, and shape. The metal phosphide nanoparticles are evaluated as electrocatalysts for several energy converting reactions and important performance metrics, i.e. faradaic efficiency, overpotential, and product selectivity, are discussed.

2:00 PM EN06.10.03
Multi-Component Electrocatalysts for CO₂ Valorization beyond Conventional Reactivity Yueshen Wu¹,¹, Xu Lu¹,¹, Xiaolei Yuan² and Hailiang Wang¹,¹; ¹Yale University, United States; ²Soochow University, China

Electrochemical CO₂ reduction reactions promise the interconversion of carbon emissions to fuels and value-added chemicals with renewable electricity. Exploration of multi-component electrocatalysts with unconventional reactivity (e.g. uncommon mechanistic pathway, bifunctionality or new product) is not only scientifically interesting, but could also lead to new device-level functionality. As a case in point, we report a new Pb-Pd alloy system for CO₂-to-formate interconversion that enables controllable utilization of alternative energy by integrating the functions of a CO₂ electrolyzer, a liquid fuel container and a fuel cell in one device. The alloy system reversibly restructures its phase, composition, and morphology and thus alters its catalytic properties under controlled electrochemical conditions. Under cathodic conditions, the catalyst is relatively Pb-rich and is active for CO₂-to-formate conversion over a wide potential range; under anodic conditions, it becomes relatively Pd-rich and gains stable catalytic activity for formate-to-CO₂ conversion. The bifunctional activity and superior durability of our Pb-Pd catalyst leads to the first proof-of-concept demonstration of an electrochemical cell that can switch between the CO₂ electrolyzer/formate fuel cell modes with stable operation for twelve days.

Design Considerations for Applied Electrochemical Carbon Dioxide Conversion Catalysts Stafford W. Sheehan; The Air Company, United States

Approaches to make fuel and fine chemicals from carbon dioxide, water, and renewable electricity are being widely researched. One advantage of technologies that can produce chemicals in this manner is their potential for on-site production. This is a key value proposition currently being realized by companies that sell on-site electrochemical hydrogen generators. Translating this value proposition and design feature of water electrolyzers for on-site production of chemicals such as carbon monoxide, formic acid, ethylene, and ethanol requires understanding the unit economics and early-stage markets for small-scale carbon dioxide conversion systems. With an understanding of what an integrated electrochemical carbon dioxide conversion system looks like, specifically capital requirements and balance of plant, the metrics required for carbon dioxide conversion catalysts can be determined. Starting with outlining the real-world requirements for carbon dioxide conversion systems, we will discuss the important design considerations, metrics, and cost factors to define targets for heterogeneous and homogeneous catalysts for carbon dioxide conversion.

Towards the Efficient Electrosynthesis of Hydrogen Peroxide and Ammonia on Solid Surfaces Ifan E. Stephens; Imperial College London, United Kingdom

Electrochemical synthesis methods can provide sustainable routes to our most coveted chemicals. In this contribution, I will discuss our recent progress in the heterogeneous electrocatalysis of H₂O₂ and NH₃ production. Both chemicals are currently synthesised in enormous quantities, in large centralised reactors, far from the point-of-consumption. The logistical and safety challenges intrinsic to the transportation of these chemicals set them beyond the reach of many end users. In contrast, their electrochemical synthesis is far more attractive.

Efficient electrochemical H₂O₂ production requires a catalyst that can steer the reaction away from the formation of the most thermodynamically stable product, H₂O. To this end, porphyrin like structures offer advantages over pure
metal structures by lieu of their isolated reactive sites. We emulated the reactivity of porphyrins by producing mercury-based alloys, which demonstrated unprecedented selectivity, activity and stability.1,2 I will provide an overview of the factors controlling H2O2 production, focussing on the role of (i) catalyst structure at the atomic scale (ii) electrode mesostructure and (iii) electrolyte pH. I will also compare results from model rotating ring disk electrode to tests in real electrolytic devices.3

Current ammonia production via the Haber Bosch process requires high pressures, high temperatures and consumes >1% of our current fossil fuel production. To the contrary, nitrogenase in nature catalyses N2 reduction at room temperature and atmospheric pressures. At present, sold electrodes are rather inactive and unselective. The translation of the activity and selectivity of nitrogenase to a solid inorganic surface would enable the efficient on-site on demand synthesis of ammonia, powered by renewable electricity.

While we have made huge progress in the electrocatalysis of H2O2 production, there remains much to be learnt about N2 electroreduction. We recently used quantitative isotopic labelling experiments to provide unequivocal proof that Li-based electrodes are able to reduce N2 to NH3 in non-aqueous electrolytes. Our work provides a solid foundation for further progress, and enables scientists to distinguish false positives from true breakthroughs. Nonetheless, the efficiency we reported is rather low, i.e. there is still ample room for improvement. Drawing insight from the nitrogenase enzyme, I will discuss different avenues towards more efficient N2 reduction.

3:45 PM EN06.10.06
**Lithium-Mediated Nitrogen Reduction to Ammonia at Ambient Conditions** Karthish Manthiram; Massachusetts Institute of Technology, United States

The Haber Bosch process has provided a large-scale method of synthesizing ammonia for a century. The large carbon footprint and process conditions which limit modularity have led to new efforts to uncover routes through which ammonia can be produced at ambient conditions using potential. Lithium-mediated routes have emerged as a set of methods which can lead to high selectivities for ammonia synthesis. We are particularly interested in molecular-level understanding of the kinetics of the cathodic reaction through which the nitrogen triple bond is broken and subsequent nitrogen-hydrogen bonds are formed. We have uncovered the reaction network through which ammonia is produced in competition with hydrogen. Our work has shown the importance of transport in controlling this reaction, providing critical insights that have led to high rates of ammonia synthesis and a path towards future increases in both rates and selectivities.

4:00 PM EN06.10.07
**Bioelectrochemical TiN|FDH Catalyst for CO2 Reduction to HCOOH** Federica Arena1,2, Giorgio Giuffredi1,2, Stefano Donini1, Emilio Parisini1 and Fabio Di Fonzo1; 1Istituto Italiano di Tecnologia, Italy; 2Politecnico di Milano, Italy

Among the many strategies proposed to convert generated CO2 into value-added chemicals and energy carriers, its electrochemical conversion using bioelectrochemical systems (BES)1 is extremely promising. The advantage of this new technology lies in the possibility of exploiting the enzyme properties catalysing the reduction reaction with a high selectivity and specificity toward products with a low overpotential applied, overcoming the limited selectivity problem that affects the usually-employed metallic electrocatalysts for CO2 reduction.
In this work, we present a novel BES, where the NAD-dependent enzyme Formate Dehydrogenase (FDH) from Thiobacillus sp. KNK65MA [2] is expressed by heterologous production in E. coli BL21 (DE3) and deposited on a nanostructured mesoporous support of Titanium Nitride (TiN) realized by Pulsed Laser Deposition. Thanks to PLD, we can realize a nanostructured support with high surface area and tree-like morphology. By optimizing the synthesis parameters, it is possible to obtain a nanostructured, hierarchical support that maximizes the available surface area for catalyst absorption, thanks to its BET area of 169 m² g⁻¹, and enhances the bio-interface between enzyme and inorganic electrode by exposing a high density of binding sites for the FDH. We quantify the amount of immobilized enzymatic catalyst on the nanostructure through standard enzymatic assays, demonstrating that the nanostructuration of the TiN support increases the surface area available for enzyme immobilization, achieving a maximum enzyme adsorption of 59 µg cm⁻² for the BES. The TiN support is firstly characterized electrochemically, to verify its mechanical and chemical stability in the electrolyte solution. Subsequently, the enzymatic electrosynthesis of formic acid from CO₂ is investigated at different applied potentials, showing a productivity for formic acid that ranges from 1.5 to 3.7 mmol mg⁻¹enzyme h⁻¹ according to the applied overpotentials. Finally, post-catalysis characterization of the hybrid system shows that the amorphous nanostructure does not undergo any important modifications in its morphology and composition, thus demonstrating the mechanical stability of the TiN scaffold.

This performance, which is unparalleled in previous studies involving enzymes of the FDH family immobilized on inorganic supports, stems from a combination of are the best for inorganic support-immobilized enzymes of the FDH family, achieved thanks to the high reducing activity of TsFDH and the high contact area offered by the nanostructured TiN support, and demonstrates the feasibility and as well as the potential for a biotechnological device in terms of featuring product specificity and stability.

Creating Renewable Fuels—Spectroscopy and Energetics of CO₂ Electrolysis Xueli Zheng and Yi Cui; Stanford University, United States

CO₂ electrolysis into value-added fuels represents a renewable-electricity-powered strategy to reduce today’s dependence on conventional fossil fuels, mitigating net CO₂ emissions. However, the sluggish electroreduction of CO₂ (CO₂RR) and water oxidation reaction (WOR) limit the performance for CO₂ electrolysis. In this talk, I will describe my research efforts to develop, understand, and eventually design new catalysts for CO₂RR and WOR using computational materials science, in situ/ex situ synchrotron X-ray spectroscopies, and advances in materials chemistry. First, I will report a concept to modulate electronic structures of active sites for CO₂RR by incorporating the third element in an intimately integrated fashion. Specifically, guided by theoretical predications, we synthesized the designed CuSn₃ alloy and sulfur-modulated-Sn catalysts, and found they selectively produced formate from CO₂RR at low overpotentials. Next, I will describe the development of a room temperature sol-gel technology to produce atomically dispersed metal oxy-hydroxides with high WOR activity. Herein, we showed the gelled FeCoW and NiCoFeP oxy-hydroxide materials has potential industrial applications. In situ/Ex situ X-ray absorption and computational studies, taken together, reveal that the enhanced energetics for CO₂RR and WOR resulted from the ready promotion of favorable local coordination environments and electronic structures.

8:30 AM *EN07.01.01
HydroGEN—A Consortium Working on Efficient and Advance Water Splitting Materials (AWSM) Huven N. Dinh1, Katie Randolph2, Adam Z. Weber1, Tadashi Ogitsu4, Anthony H. McDaniel5, Richard Boardman6, Elise Fox7, James Vickers2, David Peterson2, Eric L. Miller2 and Ned Stetson2; 1National Renewable Energy Laboratory, United States; 2Department of Energy, United States; 3Lawrence Berkeley National Laboratory, United States; 4Lawrence Livermore National Laboratory, United States; 5Sandia National Laboratories, United States; 6Idaho National Laboratory, United States; 7Savanah River National Laboratory, United States

HydroGEN (https://www.h2awsm.org/) Energy Materials Network (EMN) is an U.S. Department of Energy (DOE) EERE Fuel Cell Technologies Office (FCTO)-funded consortium that aims to accelerate the discovery and development of advanced water splitting materials (AWSM) for sustainable, large-scale hydrogen production, and to more effectively enable the widespread commercialization of hydrogen and fuel cell technologies. This is in line with the H2@Scale initiative (https://www.energy.gov/eere/fuelcells/h2-scale), with the goal to meet U.S. DOE’s ultimate production cost target of $2/kg H2. HydroGEN EMN is a six national laboratories consortium comprises National Renewable Energy Laboratory (NREL) - lead, Lawrence Berkeley National Laboratory (LBNL), Sandia National Laboratory (SNL), Lawrence Livermore National Laboratory (LLNL), Idaho National Laboratory (INL), and Savannah River National Laboratory (SRNL).

The HydroGEN Consortium offers more than 80 materials capabilities nodes to help address RD&D challenges in efficiency, durability and cost. The capabilities span computational tools and modeling, materials synthesis, characterization, process manufacturing and scale-up, and analysis. Detailed descriptions of all the HydroGEN nodes are available in a searchable format on the HydroGEN website (https://www.h2awsm.org/capabilities), including information such as the host National Lab, the capability experts, and a synopsis of the node’s unique aspects and capability bounds. By design, the nodes are cross-cutting, and any given node may be useful for one or several advanced water splitting (AWS) technologies. Leveraging the HydroGEN Consortium’s leading technical experts and extensive collection of unique capabilities is expected to help advance all the advance water splitting technologies, including advanced electrolysis (low and high temperature), photoelectrochemical (PEC) and solar thermochemical (STCH) routes which includes hybridized thermochemical and electrolysis approaches to water...
This presentation will provide an overview of the HydroGEN EMN consortium and highlight some water splitting materials projects. These highlights will include theory and experimental approaches for understanding and characterizing water splitting materials. HydroGEN looks forward to growing its community of industry, university and laboratory collaborators that can partner with member-laboratory experts by way of CRADAs and potential future FOAs.

Monolayer MoS2 with Better Hydrogen Evolution Catalysis Than Pt
Guoqing Li; North Carolina State University, United States

The development of low-cost high-performance catalysts for hydrogen production via water splitting stands as a key step towards addressing modern energy and environment challenges. We demonstrate a strategy to enable earth-abundant MoS2—a better catalyst than Pt, the best catalyst to date but too precious to be practically useful, for the hydrogen evolution reaction (HER) of water. The strategy is developed by leveraging on new fundamental understanding for the HER catalysis of MoS2. We find that substrates can affect the catalytic activity of MoS2 by forming an interfacial tunneling barrier with MoS2 and also modifying the chemical nature of MoS2 through charge transfer. As a result, we achieve excellent catalytic performance at the monolayer MoS2 films with optimal densities (7-10%) of sulfur vacancy by using substrates that are able to form low interfacial tunneling barriers and transfer electrons to MoS2, such as Ti. The catalytic performance of monolayer MoS2 films may be further improved by crumpling the films on Ti-coated flexible substrates because the crumpling gives rise to compressive strain in MoS2 that may lower the Tafel slope although generates no obvious effect on the exchange current density. The better-than-Pt performance of MoS2 is remarkably stable with no degradation after continuous reaction for more than two months. This work provides a viable solution for the challenge of hydrogen evolution from water and paves the way towards the utilization of hydrogen energy.

9:15 AM EN07.01.03
Highly Efficient Overall Water Splitting in Acid with Metal Nanosheets
Dongshuang Wu, Kohei Kusada and Hiroshi Kitagawa; Kyoto University, Japan

Water is the only available fossil-free source of hydrogen. Splitting water electrochemically is among the most commonly used techniques, however, it accounts for only 4% of global hydrogen production, predominately because of the high cost and low performance of catalysts promoting the oxygen evolution reaction (OER) [1]. Currently, only Ir oxides show moderate stability for OER in acid but still require high overpotentials. In contrast, Ru is the most active OER catalyst and is nearly 5–16 times cheaper than Ir these five years, however, Ru has a serious degradation problem [2]. Here, we report a highly efficient catalyst in acid, that is, solid-solution RuIr nanosized-coral (RuIr-NC) consisting of 3 nm-thick sheets with only 6 at% Ir. Among OER catalysts, RuIr-NC shows the highest mass/intrinsic activity and unprecedented stability (Figure 1). An electrolyzer using RuIr-NC as both electrodes can reach 10 mA cm\(^{-2}\) at 1.485 V for 120 h without noticeable degradation, which outperforms known systems. This electrolyzer is also significantly less expensive than the commercial IrOx and Pt system. Operando spectroscopy and atomic-resolution electron spectroscopy indicate the high-performance results from the ability of the unique facets of RuIr-NC to resist the formation of dissolvable metal oxides and to transform ephemeral Ru into a long-lived catalyst.

Importance of Interfacial Band Structure between the Substrate and Mn3O4 Nanocatalysts During Electrochemical Water Oxidation
Moo Young Lee, Heonjin Ha and Ki Tae Nam; Seoul National University, Korea (the Republic of)

Inspired from the Mn4CaO5 cluster in natural Photosystem II, attempts to replace conventional precious metal based electrocatalysts for oxygen evolution reaction (OER) with Mn-based ones have been intensively conducted. Recently, we successfully synthesized uniform and assembled Mn3O4 nanoparticles (NPs) with superior OER activity to conventional bulk Mn oxides, and revealed highly stabilized Mn(III) species on the surface and different OER mechanism from the conventional ones. Using our unique NPs as a structural platform, we have been now conducting the detailed mechanistic investigations such as how the surface of our NPs changes and how the electrons transfer throughout our NPs during OER.
In this regard, we strongly believe that understanding and controlling the charge transfer during OER is not only helpful in comprehending the reaction mechanism but also important in establishing rational strategies of catalysts design. From the previous literature, we think that the overall charge transfer processes in the film-type OER catalysts can be categorized into three transfer pathways: the electrons should transfer through (i) electrolyte-catalysts interface, (ii) inner catalysts, and (iii) catalysts-substrate interface. Among the three pathways, the importance of the charge transfer at the catalysts-substrate interface has not been investigated, that is, there is a lack of interpretation on the interfacial effects between the catalysts and the substrate.

In this study, we discovered the importance of interfacial band structure between the substrate and Mn$_3$O$_4$ NPs for OER, which has not considered in electrocatalytic systems so far. We designed the band structure model of the catalysts-substrate interface and explained the substrate dependent OER activity of Mn$_3$O$_4$ NPs. Moreover, we improved the OER activity of Mn$_3$O$_4$ NPs by introducing the metal interlayer with a proper band structure. We further investigated substrate dependent impedance analysis, resulting in the same tendency to the expectation from our interfacial band structure model.

Quantum-Mechanical Embedding Methods for Surface Catalysis Florian Libisch; Technische Universität Wien, Austria

The charge transfer reactions upon dissociative absorption of O2 on metal surfaces is critical for many catalytic processes, yet poses a challenging problem for state-of-the-art ab-initio theoretical modeling. For example, the experimentally observed activation barrier for O2 dissociation on Al (111) is not captured by conventional density functional theory. However, accurate wavefunction-based methods that are well suited to handle the multireference character of the charge transfer state are ill suited to describe extended metal surfaces. Embedding methods offer a way forward, by combining highly accurate wave-function based approaches at the absorption site with an environment described by density functional theory. In the case of O2 on Al(111), such an approach naturally yields an adiabatic barrier [1]. I review our recent advances and challenges in solving catalytic problems using embedding methods, including the build-up of six-dimensional potential energy surface (PES) suited for quasi-classical trajectory calculations [2], projection-based approaches that enable freeze-thaw cycles, and the extension to high-level methods such as Quantum Monte Carlo or Coupled Cluster that can treat periodic boundary conditions.

10:45 AM EN07.01.06
Stacks of Highly-Ordered Nanowire Arrays Achieve Ultra-High Mass Activity for Oxygen Evolution Reaction and Efficient Transportation of Evolved Oxygen Ye Ji Kim and Yeon Sik Jung; KAIST, Korea (the Republic of)

Although hydrogen is the most abundant element in the universe and can be used as a fuel with zero carbon emissions, its economic and stable production still remain as an important issue. One of the promising routes of H$_2$ production is polymer electrolyte membrane water electrolysis (PEMWE), which require noble metal electrocatalysts (e.g., Pt, Ir, Ru) for efficient oxygen evolution reaction (OER). However, to reduce the high capital expense resulting from the high loading of noble metal electrocatalysts, their electrochemically active surface area (ECSA) and specific activity need to be maximized. Here, we suggest woodpile-structured Ir electrocatalysts, consisting of 3-dimensional (3D) stacks of highly-ordered nanowire building blocks, as a novel catalyst structure to markedly improve mass activity compared to conventional nanoparticle-based catalysts. We show that the 3D Ir nanowire stack can be controllably fabricated via solvent-assisted nanotransfer printing (S-nTP). The woodpile-structured Ir electrocatalysts fulfill simultaneously (1) a large electrochemically active surface area, (2) long-range connectivity of building blocks for high electronic conductivity, (3) well-defined pore structures for highly efficient transport of evolved gas species, and (4) extensive geometric controllability for maximization of catalytic performances. With these aspects, Woodpile-structured Ir thin film achieves a high mass activity of 3.7 A/mg (at 1.5 V vs RHE) in half cell and 140 A/mg (at 1.8 V) in single cell, which is ~36 times higher than that of the state-of-the-art commercial Ir nanoparticle catalyst. Based on the advantages from structural engineering, OER mass activity over 80% of its initial values was
achieved during more than 500 repeating chronoamperometry cycles. Furthermore, in order to clarify the substantially improved surface specific activity and mass activity of OER electrode, we performed systematic analysis on the effect of a facile escape of evolved O2 gas bubbles with a systematic control of the 3D geometry. Although there is no experimental demonstration, previous studies suggested possibility for increase in the specific activity due to the facilitated mass transport. Our S-nTP technology enables extensive control of the 3D geometry (e.g. parallel vs. perpendicular stacks) without changing other factors related to catalytic activities such as physiochemical characteristics and ECSA. Systematic tuning of 3D geometry and nanowire building blocks revealed that O2 bubble transport is the key limiting step in the OER catalysts, providing practical design rules for more efficient OER electrode in PEMWE.

11:00 AM EN07.01.07
Zipping Up Ni-Fe Hydroxide-Coated Hematite Nanowires—A Citrate-Chelating Strategy Promotes Photoelectrochemical Water Splitting
Tianyu Liu1, Mingyang Li2, Yexiang Tong2 and Yat Li1; 1University of California, Santa Cruz, United States; 2Sun Yat-sen University, China

Oxygen evolution reaction (OER) catalyst coatings improve the photoelectrochemical (PEC) water splitting performance of photoanodes via facilitating charge transfer across electrode/electrolyte interfaces and passivating surface hole-trap states. Unfortunately, the occurrence of interface segregation between photoanodes and their OER coatings often impedes fast charge transport and therefore, hinders the performance enhancement. This presentation will introduce a citrate-assisted strategy to mitigate the challenge on the interface quality. We discover that sodium citrate, a molecular linker chelating both hematite (α-Fe2O3) nanowires and Ni-Fe hydroxide [NiFe(OH)x] OER catalyst overlayers, results in seamless, conformal, and pinhole-free coatings. Such the high-quality photoanode/OER catalyst interfaces enable the hematite nanowire photoanode to achieve an early turn-on potential of 0.53 V vs. reversible hydrogen electrode, corresponding to an ultralow OER overpotential of 0.13 V. The turn-on potential is approximately 50% lower than those of the state-of-the-art hematite photoanodes encapsulated in transition-metal-oxide OER catalysts. The overall characterization results on morphologies and photoelectrochemical activities presented in this presentation will not only provide guidelines to experimentally design and prepare high-performance photoelectrodes, but also inspire theoretical multiscale models to fully reveal the benefits of molecule-zipped electrode/catalyst interfaces towards efficient and cost-effective water splitting.

11:15 AM EN07.01.08
Solution-Based Growth of ZnO@ZIF-8 Core-Shell Nanowires-MOF for Efficient Photoelectrochemical Water Splitting
Alejandro G. Galan, Andrew Gallant, Del Atkinson and Dagou Zeze; Durham University, United Kingdom

The search for new materials functionalities has led to development of many different types of composite materials that bring enhanced benefits from the synthetic combination of different materials properties arising from their chemical and structural characteristics.

The evolution of nanomaterials over the last few decades has prompted widespread research on their integration into a range of applications resulting from their outstanding physical, optical and electric properties. Nanowires (NWs) have been at forefront of these developments due to the variety of NW materials, especially semiconductors, highly controllable growth coupled with the large surface to volume ratio and the high aspect ratio. ZnO in particular is highly researched due to its wide band gap (3.37 eV) and high exciton binding energy (60 meV) that confers interesting piezoelectric and optoelectronic properties. In recent years, research interest in metal-organic frameworks (MOFs) has developed rapidly. MOFs are a zeolite-like nanomaterial that have been extensively studied due to their remarkably high surface area, enabling catalytic and gas storage properties. MOFs are reticular nanomaterials formed by transition metal cations coordinated by multidentate organic linkers. This combination results in a crystalline material with a flexible structure that can be tuned accordingly to the organic linker chosen. Among the many existent MOF families, the zeolitic imidazolate frameworks (ZIF) are one of the most researched because of their exceptional thermal and chemical stability. ZIF-8 is a standout MOF comprised of zinc as transition metal nuclei and imidazolate linkers as the coordinating agent.

Here, these different forms of nanoscale materials prompted the idea for synergetic combination to create novel nanocomposite materials that exploit the individual outstanding properties, in this case for ultimate application in hydrogen production. In this work, the idea is the realisation of the integration of ZnO NWs and ZIF-8 to form a
core-shell structure in which ZnO is the core and ZIF-8 is the shell around it (ZnO@ZIF-8) via a low-cost and fast production processes. The ZnO NWs are grown through a typically used chemical bath deposition method while the ZIF-8 shell is grown by surface conversion of the NWs using spin coating of a methanol solution containing the imidazole linker. The cheap and easy route to grow the core-shell structure through this process is remarkable, especially considering that the most commonly used alternative is a hydrothermal growth that requires the use of a pressure vessel, water/dimethylformamide mixtures and long reaction times. In our case, only few droplets of a methanol solution are required to obtain comparable results.

This work presents the structural analysis and the optoelectronic characterisation of these nanocomposite materials and aims to show the first results using ZnO@ZIF-8 structures as a photoanode for the photoelectrocatalytic (PEC) water splitting of water. Electron microscopy and x-ray analysis are used to study the structure and voltammetry and optical methods are sued to study the electronic properties. The effect of different coating conditions are compared to demonstrate the control over the growth of the MOF shell in relation to thickness and the long-range homogeneity. It is shown that the shell thickness is a critical factor that can directly influence the performance of the photoanode by controlling the electrolyte diffusion time to the ZnO NW core. The effectiveness of the core-shell structure as photoanode is compared to as-grown ZnO NWs. The PEC tests also show that the presence of the shell in the core-shell structure passivates the surface states of the ZnO core, improving its stability over time, and protecting it from photocorrosion. This in turn results in an improved photocurrent density and better durability, meaning that the shell improves both the performance and lifetime of the photoanode.

11:30 AM EN07.01.09
Coupling Interface Constructions of 2D Nanosheet Arrays/FeNi Heterostructures for Efficient Electrochemical Water Splitting Qian Xiang, Yi Wu, Wenlong Chen, Fan Li, Tao Deng and Jianbo Wu; Shanghai Jiao Tong University, China

Water splitting is considered as a pollution-free and efficient solution to produce hydrogen energy. Low-cost and efficient electrocatalysts for the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER) are needed. Recently, chemical vapor deposition is used as an effective approach to gain high-quality MoS2 nanosheets (NSs), which possess excellent performance for water splitting comparable to platinum. Herein, MoS2 NSs grown vertically on FeNi substrates are obtained with in situ growth of Fe5Ni4S8 (FNS) at the interface during the synthesis of MoS2. The synthesized MoS2/FNS/FeNi foam exhibits only 120 mV at 10 mA cm−2 for HER and exceptionally low overpotential of 204 mV to attain the same current density for OER. Density functional theory calculations further reveal that the constructed coupling interface between MoS2 and FNS facilitates the absorption of H atoms and OH groups, consequently enhancing the performances of HER and OER. Layered double hydroxide (LDH) has also been widely applied to electrocatalysis for water splitting, especially toward the OER, owing to its flexible layered structure and multifunctionality. Herein, FeNi LDH nanosheet arrays are directly synthesized on various metal foils by a facile hydrothermal method. Compared with single Fe or Ni substrates, the obtained FeNi LDH/FeNi foil exhibited an ultrasmall onset overpotential of ~90 mV, high catalytic activity (overpotential of 130 mV @ 10 mA/cm²), and durable stability in 0.1 M KOH electrolyte. We also demonstrate, by utilizing density functional theory calculations, that the growth of the hydroxide interfacial layer between LDH and FeNi foil makes the LDH possess more favorable adsorption to the OH intermediate during OER than the pure LDH. This reveals that the vertical FeNi LDH arrays on the FeNi alloy substrate are prone to be an efficient catalyst toward water splitting. These newly developed synthesis of vertical grown nanosheets arrays on the FeNi substrates with low overpotentials and high performance strongly demonstrated the potential applications of 2D nanosheet arrays electrode for electrocatalysis, especially for high access of ion or gas molecule as well as excellent electron and ion conductivity. The findings in this work could impact the design and fabrication of 2D nanosheet arrays heterostructures electrodes for the application of catalysis, environmental science, and surface reaction.

Identifying the Limiting Processes at Electrochemical Interfaces—From Experimental Data to Multiscale Modeling
Kiran George, Matthijs van Berkel, Xueqing Zhang, Vivek Sinha, Rochan Sinha, Yihui Zhao, Aafke Bronneberg and Anja Bieberle-Hütter; DIFFER, Netherlands

Electrochemical interfaces are the heart of many alternative, sustainable energy applications. They determine the efficiency and the overall performance. However, in most cases we do not know which processes take place at the interface and which processes are limiting the performance. Experimental electrochemical measurement methods cannot measure mechanisms directly; measuring intermediate species is rather challenging [1,2]. Analysis methods, such as equivalent circuit fitting for electrochemical impedance data, do not allow to link the electrochemistry directly to the measured data. Modeling of these interfaces is a multiscale challenge as discussed in [3] and is still in its infancy.

In this talk, we introduce the audience to this dilemma with a case study on water oxidation in photo-electrochemical water splitting. We will discuss our recent experimental results on metal oxide (Fe₂O₃, WO₃) – electrolyte interfaces [4-7]; in particular, we will discuss electrochemical and operando infrared spectroscopy data in the field of water splitting. Based on these studies, we will show the limitations of experimental studies in analyzing the limiting processes at the interface. We then introduce our new multiscale modeling approach that allows simulating electrochemical data directly from an electrochemical model [8,9]. We use a combination of atomistic and microkinetic modeling. We will show our approach step by step and will present simulated, electrochemical data, such as current-voltage curves and electrochemical impedance spectra. In addition, we will show surface coverage plots which are experimentally not available and will compare the simulated, electrochemical data to the experimental data. Furthermore, we will introduce kinetic Monte Carlo simulations to complement and extend the current multi-scale modeling approach. Our new multiscale modeling approach is generic and can be used for other electrochemical interfaces, such as those in fuel cells, electrolyzers, or batteries.

2:00 PM EN07.02.02
The Role of Overlayers on Water Splitting Catalysis
Maytal Caspary Toroker; Technion-Israel Institute of Technology, Israel

Understanding the role of an overlayer material on a catalyst is crucial for improving catalytic activity. hematite (α-Fe₂O₃) is a widely studied catalyst commonly used for solar water splitting. It was found experimentally that the water splitting efficiency with α-Fe₂O₃ was enhanced by deposition of an α-Al₂O₃ overlayer. In order to understand the origin of this improvement, we perform first-principles calculations with density functional theory + U on the α-Fe₂O₃(0001) surface with an α-Al₂O₃surface overlayer. In agreement with experiment, we find that α-Al₂O₃ coverage decreases the overpotential required for water oxidation on α-Fe₂O₃. We explain this improvement through the decrease in the work function of α-Fe₂O₃ upon α-Al₂O₃ coverage that aids in extracting electrons during the water oxidation reaction. We suggest that selecting an overlayer with a smaller work function than that of the catalyst as a strategy for future development of better catalysts.
Anodic Instability of the SrIrO3 Water Splitting Catalyst—In Situ Microscopy and Electrolyte Variation Studies

Andrew Akbashev1,2 and William C. Chueh1,2; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States

Structural instability of highly active oxide catalysts during electrochemical water splitting poses a significant challenge on the way to their implementation. The structural, morphological and electronic changes in materials under oxidizing conditions largely determine the resulting catalyst’s integrity at the solid-electrolyte interface. In some cases, the structural evolution of materials can be driven or accompanied by the dissolution and/or precipitation processes that are controlled by the electrolyte formulation and pH. Providing insight into the degradation mechanisms is crucial for distinguishing and classifying possible pathways and factors affecting the degradation kinetics.

In our work we study strontium iridate (SrIrO3) that, while being among the most active catalysts reported so far, exhibits structural instability during the oxygen evolution reaction. For quantitative analysis of degradation, we use SrIrO3 epitaxial thin films that have an easily characterizable surface with well-defined step terraces. We perform microscopic studies of the degradation process of SrIrO3 via a combination of in situatomic force microscopy (AFM), ex situcharacterization techniques (XPS, XRD, TEM) and variation in the electrolyte composition. In our in situAFM experiments we built a three-electrode flow cell that enables a high flux and efficient replenishing of the electrolyte, which allow us to reach high anodic potentials and reaction currents above those typically used to assess materials stability (over 10 mA/cm²). By enabling a reference height during in situelectrochemical AFM, we track morphological evolution and quantify the dissolution rate of SrIrO3. We demonstrate that the degradation of SrIrO3 catalyst follows different pathways in acidic and basic electrolytes. Furthermore, we found specific electrolyte formulations that can suppress the degradation of SrIrO3 and impede the kinetics of its anodic dissolution.

Structure Predictions in Wet Environments for Ethanol and Water Adsorption on Anatase TiO2 (101) Surfaces

Giuseppe Fisicaro1, Simona Filice1, Silvia Scalese1, Giuseppe Compagnini2, Riccardo Reitano2, Ioannis Deretzis1, Luigi Genovese3, Stefan Goedecker4 and Antonino La Magna1; 1CNR Institute for Microelectronics and Microsystems, Italy; 2Dipartimento di Scienze Chimiche, Università di Catania, Italy; 3Dipartimento di Fisica e Astronomia, Università di Catania, Italy; 4Laboratoire de simulation atomistique (L_Sim), France; 5Department of Physics, University of Basel, Switzerland

Titanium dioxide exhibits superior photocatalytic properties, mainly occurring in liquid environments through molecular adsorptions and dissociations at the solid/liquid interface. The presence of these wet environments is often neglected when performing ab-initio calculations for the interaction between the adsorbed molecules and the TiO2 surface. In this study we consider two solvents, i.e. water and ethanol, and show that the proper inclusion of the wet environment in the methodological scheme is fundamental for obtaining reliable results. Our calculations are based on structure predictions at a density functional theory level for molecules interacting with the anatase TiO2 (101) surface under both vacuum and wet conditions. A soft-sphere implicit solvation model is used to describe the polar character of the two solvents. The integration of ab-initio structure predictions and continuum modelling for the solvent allows to tackle the various scales of a solid/liquid interface with a reduced computational cost. As a result, we find that surface oxygen vacancies become energetically favorable with respect to subsurface vacancies at the solid/liquid interface. Ethanol molecules are able to strongly passivate these vacancies, whereas water molecules only weakly interact with the (101) surface, allowing the coexistence of surface vacancy defects and adsorbed species. Infrared and photoluminescence spectra of anatase nanoparticles exposing predominantly (101) surfaces dispersed in water and ethanol support the predicted molecular-surface interactions, validating the whole computational paradigm. The combined analysis allows for a better interpretation of TiO2 processes in wet environments based on improved computational models with implicit solvation features.

Formation of Polarons—Their Electronic Structures and Effects in Metal-Oxide-Photoelectrocatalysts: α-Fe2O3 and BiVO4

Hori Pada Sarker1, Wolfram Jaegermann2 and Muhammad N. Huda1; 1The University of Texas at Arlington, United States; 2TU Darmstadt, Germany
Production of H₂ from water splitting via photo-electrochemical process is one of the most talked about potential green technologies. The key material for this technology is photo-electro-catalyst. These materials are required to absorb sunlight, excite and transport charge carriers efficiently, and thereby split water molecule at the liquid-semiconductor interface. Metal-oxides are thought to be the most stable materials under the intense interfacial reactive conditions. Despite some of the metal-oxides have near-suitable bandgap, the overall solar to hydrogen generation efficiencies by water splitting are not as high as expected. One of the reasons for this deficient efficiency is attributed to the poor transport properties in metal-oxides, especially in the 3d transition metal-oxides. In this presentation, two representative metal-oxides photo-catalysts will be considered, α-Fe₂O₃ and BiVO₄. Despite being efficient solar absorber materials, these have poor charge transport properties. From detail electronic structure calculations, polaronic states of these oxides will be depicted. In addition, it will be shown that how these polaronic states affect not only the transport properties but also the open circuit voltages, Vₜ. We will also discuss how well these computational results compares with the recent experimental outcome. The work of MNH is supported by National Science Foundation, grant #1609811. Computations were performed on Texas Advanced Computing Center.

Recent Method and Application Advances in Multiscale Characterization of Carrier Transport in Materials for Water Splitting, Such as Cation- and Anion-Doped Bismuth Vanadate: Michel Dupuis¹, Vinawan Pasumarthi¹, Pavan Kumar Behara¹, Tai Feng Liu¹,³ and Can Li¹,³; ¹University at Buffalo, The State University of New York, United States; ²Henan University, China; ³Dalian Institute of Chemical Physics, China

The holy-grail in efficient and cost-effective conversion of solar energy into electrical and chemical energy is solar energy-driven water splitting using semi-conductor-based photo-catalysts. Overall conversion efficiencies of best systems so far are however far from the level needed for practical applications. Viable materials must exhibit good visible light absorption and carrier generation, good carrier transport, and good carrier redox reactivity. This presentation will focus on multiscale modeling of carrier transport in semi-conductors, combining quantum chemical calculations of polaron hopping by Marcus/Holstein theory and kinetic Monte Carlo (KMC) modeling of mesoscale transport. We will highlight recent method developments for cation- and anion-doped BiVO₄.

Relationship between the Photocatalytic Hydrogen Ion Reduction and Charge Carrier Dynamics of Pt/Cd₁₋ₓNxS catalysts: Tayirjan T. Isimjan¹, Partha Maity², Omar A. Mohammed² and Hicham Idriss³; ¹SABIC-CRD at KAUST, Saudi Arabia; ²KAUST, Saudi Arabia; ³SABIC-CRD-KAUST/University College London, Saudi Arabia

The doping induced local impurity brings a significant modification to photocatalytic performance of the semiconductor. Finding the correlation between charge carrier dynamics and catalytic performance of the semiconductors offers useful information both for the fundamental understanding of the catalytic mechanism and the catalyst optimization. Here, the electron transfer during the hydrogen ion reduction reaction in the presence of Pt/CdS doped with Ni²⁺ (Cd₀.₉₈Ni₀.₀₂S) was studied using fs-pump probe transient absorption spectroscopy (TAS) complemented by photocatalytic tests. Cd₀.₉₈Ni₀.₀₂S is composed of both hexagonal and cubic phases with average particles of 7 nm in size; determined from TEM. TAS of Cd₀.₉₈Ni₀.₀₂S in the presence and absence of the hole scavenger (benzyl alcohol) and in the presence and absence of Pt helped to further probe into the origin of the two most pronounced signals in the 400-800 nm range: the ground state bleaching (GSB) at ca. 480 nm and the photo-induced absorption (PIA) at ca. 600 nm. The first is largely linked to electron de-excitation lifetime and the latter to hole lifetime. From the decay kinetics, it was possible to compute for the charge transfer yields (f) from the semiconductor to the Pt metal particles (electron sink) and for hole trapping lifetime in the presence of benzyl alcohol. The rate of the photocatalytic hydrogen production shows a positive relationship with the decay kinetics obtained by fs-pump probe measurements.

Highly Efficient Membrane Electrode Assembly with Less than 10 nm NiFe-Layered Double Hydroxides for Anion Exchange Membrane Water Electrolysis: Hiroyuki Koshikawa, Hideaki Murase, Takao Hayashi, Kosuke Nakajima, Hisanori Mashiko, Seigo Shiraiishi and Yoichiro Tsuji; Panasonic Corporation, Japan
Anion exchange membrane (AEM) water electrolysis is expected to offer a way of converting and storing electrical power generated from renewable energy into hydrogen. However, the development of a membrane electrode assembly (MEA) that are free of noble metals in the catalyst layer and capable of outperforming conventional Pt and Ir-based catalysts, remains a major challenge. Layered double hydroxides (LDHs) are known to exhibit high activity toward oxygen evolution reaction (OER) proceeding at the anode, and increasing the effective surface area by the miniaturization of LDH is a useful strategy to improve OER activity. In the present study, we report a one-pot synthesis of nanometer-sized NiFe-LDH through the application of a spontaneous gelation-deflocculation method and evaluated its electrochemical properties.

Nanometer-sized NiFe-LDH was synthesized by liquid phase reaction in the presence of a chelating agent. The distribution of the LDH particle size was measured by small angle x-ray scattering and the average diameter was calculated to be 7.2 nm, which is less than one tenth of the diameter of conventional LDHs. The chelating agent introduced into the media was thought to increase the concentration of metal hydroxide nuclei and suppress excessive growth of the LDH crystal, resulting in the synthesis of nanometer-sized LDH. NiFe-LDH showed superior OER activity compared to conventional iridium dioxide (IrOx) catalyst in terms of the overpotential required for flowing 10 mA cm\(^{-2}\) (254 mV for NiFe-LDH and 261 mV for IrOx). This overpotential for NiFe-LDH is one of the lowest reported for non-noble metal-based OER electrocatalysts. Notably, an MEA for AEM water electrolysis using NiFe-LDH as an anode catalyst exhibited an energy conversion efficiency of 74.7% in 1 M KOH for flowing 1 A cm\(^{-2}\) at 80 °C. This efficiency is the highest among MEAs implemented with LDH reported to date, and offers a viable replacement for IrOx anode catalyst. Further optimization of the synthesis conditions of our NiFe-LDH and the formation processes of the catalyst layer of the MEA will substantially increase the efficiency.

Semiconductor Photocathodes Modified with Transparent Reduced Graphene Oxide Films Loaded with Molecular Sensitizers and Electrocatalysts for Hydrogen Evolution Molly M. MacInnes, Nicolai Lehnert and Stephen Maldonado; University of Michigan, United States

This presentation will describe thin, smooth reduced graphene oxide (RGO) films that also contain either a dissolved hydrogen evolution reaction (HER) molecular catalyst (cobalt (III) bis[benzenedithiolate]) and/or a molecular chromophore on p-type gallium phosphide (GaP) photocathodes. Molecular electrocatalysts and dyes can be employed heterogeneously by immobilization onto an electrode surface but the mode of attachment is typically specific to the particular electrode type. We have developed a method of depositing thin (~10 nm), adherent graphene oxide films that can physisorb molecular species through π-π interactions. These thin films are deposited on a variety of electrode materials by spin coating graphene oxide suspensions. Immersion of these films in non-aqueous solutions of cobaltocene followed by drying produces flat, highly conductive reduced graphene oxide films that are platforms for the physisorption of molecular species. Electrochemical, photoelectrochemical, and spectroscopic data will be presented that demonstrates the robustness of these films and their ability to be modified with a molecular HER electrocatalyst or with a molecular dye. Additionally, finite-element modelling data will be presented that investigates activities of molecular catalysts immobilized on the outer-most surface as well as intercalated within the RGO film. The utility of these films for sensitization and protection against corrosion processes will be featured.

Highly Flexible and Efficient Photoanodes Using Surface Functionalized Metal-Oxide Nanostructures for PEC Applications Koteeswara Reddy Nandanapalli, Devika Mudusu, Jinkyu Song, Kyung-In Jang and Sungwon Lee; Daegu Gyeongbuk Institute of Science & Technology (DGIST), Korea (the Republic of)

Recent years, the development of flexible devices for various day-to-day applications including energy harvesting devices, medical devices, wearable electronics, energy storage, communications, sensors, has received great attentiveness owing to their affordability, applicability & wearability, light-weight, and conformality [1]. In this direction, we have developed highly flexible and light-weight heterostructures with an overall thickness of ~50 µm by using low-temperature techniques [2]. Surface passivated vertically aligned zinc oxide (ZnO, ~1 µm length) nanostructures with amorphous cobalt-oxide (CoO\(_2\), < 2 nm thickness) have been developed on different electron-collecting layers deposited flexible sheets. The impact of the electron-collecting layer on the morphology and structure of ZnO nanostructures along with their electrical properties has been investigated. Then, the photoelectrochemical water-oxidation performance of the heterostructures along with their chemical stability and durability were studied. Besides these, the influence of multiple bendings on the device performance of the

Integrating Supramolecular Photocatalysts into Photoelectrocatalytic Devices Elizabeth A. Gibson; Newcastle Univ, United Kingdom

Efficient dye-sensitized photocathodes offer new opportunities for converting sunlight into storable energy cheaply and sustainably,[1] We are developing dye-sensitized NiO cathodes for the photo-reduction of carbon dioxide or water to high energy products (solar fuels) using the lessons we have learnt from solar cells.[2] The potential advantage of this strategy is it exploits the selectivity of a molecular catalyst in a robust device. Assembling two photoelectrodes in a tandem configuration (see figure) enables water oxidation at the photoanode to supply electrons to the photocathode to be consumed in the reduction of e.g. H⁺ to H₂. Generating hydrogen on one electrode and oxygen on another enables the two gases to be collected separately. Additionally, by separating the functions of light absorption, charge transport and catalysis between the colloidal semiconductor and molecular components, the activity of each can be optimised, rather than relying on one material to have all the necessary credentials. The electron-transfer dynamics are key to the performance and a major challenge is slowing down charge recombination between the photoreduced dye and the oxidised NiO so that chemistry can take place.[3] Highlights from recent work examining charge-transfer at the interface between NiO and new supramolecular photocatalysts using transient absorption spectroscopy and time-resolved infrared spectroscopy will be presented. The effect of the environment on the kinetics will be discussed. The relationship between the structure, dynamics and performance of the photoelectrocatalytic devices will be summarized.

Artificial Photosynthesis Using Perovskite Materials: A SrSnO₃ Case Study Conor J. Price, Ned T. Taylor, Francis H. Davies, Shane G. Davies and Steven P. Hepplestone; University of Exeter, United Kingdom

Photoelectrolysis offers a mechanism for long term, clean energy storage via hydrogen production. Recently, several perovskites have shown promise for this application [1,2]. Perovskites, ABX₃, are highly customisable, with several options for the A, B and X ions. This results in a large range of tailorable properties, such as the band gap and the relative stability, making them highly suitable for photoelectrolysis. The bulk properties of many perovskites have been explored [2,3]. However, their potential for photoelectrolysis is mainly governed by surfaces, making their study critical.

Using techniques such as density functional theory, we develop a large scale theoretical screening process to tackle
the large range of A, B and X combinations. We can further tailor the surface band structure with aggregates/surface coatings. Here we present the results of this method for a group of stannate perovskites, highlighting a case study perovskite, SrSnO\(_3\). We examine the effect of forming surfaces and the introduction of adsorbants (hydrogen, oxygen and OH groups) onto the surface, taking note of the band alignment with respect to the evolution potentials. These adsorptions allow us to investigate the intermediate energetics of the hydrogen evolution and oxygen evolution, and the overpotentials associated with these reactions. We then conclude with a discussion of how aggregates/surface coatings can be used to tailor the surface properties for more efficient water splitting.

Understanding the Complex of 3d Transition Metal Dopants and Sulfur Vacancies in the Activation of MoS\(_2\) Basal Plane for HER—From Structures to Intrinsic Descriptors Mingjie Liu and Qin Wu; Brookhaven National Laboratory, United States

MoS\(_2\) based materials as promising alternative electrocatalysts for hydrogen evolution reaction (HER) have been studied extensively. The activation of MoS\(_2\) basal plane for HER can be achieved by introducing transition metal dopants or sulfur vacancies. The activation is known as strengthening the hydrogen atom binding on “active” sites compared with on pristine MoS\(_2\) basal plane. The intrinsic descriptors for hydrogen binding, however, are still ambiguous in contrast to the d-band center for transition metals. In this work, we systematically studied 3d metals (Ti, V, Cr, Mn, Fe, Co, Ni, Cu, and Zn) doped in MoS\(_2\) from their local structures to the intrinsic descriptors for hydrogen binding. We found that the metal dopants prefer to form clusters, and the sulfur vacancy formation is strongly affected by the local dopants configuration. Two mechanisms for hydrogen adsorption on MoS\(_2\) based materials with dopant/vacancy complex are clarified. The intrinsic descriptors for both mechanisms are proposed respectively. Our results illustrate the dopant and vacancy can synergistically form and catalyze HER effectively. The intrinsic descriptors would be beneficial to understand this system and provide guidelines for other transition metal dichalcogenides HER catalysts design.

Fundamental Energetics of n-Si/SiO\(_x\)/p-NiO Photoanode for Water Oxidation and Sulfur Doping Effect on PEC Performance Jemee Joe, Thi Anh Ho, Changdeuck Bae and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

n-Si/metal oxide heterojunction structures have been intensively investigated for application in photoelectrochemical (PEC) water splitting obtaining high voltages and preventing surface photocorrosion. Thanks to the relatively high conduction band offset compared to the valence band offset with Si, p-NiO has been studied as both hole-selective and photocatalytic layers on Si surfaces. However, most of the Si/NiO heterojunctions focused on NiO\(_x\) to date, and the studies on relevant energetic are lacking due to the properties of the materials of NiO\(_x\) with unknown phases and the related surface reactions. Here, we describe the energetic study of simple stoichiometric NiO on n-Si and its relation to the water oxidation reactions. Atomic layer deposition (ALD) technique was used for fabricating NiO films for it could offer pin-hole-free, and compact layers in an ultraprecise manner, and systematic study. Moreover, doping sulfur in NiO further tuned the surface energetics by modifying the resulting conductivity. Our optimized n-Si/SiO\(_x\)/p-NiO(S) photoanodes showed well over 24 h of stability under 1 sun illumination with 27 mAcm\(^{-2}\), suggesting a great potential for efficient PEC water splitting.

Concurrent Photocatalytic Hydrogen Generation and Dye Degradation Using MIL-125-NH\(_2\) under Visible Light Irradiation Stavroula Kampouri\(^1\), Tú Nguyên\(^1\), Mariana Spodaryk\(^1,2\), Robert Palgrave\(^1\), Andreas Züttel\(^1,2\), Berend Smi\(^1\) and Kyriakos Stylianou\(^1\); \(^1\)Ecole Polytechnique Federale de Lausanne, Switzerland; \(^2\)EMPA Materials Science and Technology, Switzerland; \(^3\)University College London, United Kingdom

Solar to hydrogen (H\(_2\)) energy conversion represents the Holy Grail of energy science and technology. For decades, numerous materials have been developed and used as photocatalysts for this purpose. However, their inadequate visible light absorbance, poor stability and fast charge recombination have prevented their wide, industrial-scale
deployment. Additionally, the use of noble metal-based co-catalysts and the toxicity of the majority of electron donors employed in these photocatalytic systems limit the profitability of this technology. This study aims to tackle these issues using a two-fold strategy. Firstly, we systematically studied the impact of different transition metal-based co-catalysts towards the photocatalytic water reduction, when they are physically mixed with the visible-light active MIL-125-NH₂. All co-catalyst/MIL-125-NH₂ photocatalytic systems were found to be highly stable after photocatalysis, with the NiO/MIL-125-NH₂ and Ni₂P/MIL-125-NH₂ systems exhibiting high hydrogen (H₂) evolution rates of 1084 and 1230 μmol h⁻¹ g⁻¹, respectively. Secondly, we investigated how different electron donors affected the stability and H₂ generation rate of the best Ni₂P/MIL-125-NH₂ system and found that triethylamine fulfills both requirements. By understanding the impact of these components, we then replaced the electron donor with rhodamine B (RhB), a dye that is commonly used as a simulant organic pollutant, with the aim of integrating the visible-light driven H₂ evolution with water remediation in a single process. This is the first study where a metal-organic framework (MOF) system is used for this dual-photocatalytic activity under visible light illumination and our proof-of-concept approach envisions a sustainable wastewater remediation process driven by the abundant solar energy, while H₂ is produced, captured and further utilized. The discovery of such photocatalytic systems paves the way for the development of processes using wastewater to produce clean H₂ and our approach could be extended to other applications where the concurrent oxidation and reduction of species could be of great importance.

Defective But Effective—The Role of Defects in Oxide-Based Electrocatalysis Ana B. Munoz-Garcia; Univ of Naples Federico II, Italy

Ab initio simulations play an increasingly important role in materials sciences. In the energy conversion scenario, computational modeling can elucidate, with atomic resolution, the subtle composition-structure-property relationships behind the performance of functional materials and complex interfaces. In heterogeneous electrocatalysis, the underlying bulk and surface charge/mass transport events are often strongly dependent on the presence/absence of structural defects. Thus, a deep knowledge of defect chemistry is key for understanding, tuning and optimizing the properties of different catalysts.

In particular, this contribution will report recent advances in the DFT-based characterization of the role of defects in strongly correlated oxides as electrodes in (photo)electrocatalytic devices. Three case studies will be presented: (i) a new triple-conducting oxide based on Sr₂Fe₁.₅Mo₀.₅O₆ perovskite with promising bifunctional catalytic activity towards oxygen reduction and evolution reactions [1-3] (ii) Fe-doped ZrO₂ for low temperature SOFCs [4] and (iii) CuFeO₂delafossite for CO₂photoreduction [5]. In all cases, we will discuss how surface oxygen vacancies -boosted by aliovalent doping- enable better performances and change product selectivity.

Exciton Delocalization vs Charge Separation in Biomimetic PBI-Based Supramolecules for Artificial Photosynthesis

Maurizio Prato, Marcella Bonchio and Giulio Cerrulo; 1Politecnico di Milano, Italy; 2University of Padova and CNR-ITM, Italy; 3University of Trieste, Italy

Converting solar energy into chemical energy with the aid of a photocatalyst is a promising strategy to solve long-term energy problems. Specifically, engineering a synthetic analogue of a photosynthetic unit which absorbs sunlight and uses it to split water, is an ambitious challenge towards the achievement of an artificial photosynthesis. Towards this goal, major synthetic efforts have been focused on the design of dyads based on a light-absorber (usually a Ru–based complex) and a water oxidation catalyst (WOC). Upon dyad photoexcitation an electron transfer event occurs, however it is usually strongly quenched by possible ultrafast intra-dyad recombination, thus limiting the dyad efficiency.

Recently, some of us proposed a new synthetic strategy inspired by the concept of the ‘quantasome’, defined as the minimal photosynthetic unit responsible for the solar-energy conversion. A quantasome uses a self-assembled light-harvesting antenna in combination with one catalytic cofactor. The artificial quantasome reported here is specifically designed for oxygen evolution. It exploits the self-assembly of multiple perylene bisimides (PBI) chromophores which interact with a Ru-polynoxometalate WOC (Ru4POM). The resulting [PBI]5Ru4POM complex shows an amphiphilic structure and dynamic aggregation into large two-dimensional domains, forming cylindrical units where five PBIs surround one Ru4POM. The PBI self-assembly induces a clear red-shift of the optical absorption, suggesting strong excitonic delocalization. The interplay between the creation of excitonic states, the formation of charge transfer states and the deactivation of the excitons dictates the efficiency of the quantasome.

Femtosecond transient absorption shows that upon excitation of the PBI moieties, the [PBI]5Ru4POM singlet excited state undergoes an ultrafast (ca. 1ps) decay to a charge transfer (CT) state, followed by a formation of a stable charge-separated state1. The ultrafast CT formation is taken as signature of a good quantum efficiency. Nevertheless, a clear understanding of the formation of a favorable PBI-based excitonic manifold is still lacking. Here we apply two-dimensional electronic spectroscopy (2DES) to study the interplay between exciton delocalization and CT formation in the [PBI]5Ru4POM quantasome. 2DES represents a suitable tool to study exciton delocalization in multi-chromophores systems, providing a series of excitation/detection correlation energy maps at different probe delays T. Exploiting sub 20-fs broadband visible pulses, we report a 2DES measurement obtained on the quantasome and we compare it with the ones obtained from an isolated PBI in solution and a self-assembled PBI aggregate.

In 2DES maps, we distinguish two contributions: the signals on the diagonal and the ones observed out of the diagonal (cross-peaks). For the quantasome, at early times (T<20fs), we observe instantaneous positive diagonal peaks appearing in the blue/green spectral region (500-550 nm), reflecting the bleaching of the PBIs excitonic transitions, as well as one negative cross-peaks in the red-shifted detection window at 550/700nm excitation/detection wavelength, assigned to a photoinduced absorption from individual PBI excited states (as confirmed by a reference 2DES map on isolated PBI). At later times (T=100fs) we notice the formation of a second negative cross peak at the 550/600nm wavelengths, completed in about 1ps. Interestingly, similar signal is also
observed in the PBI aggregate and we ascribe it to an excited state absorption band from the PBI exciton manifold. By comparing the spectral shapes and the timescales of the two crosspeaks in the PBI aggregate and in the quantasome we distinguish excitonic effects from electron transfer events. Our results will contribute in understanding the design principles underlying the PBI-based supramolecular systems for efficient artificial photosynthesis.

Oxygen Evolution Reaction of Epitaxially Stabilized Columbite IrO$_2$
Kyuho Lee$^1$, Raul A. Flores$^{1,2}$, Yunzhi Liu$^1$, Michal Bajdich$^1$, Yasuyuki Hikita$^2$, Robert Sinclair$^1$ and Harold Y. Hwang$^{2,1}$; $^1$Stanford University, United States; $^2$SLAC National Accelerator Laboratory, United States

The conversion of electrical energy into hydrogen gas via water electrolysis is widely considered to be a promising energy storage mechanism to compensate the intermittent nature of the leading sources of renewable energy.$^{1,2}$ The key to enhancing the overall efficiency of polymer electrolyte membrane (PEM) electrolyzers lies in the development of acid-stable catalysts for the oxygen evolution reaction (OER), the rate-limiting half-reaction of water electrolysis.$^2$ Recently, ternary iridium oxides have been reported to show high catalytic activity and stability in acid, often associated with the formation of distinct IrO$_x$ structures at the surface by the leaching of the second cation.$^{3,4}$ Various Ir-O structures, including polymorphs of IrO$_2$, are identified as possible candidates for these highly active IrO$_x$ structures.$^3$ In parallel, theoretical calculations predict that some polymorphs of IrO$_2$, including columbite IrO$_2$, could be more active OER catalysts than the conventional rutile IrO$_2$.$^5$ These studies strongly motivate the synthesis of new polymorphs of IrO$_2$, but their stabilization has been limited due to the outstanding stability of rutile IrO$_2$.$^{5-7}$ An effective approach to overcome this challenge is to employ heteroepitaxy, in which the metastable polymorph is preferentially stabilized by growing on a well lattice-matched substrate due to enhanced interfacial energy.$^8$ We have successfully stabilized columbite IrO$_2$ (100) in epitaxial thin films for the first time using pulsed laser deposition. X-ray diffraction and transmission electron microscopy measurements are used to identify and characterize the structure of these films. Measurements of the OER catalytic activity of columbite IrO$_2$ (100) thin films reveal clear differences from their rutile counterpart. Details of the activity and comparison with theoretical calculations will be discussed.

Effect of Dissolved O$_2$ on Band Alignment at n-GaN/NaOH Interface
Yuki Imazeki$^1$, Supawan Ngamprapawat$^1$, Masahiro Sato$^1$, Katsushi Fujii$^2$, Tsutomu Minegishi$^1$, Masakazu Sugiyama$^1$ and Yoshiaki Nakano$^1$; $^1$The University of Tokyo, Japan; $^2$RIKEN Center for Advanced Photonics, Japan

For efficient solar-to-hydrogen conversion via photoelectrochemical water splitting, semiconductor electrodes such as Fe$_2$O$_3$ and BiVO$_4$ have been developed. On such n-type semiconductors, O$_2$ gas is generated by photoelectrochemical water oxidation. Therefore, amount of dissolved O$_2$ increases with the progress of water splitting in the vicinity of semiconductor/electrolyte interface. Band alignment around the interface has an essential impact on the carrier transport which dominates the progress of photoelectrochemical reactions, and the dissolved O$_2$ will certainly affect the band alignment. We therefore investigated the band alignment under illumination at the interface with and without dissolved O$_2$ using n-GaN/NaOH as a model system. The band alignment at the semiconductor/electrolyte interface is characterized by the flat band potential and the (quasi-) Fermi level of a semiconductor. The former can be obtained via Mott-Schottky analysis and the latter can be measured as open-circuit-potential (OCP). These measurements were performed with the three electrodes system.
which consists of a single crystalline n-GaN (0001) photoanode, a platinum wire as a counter electrode and a Hg/HgO/1M NaOH (+0.113 V vs. SHE) as a reference electrode. Before a measurement, the surface of the n-GaN electrode was conditioned by electrochemical reduction using cyclic voltammetry from -0.25 to +0.45 V vs. RHE in a 1M NaOH degassed by evacuation. To characterize the band alignment under illumination, a He-Cd laser (325 nm) was used for excitation of carriers in n-GaN. To evaluate the drift of Fermi level under illumination, OCP was measured as a function of photon flux ranging from 1.1×10⁹ to 7.5×10¹⁶ s⁻¹cm⁻² either in degassed 1M NaOH or in the same electrolyte bubbled with O₂ at 1 atm.

Without illumination, the flat band potential was -0.53 and -0.60 V vs. RHE for the degassed and the O₂-bubbled NaOH, respectively. The negative shift in the flat band potential with dissolved O₂ would be due to the potential difference at the electric double layer, since adsorbed oxygen on the surface of n-GaN may alter the structure of the double layer. Fermi level was evaluated as +0.70 and +0.73 V for the degassed and the O₂-bubbled NaOH, respectively. As a result, band bending was increased from 1.23 to 1.33 V with O₂ bubbling. OCP, i.e., Fermi level, is the potential at which anodic current is balanced with cathodic current. Therefore, its positive shift would be due to the increased cathodic current by oxygen reduction reaction.

Under illumination, OCP approached the flat band potential with increasing photon flux, assuming that the flat band potential was never changed by illumination. Between photon flux of 1.1×10⁹ and 1.2×10¹¹ s⁻¹cm⁻², O₂ bubbling resulted in larger band bending by 0.09 - 0.14 V compared to the values at each photon flux for the degassed NaOH. In contrast, between photon flux of 1.2×10¹² and 1.9×10¹⁴ s⁻¹cm⁻², band bending was 0.01 – 0.03 V smaller with O₂ bubbling. When OCP exceeded the redox potential of H₂ evolution, the behavior of OCP versus photon flux was affected by the existence of dissolved O₂.

The observation above seems to indicate that O₂ dissolved in an electrolyte adjacent to the semiconductor surface induces at least two phenomena: (1) a structural change in the electric double layer due to the adsorption of oxygen on the semiconductor surface, (2) removal of electrons from the semiconductor surface due to oxygen reduction current, resulting in the increase of band bending in the semiconductor. The relative impact of these phenomena on the band alignment may depend on several factors such as illumination intensity, O₂ concentration in an electrolyte and the atomistic structure of the surface. The combination of Mott-Schottky analysis and OCP measurement as a function of light intensity will provide quantitative clues for the fundamental clarification of such impact of dissolved O₂ in an electrolyte.

Oxygen Electro-Adsorption Kinetics on Well-Defined Oxide Surfaces Ding-Yuan Kuo, Hanjong Paik, Darrell G. Schlom and Jin Suntivich; Cornell University, United States

We present our measurements of the oxygen electro-adsorption kinetics on IrO₂ and RuO₂ surfaces and their implications for our oxygen evolution reaction (OER) understanding. The slow kinetics of the OER is currently the largest source of inefficiency in water-splitting devices. The common picture is that the slow OER kinetics is a reflection of the OER’s multi-electron nature; as the OER takes place, the catalyst must stabilize a series of proton and electron transfer events via surface electro-adsorption. We present our measurements of the kinetics of these electro-adsorption events, specifically the deprotonation of H₂O* to OH* and OH* to O*, two of the elementary steps of the OER. Our approach uses rate-dependent cyclic voltammetry to isolate the electro-adsorption rate constants from the electrochemical driving force. We further vary the electrolytes to examine how the rate constant varies with pH to reveal the nature of the proton and electron transfers on IrO₂ and RuO₂. Our measurement provide insights into the electro-adsorption process on oxides and information on the kinetics of the elementary steps within the OER.

BSE Calculations for Hematite Water Splitting Nadav Snir and Maytal Caspary Toroker; Technion-Israel
Hematite is a widely-studied photo-anode in photoelectrochemical cells (PEC) due to its visible-light band-gap (~2.2 eV) and chemical stability. There are many DFT+U studies for the electronic structure of hematite. In current work we go into more accurate calculations of hematite's absorption spectrum using the one-shot Green's functions (\(G_0W_0\)) and Bethe-Salpeter equations (BSE) methods which take excited states into account. We compared the calculated absorption spectra to experimental spectra and found a match in peak energy position. Furthermore, we found anisotropy of the absorption spectrum that is concurrent with the crystallographic structure of hematite. We also calculated the absorption spectra of hematite intermediates during the oxygen evolution reaction using the \(G_0W_0\)-BSE method and found that the *O intermediate is the dominant species under bias.

Sn-Addition on Polycrystalline Hematite Reduces the Grain Boundary Blocking Effect Enhancing the Electronic Conductivity
Mario R. Soares¹, Edson R. Leite¹ and Flavio L. De Souza²; ¹UFSCar, Brazil; ²University Federal-ABC, Brazil

The poor electronic properties of polycrystalline hematite have been prevent its potential application as photoanode for light induced water splitting. Despite some progress have been made overcome this limitations remains as important challenge in the solar fuel production field [1-2]. The present work showed that the Sn-addition enhances the electronic transport of polycrystalline hematite (α-Fe₂O₃) by reduces the grain boundary block effect. A controlled sintering process allowed us freezing the state of electronic defects, in which the electrical properties of hematite are governed by the grain boundary and Sn segregation. Electrical measurements showed that the current flows preferentially through the grain boundary with presence of Sn-segregated. Sn-addition probably leads to decrease the grain boundary resistance. Atomic force microscopy and electric force microscopy (AFM/EFM) measurements confirm the results of the impedance analysis. The identification of preferential grain boundaries for electrical conductivity may have a direct influence on the light-induced water splitting performance of the hematite photoanode.

2:30 PM EN07.04.04
Optimization of Photoelectrochemical Performance of Hematite for Solar Water Splitting
Mmantsae M. Diale; University of Pretoria, South Africa

Hematite has attracted much attention due its superior properties for applications as a photoanode in a solar water splitting. Thin films and nanostructures of hematite were synthesized on fluorine-doped tin oxide by spray pyrolysis, dip coating and spin coating. X-ray diffraction results revealed (104) and (110) planes for all films, describing the rhombohedral structure of hematite. Raman spectra of the films confirmed two A₁g and five E₅g vibrational phonon modes of hematite. Scanning electron microscopy films showed nanoparticles of grain sizes varying from 30 to 40 nm. Cross-sectional images revealed film thickness of 430, 452 and 622 nm 521 nm for films prepared by spray pyrolysis, dip and spin coating techniques respectively. The films had an indirect band gap ranging from 1.96 to 2.30 eV. We carried out pump probe spectroscopic measurements on spin-coated samples to determine the electron-hole recombination rates in photo-excited samples. We obtained three distinct relaxation decay and recombination lifetimes in the ranges of sub-picosecond, hundreds of picoseconds and single digit nanoseconds. Furthermore, ab-initio studies of surface doped hematite films using Cu, Zn and Cu/Zn co-doping showed thermodynamic stability.

Engineering IT-MoS₂ with Transition Metal Doping as Efficient Electrocatalysts for Alkaline Hydrogen Evolution Reaction
Nuwan H. Attanayake¹, Lakshay Dheer², Sasitha C. Abeyweera¹, Umesh V. Waghmare² and Daniel R. Strongin¹; ¹Temple University, United States; ²Jawaharlal Nehru Centre for Advanced Scientific Research, India
Molecular hydrogen is considered as one of the most promising energy carriers due to their high energy density and environmental friendliness. The emission of unprecedented amounts of greenhouse gases during the combustion of fossil fuels is believed to be a major cause in climate change. Thus, greener fuels are sought after more than ever. The production of hydrogen gas by electrolysis of water or hydrogen evolution reaction (HER) using energy from renewable sources is one of the most evaluated areas as a viable solution. These extensive studies have identified many earth abundant materials to perform with high energy efficiency in the reduction of protons to hydrogen gas in acidic media. Nevertheless, there are few studies to accommodate materials as catalysts to reduce water to hydrogen gas in alkaline conditions. This would be a vital factor since the more challenging oxygen evolution reaction (OER) catalysts show good efficiencies in alkaline conditions (i.e. pH 14). Thus, materials which would split water to generate hydrogen in alkaline conditions are sought after as it would allow the water splitting reaction to be carried out in one electrolyte. MoS$_2$ gained a lot of attention as an efficient catalyst in reducing protons to hydrogen in acidic conditions. Nevertheless, they suffer in stability and activity in alkaline conditions. In this study we report the synthesis of doped 1T phase of MoS$_2$ to gain stability and provide improved activity than the pure 1T phase of MoS$_2$. The metallic 1T phase of MoS$_2$ was successfully doped with with varying concentrations of Co and Ni atoms in the basal planes of these MoS$_2$ sheets. This doping reduced the overpotential (@10 mA/cm$^2$) for the HER to 110 mV from 220 mV, relative to pure 1T phase in alkaline conditions with 10% of Co dopants in them. 10% Ni doping gives 120 mV overpotential for the HER at the same current density. These doped materials show low tafel slopes (~125 mV/dec) and good stability for the HER for more than 24 hours. We use density functional theory (DFT) calculations to explain the improvement in the catalytic activity and stability in these doped materials. These calculations suggest that the introduction of the impurities in these sheets lowers the energy required for the water dissociation step and reduces the binding energy towards the hydroxyl ions that wouldn’t leave the surface on pure MoS$_2$. Furthermore, the calculations show that the introduction of the dopants reduce the H binding energy on the active sites which is a crucial factor in efficient HER catalysis.

3:00 PM BREAK

3:30 PM *EN07.04.06 Multiscale Modelling Strategies for Alloy Design Javier Llorca$^{1,2}$; $^1$IMDEA Materials Institute, Spain; $^2$Technical University of Madrid, Spain

Materials are transversal to all technologies and they are always at the core of the major disruptive discoveries. Either the synthesis of a material with novel properties leads to a technological breakthrough or current engineering materials are introduced and slowly improved for novel applications following a trial-and-error strategy. Both circumstances act as limiting factors of technological progress but advances in computer power and modeling tools have changed this scenario. In particular, a large number of modeling tools are nowadays available for particular ranges of length and time scales (density functional theory, molecular mechanics, computational thermodynamics, finite elements and finite differences, etc.). They have already proven their potential to predict the formation, structure and properties of materials and have been used to design materials with improved properties or unexpected structures, such as new catalysts or Li-based materials for batteries.

These success stories were possible because the critical structure or properties depended on phenomena with a particular time and length scale, which could be simulated using only one of the techniques mentioned above. This is not always the case and, in fact, it is unlikely to occur in materials for engineering applications. For instance, balanced mechanical properties (stiffness, strength, toughness) depend on many different processes which take place along nine or more orders of magnitude in length scales (from nm to m) and this dependence on different length scales is more evident in multifunctional (smart) materials.

In this talk, a roadmap for multiscale modelling of engineering materials for structural applications is presented around two pillars of virtual processing and virtual testing. In the first pillar, the microstructural development during processing is simulated through a cascade a simulation tools including ab initio calculations, cluster expansion and kinetic Monte Carlo to determine the phase diagram and the interface mobility. This information is used in combination with classical nucleation theory and phase-field modelling to obtain the microstructure (grain size, size, shape and spatial distribution of second phases). Virtual testing is accomplished by means of computational homogenization of a representative volume element of the polycrystalline microstructure, in which the properties of the single crystals and grain boundaries were obtained from ab initio, molecular dynamics and dislocation dynamics.
in combination with transition state theory. The roadmap is demonstrated in the development of Al-Cu alloys for aerospace applications. Future applications of this strategy to design new materials for enhanced electrocatalytic water splitting by elastic strain engineering is outlined.

4:00 PM EN07.04.07
Carbon-Based Heterojunction with Optimizing Oxygen Concentration for Photoelectrochemical Water Splitting Minyeong Je†, Yelyn Sim‡, Uk Sim‡ and Heechae Choi†; †University of Cologne, Germany; ‡Chonnam National University, Korea (the Republic of)

Recently, two-dimensional (2D) carbon-based heterojunction materials have exhibited high photocatalytic activities for water splitting and hydrogen evolution reaction (HER). Reduced graphene oxide (rGO) and graphitic carbon nitrides (C,N) have attracted strong research interests in junctions because of excellent compatibility with other 2D materials and versatile functionalities. However, the functionality of rGO-C,N heterojunction is not very reliable, which means that the water splitting photocatalytic activity largely fluctuates with fabrication conditions. In this study, the effect of oxygen/carbon (O/C) ratio of rGO and C-O binding chemistry on the physicochemical properties and possibility to fine tune the photocatalysis of rGO-C,N composite was systematically and theoretically investigated using density function theory (DFT) calculations. Interestingly, from DFT calculations results, the work functions of pristine rGO (PrGO) and defective (DrGO) were found to be linearly increase with O/C ratio. Especially, it indicated that PrGO and DrGO with O/C ratio range from 4% to 13% have a suitable work function value for the photocatalyst in junctions with C,N, considering feasibilities of charge separations and water redox levels. It revealed that the charge transfer only occurs in PrGO with 4% O/C ratio and DrGO with 8% and 13% O/C ratio. Free energy diagram and volcano plot of H adsorbed on PrGO and C,N/DrGO heterojunction was investigated to further understand the HER mechanisms. Furthermore, the experimental results were well verified that the rGO-C,N heterojunction having the proper O/C ratio shows the enhanced water splitting photocatalytic activity. Thus, it was demonstrated through DFT calculations and experimental results that controlling the proper O/C ratio is very important in the rGO-C,N heterojunction.

4:15 PM EN07.04.08
Zn:BiVO₄/Mo:BiVO₄ Homojunction as Efficient Photoanode for Photoelectrochemical Water Splitting Jae Myeong Lee¹, Ji Hyun Baek¹, Xinjian Shi², Gill Sang Han¹, Dong Hoe Kim¹, Hyun Suk Jung¹ and Xiaolin Zheng²; ¹Sungkyunkwan University, Korea (the Republic of); ²Stanford University, United States; ³Sejong University, Korea (the Republic of)

Photoelectrochemical (PEC) water splitting has been extensively studied as a method to convert sunlight and water to hydrogen. Among the many obstacles facing PEC water splitting, a critical challenge is the lack of efficient photoanodes for the water oxidation reaction. Here, we demonstrate a n-n+ type-II homojunction of Zn:BiVO₄/Mo:BiVO₄, which enhance the bulk transport and surface charge transfer processes of the well-studied BiVO₄ photoanode. In this homojunction, the Zinc and Molybdenum dopants move the BiVO₄ Fermi level closer to valence band maximum and conduction band minimum, respectively, establishing a n-n+ type-II homojunction. The staggered band alignment between Zn:BiVO₄ and Mo:BiVO₄ facilitates electron-hole separation between the interface of two layers. The Molybdenum is a well-known donor dopant for BiVO₄ and increases the donor concentration, leading to higher electrical conductivity. The Zinc dopant increases the number of oxygen chemisorption sites at the surface layer, reducing surface recombination rate. In summary, we demonstrate that a Zn:BiVO₄/Mo:BiVO₄ homojunction structure improves both charge transport and transfer efficiency.

4:30 PM EN07.04.09
Investigation of Highly Stable Proton Exchange Membrane Water Electrolyzers with Low Catalyst Loading and Reduced Hydrogen Crossover Ryan Ouimet¹,¹, Reza Mirshekari¹, Haoran Yu¹, Zhiqiao Zeng¹, Leonard Bonville¹, Prasanna Mani², Allison Niedzwiecki², Chris Capuano², Katherine Ayers² and Radenka Maric¹,¹; ¹University of Connecticut, United States; ²Nel Hydrogen, United States

Hydrogen, with a global production rate of about 50 billion kg/year, is one of the world’s most important chemicals [1]. Today, hydrogen is mainly produced from natural gas and coal, generating CO₂ as a byproduct. Recently, Proton Exchange Membrane Water Electrolyzers (PEMWEs) have been gaining in interest worldwide as a renewable energy source for hydrogen production. However, the product costs have not yet reached the market targets, mainly due to the immaturity of the manufacturing processes and materials cost. The catalyst coated membrane (CCM) is
the largest cost contributor to the cell, due to the high catalyst loadings of platinum group metals (PGMs) and the current labor-intensive methods for CCM fabrication. In order to address the catalyst cost issue, there is a need to reduce the catalyst loading and develop the manufacturing process. Furthermore, stability and long-term operation at high current density has been challenging for electrodes with low PGM loading (less than 1 mg cm$^{-2}$). Recent literature has shown long-term catalyst stability from hundreds to several thousand hours of cell operation. Lewinski et al. [2] have demonstrated a nano-structured thin film (NSTF) cell with Ir anode loading of 0.25 mg cm$^{-2}$ which achieved stability of 5000 h at 2 A cm$^{-2}$. Rozain et al. [3] have also studied a low-loaded Ti supported Ir oxide anode catalyst (0.12 mg cm$^{-2}$) which showed more than 1000 h of operation at 1 A cm$^{-2}$. On the other hand, one of the principal technical issues hampering the extensive use of PEMWEs is hydrogen crossover which causes a serious safety hazard in the anodic compartment where oxygen is produced as the lower explosion limit of hydrogen in oxygen is about 4 vol%. It has been shown that the integration of a recombination layer incorporated directly into the membrane has significantly improved the hydrogen crossover with the ability to decrease this safety hazard [4]. In this work, a novel single-step electrode fabrication process, Reactive Spray Deposition Technique (RSDT), was employed to reduce the electrode manufacturing cost and develop 86 cm$^{2}$ full CCMs with low catalyst loadings (cathode: Pt/Vulcan XC-72R with loading of 0.3 mgPt cm$^{-2}$, anode: IrO$_2$/Nafion® with loading of 0.2-0.3 mgIr cm$^{-2}$) which meet the desired stability of >1000 h at 1.8 A cm$^{-2}$, 50 °C, 400 psi hydrogen pressure. A Pt recombination layer directly introduced into the membrane was also used to reduce hydrogen crossover to the commercial threshold. The microstructural characteristics of the RSDT-derived CCMs were studied by Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM). Stability and cell performance of the RSDT-derived CCMs were investigated using diagnostic tests including polarization analysis, cyclic voltammetry and electrochemical impedance spectroscopy.

From Rusting to Solar Power Plants—A Successful Nano-Patterning of Stainless Steel 316L for Visible Light-Induced Photoelectrocatalytic Water Splitting Nageh K. Allam; American University in Cairo, Egypt

A novel propitious nanoporous anodized stainless steel 316L (NASS316L) photoanode was developed for water splitting. The anodization could successfully produce a uniform nanoporous (∼ 90 nm in pore diameter) array (∼ 2.0 m thick) of NASS316L with a high pore density. Several techniques, including FESEM, EDX, XRD, XPS, ICP-OES, and UV–vis-NIR spectrophotometry, were employed to characterize the catalyst and to assess and interpret its activity toward water splitting. Surprisingly, the NASS316L retained almost the same composition of the bare stainless steel 316L, which recommended a symmetric dealloying mechanism during anodization. It also possessed a narrow band gap energy (1.77 eV) and a unique photoelectrocatalytic activity (∼ 4.1 mA cm$^{-2}$ at 0.65 V versus Ag/AgCl, 4-fold to that of α-Fe2O3) toward water splitting. The onset potential (∼0.85 V) in the photocurrent-voltage curve of the NASS316L catalyst demonstrated a negative shift in its Fermi level when compared to α-Fe2O3. The high (23% at 0.2 V vs Ag/AgCl) incident-photon-to-current conversion efficiency and the robust durability revealed from the in situ analysis of the produced H2 gas continued recommending the peerless inexpensive and abundant NASS316L catalyst for potential visible-induced solar applications.

Understanding the Reasons for the Absence of Photoactivity in β Manganese Vanadate (Mn$_2$V$_2$O$_7$) Yash Gargasya; University of California, Irvine, United States

With depleting fossil fuels reserves and their possible role in accelerating climate change, solar energy stands out as one promising source for providing clean energy at a multi-terawatt scale to meet ever-increasing global energy demand. The challenge of its intermittent nature can be tackled by storing it in an energy dense material like chemical fuel. Water can be the abundant raw material for this conversion process. Thus, photoelectrochemical water splitting can be one possible route to solve the energy crisis.

Till date, no semiconductor deployed for photoelectrochemical water splitting has met the stringent criteria of the right bandgap of 1.6-2 eV, optimal band edge positions (CBM, few mV negative of HER and VBM, 300-500 mV positive of OER), electrochemical stability (at alkaline pH for OER) and good electron transport properties. However, manganese vanadate (Mn$_2$V$_2$O$_7$), has been reported to have 1.8 eV bandgap, near optimal band edge positions, electrochemical stability in the alkaline pH and Mn 3d orbital based valence band leading to curvature in the valence band light holes.

In this work, we have developed a simple spin coating method to fabricate tunable, nanoporous thin films of manganese vanadate. The grain size can be tuned from 20nm to 200nm whereas the film thickness can be tuned from 100nm to 1.5 microns. The direct bandgap has been found to be 2 eV. Contrary to previous reports, the material is found to suffer from serious stability issues. It dissolves in neutral, acidic and mildly acidic pH within minutes, and undergoes vanadium leaching and amorphousization at alkaline pH. It is relatively stable in mildly alkaline pH, but, use of common buffer ions like phosphate accelerate the film dissolution even in this pH due to low Ksp of manganese phosphate.

Also, unlike previous reports, the material shows no photoactivity in pristine form or when stabilized by atomic layer deposited TiO$_2$. Photoluminescence spectrum suggests the possibility of very small charge carrier localizing domains resulting in an uncharacteristically broad PL peak. Further studies have been done using transient absorption spectroscopy to study the carrier lifetime to probe long-lived traps and bulk charge carrier recombination. XPS measurements have been conducted to study the chemical environment of the film surface and exchange current density and impedance has been measured to probe the presence of any resistive surface layer impeding the charge transfer across the interface.

EN07.05.02

Developing Stable and Efficient Water Splitting Devices for Solar H$_2$ Production under Concentrated Light Mohd A. Khan$^1$, Purushothaman Varadhan$^2$, Hicham Idriss$^1$ and Jr-Hau He$^2$; $^1$SABIC, Saudi Arabia; $^2$King Abdullah University of Science and Technology, Saudi Arabia

Photoelectrochemical (PEC) water splitting into hydrogen and oxygen molecules has been touted as the most promising route for converting solar energy into a storable form. After decades of research solar-to-hydrogen (STH) efficiencies are now approaching 20% using III-V semiconductor solar cells, making the process close to implementation. Yet, the high cost and instability of these cells prohibit their practical use. Stable water splitting reactions should yield stoichiometric hydrogen and oxygen and these are seldom reported. Herein this work we demonstrate the importance of measurement of gaseous products (H$_2$ and O$_2$), and show cases where total inactivity was observed due to corrosion while current measurements indicated stable and high performances. At the same time, we demonstrate integrated water splitting devices that use nickel for stoichiometric (2:1) hydrogen and oxygen production. Specifically we demonstrate over 400 hours of stability @ 12 % STH under 1 sun condition. In parallel we also demonstrate the use of concentrated light for as means for lowering the cost of H$_2$ production. Specifically we report demonstrate devices that work under 25 suns @ 10% STH with stability of more than 250 hours, paving the way to developing practical solar H$_2$ generators.

EN07.05.03

Activation of Reaction Sites in Multinary Phyllosilicate Catalysts for Electrochemical Water Oxidation Byunghoon Kim, Ju Seong Kim and Kisuk Kang; Seoul National University, Korea (the Republic of)

The practical realization of a water-splitting system necessitates the development of high-performance oxygen
evolution reaction (OER) catalysts. Despite tremendous research efforts aimed at identifying earth-abundant 3d transition-metal-based catalysts, their insufficient catalytic efficiencies continue to jeopardize their real-world application. Herein, we introduce amorphous cobalt–iron phyllosilicates (ACFPs) as highly efficient OER catalysts. The ACFPs were designed by tailoring the metal chemistry of the phyllosilicate framework and prepared using a facile room-temperature precipitation method. Structural characterization using X-ray diffraction, Fourier-transform infrared spectroscopy, and X-ray absorption spectroscopy revealed that the ACFP structure consists of laminations of silicate (SiO₄) layers and layered Co–Fe (oxy)hydroxide motifs. The OER properties of the ACFP series were also sensitively affected by the Co/Fe ratio, with an exceptionally low overpotential (η ~ 329 mV for a current density of 10 mA cm⁻²) delivered at the optimized composition of 40 at.% Fe. This catalytic efficiency is greater than that of the structurally analogous Co–Fe (oxy)hydroxide as well as those of pure Co phyllosilicate and pure Fe phyllosilicate, suggesting the beneficial role of the phyllosilicate framework along with the synergistic interplay of Co and Fe ions in the framework. Density functional theory calculations revealed that the introduction of Fe at the surface of Co phyllosilicate perturbs the local structural environment of oxygen sites, providing additional active sites. This work enables more rapid optimization of novel phyllosilicate-based OER catalysts and suggests a valid strategy for the design of high-performance catalysts by chemically tuning both the redox-active and redox-inert elements concomitantly.

EN07.05.04
Quantification of Surface Reactivity and Step-Selective Etching on Single-Crystal BiOI(001) Julia Martin, Roy Stoflet, Katarina Himmelberger, Alexander D. Carl and Ronald L. Grimm; Worcester Polytechnic Institute, United States

We synthesized single-crystal BiOI to characterize the interplay between etching chemistry and interfacial chemical and electronic structure at the (001) face of this emerging solar-relevant, 2-D-layered material. Experiments utilized BiOI single-crystals grown from BiOI powder via physical vapor transport (PVT) and via chemical vapor transport (CVT) with elemental I₂ as a transport agent. Optical images of nascent crystals reveal 1–10 mm² (001) facets but microscopic defects and pitting. Etching studies alternatively included ten-second exposures to 6 M aqueous HF, 6 M HCl, and a stepwise treatment of HF with an acetone rinse. Optical images of HF- or HCl-etched samples demonstrate clean terrace-rich regions and increased scattering at step-rich regions. X-ray photoelectron spectra (XPS) of HF- or HCl-etched, step-dense regions reveal increased iodine as well as fluoride or chloride features, while XRD presents BiI₃ features. We attribute optical, XPS, and XRD results to the dissolution of interfacial bismuth oxides and the concomitant formation of BiI₃ at the steps of the BiOI(001) face. Surface analyses of samples subjected to sequential HF and acetone rinsing demonstrate no detectable BiI₃ by XRD, and Bi:O:I photoelectron area ratios demonstrative of stoichiometric BiOI. In concert with separate studies demonstrating high solubility of BiI₃ in polar organic solvents, the sequential HF and acetone treatments appear to yield chemically pristine BiOI(001). Ultraviolet photoelectron spectra (UPS) of these surfaces demonstrate significant differences in work-function and Fermi-edge values for nascent, for HF-etch, and for HCl-etched BiOI(001) as compared to tape-cleaved, pristine BiOI(001). Importantly, UP spectra of BiOI(001) subjected to a sequential HF and acetone treatment resemble spectra of tape-cleaved, pristine BiOI(001). In concert, the sequential HF and acetone treatment yields BiOI(001) that best mimic the chemical and electronic structure of tape-cleaved surfaces. We discuss these results in the context of polycrystalline BiOI samples for tandem junction photovoltaics (PV).

EN07.05.05
Doped Diamond-Like Carbon Films for Electronic Applications Philip Schneider¹, Marie Francoise C. Millares¹, Iulian Gherasoiu² and Harry Efstathiads³; ¹SUNY Polytechnic Institute College of Nanoscale Science and Engineering, United States; ²State University of New York Polytechnic Institute, United States

Diamond is rapidly emerging as an outstanding semiconductor material for the 21st century. New device applications are envisioned based on its superior properties such as an ultrawide bandgap, the highest electron and hole mobilities, high electric field breakdown strength, all combined with unmatched thermal conductivity and radiation hardness. Toward the realization of its promises as a material for electronic devices, the successful doping of the diamond with boron and phosphorus are important stepping stones. Various techniques are used for the synthesis of diamond including detonation that results in the formation of micron-sized aggregates of nanometer scale diamonds, high-pressure, high-temperature chemical vapor deposition (CVD) or plasma-enhanced CVD. This work focuses on the fabrication of Diamond-Like Carbon (DLC) through Plasma-Enhanced Chemical Vapor Deposition, and on the
measurement of the properties of the material doped with boron and phosphorus from surface a source. The drive-in and activation of the dopants is done through thermal annealing. By testing different annealing temperatures, we are able to observe how the structural, optical and electrical properties of the carbon films were affected. It was found that synthesizing DLC at low temperatures (~100°C) in conjunction with annealing enhances the material crystallinity, its conductivity and allows higher transparency of the film.

**Sodium Flame Synthesis of Nano-Structured Powders for Catalytic Applications** Mary Krause, Geoff Smith, Nick Yin, Larry Wang and Grodon Smith; Global Advanced Metals USA, Inc., United States

Nano-structured, high surface area metal or ceramic powders have a growing interest within many markets including energy conversion, catalysts, and electronic materials. Manufacturing high purity metal powders at an industrial scale is a challenge due to trace impurities impacting powder performance. In particular, oxygen, nitrogen, and carbon impurities can adversely affect the physical and chemical properties of refractory metals such as titanium, tantalum, tungsten, and niobium. Here we present a nano-structured powder produced using a scalable sodium synthesis technology. Primary particle size and aggregate morphology of the resulting powder can be optimized for the given application by adjusting process parameters including optional metal or gas doping. In one such application, we adapt the powder for photocatalytic applications with promising performance.

**EN07.05.07**
**Synthesis, Characterization and Application of MoO₃ by Hydrothermal Route Assisted by Microwaves as an Adsorbent of Organic Dyes** Larissa O. Garcia¹, Fenelon M. Pontes¹, Rafaela F. Silva¹, Regina A. Capeli¹ and Elson O. Longo²; ¹UNESP São Paulo State University, Brazil; ²UFSCAR- Federal University of São Carlos, Brazil

Dyes and pigments, released from several industries such as textile, food, paper and cellulose, cosmetic and plastic industries, are the main organic pollutant compounds in wastewaters. The presence of dyes in water sources, even at low concentrations is very harmful to human beings and microorganisms. A dye can generally be described as a colored substance that has an affinity to the substrate to which it is being applied and is used to impart color to materials of which it becomes an integral part. Most of the current treatment methods work through biological treatment processes, coagulation, oxidation, filtration, membrane separation, and adsorption. Among these methods, Adsorption presents advantages due to its simplicity, effectiveness, and cost-benefit. As adsorbent material, we have the MoO₃, an example of transition metal oxides has been widely used because of their different properties such as electrochromism, thermochromism, and photochromism, as well as having three polymorphs, which are called α-MoO₃, β-MoO₃, h-MoO₃. [1-4] In this work were synthesized MoO₃ nanostructures characterized by the techniques of XRD and BET where it was possible to observe that the prepared samples had the hexagonal, h-MoO₃ phases with a surface area of 6.5 m²/g and a mean crystallite size of 50,56 nm, and orthorhombic, α-MoO₃ with surface area of 14 m²/g mean crystal size of 25.80 nm for the sample using 20 mL of 6M HNO₃. MEV and TEM analyzes showed hexagonal prisms and nanobelts with a diameter of 200 nm and a length of 2μm. The spectra in the Infrared Region allowed identifying the presence of residual organic matter in the synthesis process. Diffuse reflectance spectra in the ultraviolet and visible region allowed to calculate the Band-Gap of h-MoO₃, in the value of 2.65 eV and 2.90 eV for the α-MoO₃ phase. For the adsorption study using different concentrations of Rhodamine B and Methylene Blue, was obtained spontaneous, endothermic, chemical nature adsorption.

**EN07.05.08**
**The Importance of the Interfacial Contact—Is Reduced Graphene Oxide Always an Enhancer in Photo(Electro)Catalytic Water Oxidation?** Zhirun Xie¹, Hui Ling Tan² and Yun Hau Ng³; ¹University of New South Wales, Australia; ²Kyushu University, Japan; ³City University of Hong Kong, Hong Kong
Optimization of the interfacial contact between graphene and semiconductor has been proposed to be essential to improve their charge interactions. Herein, we fabricate bismuth vanadate-reduced graphene oxide (BiVO$_4$/rGO) composites with tailored interfacial contacting extent and reveal their opposite behaviors in the photoelectrochemical (PEC) and powder suspension (PS) water oxidation systems. The BiVO$_4$/rGO with high rGO coverage (BiVO$_4$/rGO HC) features a remarkable superiority in PEC photocurrent enhancement to its low rGO coverage analogue composite (BiVO$_4$/rGO LC). On the contrary, BiVO$_4$/rGO HC shows detrimental effect while BiVO$_4$/rGO LC exhibits an enhanced performance for oxygen evolution in the PS system. This phenomenon is attributed to the changes in the hydrophobicity of BiVO$_4$/rGO composite in conjunction with the interfacial contact configuration. Enriched BiVO$_4$/rGO interfacial contact is found to improve the charge separation efficiency and charge transfer ability as well as the energetics of the composite material, explaining the superior PEC performance of BiVO$_4$/rGO HC. However, the highly hydrophobicity of BiVO$_4$/rGO HC ensuing from the higher rGO reduction degree triggers poor water miscibility, reducing the surface wettability and therefore hampering the photocatalytic O$_2$ evolution activity of the sample. This work also highlights water miscibility as the governing issue in the PS system.

EN07.05.09
The Remarkable Structure of Surface-Terminated Grain Boundary in Perovskite Oxides and Implications for Oxygen Electrocatalysis Yoon Heo, Hyung Bin Bae, Seungkyu Choi and Sung-Yoon Chung; KAIST, Korea (the Republic of)

A grain boundary forms as an internal interface when two crystalline grains with mutually different crystallographic orientations are in direct contact with each other. As a result, atomic arrangement at grain boundaries differs from that of the bulk, showing serious displacements deviating from the original symmetric positions. As these symmetry-broken configurations are difficult to achieve in the bulk crystals, grain boundaries are considered distinctive platforms that can exhibit new physical properties. By using both sintered polycrystals with various grain sizes and thin films on bicrystal substrates, it is directly verified that surface-terminating grain boundaries in LaCoO$_3$ and LaMnO$_3$ are exceptional in oxygen evolution electrocatalysis, showing more than an order of magnitude higher activity. A combination of atomic-scale structure observation and density functional theory calculations demonstrates that the displacement of atoms in metal–oxygen octahedra correlates with significant splitting of the degenerate transition-metal 3d orbitals, and subsequently much easier charge transfer between metals and oxygen is attained. In addition to identifying the grain boundaries as strikingly active sites, the findings suggest that symmetry breaking by atom displacements in metal–oxygen octahedra is an efficient approach to remarkably enhance the oxygen electrocatalytic efficiency in perovskite oxides.

EN07.05.10
Tailoring the d-Band Center and Electronic Structure of Co-N$_4$ Electrocatalyst for Hydrogen Evolution Reaction Sabhapathy Palani$^{1,2,3}$, Indrajit Shown$^1$, Wei-Fu Chen$^2$, Kuei-Hsien Chen$^{1,2}$ and Li-Chyong Chen$^{2,2}$; $^1$Academia Sinica, Taiwan; $^2$National Taiwan University, Taiwan; $^3$National Tsing Hua University, Taiwan

Electrochemical hydrogen generation via the hydrogen evolution reaction (HER) offers a promising solution for a green renewable-energy generation. Platinum (Pt) and Pt-based nanomaterials are mostly served as an efficient electrocatalyst for HER; however, due to its high cost and low abundance limits its large scale commercial application. Therefore, developing nonprecious metal based electrocatalyst for HER is highly necessary for large scale hydrogen production. Over the past decades, tremendous efforts have been made for Pt free electrocatalysts for HER. Recent advances in carbon nanomaterials (RGO, CNT, etc.) have shown their promising future in energy-related electrocatalytic reactions (ORR, OER, and HER) especially, after heteroatom (such as N, B, P, and S) doping, the catalytic activity enhanced. Among all the reported electrocatalysts, the co-doping of trace transition metals on heteroatoms doped carbon materials leads to form metal complexes (Ex. Co-Nx), showing promising HER activity in the aqueous electrolyte. In addition, the reported density functional theory (DFT) simulation shows that when combining both coordinations into one complex, the optimized charge distribution results in an ideal value of $\Delta G_0$ in Metal-Carbon-Nitrogen (M-C-N) hybrid system and which is much better than the single or mixture system of M-C and M-N.

In this presentation, we will demonstrate a new HER electrocatalyst based on Co-N$_4$ system. The cobalt-based catalysts are prepared by a one-step pyrolysis process at the high temperature in which vitamin-B12 (metal precursor) and thiourea (sulfur precursor) together with reduced graphene oxide (RGO). We observed that the electrocatalytic activities of synthesized catalysts are strongly related to the pyrolysis temperature, metal loading,
and acid leaching. The as-synthesized catalyst was characterized by XRD, XPS, and XAS. The results indicate that Co-corrin complexes (Vitamin B12) together with RGO have been decomposed at the high temperature to form new structure (ex. N-Co-C and N-Co-S). Furthermore, the density functional theory (DFT) calculation reveals, this conjugation induces downshift of the d-band center of cobalt, which decreases its hydrogen binding energy. The downshift of d-band center favors the electrochemical desorption of adsorbed hydrogen and leads to a relatively moderate Co–H binding strength, which helps for enhanced hydrogen evolution reaction. The comparison of HER activity and stability of cobalt electrocatalyst in alkaline and all pH electrolytes will be discussed at the meeting.

EN07.05.11
Ni(OH)2-WP Hybrid Nanorod Arrays for Superior Electro catalyst toward Hydrogen Evolution Reaction in Alkaline Media Kijung Yong and Dokyoung Kim; Pohang University of Science and Technology, Korea (the Republic of)

The development of efficient non-noble hydrogen evolution electrocatalysts in alkaline media is crucial for sustainable production of H2 through water electrolysis. Generally, the mechanism of hydrogen evolution reaction (HER) consists of a generation of hydrogen intermediates (Volmer reaction) and followed electrochemical desorption (Heyrovsky reaction) or H2 recombination (Tafel reaction). Compared with the process in acidic media, HER in alkaline solution requires extensive energy barrier owing to slow kinetics of water dissociation step caused by different reacting species in Volmer and Heyrovsky reaction in acidic (H3O+) and alkaline (H2O/OH−) media. To overcome this problem, an alkaline HER catalyst composed of Ni(OH)2-WP nanorod arrays on carbon paper was synthesized via thermal evaporation and electrodeposition. This hybrid catalyst exhibited outstanding HER activity and required a low overpotential of only 77 mV to drive current density of 10 mA/cm2 and a Tafel slope of 71 mV/dec. The hybrid catalyst also showed long-term electrochemical stability, maintaining its activity for 24 h. This improved HER efficiency was attributed to the synergetic effect of WP and Ni(OH)2: Ni(OH)2 effectively lowers the energy barrier during water dissociation and also provides active sites for hydroxyl adsorption, whereas WP adsorbs hydrogen intermediates and efficiently produces H2 gas. This interfacial cooperation offers not only excellent HER catalytic activity but also new strategies for the fabrication of effective non-noble-metal-based electrocatalysts in alkaline media.

EN07.05.12
NiCoP Double Transition Metal Phosphide/Ti3C2 MXene 3D Architecture as Efficient Bifunctional Photocatalyst for Solar Water Splitting Jiyeon Kang1, Seulgi Kim1, Sungho Song2 and Dongju Lee1; 1Chungbuk National University, Korea (the Republic of); 2Kongju National University, Korea (the Republic of)

Hydrogen energy is the ultimate challenge for achieving clean and sustainable energy in the current situation of environmental destruction caused by fossil fuels. Photocatalytic and photoelectrochemical water splitting under irradiation by sunlight has received much attention for production of renewable hydrogen from water on a large scale. Among various photocatalytic materials, transition metal phosphides have been studied as promising catalysts for hydrogen evolution reaction (HER) in solar water splitting, but have issues due to their low conductivity and stability.

Herein, three-dimensional (3D) porous architecture was fabricated with Double transition metal phosphide and conductive two-dimensional MXene hybrids. Ti3C2 MXene was used as a co-catalyst for exciton separation and charge transfer acceleration as well as a support material for the stability of NiCoP catalyst, due to its high conductivity and mechanical strength. Not only the 3D interconnected architecture with large electrochemically active surface area and structural stability but also the synergistic effect between the electrochemical activities of NiCoP and MXene Ti3C2 leads to excellent electrochemical performance.

EN07.05.13
Engineering Facet-Heterojunction Rutile TiO2 Photocatalyst for Highly Efficient Overall Water Splitting Chaomin Gao, Lina Zhang, Shenguang Ge, Xin Cheng and Kang Cui; University of Jinan, China

Rutile TiO2 in principle is a more potential photocatalyst owing to its narrower bandgap, higher thermodynamically stability and less intragrain defects when compared with anatase TiO2. Nevertheless, rutile TiO2 still hasn’t achieved the comparable photocatalytic activity with anatase-based TiO2 on account of its high recombination rate of electron-hole pairs. Electrons in rutile are deep trapped, which shows shorter lifetime in picosecond region,
however, the amount of electrons in microsecond to millisecond region is larger. In order to effectively separate the long-life electron, a novel rutile facet heterojunction TiO₂ with long-distance electronic pathway was firstly proposed to match the transportation of long-life electron, aiming to suppressing the carrier recombination and improving the photocatalytic activity. Here, a structural rutile TiO₂ with facet heterojunction mechanism, which could promote the separation of charge carriers efficiently, was designed for photocatalytic overall water splitting with the two-step hydrothermal strategy. In addition, compared with rutile TiO₂ nanorod, more than 60 and 25 times higher of generated photocurrent and H₂ productive rates are obtained for rutile facet heterojunction TiO₂, respectively.

EN07.05.14
Realizing Multiple Heterojunction within Single Titanium Dioxide Nanoparticles for Highly Efficient Solar Hydrogen Production Yoonjun Cho and Jong Hyeok Park; Yonsei University, Korea (the Republic of)

The surface disorder-engineering of TiO₂ has been drawing intensive interests in tuning surface energy states and thus boosting photocatalytic activity, but yet remains on application as in surface disorder layer. Selective localization of this disorder layer has not been reported so far, of which it can provide unpredictable strategy within the heterojunction interfaces to achieve novel metal-free photocatalysis. Conventional TiO₂ polymorph with mixed-phase heterojunction (anatase and rutile, Degussa P25) possessing energetic type-II band alignment at the interface, outperforming single-phase TiO₂ is employed in this work for single material photocatalyst.

Here we report conceptually different synthetic process to selectively localizing the crystal disorder layer between the anatase and rutile phase of a single TiO₂ nanoparticle, for highly efficient photocatalytic hydrogen (H₂) generation. Phase selective disorder-engineering of rutile TiO₂ followed by thermal re-oxidation below the phase transformation temperature could realize multiple heterojunction of anatase/disorder layer/rutile within a single P25 nanoparticle (denoted as DE-P25). The multiple heterojunction was thoroughly confirmed and analyzed by electron energy-loss spectroscopy (EELS) and electron holography mapping for the first time. EELS Ti-L₂,₃ spectrum geometry of DE-P25 showed distinctive oxygen-deficient variation between the two crystals which corresponds with the drastic decrease of potential and negative charge density within the disordered layer due to localized unpaired electrons. Also, PL decay profiles exhibiting dramatically enhanced charge separation efficiencies of DE-P25 indicate that the rutile phase incorporated with the disordered layer in the TiO₂ nanoparticle induces dominant direct excitation formation and reduces the self-trap of charge carriers, thus suppressing the electron/hole recombination.

The novel designing of multiple heterojunction in single TiO₂ nanoparticles could not only demonstrate efficient charge separation through interfacial charge polarization, but also novel metal-free H₂ generation rate of 3.994 μmol/cm² h⁻¹, which is ~11 times higher than that of Pt-decorated P25. This rational approach can provide breakthrough in stagnated efficiencies of metal oxide-based materials for commercial-scale photocatalytic H₂ production.

EN07.05.15
Effect of the Potential Deposition on the Photoelectroactivity of the SnSₓ/ SbₓS₃ Thin Films Moisés A. de Araújo¹, Francisco Willian d. Lucas² and Lucia Helena Mascaro¹; ¹Universidade Federal de São Carlos, Brazil; ²Universidade de São Paulo, Brazil

Semiconductor-based materials containing earth-abundant and low-toxicity elements are preferably desired to be applied either in photoelectrochemical or photovoltaic cells. Fitting these conditions, there are tin sulphide and antimony sulphide. Both materials have a narrow band gap and a high absorption coefficient. Most of the methodologies developed so far for the production of these materials are based on vacuum technique, which is a high cost method. Very little attention has been given for other methods known to be low-cost, such as, electrodeposition. In light of all these, the aim of this work is to evaluate the electrodeposition potential of ShSn followed by sulphurisation on the photoelectroactivity of this material. Additionally, the microstructure, morphology and optical properties of the unsulphured and sulphurised films were also studied. The electrodeposition of the films were carried out potentialistically at -1.07, -1.14 and -1.18 V vs Ag/AgCl/Cl⁻(sat. KCl) on FTO substrate with a deposition charge density of -332 mC cm⁻². The bath composition was 2 mM SnCl₂ and 4 mM K₂Sb₂(C₂H₂O₆)₂ dissolved in 0.1 M KNa(C₂H₂O₃) pH 6.0. The electrodeposited films were subsequently sulphurised at 270 °C per 3 h under sulphur vapour and argon gas flux. The XRD data for all unsulphured films were indexed to the SbSn and Sb phases, which was additionally confirmed by Raman spectra. Once sulphurised, the XRD and Raman data
indicated the Sb$_2$S$_3$ and SnS phases for all the electrodes. The SnS$_2$ phase was detected for the sulphurised films electrodeposited at -1.07 and -1.14 V. Regarding the optical properties, the estimated optical band gap for a direct (allowed) electronic transition of all the sulphurised films were around 1.8 eV. This value can be attributed to both Sb$_2$S$_3$ and SnS phases. Concerning the morphology of the films, the SEM images showed dendritic like morphology for the unsulphured films electrodeposited at -1.14 and -1.18 V, whilst the film obtained at -1.07 V presented cubic like morphology. The sulphurised films obtained at -1.07 and -1.14 V showed rode like morphology and the sulphurised one which was electrodeposited at -1.18 V had needle and small rods like morphologies. The photoelectrochemical assessments were performed in 0.5 M Na$_2$SO$_4$ + 1 mM 4-nitrophenol at pH 2.0 and under a solar simulator (100 mW cm$^{-2}$, AM 1.0 G). The results revealed that the electrodeposited film at -1.14 V resulted in the highest cathodic photocurrent density once sulphurised which was -113 μA cm$^{-2}$ at -0.315 V. We believe that the SnS$_x$, (SnS + SnS$_2$) and Sb$_2$S$_3$ phases formed a heterostructure SnS$_x$/Sb$_2$S$_3$ in the film which facilitates carriers separation and transportation and improves photocurrent density values. In order to confirm it, Sn and Sb films were prepared from the optimal electrodeposition condition and then sulphurised at the same condition as mentioned previously. The characterisation analysis showed that the sulphurised Sn film was made up of SnS and SnS$_2$, whilst Sb$_2$S$_3$ phase was identified for the sulphurised Sb film. In terms of photocurrent density values, sulphurised Sn and Sb films had cathodic photocurrent densities of -2.4 and -12.2 μA cm$^{-2}$, respectively. These results confirm the existence of the heterostructure SnS$_x$/Sb$_2$S$_3$ as its photocurrent density value was higher than the photocurrent density for the individual sulphurised phases SnS$_x$ and Sb$_2$S$_3$. Band diagrams for the sulphurised Sn and Sb films were constructed from Mott-Schottky analysis and band gap data. The results showed that the valence band maximum (VBM) and conduction band minimum (CBM) of the Sb$_2$S$_3$ film are shifted to lower energy vs. vacuum compared to the SnS$_x$ film. This band energy position favours the transportation of the photogenerated minority carriers from SnS$_x$-CBM to Sb$_2$S$_3$-CBM, increasing the charge separation and, consequently, the photocurrent.

**The Effect of Electrochemical Pre-Treatment in Sulfide Solutions on the Performance of Iron-Based Oxygen Evolution Catalysts**

Billal Zayat, Debanjan Mitra and Sri Narayanan; University of Southern California, United States

Electrochemical splitting of water is a very attractive technique for the production of clean hydrogen. Water electrolysis under alkaline conditions is particularly attractive compared to acidic water electrolysis because of the potential for a lower cost system. The alkaline system avoids the need for precious metals and perfluorinated membranes. However, the oxygen evolution reaction (OER) has sluggish kinetics leading to increased voltage losses and hence, reduced energy efficiency.\(^1\) Therefore, the development of a robust and low-cost alkaline water electrolyzer relies on developing inexpensive, durable, and efficient electrocatalysts for OER. Due to the instability and high cost of noble metal oxides such as RuO$_x$ or IrO$_x$,\(^2\) transition metal oxides anchored on a nickel substrate are commonly used for OER in alkaline conditions.\(^3,4\) The overpotential for these electrocatalysts is approximately 300 mV at 10 mA/cm$^2$.\(^5\) This relatively high overpotential coupled with the still expensive cost of a nickel substrate shows that there is a need to improve the catalyst performance and also reduce the cost of nickel-based substrates.

We report here on the performance characteristics of an inexpensive, durable, and efficient OER electrocatalyst with a high-surface area low-carbon steel mesh substrate. The first step in the electrode fabrication involved pre-treating the steel mesh by polarizing the electrode under alkaline conditions in a solution of sodium sulfide. This pre-treatment step increases the surface area of the steel mesh substrate by forming iron hydroxides. The modified steel substrate is then treated with nickel nitrate and annealed at 200°C to form a catalytically active nickel hydroxide layer. The electrode is rendered exceptionally robust in 30% potassium hydroxide and highly active towards OER in alkaline conditions by surface modification with nickel.\(^6,7\)

This electrode has the dual advantage of having a low overpotential of 227 mV at 10 mA/cm$^2$ while being significantly less expensive than common electrodes with nickel-based substrates. In addition, it shows excellent stability over 100 hours of continuous oxygen evolution with no loss in performance. This enhanced activity compared to what has been previously reported by our group\(^6,7\) is attributed to the increased catalytic surface area due to the sodium sulfide pre-treatment. Furthermore, we have examined the effect of changing the pre-treatment conditions, especially the number of pre-treatment cycles, and studied its effect on the surface area and catalyst performance. We have also studied the electrochemical and morphological characteristics using electrochemical impedance spectroscopy, SEM, and XPS.

Finally, we demonstrated a fully-functioning “all-iron” alkaline electrolyzer that uses the surface-modified steel for the OER electrode and nickel-molybdenum co-sputtered steel for the hydrogen evolution reaction electrode. The cell
achieves a voltage of 1.7 V at 100 mA/cm² at 70°C. The cell also shows outstanding stability during a 100-hour test at 1000 mA/cm² at room temperature with a cell voltage of 2.1 V.

Electron Transfer in the Solid State—Extension of the Corresponding Orbitals Transformation for Calculating Electron Transfer Parameter VAB to Periodic Systems Payan Kumar Behara and Michel Dupuis; University at Buffalo, The State University of New York, United States

We are interested in the fundamental characterization of solar-to-fuels conversion systems in the three phases of ‘light absorption’, ‘carrier transport’, and ‘carrier reactivity’, all contributing to the overall photo-electro-conversion efficiency. Our major focus is on ‘carrier transport’, specifically the modeling of transport of photo-generated electrons and holes in complex crystalline materials.

Our approach is based on the two-state model of Emin/Holstein/Marcus1–2 in which a key quantity is the electron-transfer coupling matrix element, V_AB, a measure of the strength of overlap between the initial and final electron-localized states. We report on the extension of the molecular method of Farazdel et al.3 to solid state periodic systems. The implementation handles any periodic HF- or DFT-based spin-constrained initial and final states and is carried out in the framework of the CP2K code.4 Test cases will be presented.

This work is supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award # DE-SC0019086.

EN07.05.18

Cobalt Molybdate-Based Electrocatalyst for Efficient Hydrogen Evolution in Alkaline Media Siyu Zhao; University College London, United Kingdom

Nowadays, much attention has been put on green energy production. Hydrogen is one of the most promising energy sources in the future. Electrolysis of water to generate hydrogen is one of the important strategies to produce hydrogen and much effort has been paid to develop costless, efficient and long lifetime electrocatalysts. Recently, transition metal phosphides (TMP) are largely explored due to its excellent hydrogen evolution reaction (HER) performance and low cost. However, the stability of TMP for long-time use is restricted due to its intrinsic structure and therefore HER performance is restricted. Moreover, although the HER mechanism in acid media is well documented, there is still large to explore in alkaline media for HER reaction. In this work, cobalt molybdate phosphides was successfully prepared to make a self-standing electrode. The optimised electrodes showed a small overpotential to reach a current density of 10 mA cm⁻² in alkaline media. The electrocatalysts also showed an excellent stability in a 48h test. Furthermore, DFT calculation combined with XPS tests revealed the whole process to induce P in the reaction and could give some insights to explain the role of P in HER. Results of in situ techniques showed some interesting phenomenon happened at the interface and gave some insights in explaining the HER.
mechanism in alkaline media.

**Enhanced Photoelectrochemical Performance of Ternary Ag/PaNi/NaNbO3 Nanocomposite Photoanode for PEC Water Splitting**

Dheeraj Kumar and Neeraj Khare; Indian Institute of Technology Delhi, India

The consumption of petroleum derivatives, for example, coal, oil and gaseous petrol have turned into a worldwide issue of environmental concern. The energy utilization is quickly increasing with rising population because of which there is a necessity of using sustainable green renewable energy sources to satisfy the needs of energy supply [1]. The solar based energy can be converted and stored in the form of fuels, for example, hydrogen (H2) by water splitting [2]. Hydrogen is an ideal green fuel and can replace fossil fuels in the future Photoelectrochemical (PEC) water splitting is one of the most promising methods for H2 generation on a large scale using a semiconductor nanocomposite materials. [3, 4].

In the present work, a ternary Ag/PaNi/NaNbO3 nanocomposite photoanode has been successfully fabricated by chemically grafting of Ag nanoparticles (NPs) over binary PaNi/NaNbO3 nanocomposite for PEC water splitting applications. The Ag NPs on the surface of binary PaNi/NaNbO3 nanocomposite, act as a photosensitizer under visible-light illumination due to the surface plasmonic effect. The ternary Ag/PaNi/NaNbO3 nanocomposite photoanode exhibit an enhancement in the PEC activity as compared to binary PaNi/NaNbO3 and NaNbO3 photoanodes. Under light illumination, the current density of the ternary Ag/PaNi/NaNbO3 nanocomposite has been achieved to be ~ 5.93 mA/cm² (at 1V vs. Ag/AgCl), which is ~5 fold and ~2 fold higher than pristine NaNbO3 and binary PaNi/NaNbO3, respectively. The enhanced PEC activity of ternary Ag/PaNi/NaNbO3 composites is attributed to the improved light absorption in the visible part of the solar spectrum due to (1) the surface plasmonic effect (as Ag NPs act as photosensitizer for visible-light harvesting), because of coupling with PaNi intermediate material which is used as a remarkable electron transporter which easily effectively separate the e- - h+ pairs and decrease the recombination rate, and due to type-II heterojunction formation between PaNi and pristine NaNbO3. The results show the potentiality of fabricated ternary Ag/PaNi/NaNbO3 photoanode materials towards improved PEC water splitting application.

**Exfoliated NiPS3 Nanosheets as an Oxygen Evolution Reaction Electrocatalyst**

Raksha Dangol1, Zhengfei Dai1,2, Apoorva Chaturvedi1 and Qingyu Yan1; 1Nanyang Technological University, Singapore; 2State Key Laboratory for Mechanical Behavior of Materials, Xi’an Jiaotong University, China

Nanostructuring is an important aspect of synthesis of nanomaterials. 2D materials, considered as promising group of materials for electrocatalysis, can be easily exfoliated into nanosheets by ultrasonic-sum-solvent assisted methods. Nanosheet structures, thus formed, have a large surface area which, expose higher active sites and give rise to fast electron transport during water splitting process. Hence, this process is used to exfoliate bulk NiPS3, a representative material from MPX3 family synthesized using Chemical Vapour Transport method, by the application of ultrasonic bath for a good yield of NiPS3 nanosheets. Various solvents were systematically investigated for obtaining high yield of the nanosheets, whereby Formamide had the highest yield among the ten commonly used solvents. Thus-obtained nanosheets are employed as an oxygen evolution reaction (OER) catalyst. The NiPS3 nanosheets demonstrate an excellent electrocatalytic OER properties, like a low overpotential of 301 mV at the current density of 10 mA cm² and a small Tafel slope of 43 mV dec⁻¹ and a remarkable long-term stable performance. Upon further investigation on the performance, it was observed that the improved catalytic activity was due to a large electrochemically active surface area and high intrinsic activity. It was also found that the in-situ formation of NiOOH and its interface enhances the OH⁻ adsorption and reduces Gibbs free energy of the reaction intermediates.

**EN07.05.21**

**In Situ Raman Spectro-Electrochemical Studies of Support-Catalyst Interface of Nanocarbon Florets**
Supported Co₃O₄ with an Energy Efficient Electrocatalysis under a Magnet  
Jayeeta Saha; Indian Institute of Technology Bombay, India

The demand for worldwide energy calls for the need to build up an effective technology for the manufacture of a clean and sustainable energy source as a fuel cell. Hydrogen is considered as the cleanest and high specific energy density fuel source. The object is to provide catalysts with a catalyst-support which can produce maximum hydrogen with a minimum applied energy, i.e., high current density with low overpotential. For this purpose, comprehending the mechanistic involvement of support-catalyst interface is critical for effective designing of industrially relevant electrocatalytic processes such as alkaline hydrogen evolution reaction (alHER). The understanding of kinetically sluggish alHER exhibited by both Pt and Pt-group-metal-free catalysts is primarily derived from indirect electrochemical parameters such as Tafel slope. Addressing these lacunae, we establish the critical role of nanocarbon florets (NCF) based electrochemical support in generating key cobalt-oxohydroxo (OH-Co=O) intermediate during alHER through operando Raman spectro-electrochemistry. Specifically, interfacial nano-engineering of a newly designed carbon support (NCF) with a spinel Co₃O₄ nanocube catalyst is demonstrated to achieve facile alHER (-0.46 V @10 mA/cm²). Such efficient alHER is mainly attributed to the unique lamellar morphology with high mesoporous surface area (936 m²/g) of NCF that catalyzes the rate-determining water dissociation step and facilitates rapid ion diffusion. The dissociated water drives the formation of OH-Co=O intermediate, spectroscopically captured for the first time through the emergence of \(\text{OH-Co} = \text{O} \) Raman peak (1074 cm⁻¹). Subsequent alHER proceeds through Volmer-Heyrovsky route (119 mV/dec) via \(T_{\text{d}}\) Co\(^{2+}\leftrightarrow Co^{3+}\leftrightarrow Co^{4+}\) oxidative pathway. Concomitant graphitization of NCF through the disappearance of \(\text{sp}^3\text{C-H (2946 cm}^{-1})\) supports the cooperative dynamics at the Co₃O₄-NCF interface. Thus, NCF positively contributes to the lowering of overpotential with low charge-transfer resistance (\(R_{\text{ct}}=35.8 \, \Omega\)) and high double layer capacitance (\(C_{\text{dl}}=410 \, \text{mF/cm}^2\)). Thus, the participation of both catalyst and its support to enhance HER activity is thereby confirmed in contrast to conventionally established understanding of passive support.

Further, for the mass production of hydrogen, the term “magneto-electrolysis” plays a crucial role, where the magnetic fields influence the performance of electrocatalysis processes. Thus we explore the interactions of magnetic fields with electrocatalysts and the control to the formation of the diffusion layer over the electrode-electrolyte interface. This effect in the reaction interface directs the mass transport of reactive components at the electrode surface and control the reaction rate at the electrode-electrolyte interface. This magnetization behavior is present after removal of the small disc magnets, indicating the remanent magnetization of the para/ferromagnetic catalyst, which plays a crucial role in the electrocatalytic enhancement process. Therefore, by using a 0.05 T magnetic field the overpotential of Co₃O₄-NCF was reduced by 12%. The total energy saved by using the 0.05 T magnetic field is 13% of its normal usage. Thus, magneto-electrocatalysis can be the next energy efficient technique for hydrogen evolution and subsequently magneto-catalysis become the alternative of electrocatalysis for water splitting.

EN07.05.22
Triggering Catalytic Active Sites for Hydrogen Evolution Reaction by Intrinsic Defects in Janus Monolayer MoSSe  
Wenwu Shi and Zhiguo Wang; University of Electronic Science and Technology of China, China

Janus transition-metal dichalcogenides have been predicted to be promising candidates for hydrogen evolution reaction (HER) due to their inherent structural asymmetry. However, the effect of intrinsic defects, including vacancies, antisites, and grain boundaries, on their catalytic activity is still unknown. MoSSe provides an ideal platform for studying such defects, since theoretical calculation has indicated that the formation energies of point defects and grain boundaries on MoSSe were lower than that of pristine MoS₂ monolayer. In this work, density functional theory is utilized to study all of the possible intrinsic defects on the MoSSe monolayer for HER. The MoSSe monolayer with 4/4, 4/8a, 5/7b, 8/10a GBs, vacancies (Vs, Vsₐ, Vsₐₐ, Vₘ₉, Vₘ₉₃), and antisite defects (MoSSe, Seₘ₉, Sₘ₉) shows enhanced HER performance. The adsorption behaviors of hydrogen on defects were explained by using a “states-filling” model. The adsorption energy of hydrogen during catalysis changes linearly with the work required to fill unoccupied electronic states within the catalysts. The work required to fill the unoccupied electronic states of MoSSe monolayer can be described via an integral formulation of the DOS of catalyst.

The electronic structures of Janus MoSSe were further analyzed to reveal the deep mechanism of enhanced catalytic activity for HER by introducing defects. The pristine Janus MoSSe shows a direct band gap of 1.55 eV. It is difficult for H to donate its electron to Janus MoSSe by overcoming large barrier of 1.55 eV. Therefore, unstable adsorption states were formed when the H atom adsorbed on the MoSSe surface. However, for MoSSe with Vs and 8/10a GBs, defective states appear below and above the Fermi energy. The gap states would provide an unoccupied state near
the Fermi energy. The Fermi energy level shifts up after H adsorption, which is due to the transfer of charge from H atom to MoSSe. Our calculation reveal that the introduction of gap states in hydrogen adsorbed systems is the origin of enhanced HER activity.

**EN07.05.23**

**Microkinetic Modeling of Water Oxidation in Photoelectrochemical Cells—The Impact of Surface States on the Electrochemistry**

Kiran George¹, Tigran Khachatrjan¹, Matthijs van Berkel¹,²,³ and Anja Bieberle-Hütter¹;

¹DIFFER, Netherlands; ²Technische Universiteit Eindhoven, Netherlands; ³Vrije Universiteit Brussel, Belgium

Water splitting in photoelectrochemical (PEC) cells involves two set of reactions: the hydrogen evolution reaction and the oxygen evolution reaction (OER). We focus on the OER at the semiconductor-water interface to identify limiting processes at the interface. Recently, we have developed a general approach to relate electrochemical measurements to the kinetics of multistep reactions at the semiconductor-electrolyte interface¹. The hematite (Fe₂O₃) – water interface is used as model system in this study. A microkinetic model of OER is developed and is formulated as a state-space model (SSM); the applied potential is the input and the current density is the output. By solving the model, j-V plots and impedance spectra can be simulated similar to experimental measurements.¹

According to the literature, charge transfer under illumination happen directly via the valence band and indirectly via surface states. In our model, we use Gerischer theory and hence the electron transfer rates are defined in terms of empty and occupied energy states on either side of the interface. For any given surface state the charge transfer rate can be calculated similar to the calculation of charge transfer rates via valence band or conduction band.² By using these rates in the state space model, indirect charge transfer via surface states is simulated. Charge transfer via both valence band and surface states are modeled and compared. The impact of surface state properties on the electrochemical measurements is investigated. Steady state j-V plots, impedance spectra, and linear sweep voltammetry curves simulated from the model will be presented for different energy states within the band gap. The sensitivity of these measurements to the intermediate reaction rates, voltage-scan-rate, semiconductor parameters, and other interface parameters is discussed.

**EN07.05.24**

**Bimetallic Phosphide Encapsulated on Carbon Matrix Derived from Metal-Phenolic Network as Stable and Efficient Electrocatalysts for Oxygen Evolution Reaction**

Gwan Hyun Choi, Clament Sagaya Selvam Neethinathan and Piljin Yoo; Sungkyunkwan University, Korea (the Republic of)

Rational design of electrocatalyst with high activity and stability is imperative for developing sustainable water electrolysis. In this work, we have developed bimetallic phosphide embedded in P-doped carbon layers as a stable electrocatalyst for oxygen evolution reaction (OER). Here, distinct from other metal/carbon sources, tannic acid (TA)-based metal-phenolic networks (MPNs) are utilized to design stable and efficient hybrid structures. Especially, thanks to the strong coordination between the phenolic ligands and metal ions in atomic/molecular scale, which facilitates the nanometer-sized hybrids formation with evenly distributed/embedded metal nanoparticles in few layers of graphitic carbons without any aggregations. It has been observed that every single nanoparticle (transition metals=Fe, Co and Ni) in the hybrid can serve as active site while carbon layers can prevent massive surface oxidation and poisoning under OER conditions. Precisely defined metal/carbon interface structure was achieved via simple carbonization step. The subsequent phosphidation results in metal phosphides that remarkably increases the number of active sites. Meanwhile, controlling the appropriate atomic ratio of metal and electronegative P atoms enhances the conductivity of the hybrid electrocatalyst. Since phosphidation process is diffusion-driven reaction from outmost carbon layer to inner metallic phases, the final product has the unique structural characteristics that consist of core metallic phase and peripheral metal phosphide phase with P-doped carbon layers. We have demonstrated that the bimetallic phosphide shows enhanced activity (~270mV at 10mA cm⁻², under 1M KOH alkaline condition) compared with monometallic phosphides, state-of-the-art IrO₂ and other benchmark electrocatalysts. The structural contributions to the electrocatalyst activity and long-term stability (~100 hours) has been systematically investigated by using synchrotron-based X-ray absorption spectroscopy (XAS) and photoelectron spectroscopy (XPS). Combining with structural investigations and electrochemical studies, it can be concluded that its enhanced activity stems from synergistic function of each of metal phosphide species with its

Visible/Near-Infrared Driven Photocatalyst Based on Upconversion Nanoparticles and Graphitic Carbon Nitride Yong Il Park; Chonnam National University, Korea (the Republic of)

Graphitic carbon nitride ($g$-C$_3$N$_4$) is a promising visible-light-driven photocatalyst. $g$-C$_3$N$_4$ is inexpensive, air-stable, and non-toxic material and they have been proven to exhibit high performance in photocatalysis. To use solar energy more efficiently, it is necessary to broaden the light absorption of $g$-C$_3$N$_4$ is required. To take advantage of the near-infrared (NIR) region of solar energy, the $g$-C$_3$N$_4$ was combined with upconverting nanoparticles (UCNPs). The UCNPs convert NIR photons to visible light which can activate the $g$-C$_3$N$_4$ photocatalyst. The use of visible and NIR light source improves the photocatalytic activity of the UCNP@$g$-C$_3$N$_4$ nanocomposites. In order to optimize the photocatalytic efficiency of the nanocomposite, the absorption and emission wavelengths of the UCNPs were tuned by controlling the lanthanide dopant composition. The nanocomposite exhibited excellent photocatalytic activity under simulated solar light illumination.

Effect of Electronic and Structural Properties of Transparent Conductive Colloid Mediator on Z-Scheme Water Splitting over Printable Photocatalyst Sheets Hiromasa Tokudome1,2, Sayuri Okunaka1,2, Shingo Oozu1,2, Takeshi Ikeda1,2 and Kazunari Domen3,4; 1TOTO Ltd, Japan; 2Japan Technological Research Association of Artificial Photosynthetic Chemical Process (ARPChem), Japan; 3The University of Tokyo, Japan; 4Shinshu University, Japan

Photocatalytic water splitting is attracted a significant attention as a low-cost production process for renewable hydrogen using abundant sunlight. In the reaction system using photocatalyst particles, Z-scheme system via two-step excitation can be a practical candidate instead of one-step reaction on visible-light-responsive single photocatalyst particle with difficult development. Z-scheme water splitting can drive by employing two kinds of visible light responsive photocatalysts selectable from various ones in the presence/absence of appropriate mediators such as redox ions or conductive materials. We previously reported that a Z-scheme-type printable photocatalyst sheet exhibited the solar-to-hydrogen energy conversion efficiency (STH) of 0.1%. This sheet is fabricated by screen printing and consisted of mixed films of two kinds of visible-light-active photocatalysts and a conductive mediator nanocolloid on a glass substrate. 1) Recently, we designed a new photocatalyst sheet based on transparent colloidal indium-tin-oxide mediator, attaining the STH of 0.4%. 2) In this study, we fabricated a Z-scheme-type photocatalyst sheet composed of a new transparent and low-cost mediator, antimony (Sb) -doped tin oxide (ATO), and examined the water splitting activity.

Z-scheme-type sheets were prepared via screen-printing on borosilicate glass substrates using a viscous paste including Rh-doped SrTiO$_3$, BiVO$_4$ and ATO particles. The sheets produced hydrogen and oxygen from pure water in the stoichiometric ratio under visible light irradiation. This result showed that the ATO colloid acted as an electron mediator between the two photocatalysts. Moreover, it is found that the water splitting activity varied with Sb doping concentration and particle morphology of ATO colloid.

Aerosol-Assisted Chemical Vapour Deposition of alpha-Fe$_2$O$_3$ Thin Films for Water-Splitting Matthew K. Surman, Andrew Johnson, Michael Hill and Salvador Eslava; University of Bath, United Kingdom

The global interest in developing renewable fuels as an alternative to fossil-based fuels has supported a resurgence in the use of hydrogen; at present, hydrogen is produced predominantly through the steam reformation of methane, and so research has been focused on producing hydrogen more cost-effectively from sustainable sources with a smaller carbon footprint.
Semi-conducting materials with an appropriate band-gap are able to absorb photons emitted by the Sun in order to drive the conversion of water into hydrogen and oxygen. In order for this photoelectrochemical water-splitting to take place, the band-gap of the semi-conducting material must bridge the redox potentials of the two relevant water-splitting half-reactions.

Hematite (alpha-Fe₂O₃) is a well-studied material for photoelectrochemical water-splitting; it has reported optical band-gaps between 1.9–2.2 eV, giving it a theoretical solar-to-hydrogen efficiency of around 15 %. Iron is also an earth-abundant metal, making hematite an inherently cheap-to-produce material, which raises few concerns about supply longevity.

This work focuses on the designing and synthesis of new iron(II) complexes as single-source precursors for hematite deposition using AA-CVD, which can affect the structure and morphology of the resultant films, and thus alter the optical and electronic properties of the film for more favourable photoelectrochemical water-splitting.

**Growth and Characterization of Tantalum Oxynitrate Thin Film for Solar Water Splitting**
Roberto Masso-Ferret, Javier Wu and Ratnakar Palai; University of Puerto Rico at Rio Piedras, United States

In the view of the current global energy crisis and environmental problems, it is a pressing need to explore and exploit some sustainable energy systems. Oxynitrdes are considered as important materials for photocatalytic water splitting applications. In this paper, we report on growth, optimization, and characterization of TaON thin films by sputtering on Si, glass, and sapphire substrates. Structural, electrical, and optoelectronic properties of TaON thin films were investigated using various characterization techniques. The crystalline structure of the films was analyzed using X-ray Diffraction XRD. In order to understand the conduction mechanisms of the samples, we performed current-voltage characteristics. Hall Effect measurements were done on the samples in order to determine band gap and charge carrier’s mobility. The electronic and photocatalytic properties of a prototype for water splitting will be discussed in detail.

**Enhancement of Photocatalytic Oxygen Evolution Reaction of Nanoscale BiFeO₃ Using IrO₂ Nanoparticles**
Wegdan Ramadan¹,² and Detlef Bahnemann¹,³; ¹Leibniz Universität Hannover, Germany; ²Alexandria University-Faculty of Science, Egypt; ³St Petersburg State University, Laboratory “Photoactive Nanocomposite Materials, Russian Federation

BiFeO₃ (BFO) is a multiferroics that combines antiferromagnetic and ferroelectric order well above room temperature also it is narrow band gap semiconductor (~ 2.2-2.7 eV) hence, it can harvest significant amount of visible light. Combining such desired properties on simple ternary compound makes it easier to utilize in many different folds. However, the performance of BFO in overall water splitting is still poor due to the fast recombination of the photogenerated charges and the position of its conduction band with potential less negative than that for water reduction meanwhile its valence band potential is more positive than that required for water oxidation. Here we report on the enhancement of the photocatalytic oxygen evolution reaction, OER, of BiFeO₃ nanoparticles using IrO₂ nanoparticles loaded on the BFO surface using impregnation method. OER showed two folds enhancement upon loading with 2wt% IrO₂. IrO₂ is one of the best catalyst for OER, unfortunately it is also one of the most expensive rare elements hence their applicability is limited by the high cost. Reducing IrO₂ content onto the system should be an option to make its application feasible and cost effective and loading on IrO₂ nanoparticles on the surface could be one feasible solution. Scanning the loaded IrO₂ content from 0.5 wt% to 4 wt% showed a maximum of OER at 2wt % followed by a decrease in activity. XPS showed the formation of Ir (IV) and TEM indicated non uniform distribution of it on the surface. Charge carrier life time and dynamics for pure BFO and IrO₂ loaded BFO have been studied by means of diffuse reflectance laser flash photolysis spectroscopy. Transient absorption of the charge carriers indicated a significant increase in the charge life time in the case of 2wt% IrO₂ loading compared to the other IrO₂ contents. Band positions between BFO and IrO₂ favors the formation of heterojunction at the interface between IrO₂ and BiFeO₃ that enhances the separation of the photogenerated charges
and the photocatalytic OER performance. The position of the conduction band could be manipulated by forming solid solution with SrTiO3 towards formation of Sr1−xBixTi1−xFexO3 having different x values and/or doping BFO to achieve overall water splitting which is our future work.

EN07.05.30
Effect of Hf Doping on ZnO Photo-Anode
Boulos AlFakes1,1, Corrado Garlisi1, Nituil S. Rajput1,1, ChunYu Lu1,1, Ibraheem Almansouri1, Giovanni Palmisano2 and Matteo Chiesa1,1,2; 1Khalifa University of Science and Technology, United Arab Emirates; 2UiT The Arctic University of Norway, United Arab Emirates

The urgent need for a sustainable storable alternative to oil, boosts the research on hydrogen generation using water splitting. ZnO is a promising material in this context, and has been widely studied as an anode in a water splitting solar cell. Different dopants, such as Al, Cu, Ag and N, were utilized to enhance the ZnO performance for this type of applications. In this work, ALD grown Hf doped ZnO is presented as a valid material for utilization as an anode in PEC cell. The effect of Hf doping on the photoelectrochemical performance is studied optically, structurally and electrically. A decrease in the anode resistivity, as well as an increase in the carrier concentration was observed. As a result, an impressive 250% increase in the photocurrent was obtained in the Hf doped sample in comparison to the undoped ZnO. Furthermore, DFT simulations are presented to compliment the detailed experimental characterization, to support the interpretation for this enhanced performance. Those results open the research for utilizing this material into more common water splitting structures, such as nanorods and nanowires, which can be efficiently and conformably coated through atomic layer deposition.

EN07.05.32
A Band Diagram Based Device Modeling Approach for Designing Photoelectrochemical Anodes
Botong Miao, Asif Iqbal and Kirk Bevan; McGill University, Canada

Photoelectrochemical (PEC) cells offer a promising route towards combating climate change through the production of hydrogen fuel. However, PEC cells have remained inefficient due to the sluggish oxygen evolution reaction present at the photoanode. This key inefficiency bottleneck remains a major obstacle to the large-scale commercialization of PEC cells. In this regard, operational photovoltage and photocurrent trends provide key metrics for characterizing and improving the performance PEC photoanodes. However, a quantitative band diagram approach for systematically engineering these properties is still lacking. Here, we discuss how self-consistent solutions to the semiclassical equations governing PEC cells can provide fundamental band diagram based insights into improving their operation. Our work focuses on modeling the ultimate factors determining the photovoltage and photocurrent under active operation and how these quantities can be directly correlated with electron and hole densities in illuminated PECs. In general, this study underscores the engineering opportunities provided by a rigorous device modeling based design approach.

EN07.05.33
Fabrication Process Analysis of Non-Precious Metal Electrochemical Water Oxidation Catalysts of MOx (M = Mn, Fe, Co, Ni) by Raman Spectra
Katsushi Fujii, Kayo Koike, Kei Morishita and Satoshi Wada; RIKEN, RAP, Japan

Non-precious metal oxides are often used materials for electrochemical catalysts and photoelectrochemical co-catalysts of water oxidation. The mechanisms of water oxidations on these catalysts are complicated. Not only -O but also -OOH is believed to play an important role in the water oxidation. Especially, the Fe oxide site for the case in the Fe oxide mixed in the other non-precious metal oxides is said to be the active site [1]. Unfortunately, non-precious metal oxides are usually stable in basic solution but not stable in neutral and acidic solutions even the abilities are comparable to precious metal oxide (IrOx for example) electrochemical water oxidation catalysts. The MnOx is, however, reported to be relatively stable even in the acidic solutions when the applied potential is selected [2]. The water oxidation properties of non-precious metal oxides are still obscure and discussed. The reasons for the complexity of the non-precious oxides electrocatalytic properties are probably the effects that the oxides have multi oxidation numbers, multi-crystal polymorphism, and wide nonstoichiometric compositions. Therefore, the chemical states and bonds of the metal atoms are important characteristics to analyze the properties. One of the non-precious metal oxide formations is thermal oxidation of metal nitrate aqueous solution. In this report, the chemical state
changes of the MOx (M = Mn, Fe, Co, Ni) during the catalyst formation process were observed by Raman spectra as the first step of the analysis of the metal oxide catalysts. The Raman spectra for Mn and Ni nitrate aqueous solution are relatively strong compared to those for Fe and Co nitrates. The spectra show the difference between the different metals. Comparison from their (Ni and Co) reported solid oxide Raman spectra [3,4], some of the peaks are close to its TO related modes and 2LO. The peak around 1000 to 1100 cm⁻¹, which is close to the peak assigned as 2LO in the solids, are most strong. It should be noted that the metal oxides Raman spectra were different with changes in its concentration of metal nitrate in water. The Raman spectra after dropping the nitrates on carbon paper were similar to the form in aqueous solution but changed. The Raman spectra were weakened after the anneal at 250°C for 2.5 hrs in the air. These results probably show that nonprecious metal can change its chemical form easily.

EN07.05.34
Method for Determining Bond Energy in Nanostructured Water Vitaly Bondarenko, Svetlana A. Volchek, Vladimir A. Petrovich, Valentina A. Yakovtseva, Sergey Redko and Alexander Grigoriev; Belarusian State University of Informatics and Radioelectronics, Belarus

Today, there are the following basic ideas about the structure of water as a partially self-organizing system with a dipole as an elementary structural element: (1) in addition to neutral dipole water molecules, water also contains the OH⁻ and H⁺ ions that are products of the water dissociation; (2) water contains water molecules that are linearly associated with hydrogen bonds, and the closed (by the ring principle) structural organization of water is not excluded at that; (3) water forms three-dimensional nanoclusters. Each nanocluster can contain from 100 to 500, and even up to 910 water molecules. The nanocluster size is estimated to be equal to 1.5 nm. The basis for the cluster construction is a tetragonal cell, at the vertices of which water molecules linked by the hydrogen bonds are located. This paper discusses the study of the change in the loss tangent for deionized water in the frequency range from 25 to 10⁶ Hz. The water temperature during the loss tangent registration was 293 and 323 K. The acidity value of deionized water was regulated by hydrochloric acid. Using water as an example, it is shown that monitoring the change in the loss tangent is a high sensitive method that allows determining the activation energy of relaxation processes in nanostructured water with high accuracy. The paper presents an analysis of the use of open- and closed-type sensors. The use of closed-type sensors, the electrodes of which are not in direct contact with the liquid under study, is justified for monitoring the properties of aqueous solutions. When studying the properties of water using a closed-type sensor, the sensor electrodes together with the fluoroplastic coating serve essentially to create an electric polarizing field in the volume of the liquid studied. When registering the dispersion of the loss tangent and other immittance characteristics, electrode reactions associated with the electric current passage through the metal-dielectric-liquid interface (Faraday currents) do not affect the results—they simply do not exist. At the same time, in the bulk of water and its solutions, not only polarization processes, but ion transfer processes take place as well. These processes occur simultaneously. Thus, a closed-type sensor registers mainly the volume properties of water and allows, the acidity values of the solution to be unambiguously determined at any frequency not exceeding 10⁵ Hz.

SESSION EN07.06: Novel Water-Splitting Catalysts I
Session Chairs: Jin Suntivich and Guofeng Wang

Nanometal for Hydrogen Evolution De-en Jiang; University of California, Riverside, United States

Hydrogen in metals underpins many key technologies in energy storage and conversion such as hydrogen storage.
and metal-hydride batteries, but little is known about hydrogen in many nanosystems such as gold nanoclusters. In this talk, I will discuss our recent computational efforts to elucidate the role of hydrogen in metal nanoclusters and the relevant catalytic impact. Especially, we focus on the energetics of H-metal interaction and how it changes the electronic structure of the nanosystems and impacts hydrogen evolution.

Interfacial Engineered Colloidal “giant” Core/Shell Quantum Dots Sensitized Carbon Nanotubes-TiO2 Hybrid Photoanode for High-Efficiency Hydrogen Generation Gurpreet S. Selopal1,2, Mahyar Mohammadnezhad2, Omar Abdelkarim2, Haiguang Zhao3, François Vidal2, Zhiming Wang1 and Federico Rosei2,1; 1IFFS-UESTC, China; 2INRS-EMT, Canada; 3Qingdao University, China

Solar-driven photoelectrochemical (PEC) hydrogen (H2) generation is an attractive approach for the sustainable production of clean and renewable fuels, to address future global energy demands [1-2]. However, the low photon-to-fuel conversion efficiency and long-term stability of PEC devices are major challenges to be addressed to enable large-scale commercialization. The sensitization of the wide band gap semiconductors with colloidal chalcogenide quantum dots (QDs) as light harvesters is an effective approach to extend the absorption spectrum toward the visible and near infrared region (NIR) region, leading to significant improvement of the PEC performance[3]. A specially designed “giant” core/shell QDs exhibit superior optoelectronic properties such as better photophysical/chemical stability, suppressed non-radiative Auger recombination, improved quantum yield (QY), and improved exciton lifetime and the formation of quasi-type-II core/shell by tailoring the shell thickness/composition as well as the core size [4]. Also, the carbon nanomaterials such as carbon nanotubes (CNTs), graphene, graphene nanoribbons and graphene oxide are widely used in various optoelectronic devices due to their unique structural and optoelectronic properties such as excellent conductivity, high mechanical strength and optical transparency [5]. Herein, for the first time, we explore a simple, fast and cost-effective approach to fabricate high efficiency and stable PEC devices for H2 generation, by using a specially designed colloidal “giant” CdSe/(CdSe,S1-x)5/(CdS)2 core/shell QDs as sensitizer and a hybrid photoanode with small amounts of CNTs into a TiO2 mesoporous film.

We will discuss the synergistic effect of promising optoelectronic properties of specially designed colloidal giant” CdSe/(CdSe,S1-x)5/(CdS)2 core/shell QDs and improved electron transport (reduced charge transfer resistance) within the TiO2-CNTs hybrid anodes enabled by the directional path of CNTs to the photo-injected electrons towards FTO. Resulting, PEC devices based on TiO2/QDs-CNTs (T/Q-C) hybrid photoanode with optimized amount of CNTs (0.015 wt%), yield a saturated photocurrent density of 15.90 mA.cm-2 (at 1.0 VRHE) under one sun illumination (AM 1.5 G, 100 mW×cm-2), which is 40% higher than the reference device based on TiO2/QDs (T/Q) photoanodes. In addition, enhanced stability of the PEC device based on T/Q-C hybrid photoanodes (~19% loss of its initial photocurrent density) as compared with the T/Q photoanode (~35% loss) after two hours of continuous one sun illumination will be also presented and discussed in details. These results provide fundamental insights and a different approach to improve the efficiency and long-term stability of PEC devices and represent an essential step towards the commercialization of this emerging solar-to-fuel conversion technology.

Molecular Insight into the Osmolality of Ionic Liquid with Lower Critical Solution Temperature Transition Behavior Hyungmook Kang1,2, Akanksha K. Menon1, Robert Kostecki1, Chris Dames2 and Jeffrey Urban1; 1Lawrence Berkeley National Laboratory, United States; 2University of California, Berkeley, United States

A subclass of ionic liquids (ILs) undergoes a thermoresponsive liquid-liquid phase transition of lower critical solution temperature (LCST). In liquid-liquid mixtures with an LCST transition, a single and miscible phase appears at lower temperatures, whereas the single-phase mixture separates into two immiscible phases upon heating above a critical temperature. The IL-based mixtures as draw solutes have opened up new water purification potentials such...
as forward-osmosis desalination. This study tracks the changes in long-range order and local-molecular environment of an IL-water mixture with LCST transition, experimentally and theoretically. In the mixture, the IL forms loosely hold aggregate structures that grow in size leading up to a critical temperature, whereas the aggregation of a fully miscible aqueous mixture by minor chemical modification of the anion shrinks versus increasing temperature. Radial distribution functions from Molecular Dynamics simulations support the observation of aggregation phenomena in the IL-water mixtures. For the usage as the osmosis draw solutes for water purification, the osmolality of the IL in water is measured as a function of concentration. The geometric nature of ILs introduce steric hindrance and strong attractive interaction between cation and anion causes a non-monotone trend of the osmolality. Molecular approaches considering the interaction between ions and the number of water molecules near each ion from Molecular Dynamics simulation suggest a method to define free ions in the mixture, which can improve the osmotic pressure.

9:30 AM EN07.06.04
A Combined Spectroscopic and First-Principles Approach for the Atomistic-Level Description of Semiconductor/Electrolyte Interface
Masahiro Sato, Yuki Imazeki, Takahito Takeda, Masaki Kobayashi, Susumu Yamamoto, Iwao Matsuda, Jun Yoshinobu, Yoshiaki Nakano and Masakazu Sugiyama; The University of Tokyo, Japan

Photocatalytic water splitting is one of the most attractive technologies for storing sunlight. However, today’s photocatalysts (photoelectrodes) still suffer from low efficiency or poor stability [1], and to overcome these problems, the physical basis of photoelectrochemical reactions has to be understood in more detail. Band alignment (i.e., the relative position between the conduction band minimum (CBM) or the valence band maximum (VBM) of the semiconductor and the redox potentials in the electrolyte at the semiconductor/electrolyte interface,) determines whether the reaction of interest proceeds or not, and therefore is the key factor for photoelectrochemical reactions. Nevertheless, from an atomistic point of view, little is known about the photocatalyst(semiconductor)/electrolyte interface, and the relationship between the band alignment and the geometric structure at the interface remains unrevealed.

The recent development of ambient pressure X-ray photoelectron spectroscopy (AP-XPS) has made it possible to probe the electronic structure of the semiconductor/electrolyte interface under nearly in situ conditions [2]. However, XPS results are not self-explanatory in the sense that it requires XPS signatures obtained from other experiments in order to identify the chemical elements and the nature of their chemical bonds. Considering the above, in this contribution, we probe the relationship between the band alignment and the geometric structure at the semiconductor/electrolyte interface by combining AP-XPS measurements and first-principles calculations. As a starting point, we investigate water adsorption on crystalline GaN (0001) surface to avoid excessive complexity.

The band alignment between semiconductors and electrolytes are determined by both the intrinsic and non-intrinsic properties. The non-intrinsic properties, that is, ones that cannot be determined from the bulk properties of the materials alone, are: the (1) band bending and (2) the surface dipole layer.

AP-XPS analysis allowed us to evaluate the band bending from the energy difference between the VBM and the Fermi level of the n-GaN substrate. In line with previous studies [3], the results have showed that the water adsorption on the GaN substrate reduces the band bending. The first-principles calculations have showed that the density of mid-gap states are reduced upon O, OH, or H adsorption. Taking both experimental and computational results into account, one can conclude that the band bending is reduced by the dissociative adsorption of water molecules. In addition, the O 1s spectra, which are interpreted using the computed O 1s binding energies, indicates that some portion of water molecules dissociates into O atoms as well as OH groups.

The potential shift due to the surface dipole layer is roughly estimated from the AP-XPS experiments by detecting the change in the O 1s binding energy of the water molecules in the gas phase. By comparing the results with the computed surface dipoles of various interface models and the amount of surface species estimated from the AP-XPS O 1s spectra, we have shown that the surface dipole is determined not only by the dipole of the adsorbates but also by the charge transfer between the substrate and the adsorbates.

In conclusion, we have found that it is possible to obtain an atomistic-level description of the interface-specific properties that determine the band alignment at the semiconductor/electrolyte interface. The approach described above will help us decide how to realize the desired band alignment at the photocatalyst/electrolyte interfaces.

Earth-Abundant Metal-Metalloid Materials as Highly-Efficient Oxygen-Evolving Electrocatalyst Jean Marie Vianney Nsanzimana and Vikas Reddu; Nanyang Technological University, Singapore

Abstract: Electrochemical energy conversion and storage devices, including metal-air batteries, regenerative fuel cells, and water-splitting cells are critical to satisfy the future energy demand of human society. Though electrochemical water splitting technology has been well-established among other techniques as a clean and efficient technology for hydrogen production because of the possibility of coupling to other renewable sources, such as solar and wind energy, it is still limited by the sluggish anodic oxygen evolution reaction (OER).[1] As this sluggish electrochemical reaction is also involved in many energy storage and conversion technologies, it has become a hot topic over the last decades.[2] Precious metal-based catalysts such as Iridium- and Ruthenium-based oxides and their composites are used predominantly, but the scarcity and low stability limit their application at large scale.[3] As a consequence, intensive efforts have been devoted to developing cost-effective catalysts with superior oxygen-evolving activity and stability.[4] The earth-abundant metal-metalloid materials represent an emerging family of highly efficient oxygen-evolving catalysts due to their ability for charge transfer between different elements and modified electronic structures lowering the kinetic energy barriers of the electrochemical processes.[5] Herein, we present a fast and simple method of synthesizing iron-doped amorphous nickel boride on graphene oxide sheets. The hybrid exhibits outstanding OER performance and stability in prolonged OER operation. In 1.0 M KOH, only an overpotential of 230 millivolts is required to afford a current density of 15 milliampere cm$^{-2}$ and showed outstanding stability in alkaline solution. The superior OER activity of the as-prepared catalyst is attributed to (i) unique amorphous structure to allow abundant active sites, (ii) synergistic effect of constituents and, (iii) strong coupling of active material and reduced graphene oxide. This work not only provides new perspectives to design highly effective material for OER, but also opens a promising avenue to tailor the electrochemical properties of metal boride which could be extended to other materials for energy storage and conversion technologies.

Hierarchical Sb$_2$Se$_3$ Light Absorber—Nanostructured Photocathode for Highly Efficient Solar to Hydrogen Conversion
Jaemin Park, Wooseok Yang, Jeiwan Tan, Hyungsoo Lee, Sang-gi Shim and Jooho Moon; Yonsei University, Korea (the Republic of)

For practical hydrogen production via photoelectrochemical (PEC) water splitting, proper nanostructuring enabling of sufficient light absorption and effective charge carrier transport to the electrolyte is of immense importance. In this study, we propose novel nanostructure for photocathode using Sb$_2$Se$_3$ which is nontoxic, low band gap and earth-abundant materials. The planar Sb$_2$Se$_3$ film is fabricated with molecular precursor ink to avoid direct contact of conductive substrate and electrolyte then the branch-like Sb$_2$Se$_3$ nanowires sequentially decorate the planar film by an additional facile spin coating. UV-vis spectroscopy shows that internal scattering at nanowires enables the reduced reflectance by bilayer structure. After the surface modification with TiO$_2$ and co-catalyst Pt, impedance spectroscopy and intensity-modulated photovoltage spectroscopy are also conducted to examine the charge transport of the film in which the electrons are easily transported to the electrolyte due to higher surface area. Furthermore, incident photon to current efficiency at the long wavelength for hierarchically bilayer Sb$_2$Se$_3$ based photocathode reveals increases dramatically compared with monolayer film, indicating more efficient light harvesting in wide wavelength area. Consequently, improved optical and electrical characteristics allow us to demonstrate the record high photocurrent at 0 V versus reversible hydrogen electrode up to 28.5 mA cm$^{-2}$. This implies the successful achievement of the highly efficient Sb$_2$Se$_3$ based photocathode with a hierarchically bilayer structure. Our findings clearly illustrate the impact of our Sb$_2$Se$_3$ device as a promising candidate for practical PEC water splitting.

Development of a Method to Characterize Active Sites in Photocatalysis Using Operando Transmission Electron Microscopy
Eric A. Stach, Vincent A. Verret, Pawan Kumar, Noah Glachman, Khim Karki, Daan Hein Alsem and Deep M. Jariwalla; 1University of Pennsylvania, United States; 2Hummingbird Scientific, United States

Hydrogen gas has the potential to be a clean source of sustainable energy due to its high energy density. However, greenhouse gas emissions are still a major byproduct of current hydrogen production methods. Photoelectrochemistry provides a promising, environmentally friendly route to hydrogen production. However, the atomic scale mechanisms of the photocatalysts that facilitate the water splitting reaction are currently poorly understood. Further understanding of the chemical physics governing the active hydrogen evolution sites would allow for better design of photoelectrochemical devices and thus lead to improved reaction efficiencies. This will overcome one of the major barriers impeding this promising technology. We have developed a unique operando photoelectrochemistry transmission electron microscope liquid cell sample holder which can be used to characterize these reactions in real time at nanometer length scales. This system builds upon our prior developments of operando electrochemical liquid cell holders, by including the additional provision of an optical fiber directed at the sample to provide full solar spectrum illumination. In order to provide accurate, quantitative information, it is necessary to accurately deposit the photocatalyst of interest onto microfabricated electrodes. In this research, a precise sample deposition technique utilizing an inkjet printer has been developed along with stable suspensions of known photocatalysts, leading to site-specific deposition onto the electrode chips. Specifically, this experimental design allows for correlation between I-V characteristics and real time, high magnification imaging and spectroscopy, elucidating information about photocatalytic mechanisms at the nanoscale. The following photocatalysts used were chosen because the proposed mechanism for each exhibits a spatial dependence: plasmonically enhanced catalysis for Au nanoprisms and catalytically active edge sites for MoS$_2$ flakes. These experiments will lay the groundwork for the use of this novel experimental design to investigate a wide variety of photoelectrochemical systems and will allow determination of the mechanisms by which selected photocatalysts induce water splitting and the identification of defect features that serve as the active sites.

Hydrogenated TiO$_2$-Silicon Tandem Cell Platelets for Direct Water Splitting
Helmut Karl; University of Augsburg, Germany

Hydrogenated TiO$_2$ (H:TiO$_2$ or black titania) shows highly increased absorption in the visible frequency spectrum of light in parallel with an improved photoelectrochemically (PEC) water splitting activity. These findings dragged...
interest on the properties and in particular on the synthesis, electrical properties and stability of H:TiO₂.

It became also apparent that there might be no single compound which simultaneously fulfills all requirements for unassisted (i.e. without externally applied electric fields) direct PEC water splitting, which are firstly band edge energy levels and quasi-Fermi energy level positions providing over potentials needed to enable hydrogen (HER) and oxygen evolution (OER) reactions, secondly a potential difference of more than 1.23 V, and thirdly chemical stability under highly photo corrosive working conditions.

Coupling of H:TiO₂ with a mobility energy gap E₉ of 1.5-3.2 eV with amorphous a-Si:H (E₉ = 1.1-1.8 eV), which results in a theoretical maximal solar to hydrogen (STH) efficiency of 20% in thin film tandem cell structures, could be a route toward low cost PEC water splitting systems.

Nanoparticle suspensions might play a key-role in achieving efficient and cost effective PEC water splitting. The reason for this is, that nanostructured semiconductors possess a large surface to volume ratio and by choosing an appropriate particle size, particle geometry (e.g. platelet) and catalysts mutually dependent conversion steps, which crucially determine photovoltaic and PEC performance in their bulk counterparts, can be decoupled. This concerns in particular the generation and selective separation of photogenerated electron-hole (e-h) pairs which are mainly controlled in bulk materials by diffusion, gradients of the electrical potential and finally by gradients of the quasi-Fermi energies. In nanostructures localized surface states with extremely fast charge carrier transfer times and charge carrier transport times to the interfaces much smaller than e-h pair recombination times in the bulk determine the selectivity and efficiency.

A very important feature of the here proposed PEC tandem cell platelets is the very short charge carrier transport length to the facing large surfaces. The thickness of the tandem top- and bottom-electrode can be adjusted independently from their lateral dimension and adapted to optimize photogenerated electron-hole pair separation. In contrast to conventional solar tandem cell architectures, where thick absorbing semiconductor layers are applied and carrier diffusion is important, ballistic transport of photogenerated electrons and holes to the liquid/solid and solid/solid interfaces by utilizing very thin top- and bottom-layers with H:TiO₂ and a-Si:H can be achieved.

In this work H:TiO₂ thin films were grown in-situ by fully reactive sputtering of a metallic Ti target on silicon and silica substrates. We mapped the critical process parameters consisting of the sputter gas ratio and the RF-sputter power over a wide range for determining growth condition resulting in maximal hydrogen incorporation. Quantitative depth profiling of the H-content in the H:TiO₂ thin films was performed by helium elastic recoil detection analysis (He-ERDA) which revealed an H-content of more than 2.7 at.%. The optical absorption coefficient and temperature dependent electrical conductivity will be discussed in context of the thermal stability and hydrogen content. The temperature dependent resistivity and Seebeck coefficient of H:TiO₂ thin films were determined by consecutive temperature cycles up to 723K and show to be stable up to 673 K, above which a slight increase in the resistivity was observed. First H:TiO₂-silicon-iridium tandem cell platelets will be presented an their properties discussed.

Combinatorial Thin-Film Deposition for High-Throughput Electrocatalyst Testing Anthony Thompson¹, Hector Colon-Mercado¹, Elise Fox¹, Larry Scipioni², James Greer² and Adam Shepard²; ¹Savannah River National Laboratory, United States; ²PVD Products, United States

Catalytic processes can often be improved and optimized by changing the composition of the catalyst, but it is often not feasible to explore the entire compositional space because of the time and cost of performing multiple syntheses. High-throughput methods allow for the exploration of a wide range of variables in a relatively short period of time.

Here we demonstrate the high-throughput testing of electrocatalysts for SO₂ oxidation, the electrochemical step of the Hybrid Sulfur (HyS) process for water splitting, over a full range of compositions of Au, Pt, and V. Catalysts were synthesized by combinatorial sputter deposition of multiple thin film patches onto a glassy carbon substrate and compositions were confirmed by XPS. A scanning electrochemical microscope (SECM) with a scanning droplet system (SDS) attachment was used to obtain CV curves and map electrochemical activity across the entire glassy carbon plate, allowing rapid optimization of metal ratios for the reaction.

Electrocatalysis with Graphitic Carbon Catalysts Troy Van Voorhis; Massachusetts Institute of Technology, United States

Pyrolytic graphitic carbon materials possess tantalizing activity toward a range of reactions - from hydrogen evolution, to oxygen reduction and oxygen evolution. However, the uncontrolled nature of their synthesis makes it virtually impossible to rationally improve them. Recently, graphitic carbon catalysts (GCCs) - small molecule catalysts that are directly conjugated to the edges of graphitic carbon - have been shown to possess similar reactivity but with controllable synthesis. This presentation will give an overview of the mechanism of oxygen reduction (ORR) in GCCs and present the results of several large-scale computational screening experiments aimed at improving the activity and selectivity of the catalysts. In particular, we find that the GCCs do not obey the commonly accepted scaling relations that limit ORR performance in traditional heterogeneous catalysts. We hypothesize this is due to the fact that these are organic and organometallic complexes, which are empirically known to provide a greater degree of chemical specificity than inorganic solids and surfaces. We conclude with an analysis of the transferrability of these ideas to the reverse reaction of ORR.

First-Principles Predictions of Photoelectrode Materials—From Bulk to Complex Interfaces Tuan Anh Pham¹, Tyler Smart², Yuan Ping², Brandon Wood¹ and Tadashi Ogitsu¹; ¹Lawrence Livermore National Laboratory, United States; ²University of California, Santa Cruz, United States

The generation of hydrogen from water and sunlight through photoelectrochemical cells (PECs) offers a promising approach for producing scalable and sustainable carbon-free energy. The design of high-performance PECs requires a detailed understanding of physicochemical properties of not only the semiconductor photoelectrode, but also the interface between the material and liquid water. In this presentation, we discuss how first-principles simulations can be utilized to unravel the key chemical and electronic properties of photoelectrode materials in the bulk phase and at the interface with liquid water. Specific discussion focuses on how hybrid density functional theory and many-body perturbation theory can be used to provide high-fidelity description of the electronic properties of photoelectrode materials, including their band gap and band edge positions. In addition, we show how first-principles molecular dynamics simulations can be coupled with near-ambient-pressure XPS experiments for the identification of solid/liquid interfacial chemical composition and speciation, which is necessary for devising meaningful strategies to improve PEC performance and durability. Examples for different materials, from Co₃O₄ to III-V semiconductors will be discussed, based on which we suggest a more general roadmap for obtaining a realistic and reliable description of the chemistry of complex.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Estimation of Electronic Entropy Contributions to Oxygen Vacancy Formation Reaction in Nonstoichiometric Oxides via Analysis of Electronic Structure Properties Conrad R. Cole; University of Florida, United States

The primary motivation of this work is to develop a method through which the entropy change of oxygen vacancy formation may be computed from first principles for strongly correlated metal oxides which exhibit intrinsic spin polarization. Namely, a methodology via which the electronic structure may be utilized to predict electronic entropy contributions to the overall free energy change. Leveraging electronic structure properties facilitates the process by circumventing the need for extensive combinatorics and statistical methods which are conventional approaches for entropy calculations within the realm of statistical physics. Nonstoichiometric cerium dioxide (CeO₂) and the manganite perovskites (AMnO₃) form a prototypical composition space meeting the criteria above and possessing a high degree of versatility with applications ranging from electrocatalysis and solar thermochemical energy storage to electronic and magnetic devices. The acquisition of a fundamental understanding of the mechanisms governing entropy in these materials would enhance the rate at which they may be optimized and tailored for current applications and potentially enable the discovery of novel applications for which they are ideal candidates.
It is commonly assumed that finite temperature electronic contributions to the free energy of insulators and semiconductors may be neglected due to the lack or absence of electron density near the Fermi level. This may be the case when treating ideal, pristine systems since there are no electronic levels available for population due to thermal excitation of electrons near the valence band maximum. This sizable bandgap in medium to wide gap materials limit the number of electronic configurations accessible to the highest occupied levels. The validity of this assumption is highly questionable however, especially when charged defect levels are present within the energy gap increasing the density of states near the Fermi level. Shallow defect levels with unpaired electrons near the VBM would allow for an increase in the number of microstates for thermal population of electrons contributing to the electronic configurational free energy.

The electronic density-of-states data from a structural relaxation at the HSE06 level of theory with a 12-atom Ce4O8 bulk supercell was implemented to calculate the Fermi level (electron chemical potential) as a function of temperature. The Fermi-Dirac distribution along with the normalized DOS were utilized to estimate the majority carrier concentration (assuming only electronic charge carriers) via the difference between the conduction band and valence band integrals. A greedy algorithm is utilized to evaluate the Fermi level at which the error between the calculated carrier concentration (via above parameters) at a given temperature and the predicted/estimated carrier concentration is minimized.

The corresponding electronic entropy agrees relatively well with results from work by Naghavi et al. in magnitude and variation with respect to temperature. Further validating the significance of electronic entropy contributions to the energetics of oxygen vacancy formation in ceria and other similar mixed conducting oxides which may be comparable to if not greater than structural configurational and vibrational entropic terms. Recent work by Lany highlighted this relationship between temperature, Fermi level and charged defect formation energies specifying that electronic entropy is the physical or thermodynamic consequence of this phenomenon. Specifically, the energy level of the oxygen vacancy, the conduction band effective mass and the temperature dependence of the conduction band minimum were claimed to be the electronic structure properties that govern the electronic entropy contribution to vacancy formation free energies. The work presented herein provides numerical evidence to support the claims made by Lany in a purely analytical deduction.

Multiscale Modeling of Charge Carrier Dynamics in Complex Metal Oxides for Solar Water Splitting—The Case of Anion Doping in BiVO4
Viswanath Pasumarthi, Pavan Kumar Behara and Michel Dupuis; University at Buffalo, The State University of New York, United States

This presentation will deal with computational modeling dealing with doping strategies toward enhanced carrier transport and overall photo-electro-conversion (PEC) efficiency of semiconductor electrodes, in particular BiVO4, the best anode material to date. We carried out multiscale modeling, combining DFT+U calculations of e/h polaron hopping by Marcus/Holstein theory and Kinetic Monte Carlo (KMC) modeling of collective charge carrier transport at the mesoscale. We will highlight the approach first for a stoichiometric bulk BiVO4 where simulations revealed that hole transport is bimodal, featuring fast rattling but transport-inefficient hops and slower transport-efficient hops, while electron transport is slower yet. We will then discuss the structure and stability of electron and hole polarons in the presence of sulfur doping. DFT calculations reveal that sulfur atoms substitute oxygen and act as hard traps (~ 14 k_BT) for electrons in their vicinity. We will describe how sulfur incorporation affects electron and hole transport dynamics resulting in enhanced transport efficiency. If time permits, we will highlight modeling of cation doping by W/Mo, including the design of homo-junctions for enhanced carrier separation.

Photoelectrochemical (PEC) water splitting is a renewable energy conversion process in which hydrogen and oxygen are generated from water using energy from sunlight that is attracting much interest in a sustainable energy economy. However, there exist several scientific and engineering challenges in implementing this technology at industrial scale. A broad critical challenge is to identify suitable semiconductor materials for photoelectrodes in PEC cells: they must exhibit good visible light absorption and carrier generation, good carrier transport, and good redox reactivity. Metal oxides have the promising advantages of stability in aqueous medium and wide and inexpensive availability of the constituent elements. Bismuth vanadate (BiVO4), a ternary metal oxide is one of the best performing photoelectrode material to date, with its most photoactive monoclinic phase having a wide band gap of
~2.4-2.5 eV. Systematic investigations of the performance limiting factors have led to significant progress over the past decade. Engineering the material using strategies such as nanostructuring, or metal-ion doping by tungsten (W) and molybdenum (Mo) have resulted in photocurrents to reach ~6.7 mA/cm², ~90% of theoretical maximum of ~7.5 mA/cm². Recently, anion doping with nitrogen/sulfur was found to decrease the bandgap by up to ~300 meV for improved solar spectrum absorption.

This work is supported in part by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award # DE-SC0019086.

Phenyl Oxidation at Oxygen Evolution Potentials—Impact on Alkaline Membrane Electrolyzer Durability

Dongguo Li, Ivana Matanovic, Albert S. Lee, Hoon T. Chung and Yu Seung Kim; Los Alamos National Lab, United States

The durability of alkaline membrane/ionomer is a critical requirement for commercially viable alkaline membrane water electrolysis. In this presentation, we report the oxidation of the phenyl group in the ionomer adsorbed on the oxygen evolution catalysts, which may cause performance deterioration in AEM electrolyzers. The 1H-NMR analysis in combination with rotating disk electrode studies shows that the oxidation of phenyl group occurs at oxygen evolution potentials, ca. 1.6 V under both low and high pH conditions. Further study indicates that the phenyl oxidation also depends on the nature of catalysts. Commercial Pt/C and IrO₂ noble metal catalysts exhibit much faster phenyl oxidation compared with La₀.₈₅Sr₀.₁₅Co₃ perovskite oxide. Density functional theory calculations also confirm that the phenyl adsorption is significantly less pronounced on the perovskite oxide catalyst, implying phenyl adsorption at the oxygen evolution potentials is a critical factor determining the phenyl oxidation. This research provides a path for the development of more durable AEM electrolyzers with components that can minimize the adverse impact induced by the phenyl group oxidation, such as the development of novel ionomers with fewer phenyl moieties or catalysts with less phenyl-adsorbing characteristics.

Linking Surface Properties to Electrochemical Activity of Water Splitting Catalysts

Yelena Gorlin; Research and Technology Center, Robert Bosch LLC, United States

Improvements in water splitting technology requires detailed understanding of associated electrochemical reactions, the oxygen evolution reaction and the hydrogen evolution reaction, as well as catalyst surfaces on which these reactions occur. This talk will first focus on the oxygen evolution reaction and present examples of how X-ray absorption spectroscopy characterization can be combined with electrochemistry to study the oxidation state of the catalysts under reaction conditions. Then, it will transition to hydrogen evolution reaction and reexamine electrochemical activity of precious-metal catalysts in alkaline environment. In this example, detailed analysis of the micropolarization region of rotating disc electrode experiments will be combined with calculations of the relevant surface conditions, in order to interpret the characterized exchange current densities in the context of surface properties of the catalysts.

9:00 AM EN07.08.02

Unravelling the Structure—Properties Relationship of MOCVD Co₃O₄/TiO₂ Heterojunctions for Solar Water Splitting

Adeline Miquelot¹, Olivier Debieu², Stephanie Roualdes³, Christina Villeneuve³, Nathalie Prud’homme³, Jeremy Cure³, Vincent Rouessac⁴, George Papaveros⁵, Vassilios Constantoudis⁶ and Constantin Vahlas⁷;

¹CIRIMAT, France; ²INPT, France; ³Université de Montpellier, France; ⁴Université Paul Sabatier, France;
⁵Université Paris-Sud, France; ⁶LAAS, France; ⁷CNRS, France; ⁸NCSR Demokritos, Greece

Green H₂ production by solar water splitting entirely relies on the intrinsic properties of the photocatalyst. Among
the numerous photocatalytic materials investigated on purpose, heterojunctions based on TiO₂, the quintessential component of state of the art photocatalytic systems, are expected to expand the photocatalytic activity to the visible domain of the solar spectrum. In this perspective, literature reports on the p/n Co₃O₄/TiO₂(anatase) heterostructure are contradictory as they mention either improvement or degradation of their photocatalytic activity with regard to the single anatase photoanode. The aim of the present contribution is to contribute to the elucidation of this question and, subsequently to the illumination of the impact of the intrinsic properties of this material, explored at nanoscale, on its photocatalytic activity under visible light illumination.

We process the Co₃O₄/TiO₂ heterostructure in the form of a two films stack by a sequential MOCVD process, starting from cobalt 2,2,6,6-tetramethyl-3,5-heptanedionato, Co(dmp)₃, and titanium tetra-isopropoxide, TTIP. Deposition in the temperature range 350 to 550 °C provides Co₃O₄ and anatase films with variable characteristics. We implement a multiscale, holistic microstructural, optical and electrical characterization of the two types films alone and of various Co₃O₄/TiO₂ bilayers, using state of the art techniques, microscopic (SEM-FEG including advanced image analysis, AFM, HRTEM, EBSD/TKD), spectrometric (FTIR, Raman, UV-Vis-NIR, ellipsometry, XPS, XRD, EPMA, EDX), and electrical/electronic (conductive AFM, Hall and Van der Pauw resistivity, Seebeck coefficient).

We show that, with increasing deposition temperature, anatase films evolve from dense to porous, nanotree-like columnar structures. This evolution results in a remarkable increase of the exchange surface, coinciding with a change of growth direction, from <110> to <001> and to the increase of the porosity, to a decrease of the optical absorption, and to an increase of both the electrical resistivity and the carriers density.

In the same conditions, the morphology of the Co₃O₄ films evolve in the opposite direction, from columnar to dense. These films show a minimum room temperature resistivity of 21.4 Ω.cm, and Hall resistivity measurements establish their p-type semiconducting behavior with a maximum holes density of 1.8 ± 0.8×10¹⁸ cm⁻³, and a maximum holes mobility of 0.16 cm² V⁻¹ s⁻¹. We attribute the linear T⁻¹/₄ temperature dependence of the film conductivity to a 3-dimension variable range hopping conduction mechanism of holes. The surface topographies of the deposition temperature dependent morphologies perfectly match the current maps at the AFM scale, demonstrating that the variable range hopping conduction of holes occurs through the Co₃O₄ nanocrystallites. The 66 h cumulative H₂ photogeneration from the single anatase films increases from 4.4 to 78.9 mmol.m⁻² with increasing the deposition temperature from 325 to 450 °C. This result points out the importance of the beneficial effect of the morphological nano-complexification, and of the crystallographic diversification of the exchange facets on the photocatalytic performance over detrimental aspects inherent in this evolution, namely, the decreases of the optical absorption and the increase of residual stress, also described here. We process heterojunctions by cross combining dense and columnar single layers of the two semiconductors. The resulting H₂ photogeneration is strongly reduced with regard to the anatase films, despite a strong decrease of the thickness of the external Co₃O₄ layer to less than 50 nm, aiming at the exposure of both semiconductors and of their interfacial zones to the light. This result is in agreement with the strong decrease of the electrical conductivity perpendicular to the stack. Detailed analysis of the interface is actually in progress in order to reveal the reasons of this behavior.

9:15 AM EN07.08.03
Unfolding the Effect of the O₂ and N₂ Plasma on Hydrogen Evolution Reaction of MoS₂ Lalita Sharma; Indian Institute of Technology, India

Defect engineering is widely adopted technique to increase the density of exposed active sites. Plasma technique is proved as an effective technique to tune the surface properties and edge reactive sites for greatly improving the electrochemical activities. In this report, controlled oxygen (O) and nitrogen (N) plasma used to generate defects and introduce dopants N and O in MoS₂ nanosheets to form defect-induced nanocomposite material MoS₂₋ₓₓ (X= N, O) with sulphur vacancies. Defects in the MoS₂ nanosheets help to improve the number of active sites but extra defects deteriorate electron mobility. So here mild plasma technique is used to (1) increase the hydrogen evolution reaction (HER) catalytic activity of MoS₂ S-edge and (2) electron mobility of MoS₂ nanosheets for fast electron transfer which are one of the responsible factors to increase the electrochemical activities. Electrochemical measurements prove that with the combination of both active sites along with the incorporation of O & N dopants enhance HER activities. The superior activity and stability for the hydrogen evolution reaction with low overpotential and fast electron transfer is derived from the coexistence of both doping effect and sulphur vacancies.

Comparison of Light-Intensity-Dependent Open-Circuit Potential among TiO₂, SrTiO₃ and GaN Single-Crystalline Photoanodes Supawan Ngamprapawat¹, Yuki Imazeki¹, Tsutomu Minegishi¹, Masahiro Sato¹, Katsushi
Photoelectrochemical (PEC) water splitting is a promising technology that converts solar energy into a storable energy carrier, hydrogen. Many signs of progress have been reported. Nevertheless, the efficiency and the stability of PEC water splitting is still unsatisfactory. Finding a photoelectrode material which has an appropriate alignment of quasi-Fermi energies under illumination with respect to redox potentials of water is an essential condition for the progress of PEC water splitting.

Semiconductor photoelectrodes are a key component. They are often selected based on the band-edge energies, assuming a flat-band situation. However, band bending generally exists at the semiconductor/electrolyte interface, which makes the flat-band condition unattainable under insufficient light intensity. When the light intensity exceeds a certain value, the band bending is reduced by an accumulation of photo-generated carriers. By comparing the light intensity dependence of band bending among a variety of materials, it would be possible to explore the fundamental processes governing the function of semiconductor photoelectrodes from the viewpoint of semiconductor physics, similarly to the analysis for photovoltaic devices.

In this study, light-intensity-dependent open-circuit potential (OCP) of three types of single crystalline photoelectrodes: (i) undoped and 0.05 wt% Nb-doped TiO$_2$, (ii) 0.01 wt% and 0.05 wt% Nb-doped STO, and (iii) n-type GaN on Si was investigated with varied photon flux from $10^9$ to $10^{17}$ s$^{-1}$cm$^{-2}$. A He-Cd laser (325 nm) was used as a light source. The light-intensity-dependent OCP of all materials showed a similar tendency. Plateau of OCP versus light intensity was observed at the photon flux less than $10^{11}$ s$^{-1}$cm$^{-2}$. The positions of the plateau for all materials range between -0.3 and 0 V vs SHE. These positions depend on several factors: surface condition of the photoelectrode, impurity in semiconductor, and dissolved gas in the electrolyte. Conversely, when the photon flux exceeded $10^{11}$ s$^{-1}$cm$^{-2}$, the linear relationship was clearly observed between the logarithm of photon flux and OCP, indicating the accumulation of charge carriers in the bulk of semiconductor and the reduction in band bending, in a similar manner to solid-state junctions of semiconductors.

Furthermore, the ideality factor of a diode was evaluated from the slope of the plots of OCP versus the logarithm of photon flux. The ideality factors of the doped photoelectrodes, TiO$_2$ and STO, were in a range of 1.0 – 1.3, while that of the undoped TiO$_2$ was 1.6. The ideality factor of GaN photoelectrode, prepared by the hetero-epitaxial growth on Si, was larger than 2.0. The distribution of interface states and defects, and the recombination of carriers in the depletion region could be the main reasons for the deviation from unity. These results also showed that the better crystal quality resulted in ideality factors close to unity, indicating the suppressed recombination of photo-generated carriers in the semiconductor bulk.

As the photon flux increased, the OCP shifted toward the flat-band potential. At the photon flux of $10^{17}$ s$^{-1}$cm$^{-2}$, OCP of all materials exceeded the hydrogen evolution potential, i.e. hydrogen evolution reaction (HER) became possible at the counter electrode. The difference between the OCP and the flat-band potential at high photon flux depends on materials and doping concentration; an ideal photoelectrode should show virtually no difference.

In summary, all three materials exhibited the linear relationship in the plot of OCP versus the logarithm of photon flux as it is observed in photovoltaic devices. Ideality factor of a diode at solid-liquid interfaces close to unity was obtained only for photoelectrodes fabricated from single-crystalline wafers with low defect density. The study of light-intensity-dependent OCP allows us to determine which material has a suitable photo-response for HER under certain light intensity.

**Fields Matter—Better Water Splitting Through Magnetic Field-Assisted Processing of Hematite Thin Films**

Myeongwhun Pyeon$^1$, Vanessa Rauch$^1$, Daniel Stadler$^1$, Mehmet Gursoy$^2$, Meenal Deo$^1$, Yakup Gönnülü$^1$, Thomas Fischer$^1$, Taejin Hwang$^3$ and Sanjay Mathur$^1$; $^1$University of Cologne, Germany; $^2$Selçuk Üniversitesi, Turkey; $^3$KITECH, Korea (the Republic of)

Even though the potential of hematite thin films for water splitting applications are widely accepted, researchers are still tackling the ‘rust challenge’. We report here on the influence of external magnetic fields applied parallel or perpendicular to the substrate during plasma enhanced chemical vapor deposition (PECVD) of hematite ($\alpha$-Fe$_2$O$_3$) nanostructures. Hematite films grown from iron precursors showed pronounced changes in crystallographic textures.
depending upon whether PECVD was performed with or without the influence of external magnetic field. Static magnetic fields created by rod-type (RTMs) or disk-type magnets (DTMs) resulted in hematite films with anisotropic or equiaxed grains, respectively. Using RTMs, a superior photoelectrochemical (PEC) performance was obtained for hematite photoanodes synthesized under perpendicularly applied magnetic field (with respect to substrate), whereas parallel magnetic field resulted in the most efficient hematite photoanode in the case of DTM. Our experimental data on microstructure and functional properties of hematite films showed that application of magnetic fields parallel and perpendicular have a significant effect on the crystallite size and texture with preferred growth and/or suppression of grains with specific texture in α-Fe₂O₃films. Investigations on the water splitting properties of the hematite films in a photoelectrochemical reactor revealed that photocurrent values of hematite photoanodes were remarkably different for films deposited with (0.659 mA/cm²) or without (0.484 mA/cm²) external magnetic field.

Adsorption Energetics and Surface Phase Transformations in Iridium and Ruthenium-Based Oxygen Evolution Reaction Catalysts Geoffroy Hautier; University Catholique de Louvain, Belgium

Important devices such as electrolyzers or fuel cells depend on the control and understanding of electrocatalytic processes. Ab initio techniques have been extremely useful in providing the needed insight in the catalytic mechanisms leading even to computationally-motivated design of new electrocatalysts. There remain, however, many open questions in the field and fundamental studies of the adsorption processes on model single-crystals are strongly called. In this talk, I will present recent results on combined theory-experiment approaches towards the understanding of important oxide catalysts for oxygen evolution reaction (OER) using molecular-beam epitaxy (MBE) grown single-crystals and ab initio techniques. I will especially focus on the comparison between computed and experimental adsorption energies in two model systems: RuO₂ and IrO₂, helping estimate the typical errors on the very common DFT adsorption computations performed in electrocatalysis. Finally, I will discuss more recent results on the understanding of complex phase transformations during hydrogen desorption and cyclic voltammetry especially on IrO₂ and using a combination of DFT and statistical mechanics.

11:00 AM EN07.08.07
Surface and Sub-Surface Structure of Ba₀.₅Sr₀.₅Co₀.₈Fe₀.₂O₃₋δ Perovskite Particles for Oxygen Evolution Reaction Probed by Electron Microscopy Techniques Tzu-Hsien Shen¹, Liam Spillane², Yang Shao-Horn³ and Vasiliki Tileli¹; ¹École polytechnique fédérale de Lausanne, Switzerland; ²Gatan Inc., United States; ³Massachusetts Institute of Technology, United States

Water splitting is seen as a promising way to store clean energy. However, the sluggish oxygen evolution reaction (OER, 4OH⁻ → O₂ + 2H₂O + 4e⁻) at the anode is the bottleneck that limits the water electrolysis efficiency. Perovskite family with the ability of tunable electronic structure is considered as a strong candidate to replace precious metal catalysts that currently dominate the market for oxygen evolution reaction [1]. Understanding the surface of perovskites is one of the keys to design protocols for next-generation OER electrocatalysts as most of catalytic processes occur at the surface. In this study, transmission electron microscopy (TEM) based techniques with exceptional spatial resolution are used to fulfill this purpose and perovskite Ba₀.₅Sr₀.₅Co₀.₈Fe₀.₂O₃₋δ (BSCF), a highly active OER catalyst in alkaline electrolytes [2], is taken as the target catalyst. Electron energy-loss spectroscopy (EELS) operated under scanning TEM (STEM) mode is performed by probing the surface of the as-synthesized BSCF particles dispersed in KOH. The EELS results show a profile of decreasing Ba concentration from bulk toward the surface and a reduced valence of Co ions at the very surface of BSCF. Quantitative analysis using simulated EEL data confirms the compositional alteration of the surface structure. Selected area fast Fourier transform patterns of high resolution TEM images of BSCF reveal a spinel structure of surface Co-rich phase as well as the lowering of the crystallinity as approaching the surface. STEM-EELS of the identical BSCF particle after chronoamperometric measurements in OER regime shows that the reduced oxidation state of surface Co-rich phase remains after OER.

In order to further understand how the BSCF surface structure evolves during electrochemical processes, in situ TEM methodologies are applied [3]. Real-time structural monitoring during cyclic voltammetry shows surface dissolution which is likely A-site Ba²⁺/Sr²⁺ leaching at BSCF surface [4,5]. The expansion of the BSCF particle due
to OER is also observed during cycling. In conclusion, the electron microscopic studies give information on complex surface structure of BSCF which might be related to the OER catalytic properties, and in situ TEM observation provides possible degradation mechanisms of BSCF perovskite catalysts.

Programmable NiFe/Au Barcode Nanomesh for Enhanced Oxygen Evolution Can Cui and Liao Yong Wen; University of Connecticut, United States

The oxygen evolution reaction (OER) is the most important half-reaction in renewable electrochemical energy storage and conversion, including water splitting, CO₂ reduction, and metal-air batteries. First-row transition metal oxides and hydroxides (e.g., Ni, Co, Fe and Mn) is one of the most promising alternatives to replace the precious metal oxides (e.g., Ir and Ru) in alkaline conditions. To address the large overpotential and poor stability of the low-cost transition metal oxides based OER catalysts, many strategies have been explored, including elemental doping, surface decoration by noble metal, nanostructurering et al.. However, these challenges still exist, which greatly hinder their large-scale applications.

Here, we report a novel three-dimensional NiFe/Au barcode nanomesh based on alumina nanoporous template to pursue a desirable OER catalyst. The morphological feature and composition of the NiFe/Au barcode nanomesh can be easily tuned by using different templates and electrodeposition processes. The spatial confinement effect of the uniform porous structure in a range of hundreds of nanometers could efficiently facilitate the oxygen gas evolution with small bubbles. Most importantly, the synergistic interaction of the alternating layered NiFe alloy and Au structure could not only provide a large number of active sites, but also decrease the intrinsic resistance of the formed NiFe alloy oxides during the OER, which in turn significantly decreases the required overpotential. By choosing suitable thickness ratios of NiFe and Au layers, respectively, a very low overpotential below 300 mV was obtained under a current density of 10 mA/cm², which is one of the lowest reported values from the NiFe based composites. A negligible decrease of the potential was observed even after a 3-day test. These programmable three-dimensional NiFe/Au nanomeshs may provide a new type of cost-effective and long-term stable electrocatalysts for scalable energy applications.

11:30 AM EN07.08.09
Design and Preparation of CNTs Aerogel/Wood Bilayer-Structures for Solar Steam and Sewage Treatment Lei Miao, Xiaojing Mu and Jianhua Zhou; Guilin University of Electronic Technology, China

The shortage of clean water is one of the predominant causes of human mortality, especially in remote rural areas. Currently, solar steam generation is being adopted as an efficient, sustainable, and low-cost means for water desalination to produce clean water¹. CNTs aerogel is a good solar absorber with huge surface area, high absorptance of solar irradiation, light weight and good insulation. However, the strong hydrophilicity of aerogel hinders heat localization in the pore and further decreasing water evaporation rate for pure CNTs aerogel solar evaporator. Here, in this work, we designed CNTs aerogel/wood bilayer-structures, i.e.; insertion of natural wood sheet between aerogel and evaporation interface to control the hydrophilicity of the whole evaporator and make the absorbed heat more compatible with the water to be evaporated, then the evaporation rate could be improved greatly. Chitosan and CNTs composed aerogels were prepared by one-step freeze-drying treated Chitosan and CNTs mixture. The highest evaporation rate reached up to 1.64 kg m⁻² h⁻¹ in the evaporation system with pure CNT aerogels as absorber. While, for the bilayer structure with wood as interface layer, the evaporation rate reached up to
2.22 kg m\(^{-2}\) h\(^{-1}\) which increased by about 40\% comparing to the pure CNT aerogels absorber. Infrared imager was used to record the temperature of evaporator in the process of evaporation. It is obvious that the thermal insulation and local heating properties of the composite material are much better than that of CNT aerogel. Desalination result shows that although the evaporation rate decreases slightly, it can still reach 1.86 kg m\(^{-2}\) h\(^{-1}\), which providing a new idea for efficient desalination. In addition, the two-stage filter effect can be achieved by wood sheet and aerogel composite. The macropore of the wood sheet is a primary filtration, which can be used to preliminarily remove the larger pollutants or harmful substances in the sewage. The mesoporous and microporous of aerogel are secondary filtration, which can further remove the smaller particles or harmful substances in sewage. Driven by solar energy, the whole filter system could purify waste liquid and domestic sewage effectively. Cost-effective bilayer structures could prepare solar absorber with good steam generation performance and sewage treatment capacity in large quantities, which holds great potential for practical applications, especially in remote rural areas and environmental polluted area.

Li and P Co-Doped Heptazine Based g-C\(_3\)N\(_4\) Monolayer Deepak K. Gorai and Tarun Kumar Kundu; Indian Institute of Technology Kharagpur, India

In this work, quantum chemical first principle density functional theory calculations are performed by using VASP and Gaussian09 software to investigate the geometric, electronic and optical properties of Li and P co-doped carbon nitride (g-C\(_3\)N\(_4\)) monolayer. The co-doping process results in significantly narrow the band gap of g-C\(_3\)N\(_4\). The optical absorption shows better visible-light response. Highest occupied molecular orbitals (HOMO) and lowest unoccupied molecular orbitals (LUMO) show strong delocalization and hence photo-generated e\(^-\)/h\(^+\) pair separation abilities of them are better than pristine monolayer g-C\(_3\)N\(_4\). The theoretical evidence for the possibility of using g-C\(_3\)N\(_4\) with excellent photocatalytic properties has been provided.

1:30 PM *EN07.09.01
Halide Perovskites—From Understanding Fundamental Physics to Optoelectronic Applications Sergei Tretiak and Dibyajyoti Ghosh; Los Alamos National Laboratory, United States

Hybrid organic—inorganic perovskites (HOPs) have demonstrated an extraordinary potential for clean sustainable energy technologies and low-cost optoelectronic devices. This talk overviews the main features of three dimensional (3D) and layered two-dimensional (2D) HOPs by combining solid-state physics concepts with simulation tools based on density functional theory. A comparison between layered and 3D HOPs highlights differences and similarities such as spin-orbit effects, quantum and dielectric confinements and excitonic properties. In 3D HOPs we study in depth the effects of electron-phonon coupling leading to polaron formation across the broad range of materials. Calculated electronic structure, charge density, changes the geometry, and reorganization energies are further related to experimentally measured specific vibrational modes, Huang-Rhys parameters and Jahn-Teller like distortions. These effects lead to formation of meta-stable deep-level charge states, which potentially responsible for photocurrent degradation in thin-film perovskite devices. The photophysics of 2D materials is defined by an interplay of strongly bound excitons and lower-energy states associated with the edges of the perovskite layers. The latter provide a direct pathway for dissociating excitons into longer-lived free carriers that substantially improve the performance of optoelectronic devices. Our theoretical simulations rationalize specifics of electronic structure of these materials, dynamics and a role of interfacial states. We also outline specific ways to rationally control geometry of edges in 2D HOP materials via external fields, contact interfaces and composition of organic compound. Overall, our results provide insights towards the material design for various applications.
Mechanisms for Hydrogen Evolution on Transition Metal Phosphides and Pt

Chenyang Li1, Per Lindgren2, Georg Kastlunger2, Andrew A. Peterson2 and Tim Mueller1; 1Johns Hopkins University, United States; 2Brown University, United States

Water splitting for renewable energy storage and conversion is limited by the high cost of Pt-based catalysts used for the hydrogen evolution reaction (HER). Earth-abundant transition metal phosphides have emerged as active HER catalysts with lower cost than Pt. However, the catalytically active sites and reaction mechanisms on these catalysts remain unclear. Here we present models of the HER on four different transition metal phosphide surfaces (Co2P, CoP, Fe2P, and FeP) using cluster expansions parameterized by density functional theory. By running Monte Carlo simulations, we predict the structures and energetics of adsorbed hydrogen as a function of temperature and applied potential, allowing us to determine the potential-dependent activities of different sites while fully accounting for interactions among adsorbed hydrogen atoms. For comparison, we have used the same approach to model the HER mechanisms on Pt surfaces – including Pt(111), Pt(110), and Pt(100). We demonstrate the effects of potential-dependent surface coverage on HER current density and propose mechanisms for the HER on these model surfaces. The present model provides a general and effective approach to study catalytic reaction mechanisms and probe catalytically active sites, which can facilitate the design of highly active catalysts.

Investigation of the Influence of Electrolyte Temperature on the Performance of Cu2O towards Solar Water Splitting

Iqra Reyaz Hamdani and Ashok N. Bhaskarwar; Indian Institute of Technology Delhi, India

Cuprous oxide (Cu2O) is a nontoxic and inexpensive semiconductor with the direct bandgap of 2.0 eV. It is an excellent material for solar driven water splitting, having a good theoretical solar to hydrogen conversion efficiency of 18%. Various deposition techniques have been explored for Cu2O thin film deposition, such as spray pyrolysis, sputtering, and electrodeposition, and chemical vapor deposition, thermal and chemical oxidation. However, electrodeposition is the most convenient method since it is economical and provides an easy control on the properties of the film, such as thickness, crystallinity, and roughness. Thus, Cu2O deposited by electrodeposition method is a low cost, sustainable and an efficient material. In this work, Cu2O thin films were electrodeposited on FTO substrates at different bath temperatures, at a constant bias potential of -0.4 V with respect to Ag/AgCl. A comprehensive study was carried out to investigate the effect of bath temperature on the morphological and optical properties of Cu2O. The performance of Cu2O as a photocathode in a photoelectrochemical device, and hence its application in photoelectrolysis of water towards hydrogen evolution, was determined and analyzed at three different temperatures i.e., at room temperature (25°C), 65°C and 85°C. The electrolyte used was 0.4 M copper sulfate hexahydrate and 3 M lactic acid. The pH of electrolyte was kept at 9 by the addition of 4 M aqueous NaOH. From the SEM images, the surface morphology was found to change from crystalline small grain sizes through polyhedral structures to amorphous structured fine grains as the temperature was increased from 25°C to 85°C. From the XRD studies, films deposited at higher temperature of 85°C showed the presence of CuO which was also visually detectable by the black color. All the films showed the presence of phase (111), however its intensity was highest at temperature of 65°C. The thickness of films increased from ~150 nm to 10 μm as the temperature was increased. However, in this range their uniformity decreased. The charge carrier density as evaluated from the Mott-Schottky equation, was highest for the films deposited at 65°C, and its magnitude was about 1.5 x 1029 cm–3. From the photoelectrochemical measurements, the films synthesized at 65°C exhibited the highest performance and generated a maximum photocurrent density of 1.6 mA/cm2.

Highly Flexible and Porously Structured Metal Phosphide/MXene Arrays as Efficient Bifunctional Electro catalysts for Overall Water Splitting

Clament Sagaya Selvam Neethinathan, Gwan Hyun Choi and Piljin Yoo; Sungkyunkwan university, Korea (the Republic of)

The development of efficient and stable bifunctional electrocatalysts that outperform noble metal electrocatalysts is an important task and an ongoing challenge for sustainable hydrogen generation. To accomplish this goal, an ordered hierarchical structure with more exposed active sites for strong electrolyte contact should be designed. Herein we report a synthetic strategy of binder free, free-standing and flexibly structured Mx-Py (M=Fe, Co and Ni) decorated MXene arrays as efficient bifunctional electrocatalysts. Specifically, 2-dimensional (2D) MXene sheets
prepared by improvised etching method render a flexible platform for the hierarchical decoration of highly mesoporous CoP, allowing them to exhibit remarkably high electrocatalytic performances. The phosphidation process provides enhanced conductivity and increased number of active sites for the hybrid. As a result, CoP/MXene electrocatalyst shows enhanced oxygen evolution reaction (OER) activity, with substantially lower overpotential (230 mV at 10 mA cm⁻²) compared to those of state-of-the-art IrO₂ (270 mV). Furthermore, a hybrid bifunctional electrode (CoP/MXene/CoP/MXene) exhibits highly stable and efficient overall water splitting performance (1.56V at 10 mA cm⁻²) as compared to the benchmark electrode couple IrO₂/C//Pt/C (1.62V at 10 mA cm⁻²) in alkaline solution. The hybrid electrocatalyst having Co atoms with exposed active sites accelerates the OER kinetics. Likewise, the negatively charged MXene sheets enriched with functional groups increase the proximal migration of H⁺ ions toward the cathode, thereby facilitating the HER kinetics as evidenced by DFT calculation. This study also provides a better understanding of the electronic effect induced by the MXene termination groups. Furthermore, under the OER conditions, the CoP/MXene is partially oxidized to Co-(oxy) hydroxide clusters, acting as a real active species for the efficient electrocatalytic performance. Furthermore, the post-stability analysis indicated that the massive oxidation of M-P bond (under OER experimental conditions) is suppressed by MXene layer. These promising results demonstrate the structural and compositional merits of CoP/MXene hybrid for scalable electrochemical applications. Our findings also reveal that rational tuning of Metal/MXene interface can remarkably promote the OER/HER electrochemistry. We conclude that the as-fabricated flexible and free-standing MXene-based films can be directly used as electrodes for various electrochemical applications.

2:45 PM EN07.09.05
Wafer Scale Synthesis of MoS₂-Graphene Heterostructure at Low Temperature and its HER Application
Kubra Aydin¹, Hyeong-U Kim², Vinit K. Kanade¹, Mansu Kim³, Hyunho Seok¹, Changmin Kim³, Dongmok Whang³, Jae-Hyun Lee⁴ and Tae Sung Kim³,¹; ¹Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); ²Northwestern University, United States; ³Sungkyunkwan University, Korea (the Republic of); ⁴Ajou University, Korea (the Republic of)

In this research, we successfully indicate the fabrication and characterization of MoS₂-graphene heterostructure (MGH) using Plasma enhance chemical vapor deposition (PECVD) and its HER activity. Graphene is a material that has two-dimensional (2D) planar structure of carbon atoms with small overlap between the valence and conduction bands. 2D planar structure of graphene can agree to hybrid with different materials and this agreement can lead to enhanced catalytic activity and stability. Therefore, Transition-metal dichalcogenides (TMDs) is one of materials for enhancement performance with graphene. TMDs are atomically thin semiconductors of the type MX₂, where M is a transition metal (Mo, W) and X is a chalcogen (S, Se, or Te). In addition, band gap of MoS₂ is depending on the number of MoS₂ layers. MoS₂ can be applied wide application areas because of its tunable band gap like hydrogen storage, capacitors.

Heterostructure was distinguished as lateral and vertical heterostructure. Lateral heterostructure includes different 2D layers on one plane. Vertical heterostructure is that different 2D layers are stacked up onto one plane. When graphene forms vertical heterostructure with MoS₂, the Dirac cone of graphene splits. Therefore, it can be tuned band gap of material using heterostructure method. When we consider regarding its tunable band gap and relatively high carrier mobility, MoS₂ has been investigated for applications in future electronic devices. Especially, the combination of MoS₂ with graphene opens up new possibilities in electronic applications and also shows great potential as a catalyst. Perfectly, this various band gap material finds many uses; for example, in hydrogen storage, capacitors, electrochemical devices.

First of all, Graphene was synthesized on Cu foils using chemical vapor deposition (CVD) process. Graphene was growth using CH₄:H₂ (30:50 sccm) at 1040 celsius degree for 1h and then furnace was rapidly cooled to room temperature under same atmosphere. The synthesized graphene was transferred on substrate (SiO₂/Si or glassy carbon electrode). Mo was deposited by 1 nm of thickness on transferred graphene by E-beam evaporator. it was loaded into PECVD chamber for sulfurization at 150 celsius degree under H₂S and Ar plasma for 1.5 h. Finally, MoS₂ was directly growth on graphene layer as a vertical heterostructure layer. It was characterized by using Raman spectroscopy and high-resolution transmission electron microscopy. The MoS₂ was confirmed as 5-6 layers using Raman and HR-TEM analysis. XPS analysis with depth profiling can confirm chemical states of both top MoS₂ layer and bottom graphene layer in MGH. Furthermore, hydrogen evolution reaction (HER) of MGH and bare MoS₂ was evaluated. MGH electrodes shows lower over potential and Tafel slope than bare MoS₂ electrode, which is indicating their enhanced catalytic performance. This rising up can be attributed to the high density of defects (grain boundaries and sulfur vacancies) present in MoS₂ synthesized on graphene, which is increasing the total number of active sites and then provide an effective charge transport pathway through the highly conducting
graphene layer.

Understanding Photoelectrode/Catalyst Interface for Solar Water Splitting Dunwei Wang; Boston College, United States

As a potentially low-cost, high-efficiency solar energy storage solution, solar water splitting faces great challenges. One of the issues is the poor catalytic activity and low stability. Applications of co-catalysts have been shown effective to correct the deficiency by promoting desired chemical reactions so as to minimize charge recombination at the surface and to reduce parasitic corrosion reactions. The detailed behaviors of the light absorber/catalyst interface, however, remain poorly understood. Here we present our recent research in this area. We show that the application of the co-catalysts may greatly influence the charge separation behaviors of the photoelectrode. Detailed thermodynamic and kinetic measurements support our understanding. Furthermore, we show that the photoelectrode substrate also exerts great influences on the co-catalyst behaviors. A strong interaction between the photoelectrode and the catalyst can be beneficial. The combined system may also serve as a new platform to understand heterogeneous catalysis such as water oxidation at a level previously inaccessible. The knowledge generated by our work will likely contribute significantly to the development of solar water splitting technology for a future powered by renewable energies.

4:00 PM EN07.09.07
Water Oxidation by Manganese Oxide Systems—Molecular and Layered Catalysts Inspired by Nature Michael J. Zdilla1, Daniel R. Strongin1, Eric Borguet1, John P. Perdew1, Michael L. Klein1, Ian G. McKendry2, Haowei Peng1, Richard Remsing1 and Ran Ding1; 1Temple University, United States; 2Los Alamos National Laboratory, United States

An overview of our recent progress in two areas of biologically inspired water oxidation chemistry is presented. 1) The preparation of synthetic manganese clusters that mimic the active site of the oxygen evolving complex Photosystem II has given catalysts that are able to activate water for redox reactions at low overpotentials, and has offered insights into mechanistic chemistry at these systems of potential relevance to nature. 2) The synthetic modification and optimization of layered manganese oxide catalysts, guided by theory, has offered clues into the electronic, structural, defect, and geometric features that favor redox chemistry in the interlayer of the manganese oxide phase birnessite. By a combination of theory, simulation, and experiment, the optimization of birnessite to turn it from a poor catalyst into an excellent catlayst for electrochemical water oxidation will be presented.

4:15 PM EN07.09.08
InGaAsP as a Promising Narrow Band Gap Semiconductor for Photoelectrochemical Water Splitting Joshua Butson, Parvathala Narangari, Mykhaylo Lysevych, Jennifer Wong-Leung, Yimao Wan, Siva Karuturi, Hoe Tan and Chennupati Jagadish; The Australian National University, Australia

While photoelectrochemical (PEC) water splitting is a very promising route towards zero-carbon energy, conversion efficiency remains limited. Semiconductors with narrower band gaps can absorb a much greater portion of the solar spectrum, thereby increasing efficiency. However, narrow band gap (~1 eV) III-V semiconductor photoelectrodes have not yet been thoroughly investigated. In this study, the narrow band gap quaternary III-V alloy InGaAsP is demonstrated for the first time to have great potential for PEC water splitting, with the long-term goal of developing high-efficiency tandem PEC devices, which require both wide and narrow band gap absorbers. TiO2-coated InGaAsP photocathodes generate a photocurrent density of over 30 mA/cm2 with an onset potential of 0.45 V versus RHE, yielding an applied bias efficiency of over 7%. This is an excellent performance, given that nearly all power losses can be attributed to reflection losses. X-ray photoelectron spectroscopy and photoluminescence spectroscopy show that InGaAsP and TiO2 form a type-II band alignment, greatly enhancing carrier separation and reducing recombination losses. TiO2 also greatly improves the stability of InGaAsP, which is susceptible to corrosion in acidic electrolyte. Future work will include the minimisation of reflection losses. This can be achieved by fabricating InGaAsP nanostructures, for which a large-area top-down random nano-mask technique has been developed. Beyond water splitting, the tunable band gap of InGaAsP could be of further interest in other areas of photocatalysis, such as CO2 reduction.
Identifying Active Surface Entities on Metal Oxides for Oxygen Evolution by Multimodal Surface X-Ray Probes

Hua Zhou; Argonne National Laboratory, United States

Electrocatalysts are materials designed to provide a facilitating environment for electrochemical conversion and synthesis of materials and fuels from atmospheric molecules, which is one of the most important challenges facing societal need of energy in 21st century. One of the major hurdles developing electrocatalysts is the lack of holistic information of the evolving surface structure of materials during electrochemical operation. This is particularly formidable for oxygen evolution reaction (OER), where the oxidizing environment is corrosive and can significantly rearrange the electrocatalyst surface structure. Therefore, identifying how the surface structure of materials evolves during the OER is essential to the development of more active and stable electrocatalysts and broadly to the prospect of materials and energy sustainability. Surface-sensitive X-ray probes from modern synchrotron sources including surface X-ray scattering and grazing incidence X-ray spectroscopy provide a very powerful suite of toolkits to decipher the surface subtlety and evolution. If utilizing these techniques in a well-coordinated approach, one can deliver thorough and deep fundamental insights of surface transformations (e.g. structural, chemical and electronic) during the electrocatalytic process.

In this talk, we will firstly render a brief survey of various surface sensitive X-ray techniques to specifically probe structural and chemical aspects of electrocatalytic materials, in particular the combined approach to differentiate the contribution from surface and bulk layers. Following the survey, we would like to present a few prototypic studies of metal oxide model systems for surface OER processes. First example is the detailed understanding of the interaction between water and single crystal RuO2 (110) in acidic electrolytes under OER conditions, especially surface atomic structure rearrangements as a function of potential quantified by X-ray crystal truncation rods. Unique oxygen absorbent species on the Ru sites were detected at an OER relevant potential. A new OER pathway with the rate-limiting deprotonation of the –OH group can be suggested by integrating potential-dependent surface structures with DFT-calculated energetics. The second demonstration is to present a comprehensive study of the emergent surface transformation of SrIrO3, the most active OER electrocatalyst reported to date, especially the amorphous boundary layer that forms from the pristine crystalline structure on the surface with OER cycling. In virtue of multimodal X-ray probing, a step-by-step transformation mechanism of the amorphization process could be explicitly illuminated. Our X-ray results show that the amorphization is triggered by the lattice oxygen activation and the structural reorganization facilitating coupled cation and anion diffusions is key to the realization of the OER active structure in the final SrIrO3 form which exhibits stronger disorder than conventional amorphous IrOx, partially explaining its champion OER activity.

Self-Assembling Oxide Catalyst for Electrochemical Water Splitting

Ilia Valov1, Daniel Bick2, Deok-Yong Cho3, David N. Mueller4 and Rainer Waser2; 1Research Center Juelich, Germany; 2RWTH Aachen University, Germany; 3Chonbuk University, Korea (the Republic of)

The demand on efficient and economically reasonable conversion and storage of energy from renewable power sources is an essential challenge and existential task for the modern society. Emerging technologies like metal-air batteries, fuel-cells and electrolyzers, which are mostly limited by the oxygen electrocatalysis, depend on reliable catalyst materials suited for long term application in alkaline environments. Candidates for precious metal free catalyst materials range from metal alloys to oxides and nitrides. Several perovskites have been suggested as economically reasonable catalysts for the oxygen evolution reaction (OER) and showed eligible overpotentials. Among these, the perovskite system BaCoO3 (BCO), and especially the double perovskite PrBa1-xCoO3-δ (PBCO) has shown superior properties (low overpotential) and has been identified as one of the most promising OER materials.
Application of oxides as OER electrocatalysts is limited by two general problems. The first one is their insufficient electronic conductivity. The second and main problem for all OER catalysts is the degradation of the structure (amorphisation) and electrocatalytic properties during long-term operation.

We report on a new perovskite self-assembling material system BaCo$_{0.98}$Ti$_{0.02}$O$_{3-\delta}$.Co$_3$O$_4$, which exhibits higher current densities for the OER and over 10-fold increased lifetime in comparison to the most reliable electrocatalyst (PBCO) reported up-to-date. Importantly, all electrolysis experiments were performed at temperatures typical for industrial application i.e. 353 K. By systematic modification of chemical composition/doping and defect chemistry in binder free BCO perovskite-based catalyst films, simultaneous aging and characterisation with electrochemical methods, XRD, XPS, XANES and EXAFS we were able to identify the degradation mechanism related to cation leaching and amorphization. We demonstrate that the initial crystalline structure rapidly and completely transforms to an amorphous electrochemically active material, which retains its electrochemical properties until its service life end.

Based on the combination of analysis, calculation and aging experiments, a model is derived, which is able to explain the connection between short-range order, defect chemistry and catalyst stability. This model is capable of making predictions to future OER catalyst material design.

9:15 AM EN07.10.03
In Situ Probing of Ultrafast Electrochemical Reactions with High Catalyst Mass Activities for Efficient Water Splitting Feng-Yuan Zhang; University of Tennessee, United States

Water splitting into hydrogen/oxygen with Proton exchange membrane electrolyzer cells (PEMECs) has become more attractive due to their high efficiencies even at low-temperature operation. In this talk, the ultrafast and multiscale electrochemical reactions in an operating PEMEC, including oxygen evolution reactions (OERs) and hydrogen evolution reactions (HERs), will be revealed. The in-situ probing results shows the OERs and HERs mainly occur on catalyst layers at the rim of the pores of the thin/tunable liquid/gas diffusion layers (TT-LGDLs), and there is a large portion of catalysts being not effectively utilized. Based on these discoveries, a novel thin/tunable gas diffusion electrode (GDE) is developed by depositing the catalyst on a tunable pattern that is observed to be active for the OER/HER. The thin GDEs with a total thickness of about 25 µm significantly improve the catalyst mass activity and utilization and exhibit excellent PEMEC performance with a very simple fabrication process and low cost.

9:30 AM EN07.10.04
Tailored Nickel-Iron Layered Double Hydroxide Platelet Size for Optimized Oxygen Evolution Reaction Catalysis Daire P. Tyndall, Valeria Nicolosi, João Coelho and Sonia Jaskaniec; Trinity College Dublin, Ireland

The oxygen evolution reaction (OER) has drawn significant interest in the field of renewable and sustainable energy in recent years, with potential applications for hybrid electric vehicles (HEV) in the form of electrolyzer cells for hydrogen production, fuel cells or metal-air batteries, among others. Perhaps the most significant feature of OER is the fact that it is a necessary ‘step’ in the evolution of H$_2$ gas by water electrolysis, bringing with it an associated potential (E $\approx$ 1.23 V). To overcome this potential barrier with minimum overpotential (\(\eta\)), an effective electrocatalyst is required to facilitate the reaction. Nickel-Iron Layered Double Hydroxide (NiFe-LDH) has been shown to exhibit efficient catalysis of the OER, demonstrating overpotentials in composite systems which are competitive with previously studied electrocatalysts based on rare earth metals such as ruthenium and iridium\([1]\), as well as being competitive in an economic perspective. NiFe-LDH has other advantages over rare earth catalysts such as earth abundance, cost and stability (in operating conditions)\([2]\). The nature of the material in question is that the vast majority of catalytic active sites are located at open coordination sites at the edge of the NiFe-LDH hexagonal platelets. This means that average particle dimensions will play an important role in determining the density of active sites within a NiFe-LDH electrode and hence, it’s catalytic ability.

Synthesis of high quality, planar NiFe-LDH platelets with regular hexagonal morphology was achieved using a wet chemistry method at a relatively low temperature (100 °C) using triethanolamine (TEA) as a ‘capping agent’ to allow homogeneous coprecipitation of both the nickel and iron metal centres within brucite-lake layers. Using platelets synthesized in this way, OER catalysis has been demonstrated with \(\eta = 0.36\) V, a competitive value when compared to many state-of-the-art OER electrocatalysts in the same conditions\([3]\) (5 mVs$^{-1}$, quoted at current density j $= 10$ mAcm$^{-2}$). The work aims to develop methods of post-synthetic treatment of NiFe-LDH dispersions to reduce lateral platelet dimensions and further improve edge-site density for electrocatalytic optimization. This study comes
in accordance with the growing number of high-performance electrocatalysts being studied for OER\[4\]. In this work, a combination of platelet size reduction and selection techniques are utilized to isolate particle dispersions with controlled mean platelet dimensions \(<L>\) with the aim of elucidating the relationship between \(<L>\) and \(\eta\). To do so, methods of tip-sonication and centrifugation were employed. Tip-sonication (7 h) alone can reduce \(<L>\) from 0.78 ± 0.01 µm to 0.29 ± 0.01 µm while further centrifugation in the relatively narrow range of centrifuge rates 1000 – 5000 rpm can isolate useable dispersions with \(<L>\) as low as 0.20 ± 0.01 µm. When tested in electrolyzer cell working conditions (1 M KOH, 0 – 0.6 V) electrodes based on size-selected material exhibited a clear reliance of electrocatalytic performance on the mean platelet size \(<L>\). Further, composite studies are carried out to establish ideal materials for optimizing the NiFe-LDH performance to achieve \(\eta\) values which are competitive in the field of OER catalysis.

9:45 AM EN07.10.05
Synthesis of Titanium Oxynitride Thin Films with Tunable Bandgaps for Alternative Energy Applications in the Full Solar Spectrum Range Nikhil R. Mucha\(^1\), Surabhi Shaji\(^1\), Manosi Roy\(^1\), Balamurugan Balasubramanian\(^2\), Prakash Apte\(^1\) and Dhananjay Kumar\(^1\); \(^1\)North Carolina A&T State University, United States; \(^2\)University of Nebraska–Lincoln, United States

A novel Ti\(_x\)N\(_y\)O\(_z\) (TiNO) material system with a range of \(x\) (0≤\(x\)≥1) and \(y\) (0≤\(y\)≤2) values has been synthesized in thin film form using the non-equilibrium nature of a pulsed laser deposition process. A proper control of \(x\) and \(y\) values has been found to result in the material system transformation from a metallic rock-salt structure to an insulating rutile structure (TiO\(_2\)). The in-between \(x\) and \(y\) values yield compounds with a range of bandgap materials capable of absorbing radiation in the full solar spectrum. When N atoms in TiN are partially substituted by O atoms, the top of the valence band (valence band maxima) shifts down leaving the bottom of the conduction band (conduction band minima) unaffected. Since, the valence band maximum of the oxynitride compounds is located at higher potential energy than that for pure TiO\(_2\) due to the contribution of N 2p orbitals, the partial substitution of N by O result in the reduction of bandgap values with respect to those of the extreme compounds, i.e. TiN or TiO\(_2\).

X-ray diffraction and x-ray photoelectron spectroscopy measurements have been carried out that lend evidence in support of the realization of the aforementioned values of \(x\) and \(y\). The optical measurements on TiNO films involving photoluminescence and ultra violet studies have established the existence of bandgaps in the range of 1.6 to 3.0 eV. The current voltage characteristics recorded from ITO/TiNO/Cu(Au) configurations have shown that the current (\(I\)) and corresponding voltage (\(V\)) lie in the same quadrant with a similar polarity in the dark conditions while the current and the corresponding voltage lie in quadrants with different polarity. The positive sign of power (\(I\) times \(V\) positive) under dark conditions indicates dissipation of power in TiNO while the negative of sign of the power (\(I\) times \(V\) negative) indicates the power generation capability of TiNO system. The fabrication of TiNO system via controlled oxidation has an advantage over conventional methods of bandgap manipulation of TiO\(_2\) via nitridation due to the higher activation energy of a nitridation process (672 kJ/mol) than that of an oxidation process (496 kJ/mol). As the number of photocatalysts/semiconductors that are active under visible light irradiation is very limited, our approach to develop a unique visible-light-driven TiNO photocatalytic and photovoltaic material system can open a new avenue for solar devices.

Electrocatalytic Activity of Pd-\(\text{CeO}_2\) Catalysts for Anion Exchange Membrane Fuel Cells Pamir Alpay\(^1\), Sanjubala Sahoo\(^1\), Hamish A. Miller\(^2\) and Dario R. Dekel\(^3\); \(^1\)University of Connecticut, United States; \(^2\)Istituto di Chimica dei Composti Organometallici, Italy; \(^3\)The Wolfson Department of Chemical Engineering, and the Nancy
There is significant interest in the development of platinum-free electrode materials for Anion Exchange Membrane Fuel Cells (AEMFCs) \cite{1,2}. Here we present a combined experimental and theoretical study of the Hydrogen Oxidation Reaction (HOR) activity in alkaline medium for Pd-CeO$_2$ anode catalysts. Specifically, we model Pd-CeO$_2$ substrates where Pd atoms are either adsorbed or embedded on (111) CeO$_2$ surfaces. The computations are performed using density functional theory using the generalized gradient approximation and the necessary Hubbard corrections. The HOR activity is explored using the Tafel-Volmer mechanism. The Tafel reaction is one of the rate-determining steps for HOR activity, which involves the dissociation of the H$_2$ molecule. The activity descriptors for the HOR under alkaline conditions however, have been suggested to be the H bonding energy (HBE) and the OH bonding energy (OHBE), which provides a quantification of the H and OH bond strength onto the Pd and ceria. We determine dissociation pathways for H$_2$ molecules on both Pd-CeO$_2$ substrates. Our findings show that the Pd adsorbed (111) CeO$_2$ becomes highly reactive for H$_2$ dissociation, exhibiting a low dissociation barrier compared to that of a pure CeO$_2$. Our computations are in agreement with experiments where a high HOR performance has been achieved for a bifunctional Pd-CeO$_2$ system compared to CeO$_2$ \cite{3}. Additional calculations are carried out to understand the HOR activity as a function of the concentration of adsorbed Pd atoms. Oxidized single Pd atoms or very small clusters coordinated to the CeO$_2$ oxygens show improved HOR activity. Our research provides the underlying principles towards the design of highly active HOR catalysts for AEMFC without utilizing platinum.

Enhancing the Activity of Molybdenum Diselenide for Electrocatalytic Hydrogen Evolution via Transition-Metal Doping

\textbf{Akash Jain$^1$}, \textbf{Vasu Kuraganti$^{2,3}$}, \textbf{Maya Bar-Sadan$^{2,3}$} and \textbf{Ashwin Ramasubramaniam$^1$}; \textit{1}University of Massachusetts Amherst, United States; \textit{2}Ben-Gurion University of the Negev, Israel

Electrochemical water splitting is a promising fossil-fuel free route for hydrogen production. However, the hydrogen evolution reaction (HER) is most efficiently catalyzed by expensive platinum group metals and there is significant interest in finding alternative, earth-abundant replacements. Recently, there has been progress in employing relatively inexpensive transition-metal dichalcogenides (TMDCs) like MoSe$_2$ for HER but these materials still require an appreciably larger overpotential than Pt, which reduces their efficiency. Here, we show that the catalytic activity of MoSe$_2$ can be improved significantly by doping with earth-abundant transition-metal (TM) dopants such as Mn, Fe, Co and Ni. Using density functional theory (DFT) calculations, we study the influence of these substitutional dopants on the thermodynamics of H adsorption at edges, Se-vacancy, and basal plane sites, and explain trends in adsorption energies via electronic structure considerations and structural changes arising from the atomic-size mismatch between Mo and dopant atoms. A key finding from our studies is that selected TM-dopants promote the formation of highly active Se-vacancy sites—in some cases even making these vacancies thermodynamically favorable—thereby increasing the activity of the native MoSe$_2$ catalyst. DFT calculations shed light on recent experiments on Mn-doped MoSe$_2$ nanoflowers that display improved HER charge-transfer kinetics, smaller Tafel slope, and overpotential than undoped MoSe$_2$. Overall, our work suggests that the electrocatalytic activity of MoSe$_2$ and similar transition-metal dichalcogenides can be enhanced by employing substitutional dopants, not for their inherent activity, but as promoters of highly active chalcogen vacancies.

Role of Defects and Polaron in Surface Morphology and Electronic Structure in BiVO$_4$

\textbf{Wennie Wang$^1$} and \textbf{Giulia Galli$^{1,2}$}; \textit{1}The University of Chicago, United States; \textit{2}Argonne National Laboratory, United States

As one of the most widely-studied oxides for photocatalysis, bismuth vanadate (BiVO$_4$) is a highly promising material candidate as a photoanode for water photocatalysis. In addition to having strong absorption across the visible spectrum and a conduction band edge near the hydrogen evolution potential, BiVO$_4$ is stable under aqueous conditions and relatively facile and cheap to synthesize. It has been reported that charge transport, interfacial charge transfer, and recombination events are limiting factors for photoelectrocatalytic (PEC) performance. Thus,
significant effort has gone into optimizing PEC devices based on BiVO₄, including doping, nanostructuring, and pairing with other catalysts or semiconductors. However, a major challenge in the field has been to have well-defined experimental samples and computational methodologies to disentangle the influence of surface/interface morphology, defects, and the presence of water.

Our objective is to holistically understand the connections between surface morphology and PEC performance, and bridge gaps between theoretical and experimental methods by making direct comparison between computed and measured electronic properties. Using first-principles calculations, we study the surface morphology and electronic structure of BiVO₄, and compare with single-crystalline and epitaxially-grown samples. We present our work on pristine and defective surfaces, and connect our calculations with measured band edges, work functions, and STM images. In particular, we discuss the role and formation of polarons in the bulk and at the surface [1], and their influence on PEC performance.

11:30 AM EN07.10.09
Enhanced Catalytic Activity of Edge-Exposed 1T Phase WS₂ Grown Directly on WO₃ Nanohelical Array for Water Splitting
Noho Lee, Il Yong Choi, Kyung-Yeon Doh, Jaewon Kim, Hyeji Sim, Donghwa Lee, Si-Young Choi and Jong Kyu Kim; POSTECH, Korea, Korea (the Republic of)

Among various candidates for renewable energy sources, much attention has been given to hydrogen (H₂) produced by hydrogen evolution reaction (HER) via electrochemical water splitting. As promising materials for electro-catalytic electrodes, layered 2 dimensional (2D) transition metal dichalcogenides (TMDCs) such as MoS₂ and WS₂ have drawn great attention as alternatives to precious metals such as platinum (Pt) and gold (Au). On the other hand, it is highly desirable to control the morphology and phase of electrodes materials to optimize the catalytic activity. For example, edge planes of layered TMDCs are known to be catalytically more active than basal planes due to nearly thermoneutral properties in proton adsorption. Morphological controls of TMDCs were investigated to expose edge sites effectively by tuning nucleation and growth behaviors, for example, double gyroid MoS₂ thin film using atomically controlled surface, vertically aligned TMDCs by rapid sulfurization and defects-mediated formation of in-plane edges of MoS₂ nanosheets. Controlling crystallographic phase is also important since the atomic configuration of TMDCs affects the catalytic activity substantially. Greater catalytic performances of metallic 1T phase MoS₂ and WS₂ than semiconducting 2H phase ones due to improved intrinsic reactivity and charge transfer kinetics for HER process, and strain-induced preferential formation of 1T phase WS₂, MoS₂ and MoSe₂ have been reported. Therefore, it would be very advantageous to develop an engineered nanostructure whose surface can be easily modified to facilitate the nucleation and strain-induced growth of edge-plane-exposed TMDCs with 1T phase preferentially.

Herein, hierarchical electrode consisting of edge-exposed 1T phase WS₂ grown on the array of surface-modified WO₃ nanohelices (NHs) and its enhanced catalytic performance in hydrogen evolution reaction (HER) are presented. Oxygen-deficient WO₃ NHs surface modified by a controlled annealing facilitates the formation of a rich edge-exposed WS₂ during sulfurization. In addition, metallic 1T phase WS₂ is preferentially grown on the WO₃ NHs owing to the strain induced between WS₂ and curved WO₃ NHs. Such desirable structural properties, metallic 1T phase and a rich edge-exposed morphology, for a catalytic electrode directly resulted in an enhanced HER performance in water splitting.

11:45 AM EN07.10.10
“All Electric” Ion Pumps
Gideon Segev¹,², Shane Ardo³,³, Rylan J. Kautz², David M. Larson¹,¹, Joel W. Ager¹,¹,4 and Francesca Maria Toma¹,²;¹ Lawrence Berkeley National Laboratory, United States; ²Tel Aviv University, Israel; ³University of California, Irvine, United States; ⁴University of California, Berkeley, United States

Ion pumps are devices that use external power to introduce a net ionic flux. For example, in the photosynthetic process, light is used to pump protons up a concentration gradient which will be used in sequential steps to generate fuels. In living cell membranes, nano scale channels pump different types of ions against a concentration gradient consuming energy from the hydrolysis of ATP. Although widely used in nature, there are very little technologies that can unleash the vast potential of ion pumps. Unlike electrons in electronic devices where contacts serve as nearly ideal sources and sinks for charge carriers, ions are sourced and removed by chemical reactions. These reactions are in many cases energetically expensive and require tailoring specific catalysts to the specific ions to be
pumped. In this contribution we report a first of its kind “all electric”, ion pump based on an electronic ratchet mechanism.

Electronic ratchets are devices that utilize modulation in a spatially varying electric field to drive steady state current. Similar to peristaltic pumps, where the pump mechanism is not in direct contact with the pumped fluid, electronic ratchets induce net current with no direct charge transport between the power source and the pumped charge carriers. Thus, electronic ratchets can be used to pump ions in steady state with no electrochemical reactions between the power source and the pumped ions resulting in an “all electric” ion pump.

Porous capacitor based ion pumps were fabricated by coating the two surfaces of nano-porous alumina wafers with gold. The electric field within the nano-pores is modulated by oscillating the capacitors voltage. Thus, when immersed in solution, ions within the pores experience a modulating electric field resulting in ratchet based ion pumping. The device pumping performance was studied for various input signals, geometries and solutions. The proposed ion pumps may be used as building blocks in a wide range of applications such as artificial photosynthesis, water desalination, chemical separations and many others.

Implicit Solvation with Periodic Boundary Conditions—Implementation and Application to Reactions at Interfaces Carlo Adamo1,2; 1Chimie Paristech-CNRS, France; 2Institut Universitaire de France, France

We present the implementation of an implicit solvation model in the periodic CRYSTAL code. The solvation energy is separated into two components: the electrostatic contribution arising from a self-consistent reaction field treatment obtained within a generalized finite-difference Poisson model, augmented by a nonelectrostatic contribution proportional to the solvent-accessible surface area of the solute. A discontinuous dielectric boundary is used, along with a solvent-excluded surface built from interlocking atom-centered spheres on which apparent surface point charges are mapped. The procedure is general and can be performed at both the Hartree–Fock and density functional theory levels, with pure or hybrid functionals, for systems periodic in 0, 1, and 2 directions, that is, for isolated molecules and extended polymers and surfaces [1].

As application of the implemented solvent model, we consider the reaction of CO and H2O to form CO2 and H2 on Pt(111), using periodic density functional theory (DFT) calculations. Since this reaction has already been investigated at the DFT level with different mechanisms proposed (see [2] for instance), it therefore offers a suitable playground to investigate the role of different effects on the proposed mechanisms. In particular, we compare GGA to hybrid DFT models, considering both dispersion and implicit solvation effects. We discuss the results obtained on the full reaction paths, in which transition states are fully characterized.

Anchoring Ir Single Atom Sites on NiFe Oxyhydroxides for High-Efficient Water Oxidation Reaction Xueli Zheng and Yi Cui; Stanford University, United States

The efficiency with which renewable fuels and feedstocks are synthesized from electrical sources is limited at present by the sluggish water oxidation reaction. Here, using density functional approach, we predict that the optimal energetics for water oxidation could be achieved by systematic increase of the oxidation of the Ir active sites within typical NiFe framework. We successfully anchored Ir single sites on NiFe oxyhydroxides (Ir0.1/Ni0.9Fe) via a unique cryogenic (cryo)-photochemical reduction method. Ir0.1/Ni0.9Fe catalyst exhibits the lowest overpotential (166 millivolts) at 10 milliamperes per square centimeter and retains its performance following 200 hours of operation in 1 M KOH electrolyte. In situ grazing incidence X-ray absorption spectroscopy measurements/simulations reveal that
and Bader charge analysis indicate the charge transfer between Ir and Ni/Fe/O which reveals an average oxidation state of +5.3 on Ir sites under operating conditions. The favorable coordination environment of such single sites plays important roles for the enhanced water oxidation activity.

2:15 PM EN07.11.03
Kinetics of Photogenerated Charge Carriers at Semiconductor-Electrolyte Interface in Photoelectrochemical Water-Splitting
Chang-Ming Jiang1, Jason K. Cooper2 and Ian D. Sharp1; 1Technical University of Munich, Germany; 2Lawrence Berkeley National Laboratory, United States

Understanding the identity of surface states, as well as their roles in catalyzing photoelectrochemical (PEC) reactions, is imperative for achieving efficient solar fuel production. Copper vanadate (CVO) is an emerging semiconductor photoanode material system that supports a variety of room temperature stable phases depending on the Cu:V stoichiometry. This feature of CVO provides a unique opportunity to study the role of composition, phase, and surface states on key PEC characteristics. In this work, thin films of four CVO phases: Cu5V2O10, Cu11V6O26, γ-Cu3V2O8, and β-Cu2V2O7, were prepared by reactive co-sputtering. A suite of complimentary experimental tools (including spectroscopic ellipsometry, transient absorption, and transient photocurrent) were applied to determine trends in basic optical properties, photocarrier dynamics, and surface state-induced charge trapping. Analysis of these results reveals competing bulk and surface properties; increasing Cu content provides stronger light absorption but reduces oxygen evolution activity. The rate constants for water oxidation and surface recombination are quantified as a function of composition, applied electrochemical potential, and incident light intensity. Composition trends for interfacial charge transfer and recombination rate constants indicate that Cu cations near the surface serve as trap states for photogenerated holes. Surprisingly, it is found that the surface recombination rate remains nearly constant with illumination intensity over the range of 0.1 – 1.5 suns. At the same time, the heterogeneous charge transfer rate constant is enhanced by a factor of 2 to 6, depending on composition and applied potential, over the same intensity range. Based on these results, we propose modifications to the existing kinetic model and provide insights into the kinetic factors that underlie competitive recombination and charge transfer at transition metal oxide photoelectrode surfaces.

InGaN-Si Tandem Photoelectrodes for Photoelectrochemical Water Splitting by MOCVD—Understanding System Design Considerations Necessary to Bridge Theory and Experiment
Andrew B. Wong1,2, Ye Sheng Yee1, Thomas F. Jaramillo1,2 and James S. Harris1; 1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States

For some time, it has been predicted that the development of tandem absorber photoelectrodes can allow for superior utilization of the solar spectrum for photoelectrochemical water splitting. Based on stoichiometry, InGaN has a variable band gap that can span from 3.4 to 0.7 eV, which makes it ideal for pairing with Si in tandem photoabsorber devices, in principle. Furthermore, MOCVD of InGaN directly onto a Si p-n junction can provide a path to reducing the cost of tandem absorbers towards commercialization. In this presentation, our work into the development of tandem InGaN-Si photoelectrodes via MOCVD will be discussed. Specifically, our successful growth of the designed InGaN-Si system and the performance of this system will be presented. Our efforts elucidate necessary considerations when pursuing design of photoelectrochemical systems that are relevant for discussions between experimentalists and theorists during system design. These inter-related considerations include:
- Controlling electronic trap and surface states within the absorber materials and defect tolerance
- Controlling crystallization, growth, and morphology of absorber materials
- Controlling carrier concentration and carrier type
- Reducing the density of structural defects in the absorber materials
- Managing lattice strain resulting from mismatches in lattice constant and thermal expansion coefficients
Overall, this work on tandem InGaN-Si photoelectrodes for photoelectrochemical water splitting can provide a useful case study that can inform the dialog for the coordination between experimentalists with theorists for the discovery of the next generation of materials for water splitting. This dialog continues to grow in importance as the interface between theory and experiment continues to become more robust.

3:15 PM EN07.11.05
Novel Stable Three-Dimensional (3D) Stainless Steel-Based Electrodes for Efficient Water Splitting

Haojie Zhang¹, Juliana Martins de Souza e Silva¹, Xiaopeng Li², A. Wouter Maijenburg¹, Stefan Schweizer¹ and Ralf B. Wehrspohn¹,³; ¹Martin-Luther-Universität Halle-Wittenberg, Germany; ²Shanghai Advanced Research Institute, Chinese Academy of Science (SARI-CAS), China; ³Fraunhofer-Institut für Mikrostruktur von Werkstoffen und Systemen IMWS, Germany

Stainless steel (SS) is a promising material for the preparation of high-active electrode for efficient water splitting. However, the stability of coupled electrocatalysts on the surface of SS is a significant challenge for the construction of three-dimensional stable electrodes. In this work, we present an efficient and universal process to enhance the interfacial interaction between SS and highly-active electrocatalysts for the preparation of 3D electrodes through the formation of an interfacial network of carbon nanotubes (CNTs) on the surface of SS. The strongly-interconnected CNTs network increases the surface area of the SS support that benefits the modification of highly-active electrocatalysts and also serves as an electron/charge-conductive highway between the electrocatalysts and the support. The modified electrocatalysts on CNTs further improve the performance of the water splitting. The 3D structure of the prepared 3D electrode was visualized and analyzed by X-ray microscopy. Our strategy is an efficient approach to combine highly-active electrocatalysts with SS for the preparation of active and stable 3D electrodes, that can be used further explored in various areas.

* Invited Paper

TUTORIAL
Processing and Device Optimization Strategies for High Efficiency Perovskite Solar Cells
Sunday Afternoon, December 1, 2019
Hynes, Level 2, Room 204

Halide perovskites are currently one of the hottest research topics due to their potential use in a wide variety of optoelectronic devices. Especially in the field of photovoltaics this material now outperforms most other thin-film solar cell technologies, reaching efficiencies well above 20%.

In this tutorial, we will introduce material researchers to the most important aspects related to the preparation of state-of-the-art perovskite solar cells. The first part will cover fundamental concepts regarding the preparation of perovskite films and discuss stability effects when tuning the elemental composition. The second part will cover reproducible fabrication protocols and design rules for single cell applications, with a special focus on charge carrier recombination. Finally, in the third part, aspects regarding the preparation, challenges, and prospects of perovskite-based tandem solar cell devices will be examined. The overarching goal of this Tutorial is to provide a comprehensive overview regarding important aspects in material and device preparation; this will enable students and researchers who are new to this topic to pick up the necessary knowledge needed to participate in this exciting research field.
1:30 PM  
Processing, Stabilizing, and Detoxifying Perovskites  Yuanyuan Zhou, Brown University

The first session of this tutorial will discuss the fundamental materials science that governs the most outstanding issues of scalability, stability, and toxicity in the commercialization of perovskite optoelectronics. First, fundamental understandings on the structure, formation, and degradation of halide perovskites will be elaborated with specific examples from the literature. Then, typical materials-engineering strategies that mitigate these issues will be demonstrated. Finally, a perspective on the future directions in this research area will be provided.

2:30 PM  
BREAK

3:00 PM  
How to Make Efficient Perovskite Solar Cells  Martin Stolterfoht, University of Potsdam

The second section will focus on conveying reproducible fabrication protocols for preparing p–i–n type perovskite solar cells with efficiencies above 20% efficiency. The optimization strategies are particularly focused on suppressing non-radiative interfacial recombination which is the main bottleneck of today's perovskite solar cells. Necessary measurement techniques are introduced in this tutorial which will allow researchers to quantify recombination losses in their perovskite solar cell stacks in order to identify the origin of efficiency losses.

4:00 PM  
Perovskite-based Multijunction Solar Cells  Jérémie Werner, University of Colorado Boulder

The third part of this course will cover relevant aspects related to the field of perovskite-based multijunction solar cells. First, a comprehensive overview will be given on how developments in stack design enabled the swift rise in efficiency from 0 to >28% which took place in the last 5 years. Both all-perovskite as well as hybrid perovskite-based tandem solar cells will be introduced and the pros and cons discussed. Finally, the remaining challenges and future directions of this technology will be addressed.

Understanding and Designing Interfaces and Defects in Perovskite Solar Cells Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Perovskite solar cells promise to yield efficiencies beyond 30% by further improving the quality of the materials and devices. Electronic defect passivation, and suppression of detrimental charge-carrier recombination at the different device interfaces has been used as a strategy to achieve high performance perovskite solar cells.

In this presentation, I will discuss the role of electronic defects and how these can be passivated to improve charge-carrier lifetimes and to achieve high open-circuit voltages. I will discuss the characterization of 2D and 3D defects, such as grain boundaries, crystal surface defects, and precipitate formation within the films, by synchrotron-based techniques. The importance of interfaces and their contribution to detrimental recombination will also be discussed. As a result of these contributions to better understanding 2D and 3D defects, the perovskite solar cell field has been able to improve device performance. Albeit the rapid improvements in performance, there is still a need to improve these defects to push these solar cells beyond the current state-of-the-art.

9:00 AM *EN08.01.02
Materials and Processing for Scalable Perovskite Solar Cells Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Since the first report on the 9.7% efficiency, 500 h-stable solid-state perovskite solar cell (PSC) in 2012 by our group, following two seed works on perovskite-sensitized liquid junction solar cells in 2009 and 2011, a power conversion efficiency (PCE) of 24.2% was recorded in 2019. According to Web of Science, publications on PSC increase exponentially since 2012 and total number of publications reaches over 12,000 as of May 2019, which indicates that PSC is considered as promising photovoltaics. Although high photovoltaic performance was achieved from small area cell, scalable technologies are required for commercialization of PSC. In order to shift from small-area device to large-area module, the cheap materials and an effective coating procedure are highly required. We developed cost-effective materials based on delta FAPbI3 powder for high efficiency PSC. The best PCE of 22.6% was achieved using the synthesized perovskite powder. For large-area uniform perovskite coating, a precursor solution containing perovskite cluster was developed. Homogeneous MAPbI3 perovskite film (>100 cm2) was D-bar coated within 20 s, which demonstrated the PCE approaching 18%. Bifacial stamping technique was developed, which led to both high quality FAPbI3 and MAPbI3 on a large scale at milder condition.

9:30 AM EN08.01.03
Combined Surface and Additive Engineering for High Efficiency Flexible Perovskite Solar Cells Shengzhong (Frank) Liu1,2, Yucheng Liu1 and Xuejie Zhu1; 1Shaanxi Normal University, China; 2Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China

An effective surface engineering is developed to prepare effective SnO2-based electron transport layer (ETL). Together with an additive engineering strategy, solar cell efficiency is improved to 22% when rigid glass is used as the substrate. When PET substrate is used, flexible solar cells are designed and fabricated with the cell efficiency improved to as high as 20.9%, the highest efficiency for this category of flexible solar cells. It is found that by using an additive to react with Pb2+ to form an intermediate complex. Crystallization process is slowed down during the perovskite formation, leading to enlarged grain size and improved crystalline quality. In fact, using the SnO2 ETL and the additive engineering, the trap state density of the resultant perovskite thin films is effectively reduced comparing to the films without it, demonstrating that the additive effectively retards transformation kinetics during the thin film formation process. Meanwhile, the surface modification is found critical to form a nucleation layer and a good interface for the perovskite thin film development. Furthermore, the environmental stability of the flexible solar cells is significantly enhanced comparing to the devices without them. Large area solar cells are fabricated to demonstrate its scalability.
9:45 AM EN08.01.04  
**Bottom-Up Interfacial Modification with Inorganic and Organic Materials for Highly Efficient and Stable Perovskite Cells**  
Antonio Facchetti\(^1,2\); \(^1\)Northwestern University, United States; \(^2\)Flexterra Corp, United States

Hybrid organic-inorganic perovskite solar cells (PSCs) are promising for applications due to unparalleled processing-performance characteristics. Due to improvements in both perovskite active layer composition and the use of newly-developed interfacial materials, PSC PCEs have increased steadily from ~4% to >23%. High-performance PSCs relies on: (1) Appropriate interfacial energy level alignment for reducing energy losses. (2) Minimize defects and ion vacancies at the perovskite interface and bulk to maximize charge transfer. Here, we report two complementary strategies for fabricating/modifying the device electron transporting layer (ETL) based on inorganic and organic materials. In the first strategy, we demonstrate high-quality and dense ZnO films with negligible organic impurities, high crystallinity, and a self-passivated surface by combustion synthesis enabling cells with a PCE of 19.69 %. In the second strategy, we introduce two non-conjugated multi zwitterionic organic small-molecule electrolytes (NSEs) as effective bottom-up modifier to passivate not only interfacial but the bulk defects of perovskite for solution-processed PSCs. These NSEs enable to achieve an ideal WF for the ETL of 3.78 eV, thus resulting in a barrier free electron transfer, as well as to passivate interfacial defects between perovskite and ETL, preventing back electron transfer and suppressing charge recombination. Cells based on SnO2/NSE deliver PCEs surpassing 21.18% with an ultra-high VOC of 1.19 V. Both approaches strongly suppressed hysteresis and enhance environmental stability.

10:00 AM BREAK

10:30 AM *EN08.01.05  
**Breaking the Defect Bottleneck in Halide Perovskite Semiconductors**  
Aron Walsh; Imperial College London, United Kingdom

The physical properties of semiconducting solids depend on the imperfections they contain [1]. Defects come in a few flavours: conductivity-promoting defects create free carriers that enable electronics; killer defects (deep, charged centres) trigger recombination; and charge scattering defects reduce mobility.

Our understanding of the defect chemistry and physics of halide perovskites is limited in comparison to inorganic semiconductors. I will discuss recent progress, from theory and experiment, to identify, characterise and control point defects and defect processes in this family of compounds. I will cover charge compensation mechanisms [2], carrier trapping phenomena [3], the effect of grain boundaries [4], and how this understanding can be applied to engineer defect populations and distributions. The use of ‘defect tolerance’ as a metric to develop and screen post-perovskite materials will be critically addressed.

11:00 AM EN08.01.06  
**Surface Molecule Doping of Metal Oxide Nanocrystals to Enhance Carrier Transport of Perovskite Solar Cells**  
Zhubing He\(^1,2\); \(^1\)Southern University of Science and Technology, China; \(^2\)Shenzhen Key Laboratory of Full Spectral Solar Electricity Generation (FSSEG), China

Molecular doping of inorganic semiconductor is a rising topic in the scope of organic/inorganic hybrid electronics.
In this talk, we present two typical molecular doping for NiO and SnO₂, both of which play a crucial role in carrier transport in perovskite solar cells. First, NiO hole-transport-layer was realized p-doping successfully by 2,2’-(perfluoronaphthalene-2,6-diylidene)dimalononitrile (F6TCNNQ). Determined by XPS and UPS, the Eₚ of NiOx HTLs is increased from -4.63 eV to -5.07 eV and VBM-EF declines from 0.58 eV to 0.29 eV after F6TCNNQ doping. The energy level offset between the VBMs of NiO, and perovskites declined from 0.18 eV to 0.04 eV. Combining with first-principles calculations, electrostatic-force-microscopy was the first time applied to verify directly electron transfer from NiOx to F6TCNNQ. The average PCE of CsFAMA mixed cations PSCs were boosted by ca. 8% depending on F6TCNNQ doped NiOx HTLs. Strikingly, the champion cell conversion-efficiency of CsFAMA mixed-cations and MAPbI₃ based devices got 20.86% and 19.75%, respectively.

However, it’s difficult for n-doping, especially for oxides, because rare molecules own both strong reducibility and stability simultaneously in ambient atmosphere. In the second work, a simple, air-robust and cost-effective triphenylphosphine oxide molecule successfully realizes n-doping of SnO₂. Strikingly, we discovered that electrons were transferred from the R₃P⁺-O⁻ σ-bond to the peripheral tin atoms other than the directly interacted ones at the surface. That means those electrons are delocalized. The course was verified by multi physical characterizations. This doping effect accounts for the enhancement of conductivity and the decline of work function of SnO₂, which enlarges the built-in field from 0.01 eV to 0.07 eV and decreases the energy barrier from 0.55 eV to 0.39 eV at the SnO₂/Perovskite interface enabling an increase in the conversion efficiency of perovskite solar cells from 19.01% to 20.69%.

Our discoveries offer an extremely promising molecular doping method for inorganic carrier transport layers in PSCs. This methodology definitely paves a novel way to modulate the doping in hybrid electronics more than perovskite and organic solar cells.
transformation mechanism and effective manipulation for the complex phase transformation from disordered precursors to intermediate phases and perovskite crystal during solution-casting, and the equilibrium between nucleation and growth during single-crystal fabrication. [1-8] Our findings suggest an important role of the phase transformation control for dimensional tailoring, scalable fabrication, and flexible single-crystal of perovskite. In addition, I will briefly discuss the relationship of phase transformation-crystal quality-device performance in terms of solar cells and optoelectronics.

11:45 AM EN08.01.09
Mixed Dimensional 2D/3D Perovskite Solar Cells Using Double-Sided 2D Perovskite Passivation Md Arafat Mahmud, The Duong, Yiliang Wu, Jun Peng, Heping Shen, Kylie Catchpole, Klaus Weber and Thomas White; Australian National University (ANU), Australia

Conventionally, 3D perovskite materials are used for fabricating high-efficiency perovskite solar cells (PSCs), but they demonstrate poor device stability due to their high moisture sensitivity. Conversely, 2D Ruddlesden-Popper perovskite materials exhibit high moisture stability, but render lower device performance. Therefore, mixed dimensional 2D/3D PSCs have gained substantial research interest recently due to their high efficiency and ambient stability. Contemporary studies on mixed 2D/3D PSCs are based on either a thin 2D perovskite surface layer on top of 3D perovskite at perovskite/ hole transport layer (HTL) interface or 2D perovskite incorporated in the bulk of 3D perovskite. This work demonstrates that the application of 2D surface material with appropriate energy band alignment can be as effective for perovskite/ electron transport layer (ETL) interface, as reported for perovskite/HTL interface. Using such double-sided 2D surface passivation of n-butylammonium iodide (C₄H₁₂IN) sandwiching the bulk 3D quadruple cation Cs₀.₀₇Rb₀.₀₃FA₀.₇₆₅MA₀.₁₃₅Pb₁.₅₅Br₀.₄₅ [(CH₃NH₃ (MA), CH(NH₂)₂ (FA)] perovskite enabled over 22% stabilized power conversion efficiency (PCE) with mixed dimensional 2D/3D PSCs in n-i-p device configuration. Compared to the control 3D PSCs, mixed 2D/3D PSCs demonstrate an average open circuit voltage (VOC) enhancement of 20-40 mV and enhanced fill factor (FF) by 4% absolute value. The 2D surface layer contributes to the suppression of nonradiative recombination at perovskite/ETL and perovskite/HTL interfaces, which leads to enhanced photovoltaic performance with mixed 2D/3D PSCs. XRD spectral analysis also suggests reduced surface strain of perovskite film with 2D passivation layer that contributes to the superior device performance of 2D/3D device.

SESSION EN08.02: Perovskite Solar Cell—Interface and Transport Layers
Session Chairs: Pablo Docampo, Yabing Qi, Aron Walsh and Kai Zhu
Monday Afternoon, December 2, 2019
Sheraton, 2nd Floor, Back Bay AB

1:30 PM *EN08.02.01
Perovskite Stability—Challenges and Solutions Pablo Docampo; Newcastle University, United Kingdom

Hybrid halide perovskites combine top-notch optoelectronic properties with solution-deposition. This unprecedented combination has led to the development of solar cells that outperform established industry staples such as poly-Si. The road towards these achievements has been marked by a constant improvement of perovskite deposition techniques fuelled by our increasing understanding of the crystallization processes. However, stability still remains a key challenge. Here, I will focus on the effects of moisture-induced degradation on state-of-the-art perovskite materials and put forward several strategies to minimize the effect. I will show that the composition of the perovskite critically affects its stability while popular stabilization routes, such as introducing bulky hydrophobic cations - forming 2D/3D hybrid materials - in fact do not prevent moisture ingress into the structure. Our results show that the perovskite exhibits a surprisingly effective self-healing effect when combined with a thin 2D/3D hybrid perovskite bi-layer configuration. Furthermore, the effect can be minimized by the choice of hole transporter used where our developed amide-based hole transporting materials enhance both the performance and stability of the system.

2:00 PM *EN08.02.02
Interfacial Engineering of Carbon-Based Perovskite Solar Cells Tingli Ma¹,², Fanning Meng³ and Liguo Gao³;
Using carbon materials as the back electrode for perovskite solar cells (C-PSCs) has attracted significant attention due to their low cost and excellent stability. In general, the device structure of based C-PSCs has two types, one is hole transport layer (HTL) free and another one is with HTM. For these two cases, the carbon paste electrodes (CPEs) need directly collect the photo-generated holes or/and transport the holes. Therefore, interfacial engineering between the perovskite and CPE plays a crucial role in charge collection and affects the performance of C-PSCs. Our group have been carried out the interfacial engineering between carbon layer and perovskite layer using several methods to improve the performance of the C-PSCs. Herein, we will report our recent results, including development a simple process and an effective sandwich structure-based on coal carbon materials and 2D titanium carbide for improving the efficiency of PSCs. We also review the current progress in the studies on the carbon-based PSCs.

References:

Metal halide perovskite solar cells are now effectively competing with their inorganic counterparts in terms of power conversion efficiencies. However, state-of-the-art perovskite solar cells still suffer from limited fill factor (FF), open circuit voltage (V_{oc}) and long-term stability. Charge transport layers (CTLs) are key components of diffusion-controlled perovskite solar cells, however, we found that the CTL/perovskite interfaces induce additional non-radiative recombination pathways, which limit the V_{oc} of the cell. In order to harvest the full thermodynamic potential of the perovskite absorber, the interfaces of both the electron and hole transport layers (ETL/HTL) must be properly addressed and improved. Given the knowledge obtained from our previous studies, we developed a novel polymeric surface treatment based on poly(ionic-liquid) (PIL) materials. Notably, the application of this surface modification to a triple cation Cs$_5$(MA$_{0.17}$FA$_{0.83}$)$_9$Pb(I$_{0.83}$Br$_{0.17}$)$_3$ perovskite in pin-type solar cell enables a concomitant improvement of the FF and the V_{oc}. The resulting solar cell devices show outstanding FF values of up to 83% and V_{oc} of 1.17V, which lead to extraordinarily high PCEs up to 21.5%. Through combined photoluminescence and cathodoluminescence studies we find that the PIL treatment helps to reduce the non-radiative recombination at the perovskite surface by acting as a defect passivating agent in the bare material. Additionally, we find that the recombination of charges across the perovskite/C_{60} interface is strongly reduced, increasing the V_{oc} in the actual device. Moreover, photoemission spectroscopy and conductive atomic force microscopy highlighted a specific charge redistribution at the perovskite surface upon PIL treatment, which conceivably leads to increased conductivity and charge extraction, consistently with the enhanced FF. Ultimately, the hydrophobic nature of the PIL provides a shielding coverage of the perovskite which helps to prevent degradation of the active material by moisture and air. The PIL modified devices show exceptionally long dark storage stability and enhanced lifetimes under maximum power point tracking (MPP). We show that by addressing and carefully modifying the perovskite surface/interface with this novel material, it is possible to efficiently suppress the non-radiative recombination of charges, promote the charge extraction and improve the stability at the same time. Additionally, given the simplicity of this post-treatment, our results can be representative of a more general methodology for device modification, therefore, potentially applicable to other compositions and cell architecture, including tandem solar cells. Finally, our results could open the doors to e new class of materials to be implemented in perovskite solar cells for future development.

State-of-the-art halide perovskite solar cells employ semiconductor oxides as electron transport materials. Defects in
these oxides, such as oxygen vacancies (O_{vac}), act as recombination centres and, in air and UV light, reduce the stability of the solar cell. Under the same conditions, the PbZrTiO$_3$ ferroelectric oxide employs O_{vac} for the creation of defect-dipoles responsible for photo-carrier separation and current transport, evading device degradation. Here, we report the application of PbZrTiO$_3$ as the electron extraction material in triple cation halide perovskite solar cells. The application of a bias voltage (poling) up to 2 V, under UV light, is a critical step to induce charge transport in the ferroelectric oxide. Champion cells result in power conversion efficiencies of $\sim$11% after poling. Stability analysis, carried out at 1-sun AM 1.5 G, including UV light in air for unencapsulated devices, shows negligible degradation for hours. These devices show also switching properties and thus, are also applied as solar transistors. Our results demonstrate, the application of ferroelectric/ferroelectric interfaces for efficient and stable PSCs and Solar transistors. These findings are also a step forward in the development of next generation ferroelectric oxide-based electronic and optoelectronic devices.

Stable Perovskite Solar Cells by Compositional and Interface Engineering Mohammad K. Nazeeruddin; Ecole Polytechnique Fédérale de Lausanne, Switzerland

Organic/inorganic lead halide perovskite solar cells (PSCs), reaching over 24% power conversion efficiency demonstrates that they are the most promising class of materials for next-generation thin film photovoltaics. The unprecedented increase in the device performance in less than ten years is because of improved processing protocols, and compositional engineering of cations, and anions of the perovskite material. Nevertheless, the remarkable power conversion efficiency (PCE) progression of perovskite solar cells, confronts with serious stability concerns, due to an intrinsic decomposition of the materials compromising their potentiality as a future market technology. In this talk, we discuss how to mitigate the stability of perovskite solar cells by compositional and interface engineering.

4:00 PM EN08.02.06
Inverted (p-i-n) Perovskite Solar Cells Prepared by Complex Assisted Gas Quenching on Hydrophobic Hole Transport Layers—Overcoming the De-Wetting Issues Kai O. Brinkmann$^1$, Junjie He$^{1,2}$, Felix Schubert$^1$, Jessica Malerczyk$^1$, Cedric Kreusel$^1$, Frederic van gen Hassend$^1$, Sebastian Weber$^1$, Jun Song$^2$, Junle Qu$^2$ and Thomas Riedl$^1$; $^1$Bergische Universitat Wuppertal, Germany; $^2$Shenzhen University, China

Lead halide perovskite solar cells are attractive because they can be processed from solution at low temperature. Nevertheless, the perovskite community adheres to relatively strict processing protocols to form high-performance perovskite layers with the frequently used “anti-solvent” procedure. Thus, to establish a perovskite process in a lab is closely linked with cumbersome fine-tuning, processing practice and ambient control (temperature, atmosphere). As a result, reproducibility issues from lab to lab are frequently encountered. Some of the issues associated with the anti-solvent approach can be overcome by the so called “complex assisted gas quenching” (CAGQ) technique, that replaces the anti solvent exposure by a nitrogen flow driven drying process. In any case, the perovskite precursor inks usually consist of highly polar solvents, which gives rise to de-wetting issues, especially if hydrophobic organic hole transporting layers, like poly triarylamine (PTAA), are considered. Here, we will show, that for the most frequently used solvent system of DMSO:DMF precursor de-wetting is of
particular importance as the wetting behavior deteriorates during the gradual formation of supersaturation. We unambiguously identify DMSO to be the main reason for de-wetting of the precursor solution and the consequent pinhole formation on hydrophobic hole transport layers. In striking contrast, we will show that n-methyl-2-pyrrolidon (NMP), which has a lower hydrophilic-lipophilic-balance, can be favorably used instead of DMSO to strongly mitigate these de-wetting issues. The resulting high-quality perovskite layers are extremely tolerant with respect to the mixing ratio (NMP:DMF), process handling and timing. Thus, our findings afford an outstandingly robust, easy to use and failsafe deposition technique yielding single (MAPbI3) and double (FA0.94Cs0.06PbI3) cation perovskites as well as mixed halide (FA0.6Cs0.4PbI2Br) perovskites for solar cells with high efficiencies without the need to adjust process parameters when switching between material systems. Most notably, the statistical variation of the devices with NMP:DMF solvent system is significantly reduced, even if the deposition process is performed by different persons with no significant lab experience whatsoever.[4]

We foresee, that our results will further the reliable preparation of perovskite thin films and mitigate process-to-process variations that still hinder the prospects of upscaling perovskite solar technology.

2D/3D Hybrid Perovskite Interfaces and Physics therein for Stable and Efficient Solar Cells Giulia Grancini1 and Valentin I. Queloz2,1; 1Università di Pavia, Italy; 2Ecole Polytechnique Fédérale de Lausanne, Switzerland

Solar energy can lead a “paradigm shift” in the energy sector with a new low-cost, efficient, and stable technology. Nowadays, three-dimensional (3D) methylammonium lead iodide perovskite solar cells are undoubtedly leading the photovoltaic scene with their power conversion efficiency (PCE) >23%, holding the promise to be the near future solution to harness solar energy [1]. Tuning the material composition, i.e. by cations and anions substitution, and functionalization of the device interfaces have been the successful routes for a real breakthrough in the device performances [2]. However, poor device stability and still lack of knowledge on device physics substantially hamper their take-off. Here, I will show a new concept by using a different class of perovskites, arranging into a two-dimensional (2D) structure, i.e. resembling natural quantum wells. 2D perovskites have demonstrated high stability, far above their 3D counterparts [3]. However, their narrow band gap limits their light-harvesting ability, compromising their photovoltaic action. Combining 2D and 3D into a new hybrid 2D/3D heterostructure will be here presented as a new way to boost device efficiency and stability, together. The 2D/3D composite self-assembles into an exceptional gradually organized interface with tunable structure and physics. To exploit new synergistic function, interface physics, which ultimately dictate the device performances, is explored, with a special focus on energy and charge transfer dynamics, as well as charge recombination and trapping processes happening over a time scale from fs to ms. As shown in Fig.1, when 2D perovskite is used on top of the 3D, charge transfer happens, while electron hole recombination at the perovskite/hole transporter interface is prevented. This results in improved device efficiency. In concomitance, the stable 2D perovskite is used as a sheath to physically protect the 3D underneath, with the aim to enhance the device stability. The joint effect leads to PCE=20% which is kept stable for 1000 h [3,4]. Incorporating the hybrid interfaces into working solar cells is here demonstrated as an interesting route to advance in the solar cell technology bringing a new fundamental understanding of the interface physics at multi-dimensional perovskite junction. The knowledge derived is essential for a deeper understanding of the material properties and for guiding a rational device design, even beyond photovoltaics.

Enhanced Nucleation of Atomic Layer Deposited Contacts Improves Operational Stability of Perovskite Solar Cells James A. Raiford1, Caleb C. Boyd1,2, Axel F. Palmstrom2, Eli J. Wolf1,2, Benjamin A. Fearon1, Joseph J. Berry3, Michael D. McGehee3 and Stacey F. Bent1; 1Stanford University, United States; 2National Renewable Energy Laboratory, United States; 3University of Colorado Boulder, United States

Various strategies have been explored to improve the long-term stability of metal halide perovskite solar cells, including the use of barrier and passivation layers and device encapsulation. Atomic layer deposition (ALD) has emerged as an effective tool for all of these applications, due to the precise control it affords over film thickness and
composition and the excellent barrier properties of the resultant films. In practice, ALD metal oxides are often grown on top of organic carrier transport layers in devices. For example, ALD SnO₂ grown on fullerenes is widely used for high-efficiency all-perovskite, perovskite-Si and perovskite-CIGS tandems.¹⁻³ The physical barrier and electronic properties of an ALD film grown on an organic substrate, such as a polymer, small molecule, or self-assembled monolayer largely depend on the structure of the organic material. To ensure the formation of an abrupt organic/oxide interface and avoid subsurface growth, a high density of functional sites (e.g. hydroxyls, amines) at the surface are desired to facilitate ligand-exchange reactions with the ALD metal-organic precursors.

In this work, we apply these insights to improve the nucleation, and consequently the barrier properties, of ALD metal oxides as selective contacts, with a focus on improving operational device stability. We demonstrate the application of a thin (~1 nm), nucleophilic polymer to promote the growth of ALD SnO₂ on C₆₀ as electron contacts in n-i-p devices. The nucleation-enhanced SnO₂ effectively protects against the degradation of Cs₀.₂₅FA₀.₇₅Pb(Br₀.₂₀I₀.₈₀)₃ films held at 200°C in air for up to 2 hours and upon direct exposure to water for at least 10 minutes. Ultimately, we show the integration of nucleation layers into single-junction, opaque devices with a champion power conversion efficiency (PCE) of 18.5%. On average, devices with nucleation-enhanced ALD SnO₂ and no further encapsulation maintain 82% of their initial PCE after 250 hours of continuous, illuminated operation at maximum power in air at 60°C, demonstrating a 150% improvement in stability at these harsh conditions over devices with ALD SnO₂ grown directly on C₆₀. These results highlight the impact that a high-quality contact/barrier layer can have on protecting the perovskite from various degradation pathways, such as moisture or oxygen ingress, halide egress, or metal-halide reactions. This study also presents a framework upon which to further improve the quality of barrier/encapsulation layers for various configurations and architectures of perovskite optoelectronic devices.

SESSION EN08.03: Poster Session I: Perovskite Solar Cell—Interface and Transport Layers

A Novel NDI-Based Polymer Adopted as the Electron Transport Layer in Inverted Planar Flexible Perovskite Solar Cell

Hyuntae Choi, Jihyun Min, Dohyun Kim and Taiho Park; POSTECH, Korea (the Republic of)

A novel naphthalene diimide (NDI)–based polymer (P(NDI₂DT–TTCN)) which has strong electron withdrawing dicyanothiophene group is employed as the electron transport layer (ETL) in place of the conventional fullerene-based ETL in inverted–structure perovskite solar cells (Pero–SCs). A variety of characterization techniques are used to observe and analyze the interface between perovskite and P(NDI₂DT–TTCN) or [6,6]–phenyl–C₆₁–butyric acid methyl ester (PCBM). It is confirmed that P(NDI₂DT–TTCN) helps not only to facilitate the electron extraction but also to prevent ambient atmosphere interference by forming a hydrophobic ETL surface. Furthermore, P(NDI₂DT–TTCN) shows excellent mechanical stability in flexible Pero–SCs. With these improved properties, the device performance based on P(NDI₂DT–TTCN) is superior to that of based on PCBM from 14.3% to 17% with negligible hysteresis.

A Superficial New Solid-State Synthesis of SnO₂ for High-Performance and Stable Perovskite Solar Cells

Mriganka Singh¹,²,³, Hong-Cheu Lin¹, Chih Wei Chu² and Gang Li³; ¹National Chiao Tung University, Taiwan;
Metal oxide carrier transporting layers have been investigated widely in organic/inorganic lead halide perovskite solar cells (PSCs). Tin oxide (SnO$_2$) is a promising alternative to the titanium dioxide commonly used in the electron transporting layer (ETL), due to its tunable carrier concentration, high electron mobility, amenability to low-temperature annealing processing, and large energy bandgap. In this study, a facile method was developed for the preparation of a room-temperature-processed SnO$_2$ electron transporting material that provided a high-quality ETL, leading to PSCs displaying high power conversion efficiency (PCE) and stability. A novel physical ball milling method was first employed to prepare chemically pure ground SnO$_2$ nanoparticles (G-SnO$_2$), and a sol–gel process was used to prepare a compact SnO$_2$ (C-SnO$_2$) layer. The effects of various types of ETLs (C-SnO$_2$, G-SnO$_2$, composite G-SnO$_2$/C-SnO$_2$) on the performance of the PSCs are investigated. The composite SnO$_2$ nanostructure formed a robust ETL having efficient carrier transport properties; accordingly, carrier recombination between the ETL and mixed perovskite was inhibited. PSCs incorporating C-SnO$_2$, G-SnO$_2$, and G-SnO$_2$/C-SnO$_2$ as ETLs provided PCEs of 16.46, 17.92, and 21.09%, respectively. In addition to their high efficiency, the devices featuring the composite SnO$_2$ (G-SnO$_2$/C-SnO$_2$) nanostructures possessed excellent long-term stability—they maintained 89% (with encapsulation) and 83% (without encapsulation) of their initial PCEs after 105 days (>2500 h) and 60 days (>1400 h), respectively, when stored under dry ambient air (20 ± 5 RH %).

EN08.03.03
BaSnO$_3$ Electron Transport Layer as an Alternative to TiO$_2$ for Efficient and Stable Perovskite Solar Cells
Chung Jaehoon, Seong Sik Shin and Jangwon Seo; Korea research institute of chemical technology, Korea (the Republic of)

For commercializing perovskite solar cells (PSCs), moisture-tolerant materials are required for each component of PSCs, such as electron transport layer (ETL), perovskite layer, and hole transport layers (HTL), because low relative humidity (RH) under 10–20% cannot be controlled in actual production line. Most of conversional PSCs with a high power conversion efficiency (PCE) over 20% have widely implemented Li doped mesoporous titanium oxide (mp-TiO$_2$:Li) as an n-type semiconductor for ETL. This Li treatment could facilitate an electron extraction of ETL, but could affect the device stability during the fabrication of PSCs under humid atmospheric environment due to its hydroscopic nature.

In this work, we employ mesoporous BaSnO$_3$ (mp-BSO), which is moisture tolerant ETL, and fabricate stable PSCs without sacrificing the performance. The mp-BSO based PSCs show certified PCE of 21.3% and steady-state PCE of 21.4%, which is comparable to that of mp-TiO$_2$:Li based PSCs. However, with respect to the storage stability, each device exhibits different behavior according to the humidity in air. Both devices are stable at RH-10% atmosphere. At high humid environment (RH 40%), mp-TiO$_2$:Li based device shows severe degradation even after 24 hours, whereas mp-BSO based device shows good stability similar to the result at RH 10%. This is mainly attributed to the formation of Li$_2$O on TiO$_2$ surface analysis of mp-TiO$_2$:Li (i.e. IR, XPS, and TEM). For resultant device with mp-TiO$_2$:Li as ETL, electron transfer/transport could be impeded at the interface between ETL and perovskite layer at a high humid condition. On the other hand, the device with mp-BSO exhibits a superior moisture stability. It is also supported by transient photocurrent/photovoltage and time resolved photoluminescence studies. Along with outstanding performance, mp-BSO based PSCs show excellent storage and light stability during 500 hours. We believe that this strategy of introducing mp-BSO ETL into PSCs will accelerate the commercialization of PSCs.

EN08.03.04
Complimentary Heterogenous Electron Transporting Layers to Fabricate Highly Consistent, Stable and Efficient Planar Perovskite Solar Cells
Shini Foo, Thambidurai Mariyappan, P. C. Harikesh, Nripan Mathews, Yi Zhong Huang and Cuong Dang; Nanyang Technological University, Singapore

Unlike the mesoporous configuration in which efficient charge extraction is derived from its high contact area, planar perovskite device places heavier dependence on the intrinsic characteristics of the electron transporting layer (ETL) to effectively transport photoexcited electrons from the organometal-halide absorber layer to the anode. Furthermore, the planar configuration generally demonstrates poorer power conversion efficient (PCE), device stability, and reproducibility. In this work, we present the systematic study of heterogeneous ETLs comprising of solution-processed optimized AlIn-TiO$_2$ (AITO) and SnO$_2$ as a highly effective approach to overcome these
shortcomings. By depositing a thin SnO₂ interlayer between the AITO/perovskite interface, significant improvement in recombination resistance and PCE was observed. As a result, the heterogeneous AITO/SnO₂ ETL based device exhibited nonpareil PCE of 18.9% and notable long-term stability through which 93% of its initial PCE was retained after 25 days in the absence of encapsulation. On the other hand, remarkable device stability was obtained from the consistent AITO ETL in which interquartile range (IQR) of the efficiency boxplot revealed 2.8 times reduction in the heterogeneous ETL based devices compared to the homogeneous SnO₂ ETL based devices. In essence, our results suggest the use of favourable ETLs as a straightforward yet powerful method to cover the weaknesses of individual ETLs while providing synergistic enhancements in device stability, reproducibility, and various photovoltaic parameters in planar perovskite solar cells.

EN08.03.05
Digital Alloy Contact Layers of ZnO and MgZnO for Perovskite Solar Cells Ekrai Dahal¹, Bin Du¹, Ben Isenhart¹, Olivia Sergiovanni¹, Sean Dunfield², Joseph J. Berry³ and Matthew S. White¹; ¹The University of Vermont, United States; ²University of Colorado Boulder, United States; ³National Renewable Energy Laboratory, United States

Perovskite solar cells are considered the photovoltaics technology of the future due to their low manufacturing costs and potential for high performance. Perovskite solar cells often use oxides to perform multiple functions; oxides such as TiO₂, SnO₂, and ZnO are used as electron transport layers (ETL) and NiO, WO₃ as hole transport layers (HTL). The ETL material must simultaneously have optimal conduction band alignment, facilitate carrier extraction, prevent recombination, and provide a chemically stable interface with the volatile perovskite semiconductor. The multiple requirements placed on this one layer dictate different material properties at different positions within the film, specifically bulk and interfacial properties. Given that the layer thickness ranges from 10 nm to 200 nm, the requirements demand positional control of the material composition at the nano-scale. By using the pulsed laser deposition (PLD) technique to control the chemical composition at nanometer scale to form material alloys of ZnO and MgZnO as ETL for the perovskite solar cell device, we demonstrate that digital alloy gradients can be tuned to significantly outperform either of the parent materials in perovskite solar cells.

EN08.03.06
Effect of Conduction Band Offset between SnO₂-Based ETL and Perovskite Absorber on Device Performance Ji Won Lee¹, Jin Hyuck Heo²,³, Seong Yeon Kim¹,³, Fei Zhang¹, Ji-Sang Park¹, Sang Hyuk Im², Kai Zhu¹, Joseph J. Berry³ and Jun Ho Kim¹,³; ¹Incheon National University, Korea (the Republic of); ²Korea University, Korea (the Republic of); ³National Renewable Energy Laboratory, United States; ⁴Imperial College London, United Kingdom

SnO₂-based oxide is very promising electron transport layer (ETL) for high efficient and stable perovskite solar cell. However, electron affinity of SnO₂ is rather low, considering the optimal conduction band offset (CBO) between ETL and absorber layer. We studied device simulation to get optimal CBO by tuning the electron affinity of SnO₂-based ETL and perovskite absorber. SCAPS simulation showed that power conversion efficiency (PCE) is increased from cliff-type CBO to spike-type CBO, and decreased with larger spike-type CBO. With the obtained simulation result, we fabricated SnO₂ and doped-SnO₂ ETLs with up-shifted conduction band edge and compared performance of fabricated device with simulation result. This research indicates that CBO should be optimized for higher efficiency SnO₂-based perovskite solar cell.

EN08.03.07
Effect of p-Type Doping to Dithiophene-Benzene Copolymer as Hole Transporting Layers in Perovskite Solar Cells Yoshihiko Nishihara¹,², Nobuko Onozawa-Komatsuzaki¹, Hiroaki Tachibana¹, Masayuki Chikamatsu¹ and Yuji Yoshida¹,²; ¹National Institute of Advanced Industrial Science and Technology, Japan; ²University of Tsukuba, Japan

We have investigated perovskite solar cells (PSCs) employing novel polymer semiconductor as hole transporting material (HTM). Dithiophene-benzene (DTB) copolymer-based PSCs have been reported higher short circuit current density than other polymer-based PSCs. In addition, it was expected that DTB was low cost and high stability compared to typical HTM of Spiro-OMeTAD. However, the influence of oxygen and dopant on DTB have not been examined in detail yet. In this research, we fabricated mesoporous-type PSCs employing DTB copolymer as HTM without and with dopant
under nitrogen atmosphere and measured the device performance in air. We used a lewis acid tris(pentafluorophenyl)boran (BCF) as a dopant. In case of the device without dopant, initial power conversion efficiency (PCE) showed 2.98% after exposure to air for 5 hours. However, the device performance gradually improved by keeping in dry air. After keeping in dry air for 1 week, PCE greatly improved to 16.15%. These results indicate that increase of carrier density in DTB occurred due to oxygen-doping. In case of the device with BCF dopant, initial PCE showed 13-14% after exposure to air for 5 hours. The PCE improved to 15-16% by keeping in dry air. The cause of this improvement of the initial device performance was due to increase of carrier density in DTB by BCF dopant.

EN08.03.08
Enhanced Transport and Carrier Selectivity at Perovskite Interfaces Enabled by Ordered Perylene Monolayers
Alexander D. Carl and Ronald L. Grimm; Worcester Polytechnic Institute, United States

Tandem-junction perovskite/silicon devices present the potential for highly efficient solar energy conversion devices. We investigate low-temperature organic monolayer functionalization of silicon substrates to chemically and electrically tether perovskite thin-films while maintaining carrier selectivity and a soft, flexible interface. We have covalently grafted vertically oriented perylene diimide overlayers on oxide-free Si (111) through and imide linkage to a surface-bound aniline. Secondary functionalization of the terminal anhydride with phenylenediamine yields A-type cation moieties that serve as a chemical hook for perovskite deposition. UPS characterized the band-energy levels of functionalized surfaces aligned to facilitate electron transport from MAPbI3 to the silicon substrate. Transfection Infrared Spectroscopy and X-ray photoelectron spectroscopy revealed a high coverage of vertically oriented perylene diimides. Liquid-junction photoelectrochemical experiments of MAPbI3/perylene diimide terminated, oxide-free silicon interfaces yield improved energy conversion relative to long-chain alkyl terminated silicon surfaces. We ascribe these improvements to enhanced carrier selective transport and reduced recombination. This work presents a bench-top functionalization of soft, robust, electron transport layers to further integrate low-cost perovskites with mature silicon PV.

EN08.03.09
Enhancing Electron Transport via Graphene Quantum Dot-Tin Oxide Composites for Efficient and Durable Flexible Perovskite Photovoltaics
Yu Zhou and Hong Lin; Tsinghua University, China

Recent advances in flexible perovskite solar cells (PSCs) have attracted considerable attention owing to their great potential for bendable and wearable electronic devices. Particularly, developing high-quality low-temperature processed electron transport layers (ETLs) plays a pivotal role in realizing highly efficient flexible PSCs. Herein, we develop a facile strategy to fabricate graphene quantum dot/SnO2 composites (GQD@SnO2) as effective ETLs for PSCs. Through systematically optimizing GQDs' size and concentration, higher film conductivity, better film coverage uniformity, and raised fermi energy level matching with perovskite were reached, which is remarkably beneficial to facilitate electron transfer and suppress interfacial charge recombination, resulting in great enhancement of photovoltaic performance. As a result, PSCs based on SnO2 blending with GQD of ca. 5 nm in diameter (G5@SnO2) exhibit superior photovoltaic performance with a champion power conversion efficiency (PCE) of 19.6% and an average PCE of 19.0%. Significantly, flexible PSCs based on G5@SnO2 obtain a best PCE and stabilized PCE of 17.7% and 17.2%, respectively. Moreover, these flexible devices demonstrate outstanding durability, retaining 91% of their original PCE after 500 bending cycles at a radius of 7 mm. This work provides a facile route to develop effective ETLs for high-performance flexible PSCs and paves the way for further advances in flexible photovoltaic devices and optoelectronic applications.

EN08.03.10
Fabrication and Properties of Inverted Perovskite Solar Cells with Surface-Treated Hole Transport Layer
Toshiya Kobayashi1, Masato Gocho1, Kazunori Ito1, Yuki Fukazawa1, Ryusuke Umeda1 and Hironori Ogata1,2,3; 1Hosei Univ. Grad. Sch., Japan; 2Hosei University, Japan; 3Research Center for Micro-Nano Tech., Japan

Organic–inorganic hybrid perovskite solar cells have attracted great attentions in recent years, because they can be fabricated by solution processes and the power conversion efficiency (PCE) has been drastically improved up to more than 24%. In a normal type perovskite solar cells having mesoporous structure, a metal oxide layer such as titanium oxide is used. However, it is not suitable for the application to flexible solar cells because it requires high temperature treatment for film formation. Therefore, studies on the inverted type perovskite solar cells which can be
formed a thin film at low temperature have attracted attention. Poly(3,4-ethylenedioxythiophene): polystyrene sulfonate (PEDOT: PSS) widely used for the hole transport layer, is considered to have a negative influence on the solar cell characteristics due to strong acidity, hygroscopicity, etc. Therefore, the development of chemically inert hole transport layers is one of the important challenges.1)2) Interface engineering of heterojunction interfaces which reducing the surface recombination is also a crucial strategy to improve the performance of the perovskite solar cells. In this study, inverted perovskite solar cells using metal oxide as the hole transport layer are prepared, and the effect of various acid treatments on the surface of the metal oxide layer such as NiOx, WO3, MoO3 and V2O5 on its local structure, charge transport characteristics and photovoltaic characteristics were investigated systematically. It was found that the perovskite layer prepared on the acid-treated metal oxide film exhibits higher PL quenching ratio than that on the non-acid-treated metal oxide film. In this presentation, we will report the detailed experimental results on the effect of acid treatment to metal oxide film on solar cell characteristics under various conditions.

EN08.03.11
Fully Metal Oxide Charge Selective Layers for n-i-p Structure Perovskite Solar Cells Employing Nickel Oxide Nanoparticles Kerem C. Icli1 and Ahmet Macit Ozenbas2; 1Middle East Technical Univ, Turkey; 2Middle East Technical University, Turkey

An alcohol based nickel oxide nanoparticle dispersion was prepared and used to deposit hole conductor medium for a polymeric substance free perovskite solar cell in mesoscopic n-i-p configuration. In contrast to conventional p-i-n configuration or inverted type perovskite solar cells, nickel oxide layer was spin coated directly on perovskite layer and the perovskite layer was sandwiched between two metal oxides, TiO2 and NiO, resulting in n-i-p configuration. High surface area nickel oxide nanoparticles were synthesized by precipitation and successfully dispersed in isopropanol with the aid of ball milling, which was confirmed to breakdown the aggregates and stabilize the dispersion without the assistance of a stabilizing agent. This strategy leads to deposition of nickel oxide nanoparticles on perovskite layer without damaging the underneath perovskite layer and inhibiting the charge transfer between individual nanoparticles, confirmed by scanning electron microscopy, photoluminescence quenching and J-V measurements. Ultraviolet photoelectron spectroscopy analysis showed excellent matching of the band alignment of nickel oxide layers with that of perovskite. An efficiency of 10.89% was achieved after optimizing the nickel oxide layer thickness and comparing with a hole conductor free device using J-V measurements and electrochemical impedance spectroscopy revealed that nickel oxide layer possesses excellent electron blocking ability and reduces the recombination rate, which also in turn stabilizes the power output and hysteresis of the cells. This strategy is believed to be applicable for other metal oxides employed in charge selective layers of perovskite and organic solar cells.

EN08.03.12
High Performance Inverted Perovskite Solar Cells by Reducing Electron Capture Region for Electron Transport Layers Shengnan Zuo; Shaanxi Normal University, China

The power conversion efficiency (PCE) of inverted perovskite solar cells (i-PSCs) is lower than the normal structures. The low efficiency is mainly ascribed to the inferior properties of commonly-used [6,6]-phenyl C61 butyric acid methyl ester (PCBM) electron transport layers (ETLs) such as complexity in achieving high quality films, low electron mobility, imperfect energy level for electron extraction, and large electron capture region. Herein, we develop the bulk heterojunction (BHJ) ETLs, which compose of PCBM and conjugated polymer materials. The electron mobility of BHJ film is enhanced by more than 3 times compared to pristine PCBM, and its Fermi level is close to the conduction band of perovskite. The high electron mobility and suitable energy level result in efficient electron extraction. Further, the electron capture region of BHJ film significantly decreases to 1.20 × 10^-18 cm^3 from 3.70 × 10^-17 cm^3 for pristine PCBM due to increased relative permittivity (enhanced to 5.32 from 3.66 for PCBM), leading to reduced trap-assistant recombination at perovskite/ETL interface. As a result, the PCE of i-PSCs is up to 18.84%, increased by about 15% compared to pristine PCBM. Under ambient air after 30 days, the PCE of unsealed devices based on BHJ ETLs keeps about 85% of the initial efficiency, while the devices with PCBM retain only about 49% of the initial value under the same aging conditions. Meanwhile, the unsealed devices with BHJ ETLs show about 83% of the initial efficiency under continuous illumination for 60 hours, while the devices based on pristine PCBM give about 63% of the initial value. The excellent stability is attributed to the more hydrophobic BHJ films and full coverage of perovskite surface, which effectively prevent the moisture permeation.
High Performance Perovskite Solar Cells by Using Low-Temperature-Processed Brookite-Based TiO2 Heterophase Junction

Md. Shahiduzzaman1,2, Shinjiro Umezu3, Satoru Iwamori2, Masao Isomura2, Koji Tomita2 and Tetsuya Taima1; 1Kanazawa University, Japan; 2Tokai University, Japan; 3Waseda University, Japan

In the design of electron transport layers (ETLs) to enhance the performance of perovskite solar cells (PSCs), efficient electron extraction and transport are important aspects. Herein, we examine the effect of different titanium oxide (TiO2) polymorphs such as anatase and brookite in the resultant PSCs performance. In this work, pure-phase, high-stable, high conductive, and single-crystalline brookite TiO2 nanoparticles (NPs) with an average diameter of approximately 30 nm ~ 50 nm were synthesized by a facile, nontoxic, environmentally friendly hydrothermal method by using a water-soluble titanium complex as the titanium source that helps for green and scalable fabrication of the PSCs. We design and fabricate, single-crystalline and high-phase-purity brookite-based TiO2 heterophase junctions on fluorine-doped tin oxide (FTO) as the substrate. We attempt to investigate and compare single phase anatase (A) and brookite (B) and heterophase anatase–brookite (AB) and brookite–anatase (BA) as ETLs in PSCs. The PCE of PSCs with single crystalline FTO-B only layer as the ETL was as high as 14.92% that is the highest reported efficiency of FTO-B-based single-layer PSC (Nano Lett., 2019, 19, 598). This result suggests that FTO-B acts as an active phase, which can be a potential candidate as an ETL scaffold in planar PSCs. Hetero junction FTO-AB ETLs based PSCs showed PCEs as high as 16.82%, which is higher to those of PSCs with single-phase anatase (FTO-A) and brookite (FTO-B) as the ETLs (13.86% and 14.92%, respectively). The large surface area of brookite TiO2 NPs facilitates more electron injection and subsequent transport, which can balance the electron current density and hole current density in the resultant PSCs and, therefore, can promote high performance. This facile synthesis and employing of brookite TiO2 NPs provide a clean and eco-friendly fabrication of PSCs with respect to an alternative approach to anatase TiO2 phase as the ETL bilayer.

High Power Conversion Efficiency of Perovskite Solar Cells Based on Low-Temperature Zn-Doped TiO2 Electron Extraction Layer

Ming-Chung Wu1,2, Yen-Tung Lin1, Shih-Hsuan Chen1, Ying-Han Liao1 and Shun-Hsiang Chan1; 1Chang Gung University, Taiwan; 2Chang Gung Memorial Hospital, Linkou, Taiwan

Perovskite solar cells (PSCs) has remarkably increased its power conversion efficiency (PCE) to 23.7% due to its high open-circuit voltage (VOC) and photocurrent. To make it commercialized, the modification of electron extraction layer (EEL) for improving the photovoltaic performance became another important issue. For the EEL, TiO2-based material is widely applied for the next-generation solar cells because of its non-toxicity, chemical stability, inexpensiveness, and high charge transportability. Doping Zn into TiO2 could accelerate the photo-induced electron-hole separation and could tune the bandgap of TiO2-based material. To further enhance the photovoltaic performance of PSC, we systematically study the effect of different Zn-doped TiO2 (Zn:TiO2) EEL on PSCs, including (1) planar Zn:TiO2 EEL, (2) mesoscopic Zn:TiO2 EEL, and (3) low-temperature Zn:TiO2 EEL. For the planar Zn:TiO2 EEL, it demonstrates serious hysteresis and it is unstable in the atmosphere. Although the mesoscopic Zn:TiO2 EEL based PSCs shows higher PCE than planer Zn:TiO2 EEL, the high-temperature calcination leads to cost increment and energy consumption and hinders the commercial potential. Therefore, the low-temperature process to prepare the nanostructure TiO2 layer has been regarded as a breakthrough. By optimizing the parameters of PSCs and the energy band alignment between perovskite absorber layer and 3 types of Zn:TiO2 EEL, the average PCE for PSCs based on (1) planarZn:TiO2 EEL is ~14.0%, (2) mesoscopic Zn:TiO2 EEL is ~16.8%, and (3) low-temperature Zn:TiO2 EEL reached as high as 20.4%.

High-Efficiency Flexible Solar Cells Based on a Low-Temperature UVO-Treated SnO2

Xuediao Cai, Yefang Jiang, Zhike Liu and Shengzhong (Frank) Liu; Shaanxi Normal University, China

The new perovskite material has wide application prospects in the field of photovoltaics, because of its excellent photoelectric properties such as bipolar transmission characteristics, large extinction coefficient, long carrier diffusion length, high carrier mobility, and low trap-state. However, there are still some problems that need to be
solved in the commercial application. For example: How to improve the power conversion efficiency? How to improve device stability? How to find alternative materials for Pb? How to prepare large area and flexible devices? In this work, we propose a low temperature thermal annealing and UV-ozone (UVO) assisted treatment of SnO₂ electron transport layer for rigid and flexible perovskite solar cells. It has been found that using UVO-assisted annealing treatment of SnO₂ is more conducive to form tin oxide network structure than only after thermal annealing. After UVO-assisted annealing treatment, the perovskite precursor solution can be easily spread on the surface of the SnO₂ film, the perovskite crystal has better crystallinity and larger grain size, and the perovskite film is more uniform. Furthermore, the performance of the PSC is improved, through which more sunlight could be absorbed and recombination could be efficiently reduced. A highly efficient rigid PSC with a PCE of 19.7% is obtained based on low temperature and UVO-treated SnO₂ ETLs. Based on lower temperature and UVO-treated SnO₂ ETL, flexible perovskite solar cell exhibited a high PCE of 18.88%. It is worth noting that 18.88% is higher than currently reported device efficiency, which at the world's leading level.

EN08.03.16
High-Performance and Stable Semi-Transparent Perovskite Solar Cells with Cross-Linked Hole Transport Layer
Jae Choul Yu¹, Christopher Dunn², Anthony Chesman² and Jacek Jasieniak¹; ¹Monash University, Australia; ²Commonwealth Scientific and Industrial Research Organisation, Australia

Organic–inorganic hybrid perovskites have emerged as an attractive candidate for semi-transparent solar cells (ST-SCs) due to their superior optoelectronic properties and transparency. In general, the appropriate selection of charge transport layers is considered to be the most crucial factors to both the efficient and the stability of perovskite solar cells (PeSCs). Spiro-OMeTAD with Li-TFSI and TBP dopants has been widely used as the hole transport layer in conventional opaque and ST solar cells because it has suitable energy level matching and good hole extraction ability. However, the hygroscopic nature of these dopants tends to reduce device stability because it can cause both phase segregation after moisture absorption and corrosion of the perovskite film, thereby limiting the applicability in commercial application.

Here, we demonstrated highly efficient and stable semi-transparent PeSCs (ST-PeSCs) introduced the cross-linked polymer (i.e. VNPB) as hole transport layer and dielectric-metal-dielectric (DMD, MoO₃/ultra-thin gold/MoO₃) as transparent electrode. We also explored post annealing as a facile approach towards optimizing the doping levels at our VNPB/MoO₃ interface. Experimental and analytical investigations revealed that a post annealing treatment of the VNPB-based ST-PeSCs remarkably increased charge extraction and reduced recombination of charge carriers. After optimization of post annealing treatment, we achieved a significantly improved power conversion efficiency of 16.7% with 10% average visible transmittance (AVT) compared to the device without post annealing treatment (10.9%). Moreover, the VNPB-based ST-PeSCs showed high long-term stability, maintaining 80% of the initial PCE after 360 h under continuous illumination and 50% of the initial PCE after 30 day under humid air conditions, whereas Spiro-OMeTAD-based ST-PeSCs showed a significant reduction in PCE. We emphasize that our approach can provide a new pathway to hole transport layer for hugely enhancing the efficiency and stability of ST-PeSCs.

EN08.03.17
High-Performance Perovskite Solar Cells Employing Solution-Processed Double-Walled Carbon Nanotubes
Unsoo Kim¹, Il Jeon¹, Jungjin Yoon¹, Shigeo Maruyama³, Yutaka Matsuo³, Mansoo Choi¹ and Junseop Byeon¹; ¹Seoul National University, Korea (the Republic of); ²Global Frontier Center for Multiscale Energy Systems, Korea (the Republic of); ³The University of Tokyo, Japan; ⁴Korea Institute of Science and Technology, Korea (the Republic of); ⁵National Institute of Advanced Industrial Science and Technology, The University of Tokyo, Japan

Organometallic halide perovskite solar cell (PSC) is the next generation thin film photovoltaic that harvests infinite solar energy. The strength of PSC lies in its potential price competitiveness from solution process availability and its ability to be made thin and be flexible due to high absorption coefficient of organometallic halide perovskite. However, use of brittle, indium-embedded, high-cost transparent conducting oxide (TCO) limits the commercialization of PSCs and their application to flexible devices.

Carbon nanotube (CNT) has received a lot of spotlight as a transparent electrode for electronic devices on grounds of its high conductivity, good transmittance, and abundance of elements. Single-walled carbon nanotube (SWNT) has been a subject of much research because of its low light density. However, its poor solubility restricts SWNT from cost-effective, large area available solution processes, preventing the commercialization of SWNT. Double-walled carbon nanotube (DWNT) is structurally midway between SWNT and multi-walled carbon nanotube (MWNT), with high transparency of SWNT and excellent dispersibility of MWNT. Taking advantage of these
features, we demonstrate solution processed DWNT electrodes and apply them to the PSCs. We treat nitric acid and trifluoromethanesulfonic acid (TFMS) on DWNT for optimization of sheet resistance and duration of doping effect. We systematically study the effect of the two dopants on the outer- and inner-wall through Raman spectroscopy and near-infrared (NIR) spectroscopy, and the results are consistent with the trend obtained from DFT calculation. We analyze PSCs based on DWNT with photoluminescence (PL) and dark current density-voltage (Dark J-V) measurements. Maximum power point tracking (MPPT) shows that optimized device exhibits stabilized power conversion efficiency (PCE) of 17.2% under 1 sun illumination.

EN08.03.18
Interfacial Engineering for Stability of Perovskite Solar Cell Molang Cai, Songyuan Dai and Yong Ding; North China Electric Power University (NCEPU), China

Perovskite solar cells (PSCs) are the most promising low-cost photovoltaic technology, whose power conversion efficiency has increased rapidly in a few years. In approaching the Shockley limit on a single-junction solar cell, one of the major challenges lies in interface properties of working devices. The energy alignment, charge transport and collection as well as electrical potential distribution are critical to device performances. We start with the electronic properties of perovskite layer to investigate the effect of dopant on heterojunction property, electron recombination as well as charge collection. Kelvin probe force microscopy, were employed to gain a mechanistic understanding of charge transportation in different structure of perovskite solar cells. We further use the C60/TiO2 bilayer to restrain the trap states at interfaces for achieving 83% of its initial performance after 312 h UV irradiation.

EN08.03.19
Interfacial Engineering of the Electron Transporting Layers by Self-Assembled Monolayers for High Performance and Long-Term Stable Perovskite Solar Cells Jinyoung Han1, Haejung Son2 and Dong Ha Kim1; 1Ewha Womans University, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of)

Developing perovskite solar cells (PSCs) with a high performance and a low-temperature process has great potential for the scalable, economic renewable photovoltaic devices. Among critical elements, ZnO has many advantages as electron transporting layer (ETL) in PSCs, due to promising features including a suitable energy structure and a high electron mobility, which can potentially reduce the recombination loss as ETL. Also, ZnO can be easily solution-processed at low temperature. Despite these advantages, several obstacles must be resolved to utilize ZnO for viable perovskite-based devices; one of them is the thermal instability of CH3NH3PbI3 photoactive layer deposited on ZnO ETL. The basic nature of the ZnO surface can induce the proton transfer reaction taking place between ZnO and CH3NH3PbI3 layer, which can reduce the device performance.

In this work, we demonstrated modification of the ETL by self-assembled monolayers (SAMs) to suppress the decomposition of perovskite for low-temperature processed and high performance PSC. The SAM layer was deposited on ZnO ETLs by dip coating for several hours to induce the condensation reaction between the hydroxyl group of ZnO ETL and the carboxylic acid group of the SAM layer. It was found that utilization of SAMs, especially 4-methoxybenzoic acid (MBA), 3, 4-dimethoxybenzoic acid (DMBA) and 3, 4, 5-trimethoxybenzoic acid (TMBA) on ZnO ETL prevents the direct contact between the perovskite and ETLs, avoiding the proton transfer reaction between perovskite and ZnO ETL. Also, strong dipole effect induced by a methoxy functional group of SAM interlayer can enhance the LOMO energy level and the work function of ZnO ETL, resulting in a reduction of electron transport barrier at the ZnO/CH3NH3PbI3 interface and enhancing the built-in voltage of the device. We verified the decrease in the energy gap between LOMO level of ZnO ETL and that of perovskite by photoluminescence quenching. PL intensity of ZnO/CH3NH3PbI3 was quenched after applying SAM interlayer, proving that charge transfer at ZnO/CH3NH3PbI3 interfaces was significantly facilitated via insertion of SAM interlayer. The effect was maximized when the ZnO was modified with TMBA which has the highest dipole moment among the SAM materials employed. Also, microscopic studies revealed that the perovskite active layer on TMBA modified ZnO ETLs showed optimized morphology. The power conversion efficiency (PCE) of the device was enhanced from 0.86 to 12.65% after optimizing a SAM interlayer, which was mainly ascribed for the highly increased short circuit current (JSC).
Investigation of CuSCN Hole Transport Layer for High Reliability Perovskite Solar Cells JungYup Yang1, NamHee Kwon1, MiJoung Kim1, JungSeock Oh1, MoonHoe Kim1, Daseul Hyun2 and Jinpyo Hong2; 1Kunsan National University, Korea (the Republic of); 2Hanyang University, Korea (the Republic of)

Recent advances in photovoltaic research have proved the great potential of copper(I) thiocyanate (CuSCN) as a hole transport layer (HTL) for organic inorganic hybrid perovskite solar cells. Here, we have investigated CuSCN as HTL instead of conventional 2,2',7,7'-tetrakis-(N,N-di-4-methoxyphenylamini)-9,9'-spirobifluorene (Spiro-OMeTAD) and systematically observed the relationships with methyl ammonium lead iodide (MAPbI3) perovskite absorber layer. The CuSCN was completely dissolved in diethyl sulfide solvent and then deposited by spin coating method on the MAPbI3 absorber layer. For the creation of compact CuSCN layer the post-annealing process was performed with various temperatures and times using hot plate. However, we observed the undesirable decomposition from MAPbI3 to PbI2 because post-annealing process performs feature long time annealing steps at elevated temperature. To solve this problem we were investigated by the increasing of methyl-ammonium iodide (MAI) ratio in MAPbI3 precursor solution. The device and material properties were analyzed by current-voltage curve, quantum efficiency, scanning electron microscopy, UV-visible spectroscopy, and x-ray diffraction for finding the optimum condition of MAPbI3 solar cells with CuSCN HTL. When excess MAI ratio is present in MAPbI3 precursor solution, it can be compensates for the loss of any MAI and suppresses or delays the formation of a PbI2 phase during annealing.

EN08.03.21
Long-Term Thermal and Operational Condition Stable Perovskite Solar Cells with Inorganic Charge Transport Layers Grown via Atomic Layer Deposition Seongrok Seo, Seonghwa Jeong, Changdeuck Bae and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

Despite the high power conversion efficiency (PCE) of perovskite solar cells (PSCs), poor long-term stability is one of the main obstacles preventing their commercialisation. Several approaches to enhance the stability of PSCs have been proposed. However the accelerating stability test of PSCs at high temperature under the operating conditions in ambient air remains still to be demonstrated. Herein, we show interface engineered stable PSCs with inorganic charge transport layers (p-NiO and n-Al:ZnO grown via atomic layer deposition). First of all, NiO has been chosen as hole transporting layers due to its a wide band gap (~3.6 eV) and p-type semiconducting properties. It also has good optical transparency and high chemical stability, and thus has the capability aligning the band edges to the perovskite (CH3NH3PbI3) layers with efficient energy transfer. Ultra-thin and un-doped NiO films with much less absorption loss were prepared by atomic layer deposition with highly precise control over thickness without any pinholes. Thin enough (5–7.5 nm in thickness) NiO films with the thickness of few time the Debye length (L_D = 1–2 nm for NiO) show enough conductivities achieved by overlapping space charge regions. Second, the highly conductive Al doped ZnO films have been chosen as an efficient electron transporting layers while acting as dense passivation layers. This layer prevents underneath perovskite from moisture contact, evaporation of component, and reaction with a metal electrode. Finally the inverted-type PSCs with inorganic charge transport layers exhibited a PCE of 18.45 % and retained 86.7 % of the initial efficiency for 500 hours under continuous 1-sun illumination at 85 °C in ambient air with electrical biases (at maximum power point tracking).

EN08.03.22
Manganese Doped Solution Processed Nickel Oxide Hole Transport Layer for Perovskite Solar Cell Merve D. Oflaz, Hava Z. Kaya, Wiria Soltanpoor, Cem Sahiner, Gorkem Gunbas and Seleuk Yerci; Middle East Technical University, Turkey

The electrical and optical properties of the transport layers play an important role in achieving efficient and hysteresis-free perovskite solar cells. Nickel oxide (NiOx) with its wide band gap and suitable valance energy band alignment with perovskite is a promising candidate for hole extraction. Although hysteresis-free and rather stable perovskite solar cells were developed by utilizing NiOx hole transport layer, its relatively small mobility and carrier concentration prevent achieving perovskite solar cells over 20% efficiency. On this respect, there are numerous studies in the literature on doping of NiOx with various elements (i.e. Cu, Y, Li, etc.) to increase its mobility and carrier concentration. In this study, the impact of manganese (Mn) incorporation into the NiOx thin film (Mn: NiOx) is investigated to enhance the charge extraction capability of NiOx without compromising its optical properties. Nickel(II) acetate tetrahydrate and different amounts of manganese(II)acetate tetrahydrate salts are used to prepare the Mn: NiOx precursor solutions and spin coated on TCO substrates. While transmission and reflection, and
spectroscopic ellipsometry measurements are performed to determine the optical properties of uniform Mn: NiOx films, ultraviolet spectrum is utilized to determine their work function and valance energy band position. Impedance spectroscopy is carried out to determine surface passivation property and measure the mobility of the layers. We demonstrate the Mn doping into NiOx thin films provides to enhanced efficiency in hysteresis-free perovskite solar cells.

EN08.03.23
Molecular Doping of CuSCN for Hole Transporting Layer in Inverted-Type Planar Perovskite Solar Cells
Insu Jin, SangHyun Park and Jaewoong Jung; KyungHee University, Korea (the Republic of)

Among many strategies to develop high-performance perovskite solar cells, the interface engineering is considered as a promising approach for achieving high power conversion efficiency. Specifically, high optical transparency and excellent electrical properties are essential in optimized hole transport materials in the inverted-type planar perovskite solar cells. In this study, we demonstrate the molecular doping of copper thiocyanate (CuSCN) by 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ) significantly enhances the photovoltaic performance of perovskite solar cells. The incorporation of F4TCNQ in CuSCN leads to successful electron transfer from CuSCN to F4TCNQ, which affords more balanced energy level alignment at the interface of perovskite layer for hole conduction. The device analyses reveal faster charge transport and less carrier recombination in the F4TCNQ-doped CuSCN-based devices, contributing to not only the improved efficiency but also the hysteresis elimination. At the optimized doping concentration, the doped CuSCN exhibited ~35% increased efficiency as high as 14.19% in the inverted-type planar perovskite solar cells.

EN08.03.24
Normal and Planar Type Perovskite Solar Cells Based on Inorganic Electron Transporting Layers (ETLs) of SnO2 via Atomic Layer Deposition (ALD)
Seonghwa Jeong, Seongrok Seo, Hyoungmin Park and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

SnO2 has received a great deal of attention in normal and planar type perovskite solar cells with its excellent optical and electrical properties; i.e., wide bandgap, good chemical stability and can be grown by low temperature processing as an electron transporting layer (ETL). Among various deposition methods, SnO2 thin films used as ETL are deposited by Atomic Layer Deposition (ALD). ALD shows numerous advantages of being able to control film thicknesses with nanometer precision and to produce high quality thin films without any pinholes. SnO2 has a deeper conduction band, compared to TiO2 deposited by ALD which has energy level mismatch with MAPbI3, thus energetic alignment of SnO2 is more appropriate for extracting photogenerated electrons than TiO2, resulting in high power conversion efficiency (PCE ; ~ 18.3 % with pure MAPbI3 based PSCs). In addition, processing temperature of ALD-SnO2 thin films (at ~ 180 °C and/or even R.T.) is much lower than that of ALD-TiO2 thin films (~ 400 °C). Furthermore, thin films of Zn doped SnO2 also prepared in this study and showed enhanced conductivity compared to undoped ones, as a result, photovoltaic performances are improved in the normal planar structure (FTO / Zn:SnO2 / Perovskite / Spiro-OMeTAD / Ag) of the perovskite solar cells.

EN08.03.25
Organic Monomolecular Layers Enable Energy-Level Matching for Efficient Hole Transporting Layer Free Inverted Perovskite Solar Cells
Guojun Mi, Weiguang Kong, Xiao Duan and Chun Cheng; Southern University of Science and Technology, China

For perovskite solar cells (PSCs) without hole transport layer (HTL), the hole transport energy barrier (ΔEh) is defined as the energy difference between the Fermi level (EF) of the electrode and the valence band maximum (VBM) of the perovskite. Highly efficient HTL-free PSCs require that ΔEh should be reduced or eliminated to improve hole collection. In order to minimize ΔEh, one strategy is to adjust the VBM of the perovskite closer to the EF of the electrode. However, it is rather challenging because the electronic structure of the perovskite depends, to a large extent, on the specifics properties of the system, as well as the preparation and environmental conditions. Another strategy to minimize ΔEh is to shift the EF of ITO closer to the VBM of the perovskite. In this way, organic monolayer (ML) materials which have been widely used in organic electronics can adjust the electrode EF. However,
to date organic ML is rarely used to prepare efficient HTL-free PSCs. Besides, the energy level arrangement between electrode and HTL still needs optimization, and the feasibility of using organic ML to construct highly efficient PSC without HTL remains to be explored. We report the monomolecular layer strategy toward barrier-free contact of the energy level arrangement at the electrode/perovskite interface, facilitating efficient charge transfer and inhibiting non-radiative carrier recombination. The HTL-free PSCs based on ML-modified ITO produced an efficiency of 19.4%, much higher than the HTL-free PSCs (10.26%) on the original ITO, and it is even comparable to the PSCs with HTL. This study provides an in-depth understanding of the interface level layout mechanism and is helpful in designing advanced interface materials for simplified and efficient PSCs.

EN08.03.26
Perovskite Solar Cells with a Hybrid Electrode Structure Askhat Jumabekov¹, Yinghong Hu² and Gede Adhyaksa³; ¹Nazarbayev University, Kazakhstan; ²Ludwig-Maximilians-Universität München, Germany; ³FOM Institute AMOLF, Netherlands

Many factors govern the performance of back-contact perovskite solar cell (BC-PSC) devices, with the design and dimensions of the electrodes being among the key factors influencing the charge carrier collection properties, and thereby the final device performance.

The back-contact architecture for a PSC is realized by arranging both the anode and cathode on a substrate surface, with the perovskite photovoltaic layer then deposited on top. This affords a device with the perovskite photovoltaic layer in contact with both electrodes on one side (substrate side), while directly exposing the perovskite surface to illumination on the other side (front side).¹ Unlike in conventional sandwich-type architectures for PSCs, this approach reduces transmission losses and exposes the active layer for surface passivation or the application of an antireflective coating.² This new concept has recently been highlighted as a route to further increasing the efficiency of PSC devices.³

To realize the full potential of back-contact architectures for high-efficiency PSC, a deeper understanding of the underlying device physics is required. While standard models developed for sandwich-type PSC with p-i-n or n-i-p device configurations adequately describe the physical processes in the device, they cannot be as readily applied to BC-PSCs due to the nature of their architecture. This makes it challenging to contrast the performance and behavior of BC-PSCs with standard sandwich-type PSCs.

Here we present an example of a PSC device with a hybrid electrode structure, in which a single device can operate with either a vertical (sandwich-type) or lateral (back-contact) configuration of contacts. The hybrid structure was achieved by depositing an additional anode on top of a prefabricated back-contact PSC device with transparent back-contact electrodes. Comparative analysis between the sandwich and back-contact operation modes have been performed. The device performance analysis reveals that the efficiencies of PSC devices in back-contact mode is inferior when compared to sandwich mode operation. Coupled opto-electronic simulations determined that due to the intrinsically narrow depletion region near the contact interfaces, the charge collection efficiency in the back-contact device structure appears to be significantly lower compared to the sandwich device structure. These findings provides an insight into the cause of the performance disparity between these two architectures.

Practical, Thermal Atomic Layer Deposition of p-type NiO Thin Films as Hole Transporting Layers for Organic-Inorganic Hybrid Perovskite Solar Cells Hyoungmin Park, Seongrok Seo, Seonghwa Jeong, Changdeuck Bae and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

Efficiency of the halide perovskite solar cells (HPSCs) has recently reached over 24% by solution-based compositional engineering as well as surface passivation technique. Low stability of halide perovskite materials still
remains many challenging problems. Inverted configuration of HPSCs with a hole transporting layer (HTL) of inorganic materials have shown great promise to improve the resulting stability. In this study, ultra-thin films of NiO as HTLs were deposited by thermal atomic layer deposition (ALD) with H2O2 and O3 as an oxygen source. We were able to identify the difference between Ni and O compositions in the deposited thin films either by H2O2 or O3 as oxygen sources. Band diagrams of HPSCs with ultra-thin NiO layers were revisited on the basis of the optical property, and the analysis of valence band maximum and work function using ultraviolet photoelectron spectroscopy. The present study shows that a couple of nanometers-thick and pin-hole-free NiO films could be successfully prepared by ALD and served as HTLs by modifying interfacial characteristics to halide perovskite layers and by demonstrating improved stability of HPSCs.

EN08.03.28
Preparation of High Efficiency Flexible Solar Cells by Inserting KCl Modified Layer at the Interface between SnO2 and Perovskite Ye Xiaofang, Hongkun Cai and Jianjun Zhang; Nankai University, China

In recent years, flexible perovskite solar cells have received extensive attention and rapid development due to their advantages of light weight, portability, wearability, and applications in near-space. However, due to the limitations of its preparation process and other factors, high-efficiency and large-area flexible perovskite solar cells still have a lot of room for development. In our work, a flexible perovskite solar cell was prepared using a low temperature (not more than 100 °C) solution method (PEN/ITO/SnO2/KCl/Cs0.05(MA0.17FA0.83)0.95Pb(I0.83Br0.17)0.05), and the device with the highest efficiency of 17.20% was obtained by adjusting the concentration and rotation conditions of the KCl modified layer. Meanwhile, the efficiency of the large-area (1 cm2) flexible solar cell was more than 13%. At the same time, the passivation of the KCl interface modification layer inhibits the formation of the defect state, which reduces the surface composite of the perovskite and improves the carrier transport performance, and the hysteresis effect of the device is also reduced accordingly.

EN08.03.30
The Effect of Underlying Layer on Sequential Deposition of Methylammonium Lead Halide Shu-Chen Kao, Yu-Sheng Chen and Chih-Liang Wang; National Chung Hsing University, Taiwan

Perovskite solar cell (PSC) has been considered one of the most promising candidates for the next generation renewable energy device due to its power conversion efficiency over 22% in a short time. Many fabrication methods for the perovskites have been reported, such as one-step deposition, sequential deposition, vapor assisted deposition. The sequential deposition involving the conversion of perovskite from lead halide is particularly attractive because of its controllability of perovskite property via crystallization kinetics. Though previous studies have correlated the microstructure of lead halide, solution concentration, and loading time with the resulting perovskite film, the effect of underlying layer on the sequential deposition seemingly remains few.

In this regard, a series of TiO2 nanorods with the length from 200 nm to 800 nm on FTO are grown by the hydrothermal process, followed by the sequential deposition of CH3NH3PbI3. In order to investigate the effect of underlying layer, the SEM and XRD are carried out to analyze the properties of the sequential deposited CH3NH3PbI3, such as the morphology, crystallization and conversion level, on a series of TiO2 nanorods. The UV-Vis and EIS are performed to detect the optical property and charge transport, respectively, of perovskite films deposited on different length of TiO2 nanorod. J-V characteristics of the perovskite solar cells using different TiO2 nanorods are tested under AM 1.5G illumination. Our results show that the different length of TiO2 nanorod can potentially affect the level of PbI2 residue and the perovskite morphology after the sequential deposition. An optimized length of TiO2 nanorod is simultaneously beneficial for obtaining a high quality perovskite film along with the improved charge collection. More details of the performance of perovskite solar cells, influence by the underlying TiO2 nanorods, will be discussed in the presentation.

EN08.03.31
The Use of Optimized Ternary Metal Oxide and Binary Oxide as Effective Bilayer Electron Transport Layer for Highly Efficient and Stable Planar Perovskite Solar Cells Thambidurai Mariyappan, Foo Shini, P. C. Harikesh, Nripan Mathews and Cuong Dang; Nanyang Technological University, Singapore

An ideal planar electron transport layer (ETL) should possess little surface defects, high electron mobility, and well-aligned energy level with the absorbing layer. Ternary oxides exhibit promising potentials as effective electrontransportmaterialas the optical and electrical properties are easily manipulated using simple compositional
adjustments. In this paper, we examine various solution-processed ternary zinc-tin oxide (ZTO) compositions as plausible compact ETL candidates in planar perovskite cell application. Through the use of the ZTO ETLs, chemical instability previously observed in pristine ZnO ETL based device was greatly reduced with improved device stability and power conversion efficiency (PCE) of 16.41% attained in the Z1T1O ETL based device. We further explored the use of SnO2 interlayer between the ZTO/perovskite interface to form a bilayer ETL structure. Apart from prohibiting the unfavourable contact between the ZnO film with the perovskite layer, the bilayer ETL structure showed further enhancement in reproducibility, charge transfer, recombination resistance, device stability, and efficiency. Paramount PCE of 19.01%, with an average PCE of 18.18%, was demonstrated in the ZTO/SnO2 ETL based device. In addition, exceptional stability was obtained in which 90% of its initial PCE was maintained after 90 days without encapsulation. The superior performance and device stability are attributed to the improved charge extraction, favourable energy alignment, and suppressed charge recombination derived from the compatible ZTO/SnO2 bilayer. Hence, our work demonstrates the viability of ternary metal oxides as effective ETL candidates for perovskite solar cell application whereby stability and performance were further enhanced with the addition of a compatible SnO2 interlayer.

EN08.03.32
Towards Efficient and Stable Perovskite Solar Cells Employing Non-Hygroscopic F4-TCNQ doped TFB as Hole-Transporting Material

Hannah Kwon1, Dong Ha Kim1, Ju Won Lim2, Jinyoung Han1, Dawoon Kim3, Li Na Quan4, Eunah Kim1, Eun-Sol Shin5, Yong-Young Noh5, In Chung3 and Dong-Wook Kim1; 1Ewha Womans University, Korea (the Republic of); 2University of Michigan–Ann Arbor, United States; 3Seoul National University, Korea (the Republic of); 4University of California, Berkeley, United States; 5Pohang University of Science and Technology, Korea (the Republic of)

Organic-inorganic halide perovskites have found increasing potential in a wide range of optoelectronic applications due to their excellent optoelectrical properties e.g., low energy bandgaps ($E_g \sim 1.6$ eV), low exciton binding energy ($<10$ meV), long diffusion length (up to 1 μm), and high absorption coefficients ($1.5 \times 10^4$ cm$^{-1}$ at $\lambda = 550$ nm). In this context, perovskites solar cells (PSCs) have reached a rapid development of best power conversion efficiency (PCE) with a certified 23.7% efficiency up to date. In this work, we have focused our attention on the design of efficient and stable hole transporting layer (HTL) materials in organic-inorganic PSCs, towards a facile hole extraction and enhanced photocurrent generation. To date, cost ineffectiveness, insufficient hole mobility ($\sim 10^{-4}$ cm$^2$ V$^{-1}$ s$^{-1}$), and low electrical conductivity ($\sim 10^{-5}$ S cm$^{-2}$) have hindered the commercialization of the reference 2,2',7,7'-Tetrakis-(N,N'-di-4-methoxyphenylamo)-9,9'-spirobi fluorore (Spiro-OMeTAD) HTL material. Similarly, conventional additives and dopants e.g., lithium bis (trifluoromethylsulfonyl)-imide (LiTFSI) and 4-tert-butylpyridine (TBP), have been shown to enhance moisture absorption, leading to inherently low stability and reproducibility, and to disturb the equilibrium between the CH$_3$NH$_3$PbI$_3$ and its degraded components, respectively. In this work, we have developed for the first time a novel and efficient HTL material by optimized doping of a conjugated polymer, poly[(9,9-diocetylfluorenyl-2,7-diyl)-co-(4,4’-(N-(4-sec-butylphenyl)diphenylamine)] (TFB), with a non-hygroscopic p-type dopant, 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ). The F4-TCNQ-doped TFB PSC exhibited a PCE of 17.46%, which surpassed that of 16.64% and 11.01% for the reference LiTFSI+TBP-doped Spiro-OMeTAD and LiTFSI+TBP-doped TFB-based devices, respectively. The appropriate band alignment of the introduced F4-TCNQ-doped TFB HTL material with the highest occupied molecular orbital (HOMO) of the perovskite was proposed as primary factor to facilitate efficient charge extraction from the perovskite to the electrode as well as increased short-circuit current. Conducted steady-state photoluminescence (PL) and time-resolved photoluminescence (TRPL) analyses have herein further corroborated a reduced charge recombination. Most importantly, the hydrophobic nature of F4-TCNQ-doped TFB was shown to dramatically improve the long-term stability of the device under an ambient condition with RH of 45%. In detail, the device herein reported maintained ca. 80% of its initial efficiency after 10 days, significantly superior to both LiTFSI+TBP-doped Spiro-OMeTAD (ca. 30%) and LiTFSI+TBP-doped TFB (ca. 10%) counterparts. This simple, yet novel strategy is believed to reflect a promising route for a wide range of highly efficient solar cells and other photovoltaic applications.

EN08.03.33
Fluorinated Dication Templated 1D Spikes for Stable and High-Performance Perovskite Solar Cells

Jue Gong1, Zhenghong Dai1, Mingyu Hu1,2, Yuanyuan Zhou1 and Nitin P. Padture2; 1Brown University, United States; 2Kunming University of Science and Technology, China
Further improvement of environmental stability of perovskite solar cells at operation conditions is still a critical issue for matured and practical commercializations in the future. In this study, we utilize fluorinated organic cation, as in the form of 2,6-difluoro-4-ammonium pyridinium (2F4AP2+), to realize solar cell applications with power conversion efficiencies exceeding 13% and stable across 500 hours in high moisture contents (>60%) under constant illumination. Most interestingly, when 2F4AP2+ composition is highest with respect to PbI2 precursor, (2F4AP)PbI4 compound has a 1D spike-like crystal structure. Such low-dimension structure, as due to strong quantum confinement effects and special electron-phonon interaction, additionally enables broad yellow emission upon UV excitation at room temperature. Our studies demonstrate the rich chemistry and versatile optoelectronic functions of fluorinated organic-inorganic hybrid perovskite materials, and with careful tuning of the 2F4AP compositions, continuous increase in photovoltaic performance of solar cell devices with long-term stability are promisingly achievable.

Defect Engineering as a Tool to Enhance Stability in Perovskite Thin Films and Solar Cells

Katelyn P. Goetz1, Fabian Thome1, Paul Fassl2, Lukas M. Falk1, Vincent Lami1, David Becker-Koch1, An Qingzhi1, Alexander Taylor1, Fabian Paulus1 and Yana Vaynzof1; 1Universität Heidelberg, Germany; 2Karlsruhe Institute of Technology, Germany

Environmental stability remains one of the most significant challenges impeding the commercialization of perovskite solar cells. The presence of defects has been linked to the stability of perovskite devices, for example, the photoinduced formation of superoxide upon oxygen exposure in the presence of iodine vacancy defects has been shown to play a key role in the degradation of methylammonium lead iodide (MAPbI3) perovskite thin films [1]; however, the details of this process remain unclear. Recently, our group has demonstrated that the type and density of defects on the surface of MAPbI3 perovskites can be tuned by incrementally adjusting the stoichiometry of the precursor solution [2]. Herein, we exploit this method to elucidate the interaction between specific defects in MAPbI3 and the environment, and further expand it to understand these effects in bromide-based perovskites (MAPbBr3).

Our methodology is based on a multi-technique approach. X-ray photoelectron spectroscopy is used to identify the density and type of surface defect in each type of perovskite film. To then isolate the interaction of the defect with the environment, films are exposed to environments of nitrogen mixed with varying (but controlled) oxygen and water content and completed with extraction layers and an electrode. In parallel, the changes in optoelectronic properties are monitored with photothermal deflection spectroscopy and photoluminescence spectroscopy, allowing us to correlate the changes in defect type and density with changes in photovoltaic performance. Finally, the PV performance and optoelectronic properties are monitored over time to assess the shelf-storage stability as a function of defect density and type.

We find that the photovoltaic performance of the MAPbI3 samples deficient in iodine shows a tremendous drop in the short-circuit current ($J_{sc}$) upon exposure to oxygen and light, while samples with excess iodine show performance that is similar to pristine films. While the latter show low photoluminescence quantum efficiency (PLQE) and high Urbach energies, suggesting the presence of deep trap states, these states do not interact with oxygen under illumination. In contrast, the PLQE of iodine-deficient samples initially increases upon exposure to oxygen, indicative of trap healing; but this process is short lived, with significant degradation taking place after 2h, in agreement with the decline in PV performance of these samples. The bromide-based perovskite solar cells show little dependence of the initial photovoltaic performance on the trap density, but upon exposure to air and light, bromide-deficient solar cells undergo a large $J_{sc}$ boost, resulting in a near tripling of their initial PCE. These results highlight the strong role that chemical composition plays in the stability of perovskite PVs and suggest that defect engineering is a potential strategy for enhanced stability, especially in the single-cation perovskite compositions.

Recently, solar cells using an organic-inorganic hybrid perovskite (OIH) as a light absorber have attracted tremendous attention considering the unique advantages such as high absorption coefficient, favorable bandgap, fast charge transport, high dielectric constant, long carrier lifetime, and high doping tolerance etc. In just a few years, the power conversion efficiency (PCE) of perovskite solar cell (PSC) has experienced a skyrocketing increase, which has been enhanced from 3.8% in 2009 to 24.2% according to the latest report. However, the long term stability of the PSC is still a big issue. It is well known that most of the PSCs, the perovskite films are prepared by solution process. However, besides the low-cost fabrication, solution process would also introduce lots of defects at the surface and grain boundaries. In the perovskite, the defects would not only influence the performance but also have a detrimental impact on the stability of perovskite solar cell.

In this work, we try to introduce a new thieno[3,4-b] thiophene-based small molecular donor, named as 4FK, into perovskite solar cell. The 4FK could not only help separate and then further extract the carriers, but also passivate the surface defects through the formation of the Lewis adduct with the Pb\(^{2+}\) of the perovskite. Consequently, with the cooperation of passivation effect, better band alignment, and carrier extraction effect, a champion device with PCE of 19.9% for MA-based perovskite solar cell has been achieved. Our results provide a reliable way to enhance the performance and also the long term stability of perovskite solar cells.

EN08.03.36
Grain Boundary Passivation for Efficient and Stable Halide Perovskite with Suppressed Iodide Migration via Direct Backbone Attachment of Polyester Yuchen Zhou\(^1\), Yifan Yin\(^1\), Likun Wang\(^1\), Xianghao Zuo\(^1\), Chang-Yong Nam\(^2\) and Miriam Rafailovich\(^1\); \(^1\)Stony Brook University, United States; \(^2\)Brookhaven National Laboratory, United States

Organic-inorganic halide perovskites (OIHP) remains as one of the hottest research topics in the past several years due to their exceptional optoelectronic properties in broad fields relating light emitting, photovoltaic, photo-detecting, gas sensing and even photosynthesis, etc. However, the exist of grain boundaries in OIHP thin films made using current preparation method creates large number of defects/traps, resulting in possible low photo conversion efficiency (PCE) of its corresponding devices. The presence of grain boundaries can also become a “starting point” for structural degradation to take place, which makes the film highly degradable when exposing to excessive environmental stress, such as moisture, heat and light.

In this study, we effectively passivated the grain boundaries in methylammonium lead iodide (MAPI) perovskite thin films using one type of the polyester called polycaprolactone (PCL). We observed the successful attachment of PCL on MAPI grains using FTIR, AFM and (HR)TEM. The blueshifts of C=O group were found both in PCL incorporated MAPI layer and the PCL mixed PbI\(_2\) sample, which indicated the formation of coordination between electron donating O-C=O group on PCL and electron acceptor Pb\(^{2+}\) complex in MAPI via Lewis acid and base adduct. We also visualized the presence of PCL polymer on grain boundaries of MAPI by using friction mode AFM and (HR)TEM. The brighter boundaries and darker grains on friction AFM for MAPI with PCL indicated stronger interaction of AFM tip on the boundaries and implied the gathering of softer polymeric materials between the grains, while the pure MAPI barely showed the contrast difference using same AFM operation mode. The HRTEM images on both surface and the focused ion beam (FIB) prepared cross-sectional samples further proved the passivation of PCL at the boundaries with highly crystalline MAPI grain areas being separated by amorphous PCL polymer channels. The passivation has also been confirmed by showing increased photoluminescence (PL) emission intensity and decay lifetime due to reduce of boundary- borne defects/traps, which can act as centers for the non-radioactive recombination. Such optoelectronic improvement by PCL directly promoted the photovoltaic performance of the corresponding device, showing an increased open circuit voltage with the highest PCE exceeding 19%. More importantly, the direct boundary passivation by PCL greatly enhanced the stability of MAPI thin films against three major environmental stresses (moisture, heat and light). All samples with PCL incorporation largely maintained pure MAPI crystal structure with much suppressed growth of PbI\(_2\), while the reference MAPI films became degraded with obvious PbI\(_2\) appearing after the exposure. Moreover, we used the SIMS to reveal the suppression effect of ion migration (especially for iodide ion) due to the increase of the activation energy of MAPI film with PCL passivation. After heating the corresponding devices, the PCL passivated one presented only little, if any, migration of iodide towards the HTM and electrode layer, while significant migration with much stronger iodide ion signal has been detected at the HTM layer for the reference MAPI device.

We believe that the unique chain structure of PCL with the functional ester groups (O-C=O) on backbone offered the outstanding passivation by forming direct backbone attachment of PCL on the grain boundaries of MAPI. The
repeating backbone segments composed of six methylene between two attaching ester groups can serve as a strong hydrophobic moisture repellent layer and can also help maintain high structural purity of MAPI when exposing to heat and light, as well as hinder the mobile of iodide ion by increasing the activation energy of MAPI after the direct polymer chain attachment. (This work was supported by the Morin Foundation Trust and the NSF, Inspire program #1344267)

Passivated Tin Oxide Based on Acetylacetonate Complexes for High Performing Planar Perovskite Solar Cells Mousa Abuhelaiqa, Pak Sanghyun, Yonghui Lee and Mohammad K. Nazeeruddin; École Polytechnique Fédérale de Lausanne, Switzerland

Perovskite-based solar cells have overseen tremendous development reaching power conversion efficiencies exceeding 24% in the laboratory scale. Part of the development was made possible by utilizing passivated SnO\textsubscript{2} as an electron transporting layer. Chlorinated and colloidal precursors such as SnCl\textsubscript{4} and SnO\textsubscript{2} nanoparticles are usually used to fabricate efficient SnO\textsubscript{2} films. In this work, we explore the effect of halogen additives on the passivation properties yielded on SnO\textsubscript{2} films. This was done by employing three novel acetylacetonate-based precursors of which one is halide-free and two are halogenated with Cl and Br respectively. These precursors form stable, non-colloidal solutions that yield a unique SnO\textsubscript{2} film morphology as we show with TEM. Additionally, we demonstrate that the halide additives electrically passivate the SnO\textsubscript{2} film and alter the optimum annealing temperature of SnO\textsubscript{2} film formation. Our optimized SnO\textsubscript{2} films achieved high-performing planar perovskite solar cell devices with a power conversion efficiency of 22.19% (21.4% certified by Newport) with 0.16 cm\textsuperscript{2} active area, and 16.7% for mini-modules with 15 cm\textsuperscript{2} active area.

EN08.03.38
Quantum Dots Supply Bulk- and Surface-Passivation Agents for Efficient and Stable Perovskite Solar Cells Xiaopeng Zheng\textsuperscript{1}, Joel Troughton\textsuperscript{1}, Nicola Gasparini\textsuperscript{1}, Yuanbao Lin\textsuperscript{1}, Mingyang Wei\textsuperscript{2}, Yi Hou\textsuperscript{2} and Osman M. Bakr\textsuperscript{1}; \textsuperscript{1}King Abdullah University of Science and Technology, Saudi Arabia; \textsuperscript{2}University of Toronto, Canada

Defect passivation and surface modification of hybrid perovskite films are essential to achieving high power conversion efficiency (PCE) and stable perovskite photovoltaics. Here, we demonstrate a facile strategy that combines high PCE with high stability in CH\textsubscript{3}NH\textsubscript{3}PbI\textsubscript{3} (MAPbI\textsubscript{3}) solar cells. The strategy utilizes inorganic perovskite quantum dots (QDs) to distribute elemental dopants uniformly across the MAPbI\textsubscript{3} film and attach ligands to the film’s surface. Compared with pristine MAPbI\textsubscript{3} films, MAPbI\textsubscript{3} films processed with QDs show a reduction in tail states, smaller trap-state density, and an increase in carrier recombination lifetime. This strategy results in reduced voltage losses and an improvement in PCE from 18.3\% to 21.5\%, which is among the highest efficiencies for MAPbI\textsubscript{3} devices. Ligands introduced with the aid of the QDs render the perovskite film’s surface hydrophobic—inhbiting moisture penetration. The devices maintain 80\% of their initial PCE under 1-sun continuous illumination for 500 h and show improved thermal stability.

EN08.03.39
Surface and Interface Passivation of Perovskite PV Materials Hela Liber Sasson\textsuperscript{1,2} and Iris Visoly-Fisher\textsuperscript{1,2}; \textsuperscript{1}Ben Gurion University of the Negev, Israel; \textsuperscript{2}Ben-Gurion University of the Negev, Israel

Organometallic halide perovskites attract much attention in the field of optoelectronics and in photovoltaic research thanks to its high performance. However, perovskite photovoltaics have yet a major obstacle to overcome - stability. The perovskite surface plays an important role in the cells’ stability and efficiency. Surface states were previously found to induce recombination and accelerated degradation. Passivation of the surface and interfaces of the perovskite film and neutralizing surface states can be achieved by various techniques. In this research we focus on the effect of passivation using conjugated small molecules on the perovskite photo-stability. The perovskite surface is modified using porphyrin molecules resulting in the formation of new hybrid films. The molecules are added into the precursor solution and are aimed to be located at the perovskite grain boundaries. The additive porphyrins differ by their functional group while each group is designated to passivate specific surface dangling bonds towards increasing the photo-stability. We find that different functional groups differently affect the perovskite crystallization, hence the resulting solar cell efficiency and stability.

EN08.03.40
To Greatly Reduce Defects via Photoannealing for High-Quality Perovskite Films  

Duo Wang, Cuncun Wu, Wei Luo, Xuan Guo, Xin Qi, Yuqing Zhang, Zehao Zhang, Ning Zhu, Bo Qu, Lixin Xiao and Zhijian Chen; Peking University, China

The performance of perovskite solar cells (PSCs) depends on the crystallization of the perovskite layer. Herein, we demonstrate an effective photoannealing (PA) process by a halogen lamp. During the PA process, on the one hand, the lower energy photon, that is, near IR up to $\sim 1015$ nm photon, drives the crystallization of the perovskite film, similar to the conventional thermal annealing (TA). On the other hand, the higher energy photon of PA can excite the trapped carriers and release the space charges, thus leading to an ideal perovskite layer with better crystallinity and lower density of defect when compared to that of TA. A maximum power conversion efficiency (PCE) has been obtained to be 20.41% in the CH$_3$NH$_3$PbI$_3$-based planar PSCs based on PA because of the increase of J$_{sc}$ and V$_{oc}$, much higher than the control device based on the conventional TA with a maximum PCE of 18.08%. Therefore, this result demonstrates that PA is an effective method to promote the device performances and reduce the fabrication cost, which provides a potential approach for the commercial application of perovskite devices.

EN08.03.41

Trap State Passivation in Perovskite Solar Cells Using a Bifunctional Organic Molecule as a Lewis Acid-Base Adduct  

Sandeep B. Satyanarayana and Praveen C. Ramamurthy; Indian Inst of Science, India

Organic-inorganic hybrid lead halide perovskites have become the most sought-after materials for various optoelectronic applications. Their low-temperature (<150°C) and solution processability enable them to function on flexible platforms. The power conversion efficiencies of perovskite solar cells have reached 22%. Interdisciplinary efforts are going into realizing perovskite-silicon tandem cells for the better utilization of the solar bandwidth. The major drawback of these devices is their inferior stability. The high diffusivity of iodide ions in the perovskite lead to chemical reactions with atmospheric oxygen and moisture. This in turn disintegrates the perovskite structure and hence, photon absorptivity is lost. Encapsulation of these devices does improve the stability but is nowhere near standards needed for commercialization.

The shallow and deep trap states play a major role in determining the performance and stability of perovskite solar cells. These states are created by ionic defects at the at the grain boundaries and surface respectively. The use of Lewis acids and bases have been demonstrated to pacify these defects. The Lewis base interacts with the cation and the acid with the anion. The interaction of a Lewis acid or base at a grain boundaries results in defect states. These states hinder inter-grain transport and act as parasitic resistances.

In this work, we propose to design a bifunctional organic molecule with HOMO and LUMO matching the band edges of the perovskite absorber. The bifunctionality (Lewis acid and base) enables passivation of both cations and anions simultaneously. The trap state passivation inhibits ion migration in the crystal and hence improves the stability of the device. It also helps in impeding trap assisted recombination to in turn enhance device performance. The band edge matching on the HOMO and LUMO levels empowers inter-grain transport of charge carriers. This will result in larger charge carrier diffusion lengths and lower bimolecular recombination. The overall performance and stability of the device is augmented. The use of organic molecule for passivation also increases the hydrophobicity of the perovskite layer. This results in better moisture resistance for the perovskite.

The stability of the passivated perovskite is monitored through JV measurements, X-ray diffraction and absorption measurements. The interaction of the passivation molecule with perovskite is estimated using FTIR spectroscopy and is mapped using an X-ray synchrotron source. The effect of passivation is estimated by calculating the trap density of states and also observing the long-term aging behavior.

EN08.03.42

Corrosive Processing on Top of Perovskite Solar Cells Enabled by SnO$_{2}$ as Internal Barrier Layer  

Kai O. Brinkmann$^1$, Tobias Gahlmann$^1$, Junjie He$^{1,2}$, Christian Tückmantel$^1$, Tim Becker$^1$, Manuel Theisen$^1$, Johannes Bahr$^1$, Cedric Kreusel$^1$, Jun Song$^2$, Junle Qu$^2$ and Thomas Riedl$^1$; $^1$Bergische Universitat Wuppertal, Germany; $^2$Shenzhen University, China

With power conversion efficiencies (PCE) of more than 24%, halide perovskites (HAPs) now even rival silicon as photoactive semiconductor in solar cells.$^{[1]}$ At the same time, serious concerns about material stability are still inevitably linked with HAPs, e.g. when in contact with water etc.$^{[2,3]}$ The sensitivity of HAPs not only states a challenge with respect to long term stability, but likewise limits the choice of processes for the deposition of subsequent functional materials, such as charge transport layers and electrodes.
Processes involving polar solvents such as water or ethyl acetate are typically excluded as candidates for follow-up processing, as they have been shown to severely damage the HAP. Unfortunately, a wide variety of solvents that would be desirable for “green” upscaling classify as corrosive for HAPs.

In this work we will show that the use of an ultrathin, impermeable, yet conductive AZO/SnOx hybrid layer that serves as electron transport material is able to mitigate most of the above issues. This is possible due to the unique nature of the ALD grown SnOx, which is transparent, conductive and, most importantly, physically dense and impermeable to a wide variety of corrosive solvents.[4] Based on the AZO/SnOx hybrid we were able to realize perovskite solar cells with semitransparent top electrode based on silver nanowires (Ag NWs), that were spray coated from an aqueous dispersion. The resulting semi-transparent cells showed a PCE exceeding 15%. In a similar sense a carbon electrode could be doctor bladed from a paste based on ethyl acetate. This afforded the first p-i-n (inverted) perovskite solar cells with carbon top-electrode. Most importantly, if both processes were used without the AZO/SnOx protection layer, the solar cells turn out to be non-functional.

The now functional devices comprising the Ag-NW top electrode reveal a further important issue related to the interface of Ag-NW and SnOx, which shows rectifying behavior, due to a parasitic Schottky barrier between Ag-NW and SnOx. We have conducted an in-depth study using Kelvin probe analysis, photoemission spectroscopy and specific unipolar test devices. We demonstrate that the issues associate with the interfacial barrier can either be eliminated by UV-light soaking or by the introduction of a dedicated interlayer with a high carrier density n > 10^{18} cm^{-2} between Ag-NW and SnOx. Taken together, we will present the first perovskite solar cells with a water processed Ag NWs top electrode and as well as the first proof of concept p-i-n (inverted) perovskite solar cell with a carbon top electrode.

SESSION EN08.04: Perovskite Solar Cell—Processing, Additives, Material Development
Session Chairs: Henk Bolink, Shengzhong (Frank) Liu, Selina Olothof and Yabing Qi

Up-Scalable Fabrication of Metal Halide Perovskite Solar Cells and Modules Luis K. Ono, Longbin Qiu, Sisi He, Zonghao Liu, Zhifang Wu and Yabing Qi; Okinawa Institute of Science and Technology, Japan

After a decade of metal halide perovskite solar cell research and owing to the intensive research efforts across the world, there is no doubt that power conversion efficiencies (PCEs) comparable to several other photovoltaic technologies (e.g., multicrystalline Si, CIGS, CdTe) are achievable [1]. However, when moving perovskite solar cell technology from laboratory to industrial products, high-PCE, low-cost, and up-scaling are key metrics [2]. At OIST, a team of researchers in the Energy Materials and Surface Sciences Unit is making concerted efforts to develop processes (i) aiming at high PCE, (ii) high-throughput, (iii) minimum batch-to-batch variation, and (iv) compatible with large-area perovskite solar cells and modules. In this talk, we will present our recent progress on the use of chemical vapor deposition CVD [2-4] to fabricate perovskite solar cells and modules.

9:00 AM *EN08.04.02
**Vapor Phase Deposited Perovskites** Henk J. Bolink, Ana Maria Igual-Muñoz, Jorge Ávila, Daniel Pérez-del-Rey, Kassio P. Zanoni, Maria Grazia I. La-Placa, Azin Babaei, Chris L. Dressen, Yousra El Ajjouri, Francisco Palazón, Sang H. Chin, Michele Sessolo and Pablo Boix; University of Valencia, Spain

We will report on the progress on vapor phase deposited perovskites, including low bandgap Pb-Sn and wider bandgap multiple cation versions. The performance of these materials in both single and double junction solar cells will be reported. The influence of the use of thin organic charge extraction layers, using strong dopants, ionic compounds and conjugated polymers will be described.

9:30 AM EN08.04.03
**The Next Big Thing—Single-Crystal Perovskite Solar Cells With 21% Power Conversion Efficiency** Bekir Turedi1, Zhaolai Chen1, Abdullah Alsalloum1, Chen Yang1, Xiaopeng Zheng1, Issam Gereige2, Ahmed Alsaggaf2, Omar A. Mohammed1 and Osman M. Bakr1; 1King Abdullah University of Science and Technology, Saudi Arabia; 2Saudi Aramco, Saudi Arabia

Developments in perovskite photovoltaics dominantly rely on thin films of polycrystalline morphology. The record efficiency for PSCs which is 24.2% [1] is still far from their Shockley-Queisser (SQ) limit which is ~30.5% power-conversion efficiency (PCE) for methylammonium lead iodide (MAPbI3).[2] Despite the marked efforts in improving polycrystalline perovskite films, they have significant parasitic non-radiative recombination due to their inherent grain size and surface defects.[3] In contrast to polycrystalline perovskite films, single-crystal perovskites are orders of magnitude superior in terms of defect density, charge carrier mobility, and diffusion length.[4] These advantages make the single-crystal perovskites a strong candidate to achieve their SQ limit. Unfortunately, there are a limited amount of studies on single-crystal perovskite solar cells (SC-PSC), most of which show inferior PCEs compared to polycrystalline counterpart. The highest PCE so far for SC-PSCs was reported in 2017 is 17.8% by Huang and co-workers.[5]

Here, we achieved highly efficient SC-PSCs with PCEs reaching 21.1% and FFs of up to 84.3% (under 1-sun illumination).[6] This is the first time for an SC-PSC to exceed the 20% PCE benchmark. These devices, based on a ~20 micrometers-thick MAPbI3 single-crystal active layer in an inverted p-i-n structure, set a new record for SC-PSC efficiency and a new potential benchmark for FFs that PSCs should aim for, which polycrystalline PSCs have struggled to achieve. We describe the crucial fabrication steps and measurement conditions required to achieve these high efficiencies. Additionally, our study is also answering an ongoing debate over the diffusion length of carriers in perovskite single-crystals. The different methods like 1D, SCLC, and 3D methods showed a diverse range from several microns to mm. Our work confirms the extraction length should be over 40 μm since the external quantum efficiency (EQE) is over 80% all over the absorbed spectrum. While there is still room for substantial interfacial optimization, our findings highlight the promise of single-crystals for advancing perovskite optoelectronic technology, which could be a parallel growing path to the one taken by their polycrystalline counterparts.

**Bacteriorhodopsin Enhances Efficiency of Perovskite Solar Cells by Forster Resonance Energy Transfer Mechanism**

Subhabrata Das¹, Congcong Wu², Zhaoning Song¹, Yuchen Hou³, Ponisseril Somasundaran¹, Shashank Priya², Bernardo Barbìellinì⁴,⁵ and Renugopalakrishnan Venkatesan⁵,⁶; ¹Columbia University, United States; ²The Pennsylvania State University, United States; ³University of Toledo/Bowling Green University, United States; ⁴Lappeenranta University of Technology, Finland; ⁵Northeastern University, United States; ⁶Harvard University, United States

In recent years, halide perovskites have upstaged decades of development in solar cells by reaching power conversion efficiencies that surpass polycrystalline silicon performance. The efficiency improvement in the perovskite cells is related to repeated recycling between photons and electron-hole pairs, reduced recombination losses and increased carrier lifetimes. Here, we demonstrate a novel approach towards enhancing the efficiency of perovskite solar cells by invoking the Forster Resonance Energy Transfer (FRET) mechanism for predicting the strength and range of exciton transport between separated molecules based on Born-Oppenheimer approximation. FRET occurs in the near-field region as photosensitive protein, bacteriorhodopsin (bR) and perovskite have similar optical gaps. Titanium dioxide functionalized with bR protein is shown to accelerate the electron injection from excitons produced in the perovskite layer. FRET predicts the strength and range of exciton transport between separated perovskite and bR layers. We show that the cells incorporating bR/ TiO₂ layers exhibit much higher photovoltaic performance. These results open the opportunity to develop a new class of bio-perovskite solar cells with improved performance and stability.

**Polyelemental, Multicomponent Perovskite Semiconductor Libraries through Combinatorial Screening**

Michael Saliba; Technical University of Darmstadt, Germany

Perovskites have emerged as low-cost, high efficiency photovoltaics with certified efficiencies of 24.0% approaching already established technologies. The perovskites used for solar cells have an ABX₃ structure where the cation A is methylammonium (MA), formamidinium (FA), or cesium (Cs); the metal B is Pb or Sn; and the halide X is Cl, Br or I. Unfortunately, single-cation perovskites often suffer from phase, temperature or humidity instabilities. This is particularly noteworthy for CsPbX₃ and FAPbX₃ which are stable at room temperature as a photoinactive “yellow phase” instead of the more desired photoactive “black phase” that is only stable at higher temperatures. Moreover, apart from phase stability, operating perovskite solar cells (PSCs) at elevated temperatures (of 85 °C) is required for passing industrial norms.

Recently, double-cation perovskites (using MA, FA or Cs, FA) were shown to have a stable “black phase” at room temperature.(1,2) These perovskites also exhibit unexpected, novel properties. For example, Cs/FA mixtures supress halide segregation enabling band gaps for perovskite/silicon or perovskite/perovskite tandems.(3) In general, adding more components increases entropy that can stabilize unstable materials (such as the “yellow phase” of FAPbI₃ that can be avoided using the also unstable CsPbI₃). Here, we take the mixing approach further to investigate triple cation (with Cs, MA, FA) perovskites resulting in significantly improved reproducibility and stability.(4) We then use multiple cation engineering as a strategy to integrate the seemingly too small rubidium (Rb) (that never shows a black phase as a single-cation perovskite) to study novel multication perovskites.(5) One composition containing Rb, Cs, MA and FA resulted in a stabilized efficiency of 21.6% and an electroluminescence of 3.8%. The Voc of 1.24 V at a band gap of 1.63 eV leads to a very small loss-in-potential of 0.39 V, one of the lowest measured on any PV material indicating the almost recombination-free nature of the novel compound. Polymer-coated cells maintained 95% of their initial performance at 85°C for 500 hours under full illumination and maximum power point tracking. This is a crucial step towards industrialisation of perovskite solar cells.

Lastly, to explore the theme of multicomponent perovskites further, molecular cations were revaluated using a globularity factor. With this, we calculated that ethylammonium (EA) has been misclassified as too large. Using the multication strategy, we studied an EA-containing compound that yielded an open-circuit voltage of 1.59 V, one of the highest to date. Moreover, using EA, we demonstrate a continuous fine-tuning for perovskites in the “green gap” which is highly relevant for lasers and display technology.

The last part elaborates on a roadmap on how to extend the multication to multicomponent engineering providing a...
series of new compounds that are highly relevant candidates for the coming years.(6,7)

Processing Approaches for High-Performance and Versatile Halide Perovskite Semiconductor Films and Devices David B. Mitzi; Duke University, United States

Halide-based perovskite semiconductors (e.g., CH3NH3PbI3 and lower-dimensional analogs) have attracted substantial recent interest for photovoltaic and other optoelectronic application, due to large optical absorption coefficients, high carrier mobilities, long minority carrier lifetimes, and relatively benign defects and grain boundaries achieved within these materials. Coupled with the demonstrated high performance of associated films/devices, the ability to employ a diverse array of simple and low-temperature film deposition approaches provides an opportunity for very low processing costs and wide-ranging substrate form factors (e.g., flexible, light weight, curved surface). This talk will explore several recently described pathways for versatile thin-film deposition [1], including additive engineering [2], melt-processing [3,4], lamination and resonant-infrared matrix-assisted pulsed-laser evaporation (RIR-MAPLE) [5]. Considerations will include focus on grain growth, interfacial reactivity/passivation and deposition pathways for more complex 2-D hybrid perovskite films. Advances in film deposition and control offer promise of enhanced device performance, improved operational stability and greater device form factor flexibility.

Almost Hysteresis-Free Vacuum-Deposited Organic-Inorganic Perovskite Solar Cells Enkhtur Erdenebileg, Martin Kroll, Ran Ji, Zongbao Zhang, Tim Schramm, Changsoon Cho, Reinhard Scholz, Frederik Nehm and Karl Leo; IAPP, Germany

Organic-Inorganic Perovskite solar cells (PSCs) have attracted great interest over the past few years due to their outstanding power conversion efficiencies. However, operational stability still needs to be improved for broad commercial application. A commonly observed phenomenon for PSCs is hysteresis in their current–voltage characteristics, which has been suggested to be related to issues with long-term stability. Understanding of the processes involved in hysteresis may also guide the way to further improving the cells efficiencies. We fabricate planar pin organic–inorganic hybrid PSCs using three different organic transport layer architectures by vacuum deposition in a new multi-source tool and measure their hysteresis and long-term stability behavior. The organic transport layer architectures use controlled doping methods based on our pioneering work on organic doping, which is currently broadly commercially used in OLED displays.

Our results show that all-vacuum-deposited PSCs show much weaker hysteresis than in previous studies, where many types of PSCs were involved. For our devices, we also report an inverted hysteresis, where efficiency is somewhat higher for a voltage sweep from short circuit to forward-bias conditions than for the reverse sweep at lower scan rates, which has not commonly been observed in previous studies of PSCs.

Investigation of the Optoelectronic Properties and Stability of Coevaporated $\gamma$-CsPbI$_3$ Perovskites

Pascal Becker$^1$, Jose Marquez Prieto$^1$, Justus Just$^2$, Amran Al-Ashouri$^1$, Charles J. Hages$^3$, Hannes Hempel$^1$, Marko Jost$^1$, Steve Albrecht$^1$ and Thomas Unold$^1$; $^1$Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; $^2$MAX IV Laboratory, Sweden; $^3$University of Florida, United States

High-throughput experimentation can be of great advantage for exploring the complex compositional phase space of halide perovskites. Here we demonstrate the application of such techniques for the investigation of CsPbI$_3$ thin-films and solar cells. Cesium lead iodide thin films were fabricated with a lateral compositional gradient by co-evaporation of CsI and PbI$_2$ onto a non-rotating substrate. The composition, crystal structure, grain size, charge carrier mobility, lifetime and photoluminescence external quantum yield (PLQY) were determined by mapping these properties on the 5x5cm samples. Correlation of these results provides complete structure-property relationships and shows that stable high quality $\gamma$-CsPbI$_3$ can be obtained by Cs-rich low temperature deposition, without need of a high temperature annealing step. 12% efficient solar cells are demonstrated based on these results.[1]

Furthermore, samples obtained at different substrate temperatures, containing both the $\gamma$-phase and the $\delta$-phase, were annealed at 320 °C for a comparison of the properties of the as-deposited $\gamma$-phase with the $\gamma$-phase obtained after high temperature annealing. It is found that grain sizes increase from ~100 nm in the as-deposited films to ~500 nm in the annealed films, accompanied by an increase in the PLQY by about an order of magnitude (only). The degradation/conversion to the $\delta$-phase is investigated systematically for various deposition temperatures and Cs/Pb composition ratios in a humidity-controllable environmental chamber. Overall, a significantly enhanced stability is observed for the Cs-rich deposited perovskite samples.

Prospects of Perovskite PV Research Based on All-Inorganic Absorbers and New Dopant-Free Carrier Transporters

Tsutomu Miyasaka; Toin University of Yokohama, Japan

This year, we are celebrating 10 years of perovskite solar cell (PSC). Since our first discovery of PSC in 2009, enormous efforts have been put into different aspects of PSCs and the progress has been incredibly fast on all fronts. While preparing a comprehensive review[1] on the background, on-going R&Ds, and future direction of PSC research recently, we realized that, although efficiency level has gone beyond 24%, PSCs face serious challenges of practical stability and durability required for industrialization. Although compositional engineering of perovskites by mixing different cations and anions, using modulator molecules and mixing 2D and 3D structures have doubtlessly improved the stability of perovskites against heat and moisture, use of organic moieties still remain a challenge to improve the stability further. Intrinsic stability of the perovskite crystal structure and robust properties of carrier transport materials are going to be the keys to the long term durability of the device. In this respect, use of all-inorganic perovskite materials and combination with dopant-free carrier transport materials are highly desired. We have conducted some work in this direction which includes stabilization of CsPbI$_3$ black phase[2] and use of dopant-free hole transport materials (HTMs). Dopant-free HTMs combined with all-inorganic perovskites have yielded sufficiently high efficiency of 15%. Intrinsic thermal stability of the device was improved without using diffusible dopants. In our collaboration with JAXA, stability of perovskites was investigated in space environment for satellite applications. Here, organic cations in perovskite such as methyl ammonium are instable under exposure to vacuum and high temperatures >100°C. Perovskite materials demonstrate its high stability against exposure to high energy particle radiations (proton and electron beams) up to dose of $10^{15}$ particles/cm$^2$ due to use of thin absorber films that can avoid accumulation of particles and also exhibit defect tolerant nature. The lecture will also introduce our current efforts in making PSCs based on both lead and lead-free perovskites, and future perspectives of perovskite photovoltaics.

Stabilizing Halide Perovskites—Self-Repair, Defects and Sealing David Cahen1,2; 1Weizmann Institute of Science, Israel; 2Bar-Ilan University, Israel

Halide Perovskites (HaPs) present a remarkable case of just stable (against decompositon into binaries) compounds that can function as active component for PV, light-emission and radiation detection, all demanding functions, over time periods that seem incompatible with their free energy of formation (again, from the binaries). Actually, the Achilles heel of the materials is their surface, true to Pauli’s famous dictum, because of the law of mass-action: as long as the system remains a hermetically close one, it can withstand the onslaught of electronic carriers and photons. Add to that that it are to a large extent the interfaces that make the devices function (again following a famous dictum, this time from Kroemer) and.. those are made with surfaces. Thus, what might appear esoteric materials chemistry and physics issues, are highly relevant for device design. In principle, apart from the remarkable self-healing ability (known to some extent also for CIGS) this is not new as nearly every (inorganic) semiconductor material that we use today went through the process of taming its surfaces to get control over interfaces made with them. In this talk I will, depending on developments in the half year between abstract writing and presentation, present data on the self-healing and (de)stabilization processes of HaPs and put their behaviour in perspective with respect to some other semiconductors, to arrive at insights that should be useful to device design and building.

2:30 PM *EN08.05.03/EN09.05.03
Molecular Dopants on Metal Halide Perovskite Surfaces—What Do We Learn? Antoine Kahn, Fengyu Zhang, Scott Silver, Joseph C. Hamill, Nakita K. Noel, Barry P. Rand and Lynn Loo; Princeton University, United States

Surfaces of metal halide perovskites (MHP) present an interesting set of questions and challenges that are only beginning to be addressed, namely the existence, origin, density and energy of electronic surface gap states. MHP surfaces are prone to ion diffusion and chemical reactions, and to degradation under various environmental conditions and probing tools, all of which likely induce some density of electronic gap states. In sufficient density, these states affect the electronic structure and optoelectronic performance of all MHP interfaces and devices. There is currently no consensus on potential profile and occurrence of band bending in perovskite films, from substrate to surface. Available data point to a strong dependence of these profile on the nature and surface potential of the substrate on which the films are fabricated, and on the perovskite processing conditions. Limits in Fermi level excursion have been observed and also point to some low density of (surface or bulk) gap states.[1] To address some of these issues, several groups have started to use organic molecular dopants (reductants and oxidants), as “gentle” probes of the electronic occupation and density of surface states, and as modifier agents of these states. [2,3] This talk describes our recent investigations of the interaction between molecular reductants (mostly [RuCp*Mes]2+) and oxidants (Mo(tfd)3 and derivatives) and surfaces of 3D MHPs CsPbBr3 and FAxMA1-xPb(IyBr1-y)3, and the 2D Ruddlesden-Popper phase BA2PbI4. Using a combination of electron spectroscopies and contact potential measurements, we determine the sign and magnitude of surface photovoltage occurring at these free surfaces, and the extent of surface energy level shifts resulting from charge exchange with the molecular dopants. We also show evidence obtained via photoemission spectroscopy of a density of (surface) filled states above the valence band maximum of FAPbBr3 following electron bombardment, and of MAPbI3, likely due to the presence of DMSO in the precursor solution. The role of surface doping in changing the occupation of these states will be discussed.

3:30 PM *EN08.05.04/EN09.05.04
Understanding Defect Physics to Stabilize Metal-Halide Perovskite Semiconductors for Optoelectronic Applications Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy
Semiconducting metal-halide perovskites present various types of chemical interactions which give them a characteristic fluctuating structure sensitive to the operating conditions of the device, to which they adjust. This makes the control of structure-properties relationship, especially at interfaces where the device realizes its function, the crucial step in order to control devices operation. In particular, given their simple processability at relatively low temperature, one can expect an intrinsic level of structural/chemical disorder of the semiconductor which results in the formation of defects.

Here, first I will summarize our understanding of the nature of defects and their photo-chemistry, which leverages on the cooperative action of density functional theory investigations and accurate experimental design. Then, I will show the correlation between the nature of defects and the observed semiconductor instabilities. Instabilities are manifested as light-induced ion migration and segregation, eventually leading to material degradation under prolonged exposure to light. Understanding, controlling and eventually blocking such material instabilities are fundamental steps towards large scale exploitation of perovskite in optoelectronic devices. By combining photoluminescence measurements under controlled conditions with ab initio simulations we identify photo-instabilities related to competing light-induced formation and annihilation of trap states, disclosing their characteristic length and time scales and the factors responsible for both processes. We show that short range/short time defect annihilation can prevail over defect formation, happening on longer scales, when effectively blocking undercoordinated surface sites, which act as a defect reservoir. Finally, based on such knowledge, I will discuss different synthetic and passivation strategies which are able to stabilize the perovskite layer towards such photo-induced instabilities, leading to improved optoelectronic material quality and enhanced photo-stability in a working solar cell.

4:00 PM *EN08.05.05/EN09.05.05
Understanding Surface Passivation in Methylammonium Lead Tribromide Single Crystals Maria Antonietta Loi; University of Groningen, Netherlands

The surface of hybrid perovskites plays a crucial role in the performance and stability of optoelectronic devices, as it strongly influences the recombination rate of excited charge carriers. Recently, it has been reported that molecular ligands such as benzylamine are capable of significantly reducing the surface trap state density in thin films. Here I will report on the mechanism that governs the surface passivation of hybrid perovskites by benzylamine. To this end, we developed a versatile approach to investigate the influence of benzylamine passivation on the well-defined crystal surface of freshly cleaved methylammonium lead tribromide single crystals. We show that benzylamine is capable of permanently passivating surface trap states in these single crystals, resulting in enhanced photoluminescence intensities and charge carrier lifetimes. Additionally, we show that exposure of the perovskite surface to benzylamine leads to replacement of the methylammonium cations by benzylammonium, thereby creating a thermodynamically more stable two-dimensional perovskite (BA)2PbBr4 on the surface of the 3D crystal. This conversion from a 3D to 2D perovskite drives an anisotropic etching of the crystal surface, with the {100} planes being most prone to etching.

Tungsten Trioxide (WO₃) as an Electron-Selective Transporting Layer for Perovskite Solar Cell Funsoo Kim, Seongrok Seo, Hyoungmin Park and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)
Tungsten trioxide electron-selective transport layer (ETL) was formed by sol-gel method using acetylated peroxotungstic acid (APTA) solution as a precursor. The formed layer was in triclinic phase, as shown by the x-ray diffraction patterns. Both compact and mesoporous structure can be made using the same precursor solution and process, but with the Polyethylene glycol as an additive for the mesoporous films. Electronic and optoelectronic properties of the synthesized WO₃ ETL was determined from electrochemical impedance spectroscopy, photoluminescence, and UPS measurement. Three types of WO₃ layer was used for the cell fabrication, which were in compact, mesoporous, and mesoporous/compact double layer. Also, the effect of TiO₂ interlayer for the cell performance was also studied.

EN08.06.02
The Power of the Crowd—What Could be Learned by Collective Pooling of All the World’s Perovskite Device Data and How Do We Get There? Tor J. Jacobsson¹ and Eva L. Unger¹,²; ¹Helmholtz-Zentrum Berlin fur Materialen und Energie GmbH, Germany; ²Lund University, Sweden

Much research related to perovskite solar cells follows a familiar pattern. A group of postdocs and PhD students enter the lab where they with skill and determination meticulous handcraft a staggering number of solar cells, where after they carefully measure the device characteristics of the cells. This process triggers the writing of papers in which insights are summarised, and where a subset of the generated data is used for plotting figures and filling tables. Over the last ten years, this has been repeated about 10000 times. Sadly, much of the data presented in figures are non-trivial to extract, and much of the raw data newer leaves the hard drives of the students doing the work, and when they move on, the data is many times forever lost in the growing heap of unconsidered data. We firmly believe that much could be gained if more of this data could be stored in one place where it is easily accessible for the research community. So is also an increasing number of funding agencies. Such a collection of data could lead to new insights that are hard to get when the data is scattered over thousands of articles, and it could thus be a way to accelerate the pace of development. In this project, we are working on creating a platform for what could be described as a Wikipedia of perovskite device data. We will in this presentation describe what we have created, what can be conclude from the data so far accumulated, as well as the potential benefits for the perovskite community and beyond if this approach to data sharing reach full penetration in the field.

EN08.06.03
Recrystallization Mechanism of Pure and Binary MASn,Pb₁₋ₓIₓ Perovskite Complex with Methylamine Vapor Akash Singh¹,² and Sushobhan Avasthi¹; ¹Indian Institute of Science, India; ²Duke University, United States

With the advent of the deployment of halide perovskites in optoelectronics, various combinations of precursor halide salts have been tried to tune the perovskite’s photophysical properties which include changing the stoichiometric ratio of different ions that make up the perovskite structure. Simple compositional engineering opens a new world to tune the bandgap from 1.1 to 3.0 eV making the fabrication of all perovskite tandem devices and IR-RGB LED’s possible. One way to achieving efficient and stable perovskite photovoltaic devices is through improving the crystallinity and morphology of the active absorber layer. Due to the different chemistry of various halide precursors in solution, it is difficult to develop a common processing condition for thin film deposition of all the compositionally engineered perovskite.

In this work, we demonstrate a common post-deposition vapor annealing technique that improves the quality of pure and binary MASₙPb₁₋ₓIₓ perovskite thin-films. MAPbI₃ perovskite forms an optically bleached frustrated intermediate complex (MAPbI₃-xMA) when exposed to methylamine (MA) vapor for 3 seconds at room temperature. Upon removal at 25°C, the complex decomposes and gives back MAPbI₃ parent phase in the next 2-3 seconds with degassing of MA gas. This increases the surface coverage from 90 to 100% with uniform grains of 200 nm size as compared to needle-like non-uniform crystals obtained in as-deposited control films. MA exposure improved the crystallinity and carrier lifetime of these films by two times. The grain sizes are further increased to 10-15 microns by prolonging the recrystallization time to 90 minutes in a MA filled pressure-controlled glass reactor heated at 140°C.

In the case of pure MASnI₃ films, the MA exposure results into optically bleached stable Lewis pair amorphous complex of SnI₂-xMA at room temperature, with MAI crystalizing out of the film as confirmed by XRD. We find that prolonged heating of MA exposed film at 140-150°C breaks the complex back to SnI₂ which simultaneously
reacts with MAI resulting into MASnI$_3$ parent phase. Annealing below 150°C results into partial conversion to perovskite with remnant MAI primary XRD peak appearing at $\sim$10°. Annealing beyond 150°C leads to degradation of films into SnI$_2$. A step-annealing technique on MA exposed films is employed whereby the temperature is progressively increased from 25°C to 150°C and maintained at 150°C for 60 minutes to control the nucleation and grain-growth kinetics. This technique increases the grain size from 100-150 nm in as-deposited films to 1-2 microns in step-annealed films along with 7 times improvement in film crystallinity. Due to lower grain boundary density, the oxygen and moisture permeation is checked leading towards 75 nm of Burstein-moss red-shift in the absorption onset. This reveals that step-annealed MASnI$_3$ films (1.2 eV) are fairly less doped as compared to degenerate p-type self-doped as-deposited MASnI$_3$ films (1.3 eV).

For the binary MASn$_{0.5}$Pb$_{0.5}$I$_3$ (1.2 eV) perovskite films, the MA exposure forms an intermediate stable complex, but it doesn’t show any characteristic XRD peak of MAI instead, an unknown peak at 11.3° is observed, which diminishes as the film is annealed. At 85°C, the parent MASn$_{0.5}$Pb$_{0.5}$I$_3$ perovskite phase is fully recovered. Annealing below 85°C results into partial conversion to perovskite, whereas annealing beyond 85°C results into the small appearance of PbI$_2$ peak at 12.6° suggestive of degradation onset. The recrystallization temperature increases with increase in Sn content in MASn$_x$Pb$_{1-x}$I$_3$ films from 25°C, 85°C to 150°C for x = 0, 0.5 and 1.0 respectively suggestive of different affinity towards MA following different complex formation and recrystallization mechanism. The MA vapor annealing method provides a way to obtain high quality pure and binary MASn$_x$Pb$_{1-x}$I$_3$ perovskite thin-films to be employed in tandem and singlet fission devices leading towards enhanced efficiency.

EN08.06.04
Understanding the Role of Antisolvent Quenching in Film Formation, Device Performance and Reproducibility of Triple Cation Perovskite Solar Cells Alexander Taylor, Qing Sun, Fabian Paulus and Yana Vaynzof; University of Heidelberg, Germany

Hybrid organic-inorganic perovskite materials have taken the photovoltaic (PV) research world by storm, setting new power conversion efficiency (PCE) records at an unprecedented rate. However, significant irreproducibility issues continue to plague the field, even at world-leading laboratories. These issues are often due to small, unnoticed factors. For example, our group recently demonstrated that fractional variations in the precursor solution stoichiometric ratio significantly impact subsequent device performance. These findings motivated us to look for other hidden variables affecting the performance and reproducibility of perovskite PVs. Herein, we seek to further our understanding of the root causes of this irreproducibility by closely examining the fabrication procedure of cutting edge triple cation perovskite solar cells. Through a variety of characterization techniques including electron microscopy, x-ray diffraction, and others, we reveal that subtle differences during the critical “antisolvent” fabrication step lead to significant microstructural changes, and thus dramatically affect the final PV performance. By deliberately introducing device-to-device variation in this step, we find that perovskite film formation is highly altered, and show that the resulting PCE can vary from over 21% to less than 15%, for devices fabricated in the same batch and from the same precursor solutions. Additionally, we performed these experiments with 15 different antisolvents, and find that they fall into four categories based on their physical and chemical properties, with each possessing significantly different optimal processing conditions. Furthermore, by careful control over the antisolvent fabrication step, high performance (~20% PCE) can be obtained using almost all studied antisolvents. These results challenge some of the prevailing beliefs currently held by the research community, regarding not only what the highest performing antisolvents are, but also in general the role of the antisolvent in fabricating high performance perovskite solar cells.

EN08.06.05
Maximizing the External Radiative Efficiency of Hybrid Perovskite Solar Cells Dane W. deQuilettes; Massachusetts Institute of Technology, United States

Despite rapid advancements in power conversion efficiency in the last decade, perovskite solar cells still perform...
below their thermodynamic efficiency limits. Non-radiative recombination, in particular, has limited the external radiative efficiency and open circuit voltage in the highest performing devices. I will review the historical progress in enhancing perovskite external radiative efficiency and determine key strategies for reaching high optoelectronic quality. Specifically, I will focus on non-radiative recombination within the perovskite layer and highlight novel approaches to reduce energy losses at interfaces and through parasitic absorption. I will highlight a rapid photoluminescence method capable of quantifying non-radiative loss throughout the device stack. By strategically targeting defects, it is likely that the next set of record performing devices with ultra-low voltage losses will be achieved.

EN08.06.06
Extending the Photovoltaic Response of Perovskite Solar Cells into the Near-Infrared with a Narrow Bandgap Molecule
Xiaoming Zhao1, Chao Yao1,2, Tianran Liu1, Joseph C. Hamill1, Guy Olivier Ndongang Ndjawa1, Guangming Cheng1, Nan Yao1, Hong Meng2 and Lynn Loo1; 1Princeton University, United States; 2Peking University Shenzhen Graduate School, China

Metal halide perovskite solar cells (PSCs) have attracted much attention due to the rapid increase in their power-conversion efficiencies (PCEs), and their amenability to solution-processing and low-cost manufacturing. Typical lead (Pb)-based 3D perovskites show an onset of light absorption around 800 nm; extending light absorption beyond 800 nm into the near-infrared (NIR) of such photoactive layers should increase photocurrent generation and further improve photovoltaic efficiency. While efforts to tune and formulate new materials compositions have resulted in tin (Sn)-containing perovskites with narrower bandgaps than their Pb-counterparts, these new materials exhibit low chemical stability, and are often more prone to oxidation compared to Pb-based perovskites. Tandem structures composed of two or more sub-cells with complementary absorption profiles serially connected have also demonstrated enhanced photo-response compared to single-junction Pb-based perovskite solar cells. The use of a tandem structure, however, necessarily complicates processing and dramatically increases device complexity. There currently does not exist a simple and effective strategy to enhance the NIR photovoltaic response of PSCs. Here, we demonstrate a facile approach to incorporate a NIR-chromophore that is also a Lewis-base, namely IEICO-4F, into an active layer comprising CsFAMAPbI3 to broaden its photo-response and increase its photovoltaic efficiency. Given the energy-level alignment between the organic chromophore and perovskite, efficient hole and electron transfer take place readily. Compared with control experiments conducted on PSCs without IEICO-4F, these solar cells generate photocurrent in the NIR, beyond the band edge of perovskite. Given the Lewis-basic nature of IEICO-4F, its addition to the photoactive layer also effectively passivates perovskite defects. These films thus exhibit significantly reduced trap densities, enhanced hole and electron mobilities, and suppressed illumination-induced ion migration. As a consequence, perovskite solar cells with IEICO-4F exhibit an enhanced PCE of 21.6% relative to those without IEICO-4F at 20.0%, and substantively improved operational stability under continuous one-sun illumination. Borrowing from the organic photovoltaic playbook, we have successfully demonstrated the effectiveness of incorporating a narrow bandgap chromophore to extend the photoresponse of perovskite absorber. The judicious selection of the organic chromophore simultaneously increases photovoltage and photocurrent generation to PSCs, and imbues enhanced stability to their operation.

EN08.06.07
Improved Perovskite Solar Cell Efficiency by Tuning the Colloidal Size and Free Ion Concentration in Precursor Solution Using Formic Acid Additive
Lina Meng1, Shengzhong (Frank) Liu1,2 and Yucheng Liu1; 1Shaanxi Normal University, China; 2Chinese Academy of Sciences, China

Improving the quality of the perovskite active layer is crucial to obtaining high performance perovskite solar cells (PSCs). In this work, by introducing formic acid into the formamidinium lead iodide (FAPbI3) precursor solution, we managed to achieve reduced colloidal size in the solution, leading to more uniform deposition of FAPbI3 film with lower trap state density and higher carrier mobility. The solar cells based on the FAPbI3 absorber layer modified with formic acid show significantly better photovoltaic performance than that on the reference FAPbI3 film without formic acid. The device performance shows a close correlation with the colloidal size. Within the range studied from 6.7 to 1.0 nm, the smaller the colloidal size is, the higher the solar cell efficiency. More specifically, the cell efficiency is improved from 17.82% for the control cell without formic acid to 19.81% when 0.764 M formic acid was used. Formic acid has also been added into a CH3NH3PbI3 (MAPbI3) precursor solution, which exhibits a similar effect on the resulting MAPbI3 films and solar cells, with efficiency improved from 16.07% to 17.00%.
Ordered Orientation and Compact Molecule Packing Due to Coplanar Backbone Structure of Interlayer—Improvement in Fill Factor for Photovoltaic Device

Ju Hui Kang1, Doo Hun Kim2, Yong Woon Han3, Sangkug Lee1 and Ho Jun Song1; 1Korea Institute of Industrial Technology, Korea (the Republic of); 2Korea Institute of Science and Technology, Korea (the Republic of); 3Konkuk University, Korea (the Republic of)

A novel alcohol/water-soluble small molecule was obtained using a p-type planar backbone. The synthesized molecule was dissolved in organic solvents and highly polar solvents. The 3,3’-((3,3”-dimethyl-[2,2’;5’,2’’:5’’,2”’-quarterthiophene]-5,5”-diyl)bis(4,1-phenylene))bis(oxy))bis(N,N-dimethylpropan-1-amine) (QTA) film exhibited a red-shifted spectrum compared with the solution spectrum owing to its many more planar molecular conformations in the solid state. According to X-ray diffraction (XRD) measurements, the QTA film showed sharp diffraction peaks near 3.6–11.0°, which indicates the formation of an interdigitated and ordered structure as an out-of-plane peak (100) due to the alkyl side chain of the quarter-thiophene backbone. A comprehensive analysis of the out-of-plane and in-plane XRD data suggests that a large fraction of the QTA derivatives was oriented edge-on relative to the substrate. A photovoltaic device containing QTA exhibited an open-circuit voltage of 0.85 V, current density of 15.5 mA/cm², fill factor of 62.9%, and power-conversion efficiency of 8.4%. The photovoltaic device containing the QTA derivative exhibited improved power conversion efficiency compared with those containing PFN (8.0%) due to the ordered orientation and compact molecule packing of QTA. Moreover, the PCE values of the device with QTA decreased by only approximately 91 ~ 92 % after 450 hours, which showed superior durability compared with that with PFN (68 ~ 69 % after 450 hours) because of the electrochemical stability of QTA.

Influence of Antisolvent Dropping Speed and Time for Perovskite Layer Morphology

Sunhao Liu and Pratap M. Rao; Worcester Polytechnic Institute, United States

Organic-inorganic hybrid halide perovskite has emerged as a light harvest material for solar energy. Perovskite has a lot of advantages such as low manufacturability cost, unique photoelectric properties and so on. Those properties are related to the morphology of perovskites such as grain size, pinhole, and thickness. Moreover, the most common method to synthesis perovskite is a solution process method. In that method, anti-solvent plays a critical role to get the optimal perovskite layer. The kind and volume of anti-solvent have been studied in recent years. Only a few people study influence about dropping speed and time of the anti-solvent. In our research, we use a fancy perovskite, triple cation perovskite (Cs0.17(MA0.83)100−XPb(I0.83Br0.17)3). Three anti-solvents (TL, TFT, and 1,2-DCB) were used to study which is the best one for the triple cation perovskite. We try the anti-solvent dropping speed from 0.6 ml/min to 4.8 ml/min under a constant time condition and dropping time from the 10s to 60s in certain dropping speed. The changes of morphology and phase have been observed. Grain size is decreased by increasing the speed and time. The density of pinhole and thickness also decreased. The amount of black α-FAPbI3 phase is increased when we increase speed and time. We can show that the performance of perovskite solar cell is increased to 7.66% in the normal environment by changing the anti-solvent dropping speed and time.

Thermal Evaporation Applied to Perovskite Materials—Chances and Challenges

Nadja I. Klipfel, Cristina Momblona, Hiroyuki Kanda, Cristina Roldan Carmona and Mohammad K. Nazeeruddin; Ecole polytechnique fédérale de Lausanne, Switzerland

Organic-inorganic metal halide perovskite solar cells are an emerging photovoltaic technology that has the potential to compete with commercially available silicon solar cells. Over the last decade, perovskite solar cells have have undergone significant development; reaching a high power conversion efficiency of 24.2% with low material and processing costs. However, most of these certified solar cells are processed from solution, depositing the perovskite layer from solvents such as dimethyl sulfoxide (DMSO) or dimethyl formamide (DMF). Solvent-free, vacuum-based methods are mature technologies widely adopted in the semiconductor industry but marginally explored for perovskite optoelectronics. Its suitability for large-scale fabrication of high-purity systems merges with the ability of precise control over film thickness and composition, low-temperature processing and the possibility of preparing multilayer structures. All these advantages call for more in-depth investigation of this alternative device preparation method. Here we present a detailed study of the chances and challenges of the vacuum-deposition process of hybrid inorganic/organic lead halide perovskites, which once completed, will facilitate the transfer from lab scale to large-
scale application.

Mapping the Photocurrent and Photovoltage of Perovskite Films at the Nanoscale for Stability Studies
Chandra Shakher Pathak and Iris Visoly-Fisher, Ben-Gurion University of the Negev, Israel

Perovskite solar cells based on methylammonium lead iodide (CH$_3$NH$_3$PbI$_3$) and related materials have emerged as an exciting development for next generation photovoltaic technologies. Solar cells based on them have achieved impressive energy conversion efficiencies, but their stability is still limited. Understanding degradation mechanisms in such materials is key to developing strategies to increase their lifetime. The present work reports on the nanoscale characterization of perovskite photovoltaic films with respect to their stability and degradation mechanisms. We investigated the local conductance and surface potential variation of perovskite films at the nanoscale using conducting atomic force microscopy (CAFM) and Kelvin probe force microscopy (KPFM). CAFM measurements revealed that the current is larger at grain boundaries. The surface potential at grain boundaries and on top of the grain is almost similar which suggests a negligible energy barrier at grain boundaries. We investigated the effect of sunlight exposure on the nano-scale conductance and surface potential of perovskite thin films towards better understanding of photo-induced degradation mechanisms.

EN08.06.12
High Performance UV Photodetector Based on Perovskite-ZnO Heterojunction Structure
Dali Shao, Weiguang Zhu, Guoqing Xin, Jie Lian and Shayla Sawyer; Rensselaer Polytechnic Institute, United States

A high performance heterojunction ultraviolet (UV) photodetector was fabricated by growing vertical aligned ZnO nanowire arrays (ZnO NWAs) on ITO substrate followed by deposition of novel wide-bandgap inorganic perovskite Cs$_2$SnCl$_6$ nanoparticles (NPs) thin film on the top. The ZnO-Cs$_2$SnCl$_6$ heterojunction photodetector demonstrated a high external quantum efficiency of 86% at the wavelength of 378 nm and fast response speed with rise and fall time on the order of $\mu$s. In addition, the photodetector achieved a large linear dynamic range of 178dB. The excellent performance of this photodetector originates from enhanced separation and collection efficiency of the photo-generated carriers at the ZnO-Cs$_2$SnCl$_6$ hetero-interface, which will be discussed in details in terms of the energy band diagrams of the device and the carrier dynamics upon UV illumination. The results presented in this work may trigger further research interest in development of perovskite based heterojunction photodiodes.

EN08.06.13
Relationship between Lattice Strain Relaxation and Enhancement of Efficiency During Storage for Pb-Free Perovskite Solar Cells
Kohei Nishimura$^1$, Muhammad Akmal Kamarudin$^1$, Daisuke Hiotani$^2$, Satoshi Ikubo$^2$, Kenji Yoshino$^3$, Takashi Minemoto$^4$, Qing Shen$^1$, Taro Toyoda$^1$ and Shuzi Hayase$^1$; $^1$The University of Electro-Communications, Japan; $^2$Kyushu Institute of Technology, Japan; $^3$University of Miyazaki, Japan; $^4$Ritsumeikan University, Japan

The certified efficiency of Pb perovskite solar cells (PSCs) with more than 1 cm$^2$ cell is reported to be 20.9%. In the smaller cells, the cell efficiency with 23.3% has been reported, which is close to those of multi-crystalline inorganic solar cells such as 22.3% of multi Si solar cells. However, the use of Pb in electronic is limited according to the EU RoHS Directive. Thus, it is desirable to develop Pb-free PSCs. Among Pb-free perovskite candidates, Sn perovskite is one of the most promising candidates for the light harvesting layer for the Pb-free PSCs, because they have perovskite structure similar to Pb-perovskite. The efficiency with more than 9% have been reported for Sn-PSC consisting of 2D and 3D structures. In this report, the efficiency increases during the storage in N$_2$. However, no clear explanation is given regarding this observation. We have also seen similar phenomena with our SnGe PSCs where the initial efficiency is 4.48% increased to 6.90% after 3 days. Here, we will discuss the efficiency enhancement from the viewpoint of perovskite lattice relaxation during storage time. The inverted structure of ITO / PEDOT:PSS / FA$_{0.70}$MA$_{0.25}$SnI$_3$ + GeI$_2$ (5 mol%) / C$_{60}$ / BCP / Ag / Au showed an efficiency of 6.3 % immediately after fabrication and the value increased up to 7.6 % after 6th day. The increased is mainly contributed by the
improvement of $V_{OC}$ and a slightly improved FF. Interestingly, the $J_{SC}$ remains the same throughout the study. Photoluminescence peak shifted from 920nm (1st day) to 910 nm (5th day). The lattice strain determined from the Williamson-Hall plot showed a value of 1.56% on the 1st day, and decreased gradually to 0.26% on the 5th day. These results show that the efficiency enhancement during storage phenomena can be explained through lattice strain relaxation.

**Hybrid Perovskites for Solar Cells—Atomic-Scale Insights into Local Structure, Defects and Charge Dynamics**

Dibyajyoti Ghosh$^{1,2}$, Amanda Neukirch$^1$ and Sergei Tretiak$^1$; $^1$Los Alamos National Laboratory, United States; $^2$University of Bath, United Kingdom

Further breakthroughs in perovskite solar cells require advances in new compositions and underpinning materials science. Indeed, a greater fundamental understanding of perovskite materials requires atomic-scale characterization of their underlying structural, defect and transport behaviour. In this context, combined modelling-experimental work is now a powerful approach for investigating these properties at the atomistic level. In my talk I will describe such studies on hybrid perovskites [1-3] into two related areas: (i) the beneficial impact of partial A-site substitution on the iodide ion diffusion in methylammonium lead iodide (MAPI). Combining ab initio modelling and multiple spectroscopic techniques, we demonstrate for the first time that partial guanidinium substitution into MAPI strongly suppresses iodide ion transport; [1] (ii) Application of strain for systematically modifying the photovoltaic performance of halide perovskites. Charge carrier generation, transport and recombination in these materials can be largely modified by controlled lattice distortion. [2-4] These insights are very important for the future design of stable perovskite solar cells with enhanced performance.

**EN08.06.15**

**Modeling of Aggregate State Effects on Electronic Properties of Hole Transporting Materials for Perovskite Solar Cells**

Yingqian Chen$^1$, Qian Liu$^2$, Aidan Brock$^2$, Steven Bottle$^2$, John Bell$^2$, John McMurtrie$^2$, Prashant Sonar$^2$ and Sergei Manzhos$^3$; $^1$National University of Singapore, Singapore; $^2$Queensland University of Technology, Australia; $^3$Institut National de la Recherche Scientifique, Canada

A key bottleneck on way to practical application of perovskite solar cells (PSC) is the development of non-expensive, sustainable and stable hole-transporting materials (HTM). Molecular HTMs hold much promise and already allowed obtaining power conversion efficiencies (PCE) in excess of 20% while often providing better stability than the reference Spiro-OMeTAD. Further developments are still needed to improve stability, cost, and efficiency.

Ab initio - typically at the DFT level - modeling is useful to obtain and compare key electronic properties of such materials which helps rationalize their performance and helps design them rationally. While it is relatively easy to perform molecular-level DFT modeling, as is done in much of the literature, ultimately solid HTM layers are used in devices, and it is important to include effects due to molecular aggregation. Specifically, at the single molecule level, there are no significant changes in the electronic properties such as frontier orbital energies or absorption spectra of molecules differing by the length of alkyl chains. Chain length is an important design variable; redox potentials and other properties of films are known to change with chain length; there can also be strong effect on charge transport which is not captured in molecular calculations.

We will present a combined Density Functional Theory (DFT) - Density Functional Tight Binding (DFTB) and Time-dependent (TD-) DFT/DFTB modeling of the effects of aggregate state on electronic properties of diketopyrrolopyrrole based molecular HTMs which showed PCEs of about 20%. Based on experimentally measured packing structures and computed electronic properties, we show that alkyl chain length can have effects on electronic properties which would be missed in molecular calculations and which are important to understand the differences in device performance with molecules featuring different chains.

Towards Light-Rechargeable Batteries Using Hybrid Perovskites  

Angus Mathieson, Felix Deschler and Michael De Volder; University of Cambridge, United Kingdom

Increases in the global energy demand necessitate the development of new approaches to energy conversion and storage. In particular, the utilisation of solar energy could provide a basis of evolving technologies capable of meeting modern and future demands.

By combining the photovoltaic and newfound electrochemical properties of organo-metal hybrid perovskite materials in a single device, a novel photobattery technology is proposed [1]. Utilising the photovoltaic performance of perovskite materials in combination with the intercalation and conversion mechanisms available to Lithium ion species, a device with the ability both to convert light to electrochemical energy and store it is demonstrated. The motivation for such a device will be discussed, with its inherent impact in areas such as off-grid energy solutions and the internet of things. The fabrication techniques are described and characterisation techniques common to both photovoltaic and electrochemical disciplines, with their recent results are discussed. Modifications are made to conventional electrochemical coin cells and pouch cells, in order to facilitate optical access to the electrode material. Using in-operando x-ray diffraction and optical probing, the fundamental mechanisms of charge storage and ion conversion are investigated both in the presence of light, to replicate a light-charging cycle and in the absence of light.

EN08.06.17

Halide Segregation in Perovskites—Unraveling the Impact on Open-Circuit Voltage  

Suhas Mahesh¹, James M. Ball¹, David P. McMeekin², Pabitra Nayak¹ and Henry J. Snaith¹; ¹University of Oxford, United Kingdom; ²Monash University, Australia

The success of perovskite-perovskite tandem solar cells hinges crucially on the development of efficient wide-bandgap cells. However, when the Bromide content is increased to widen the bandgap, cells cease to deliver the expected increase in open-circuit voltage ($V_{oc}$). This loss is usually attributed to halide-segregation in the perovskite. Naturally the question arises: how much voltage loss does halide-segregation incur? Our work answers this question by quantifying the $V_{oc}$ loss due to halide segregation using Fourier Transform Photocurrent Spectroscopy (FTPS) coupled with thermodynamic calculations. Our results show that the main voltage loss in contemporary Br rich perovskite cells is not due to halide segregation, but the relatively low initial luminescent radiative efficiency in the mixed halide thin films. We also present a model that quantitatively predicts expected voltage loss due to halide-segregation at different bandgaps and segregation severities. Our results suggest that $V_{oc}$ of up to 1.33V is within reach, even if halide segregation cannot be suppressed, and that focusing upon maximising the initial radiative efficiency of the mixed halide films is more important than attempting to suppress halide segregation.

EN08.06.18

Light Intensity Modulated Ion Transport in p-i-n MAPb(I1-xBrx)3 Perovskite Solar Cells  

Hamza Javaid, Christie L. Ellis, Emily C. Smith and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

We studied ion migration in p-i-n MAPb(I1,xBrx)3-based solar cells at varying AM1.5G light intensities with electrochemical impedance spectroscopy (EIS). We calculated the diffusion coefficients ($D$), ionic conductivities ($\sigma_{ion}$), and capacitive elements for each hybrid organic-inorganic perovskite (HOIP)-based device. We found that $D$ values increase with increasing illumination intensity in MAPbI3, MAPb(I0.8Br0.2)3, and MAPb(I0.6Br0.4)3, whereas in MAPbBr3, MAPb(I0.4Br0.6)3, and MAPb(I0.2Br0.8)3 compositions, $D$ values exhibit a weak dependence on light intensity. Furthermore, we compared the magnitude of ion diffusion in different compositions of MAPb(I1,xBrx)3 (x= 0.2 to 0.8) and found that MAPb(I0.8Br0.2)3 has the highest resistance to ion diffusion. Interestingly, the MAPb(I0.8Br0.2)3 devices show a superior charge extraction capability to both MAPbI3 and MAPbBr3 devices. Based on our impedance analysis, we expect the MAPb(I0.8Br0.2)3 composition to be more stable and efficient than pristine MAPbI3.
Lower Toxicity Solvents for High Speed Manufacturing Richard M. Swartwout, Dak B. Dou and Roberto Brenes; Massachusetts Institute of Technology, United States

Metal organic perovskite materials have shown promise as solution processable, high efficiency, optically active semiconductors for a variety of applications. This amazing property has led many to believe these materials are capable of high-speed roll-to-roll manufacturing for large solar cells and LED displays. However, the main solvents used to dissolve traditional precursor materials are undesirable from a toxicity, coating and manufacturing perspective. Solvents like DMF and Acetonitrile are readily absorbed through the skin and are highly toxic. DMF has high surface tension, viscosity and a high boiling point limiting upper manufacturing speeds. In addition, these solvents have legally regulated exposure limits in both the United States by the Occupational Safety and Health Administration (OSHA) or by the European Union Agency for Safety and Health at Work (EU-OSHA). These exposure limits have the overall effect of practically limiting coating speed under normal ventilation conditions or requiring specialized equipment for vapor management.

To solve this problem we turn to Lead-Alkylamine complex systems as they show promise for being able to extend the solubility of lead halides into additional organic solvents. We use the Hansen solubility model to dissolve solar cell perovskite precursors into a more benign and less limited mixed solvent system of Tetrahydrofuran and Methanol. Although the resulting perovskite film crystalizes in milliseconds, we show that high power conversion efficiency is only achieved when the solution is doped with multiple organic halides improving charge carrier diffusion length as well as external photoluminescence quantum yield. This work provides a path forward for a more benign and industry focused solvent system for perovskite devices.

EN08.06.20

Machine-Learning-Assisted Design of 2D Capping Layer for Improving Perovskite Solar Cells Stability Noor Titan Putri Hartono, Shijing Sun, Zhe Liu, Armi Tiilhonen, Felipe Oviedo, Jason Yoo, Janak Thapa, Jose D. Perea, Rafael Gomez-Bombarelli and Tonio Buonassisi; Massachusetts Institute of Technology, United States

Despite perovskite solar cells (PSCs) efficiency reaching 24.2%, PSCs stability is still well behind 25-year-stable silicon wafer solar cells. To push PSCs into commercialization, improving their environmental stability is a critical step. Recent studies by Zhou et al., and Dong et al. have suggested that depositing 2D perovskite capping layer, which is also known as buffer layer in PV community, between perovskite absorber and hole-transport layers in a device can improve both environmental stability under ambient temperature with 40%-50% relative humidity (RH) and efficiency by up to 20% relative improvement [1], [2]. Understanding how various 2D perovskim capping layers can be optimized will help improving the cells stability and device architecture design process in the future. We propose a detailed study exploring 7 different types of 2D perovskites for interface layer with methylammonium lead iodide (MAPI) as the photon-absorber layer. The samples are degraded in a well-controlled environmental chamber, under high humidity (85% RH), heat (85°C), and illumination (0.17 sun). In order to accelerate the exploration process of 7 different types of 2D perovskites and numerous deposition conditions, Bayesian optimization (BO) algorithm is used to rapidly optimize each capping layer’s stability based on their deposition conditions. The preliminary results show that optimized tetrabutylammonium iodide capping layer lasts 3.6 times longer than bare MAPI films. Furthermore, by comparing the stability of various types of 2D perovskites through X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and scanning electron microscope (SEM) data analysis, we can deduce a capping layer design guideline in terms of grain size and film thickness for more stable perovskite solar cells.

Exploring the Limiting Open–Circuit Voltage by a Large Band Offset at the Interface between Electron Transport Layer and Tin-Based Halide Perovskite Layer Tomoyasu Yokoyama, Yu Nishitani, Yumi Miyamoto, Shohei Kusumoto, Taisuke Matsui, Kenji Kawano and Yukihiro Kaneko; Panasonic Corporation, Japan
Organic–inorganic lead halide perovskite materials have attracted great attention to realize low–cost and high–efficiency solar cells. The power conversion efficiency of Pb–based halide perovskite solar cells (PSCs) has increased from 3.8 % to above 20 % in the last decade[1,2]. Nevertheless, the toxicity and instability of Pb–based perovskite materials are preventing their commercial implementation. So far, Sn–based PSCs showed the most promising results in Pb–free perovskite solar cells with enough efficiencies. However, Sn–based PSCs showed a much smaller open–circuit voltage ($V_{oc}$) than Pb–based PSCs[3]. Many previous studies have focused on improve the quality of Sn-based perovskite layers, but the $V_{oc}$ of Sn–based PSCs has still been much lower than Pb–based PSCs

To increase the $V_{oc}$ of Sn–based PSCs, we focused on the interface between Sn–based perovskites and electron transport layers (ETLs). There is a large conduction band offset at the interface between Sn–based perovskites and TiO$_2$, which is often used as ETLs in both Pb–based and Sn-based devices. Such offset is essentially caused by the fact that Sn–based perovskites have the shallower electron affinity (EA) of -3.5 eV than Pb–based perovskites of -4.0 eV. Moreover, $p$–$n$ junction is mainly formed at interface between ETLs and Sn-based perovskite layers because Sn–based perovskites show $p$–type characteristics. So we investigated the relationship of the $V_{oc}$ and the conduction band offset between a perovskite layer and an ETL.

In this work, we use three oxides with different EA, SnO$_2$, TiO$_2$ and Nb$_2$O$_5$, as ETLs of formamidinium tin iodide (FASnI$_3$) PSCs. Each oxide was fabricated by the spin–coating or sputtering method. We measured that the EA of SnO$_2$, TiO$_2$ and Nb$_2$O$_5$ are -4.6 eV, -4.0 eV and -3.3 eV, respectively using the ultraviolet photoelectron spectroscopy and the UV–Vis spectroscopy. We demonstrated the performances of Sn-based PSCs in a planar $n$–$i$–$p$ heterojunction device (ITO/ATO/ETL/FASnI$_3$/PTAA/Au) using each oxide as ETLs. The $V_{oc}$ of 100 mV, 300 mV and 420 mV were obtained using SnO$_2$, TiO$_2$ and Nb$_2$O$_5$, respectively. The device with power conversion efficiency (PCE) reached 5.1 % using Nb$_2$O$_5$, which was higher than PCE of 2.5 % and 0.5 % using TiO$_2$ and SnO$_2$, respectively. As the conduction band offset between FASnI$_3$ and the ETL oxide become smaller, a $V_{oc}$ and a PCE of the device increase. Consequently, for Sn–based PSCs a conduction band offset of interface between ETLs and perovskites layers is an important factor to increase $V_{oc}$, and Nb$_2$O$_5$ is a good ETL material for high performance of Sn–based device.

EN08.06.22
The Fundamental Efficiency Limit of Perovskite-Perovskite Tandems and the Role of Light Coupling between Sub-Cells Alan Bowman, Edoardo Ruggeri, Miguel Anaya, Mojtaba Abdi-Jalebi and Samuel D. Stranks; University of Cambridge, United Kingdom

Metal halide perovskites have properties including strong absorption coefficients and long charge diffusion lengths (relative to film thickness) making them close to ideal for solar cells. For perovskite devices to achieve their efficiency limits, charge carrier recombination and the role of photon recycling within films must be better understood and controlled.

Current approaches to measure charge carrier recombination rates are typically based on time intensive and expensive transient spectroscopic measurements. Here we demonstrate that we can employ steady state approaches to extract these parameters, thereby allowing for faster screening of materials. We show the potential of this approach by a comparison with results from transient absorption spectroscopy.

To further understand photon recycling we use our methodology to quantify the photon escape probability. While there are some calculations of the escape probability in the literature, this quantity has not been previously quantified in metal halide perovskites, despite its importance for solar cell operation including photon recycling. We present measured values and compare with those previously calculated.

Using results from our rapid screening process we calculate the limiting efficiency and number of photon recycling events per initially absorbed photon within devices. We carry out calculations for a range of materials including low bandgap and wider gap mixed-halide perovskites. Our results show that in addition to minimising the charge trapping rate it is necessary to maximise the escape probability for optimal efficiency, thereby reducing the number of photon recycling events. We extend our analysis to two and three bandgap tandem configurations, demonstrating that photon recycling between absorber layers has a relatively small effect on efficiency at the maximum power
point. Our combined experimental and modelling approach allows us to target specific device parameters to reach limiting efficiencies.

Recovery of Decomposed MAPbI₃ Films Fabricated via Three Different Fabrication Routes Priyanka Chhillar, Bhanu P. Dhamaniya and Sandeep Pathak; Indian Institute of Technology Delhi, India

Mixed organic-inorganic or fully inorganic halide perovskite solar cells (PSCs) have drawn appreciable interest of research community as highly efficient light harvesters reaching efficiency of about 24% in a past few years. Despite its promising potentials to replace the other commercialized technologies, the principal hurdle is the instability issue when exposed to ambient environment. On the other one cannot wish away from the fact that lead (Pb) which is highly toxic and carcinogenic is an inseparable part of PSCs. Researchers worldwide have tried hard to replace it with some other non-hazardous counterparts but failed to achieve similar optoelectronic properties. Disposal of hazardous waste is also a major issue because of its high expenses, so safe disposal becomes a major hurdle especially for the developing countries.¹ Cost analysis studies of similar architectures have shown that a major fraction (40-60%) of the total cost embedded is owned by fluorine doped tin oxide (FTO) substrate.² Other profound contributor to the cost of the technology is the expensive spiro-OMeTAD hole transporting layer, but a number of efficient alternatives to spiro-OMeTAD have been testified. Compact titanium dioxide (TiO₂) which serves as electron transporting layer though not much cost intensive but consumes a good amount of primary energy owing to its high sintering temperature requirement. In our work we have tried efficient recycling of the final decomposed product, which is PbI₂ back to perovskite. The reuse of same Pb and hence underneath TiO₂ and FTO layers will cut down the cost of the technology, decreasing the payback time even further. This work renders a comparative study of the feasibility of efficient recycling in three different fabrication routes i.e. single step mixed halide, single step acetate and sequential deposition route. We encountered that all the films cannot be recovered expeditiously, which was corroborated from the XRD spectra. XRD spectra elucidated that the degraded sequentially deposited films cannot be completely recovered back to methyl ammonium lead iodide perovskite on incorporation of methyl ammonium iodide. Degraded sequentially deposited films have shown drastically improved crystallinity, which if somehow can be converted back to perovskite completely will result in altogether superior optoelectronic properties. Films deposited via single step acetate and sequentially deposition route has shown efficient recovery of optoelectronic properties as compared to single step mixed halide route, as ascertained from the steady state photoluminescence. Absorption spectra recorded have shown the recovery of the characteristic wide absorbance range back upon recycling. Reusing the same Pb multiple times without compromising with the optoelectronic properties will move the technology a step ahead in the path of commercialization.

Characteristics of Lead Iodide Deposited by Sputtering Method and Perovskite Preaparred from the Sputtered Lead Iodide WonKyu Lee1, Sang-Won Lee1, Jae-Keun Hwang1, Solhee Lee1, Soohyun Bae1, Yoonmook Kang2,3, Hae-Seok Lee2,1 and Donghwan Kim1,2; 1Korea University, Korea (the Republic of); 2KU-KIST Green School, Korea (the Democratic People's Republic of)

Perovskite solar cell shows great possibilities for the solar power field as exhibiting uprising power conversion efficiency from 3.81% to 23.7%. Recent study has been focused on how to get market competitiveness between other solar cells. Those attempts include deposition of perovskite on texture and large-area substrate such as textured silicon.
Perovskite layer has been mainly deposited on mesoporous or compact layer by spin-coating perovskite solution on substrate. Spin-coating method has its limitation in deposition on textured, large-area surface. It also uses a poisonous solvent such as dimethylformamide, dimethyl sulfoxide. Other deposition methods such as evaporation, electroplating and slot die coating have also been proposed as methods for depositing perovskite layer. To obtain conformal and uniform layer of perovskite material on a large-scale and textured substrate, radio-frequency (RF) magnetron sputtering can be used to deposit a uniform lead iodide film on the substrate first. Conformal perovskite layer can be prepared by sequentially interacting the lead iodide film with methylammonium iodide (MAI). Lead iodide deposited through sputtering shows uniformly packed and conformal films on planar or textured substrate. RF magnetron sputtering is competitive with other deposition methods because highly uniform and conformal lead iodide films can be deposited on textured and large-area substrate and mass production is available. Unlike evaporation method, it does not need high temperature environment hindering coating film on flexible substrate.

In this study, lead iodide films were deposited by RF magnetron sputtering. Uniform and dense lead iodide films are obtained on a 1.5 cm x 1.5 cm FTO-glass substrate coated with c-SnO2. Characteristics of film deposited under various sputtering conditions were analyzed and compared with conventional spin-coated lead iodide film. Lead iodide films deposited using same method on textured silicon were also investigated. Perovskite layer are prepared by loading certain amount of MAI solution on sputtered lead iodide films. The effect of loading time and concentration of MAI solution on formation of perovskite layer were studied. Several measurement methods were used including X-ray diffraction method, Raman spectroscopy, X-ray photoelectron spectroscopy, Ultraviolet-visible spectroscopy, Transmission electron microscopy and Atomic force microscope.

EN08.06.25

New Techniques to Extract Local Performance Parameters in Metal-Halide Perovskite Solar Cells Kyle Frohna, Miguel Anaya and Samuel D. Stranks; University of Cambridge, United Kingdom

Polycrystalline metal-halide perovskite thin films share many optoelectronic properties of their high quality, inorganic semiconductor counterparts. However, local heterogeneity of the perovskite has been shown to limit device performance. [1] Fundamental semiconductor properties such as the quasi-Fermi level splitting (QFLS), absorptance, Urbach energy and photoluminescence quantum efficiency (PLQE) energy are important metrics that determine the upper bound efficiency of solar cells made with these materials, however complete microscale measurements of these properties in perovskites have not been performed. While photoluminescence mapping is common in the field, confocal illumination and collection geometries are often employed which necessitates much higher illumination intensity and real effects can be masked by carrier diffusion away from the illuminated area. [2, 3] Wide-field illumination microscopy, where the entire imaged area is illuminated simultaneously, enables microscopy at solar cell relevant carrier densities. This technique has been used to investigate the local QFLS in perovskites, [4] and in other thin film technologies such as CIGS. [5]

Here we use a wide-field illumination, spectrally and spatially calibrated microscope to study thin films of MAPbI3 and triple cation perovskites (Cs0.05FA0.79MA0.16Pb(I0.83Br0.17)3) at 1 sun equivalent illumination intensities. We develop novel methods to measure absolute reflectance, transmittance and absorptance spectra of these films in addition to absolute-intensity calibrated photoluminescence spectra with diffraction limited resolution. Correlating these spectra allows the extraction of local QFLS, Urbach energy and PLQE. We examine local spatial correlations between these properties in order to test the assertions of detailed-balance at the scale of individual grains. The results reveal considerable microscale heterogeneity in many fundamental, device relevant parameters that, on average, match with macroscale observations. We see grain to grain heterogeneity in the emission, but also larger scale heterogeneity over clusters of tens of grains. Strikingly we find local PLQE variation by up to an order of magnitude. We also use the technique to identify the most effective defect passivation treatments to our films resulting in enhanced device performance. Finally, we note the potentially wide applicability of these methods to a broad range of other emerging semiconductor technologies.

EN08.06.26
Impact of Partial Pb\textsuperscript{2+} Substitution on Photostability and Photovoltaic Performance of APbX\textsubscript{3} Perovskites
Marina Ustinova\textsuperscript{1}, Nadezda Dremova\textsuperscript{2}, Keith J. Stevenson\textsuperscript{1} and Pavel Troshin\textsuperscript{1,2}; \textsuperscript{1}Skolkovo Institute of Science and Technology, Russian Federation; \textsuperscript{2}Institute for Problems of Chemical Physics of RAS, Russian Federation

Perovskite solar cells represent one of the most promising photovoltaic technologies. Over the past few years, the performance of perovskite solar cells was gradually improved up to >23%, which is close to the characteristics of crystalline silicon photovoltaics. However, high toxicity and low stability of complex lead halides used as absorber materials hamper commercialization of this technology. The compositional engineering of lead perovskites was actively pursued in order to improve their stability and/or performance. In particular, a partial or full replacement of Pb\textsuperscript{2+} in MAPbI\textsubscript{3} is highly desirable in terms of developing more environmentally friendly materials. Here we present a systematic study of lead substitution in MAPbI\textsubscript{3} with >20 different cations introduced in atomic concentrations ranging from 10\textsuperscript{-5} to 20\textsuperscript{-30%}. It was shown that replacing even minor fraction of lead could change significantly the perovskite film crystallinity and morphology. Importantly, the efficiency and stability of p-i-n and n-i-p perovskite solar cells were improved considerably by appropriate modification of MAPbI\textsubscript{3} films. Moreover, important relationships were established between the nature of the substituting ions (e.g. ionic radius or charge) and their effects on electronic properties and photovoltaic performance of the resulting hybrid perovskites. The obtained results should facilitate the rational design of more stable and less toxic absorber materials for advanced perovskite solar cells.

Degradation of Hybrid Perovskite Absorber Layers from an Optical Perspective—An Ellipsometry Study
Sven Peters\textsuperscript{1}, Álvaro Tejada Esteves\textsuperscript{1,2,3}, Amran Al-Ashouri\textsuperscript{2}, Silver H. Turren Cruz\textsuperscript{2}, Nga Phung\textsuperscript{2}, Antonio Abate\textsuperscript{2}, Steve Albrecht\textsuperscript{2}, Florian Ruske\textsuperscript{2}, Lars Korte\textsuperscript{2} and Jorge A. Guerra Torres\textsuperscript{3}; \textsuperscript{1}SENTECH Instruments GmbH, Germany; \textsuperscript{2}Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; \textsuperscript{3}Pontificia Universidad Católica del Perú, Peru

Organic-inorganic hybrid perovskites are a class of semiconducting materials with great potential for solar cell absorbers. This is due to their high absorption coefficients, tunable direct bandgap, demonstrated high power conversion efficiencies in devices, and disruptively low manufacturing costs. However, they are currently limited by their tendency to degrade under strong (UV-)illumination, and elevated temperatures, both critical issues for a photovoltaic material. While these degradation effects have been widely reported in their electrical behavior, there is comparatively little information on the effects on their optical constants, the refractive index and absorption coefficient.

In this work we investigate the changes in optical constants of a variety of device relevant multi-cation perovskite compositions under the effects of UV light soaking and high temperatures. The compositions investigated include the widely used triple cation perovskite (Cs\textsubscript{0.05}(MA\textsubscript{0.17}FA\textsubscript{0.83})\textsubscript{0.95}Pb(Br\textsubscript{0.17}I\textsubscript{0.83})\textsubscript{3}), Rb-stabilized and methylammonium-free compositions (Rb\textsubscript{0.05}Cs\textsubscript{0.05}(MA\textsubscript{0.17}FA\textsubscript{0.83})\textsubscript{0.90}PbI\textsubscript{3}, Rb\textsubscript{0.05}Cs\textsubscript{0.10}FA\textsubscript{0.85}PbI\textsubscript{3}), as well as MAPbI\textsubscript{3} for comparison. UV light soaking was performed with a Xe lamp in air, and heating was done in a high temperature stage with nitrogen purging at 100°C and 120°C. The optical measurements were carried out using Variable Angle Spectroscopic Ellipsometry in the wide wavelength range of 190 nm – 25 μm, from the UV to the Middle Infrared (MIR). We demonstrate that it is possible to observe degradation effects around the bandgap and high absorption regions, which are of interest for solar cell performance, while changes in chemical composition can be observed at the same time through the MIR absorption bands.

A variety of behaviors were observed with increasing degradation time under both UV and heat exposure. The most recurring was a rapid loss of methylammonium ions from the film. This was visible as a reduction of IR peaks associated to methylammonium and a decrease in film thickness, which was confirmed by SEM imaging. IR peaks related to formamidinium ions also showed a decrease, but the rates were much lower. The loss of methylammonium was coupled with phase segregation and the formation of PbI\textsubscript{2} in the film: at energies above 2 eV, a superposition of the absorption coefficients of PbI\textsubscript{2} and the base perovskite was observed, with the bandgap of PbI\textsubscript{2}
clearly visible at 2.4 eV. Overall, the most UV stable composition was the standard triple cation perovskite, closely followed by the methylammonium-free \( \text{Rb}_{0.05}\text{Cs}_{0.10}\text{FA}_{0.85}\text{PbI}_3 \), which showed the best thermal stability.

**Synthesis and Characterization of Halide Hybrid Perovskites by Sequential Physical Vapor Deposition**  
Juvet N. Fru, Nolwazi Nombona and Mmantsae M. Diale; University of Pretoria, South Africa

Recently, the interest in low-cost hole-conduction-layer-free perovskite solar cells is growing rapidly due to the high-power conversion efficiencies (exceeding 17 \%) recorded [1]. Previous studies have reported that halide hybrid perovskites thin films produced a more stable and efficient hole-conduction-layer-free solar cell when compared with its non-hybrid halide perovskites components, owing to their excellent blend of light absorption and hole-conduction properties [2]. However, far too little attention has been paid to their synthesis by physical vapor deposition, which may further increase stability. Herein, a hybrid methylammonium lead tri-iodide/methylammonium lead tri-bromide (MAPbI\(_3\)/MAPbBr\(_3\)) perovskite thin film was prepared by sequential physical vapor deposition of MAPbBr\(_3\) on MAPbI\(_3\) thin film. The structural, optical, morphological and electrical properties of the MAPbI\(_3\), MAPbBr\(_3\), and MAPbI\(_3\)/MAPbBr\(_3\) thin films were compared. X-ray diffraction patterns confirmed the tetragonal crystal structure of MAPbI\(_3\), a cubical structure of MAPbBr\(_3\) and the two clearly separate phases for MAPbI\(_3\)/MAPbBr\(_3\) [3]. In addition, the crystallite sizes were observed to decrease from 32.74 to 22.06 nm while dislocation density increased from 9.33 x 10\(^{10}\) to 2.05 x 10\(^{11}\) cm\(^{-2}\) for MAPbI\(_3\), MAPbI\(_3\)/MAPbBr\(_3\), and MAPbBr\(_3\) respectively. UV-Vis absorption spectra revealed onsets of absorption for MAPbI\(_3\), MAPbI\(_3\)/MAPbBr\(_3\), and MAPbBr\(_3\) at 760, 628 and 550 nm respectively, which correspond to respective optical bandgaps of 1.63, 1.97 and 2.25 eV. Scanning electron microscopy micrographs depicted densely packed grains which fully covered the substrates, required to minimize leakage currents. Electrical properties showed that the trap densities increased from 2.56 x 10\(^{15}\) to 1.89 x 10\(^{16}\) cm\(^{-3}\) whereas the carrier mobilities decreased from 2.34 x 10\(^{-1}\) to 1.89 x 10\(^{-2}\) cm\(^2\) V\(^{-1}\) s\(^{-1}\) for MAPbI\(_3\), MAPbI\(_3\)/MAPbBr\(_3\), and MAPbBr\(_3\) respectively. This study introduces a facile way of growing hybrid halide perovskites thin films for efficient hole-transport-layer-free solar cells.

Keywords: Hybrid methylammonium lead tri-iodide/methylammonium lead tri-bromide; sequential physical vapor deposition; hole-conduction-layer-free solar cell.

**Reap-Rest-Recovery Cycle in Perovskites Solar Cells from the Macro- to the Nanoscale**  
John M. Howard, Richa Lahoti, Erica S. Lee and Marina S. Leite; University of Maryland, United States

To date, the primary limitation of perovskite solar cell is still related to device instability. Because intrinsic and extrinsic factors such as light, temperature, bias, humidity, and oxygen can all contribute to material degradation, we propose the use of machine learning (ML) as a strategy to identify the individual and combined contribution of each aforementioned factor through a reap-rest-recovery cycle, which will be discussed in details. Moreover, we will present the dynamic electrical and optical behavior of MAPbI\(_3\), MAPbBr\(_3\), and multi-cation perovskites (including Cs and Rb ions) by implementing environmental atomic force microscopy (AFM) and micro-photoluminescence (micro-PL) microscopy. In the realm of the perovskite’s electrical response, we use Kelvin probe force microscopy (KPFM) and photoconductive (pc-) AFM to map changes in voltage and current that occur upon submitting the devices to different light treatments. Through fast-KPFM we quantify, in real-time, a dynamic open-circuit voltage (Voc) response as a function of chemical composition, resulting from ion motion. Optically, we resolve the correlation between the luminescence response of the perovskites and its chemical composition by exposing the perovskites to different environments, including loops in relative humidity ranging from < 5\% to 55\%. Combined, our microscopy probes enable us to define the contribution of each stressor to device instability, elucidating their effects on the physical behavior of the grains and boundaries composing the perovskite solar cells.

**EN08.06.30**

**Route to Efficient and Stable Perovskite Solar Cell—Interfacial Modification and Defect Passivation**  
Alan
Understanding the degradation mechanisms and realizing high operational stability have become major issues in perovskite photovoltaics. Especially, recent researches point that stable perovskite solar cells can be enabled by controlling defects of conventional devices, as well as developing novel materials.[1,2] Herein, based on our comprehension upon the defect characteristics and analyses,[3,4] we introduce our approaches for efficient and stable perovskite solar cells via the development of materials and trap controls. Using copper thiocyanate (CuSCN) for the inorganic hole-transport layer, we suggest polydimethylsiloxane (PDMS) as a novel crosslinking material for the interlayer between perovskite and CuSCN, which brings the effect of interfacial modification and defect passivation. With its unique crosslinking behavior observed, PDMS mitigates the trap formation and enhances the charge extraction at the interface realizing thermally stable perovskite solar cells with high power-conversion efficiency over 19%. By extension, further modification on the hole-transport layer is applied in order to prevent degradation of electrode and ionic interdiffusion, the dominant factors deteriorating the device performance under light and applied bias. Embracing our recent research on the stability of perovskite solar cells, the correlation between the interfacial defects and device stability will be discussed, with future insights to realize highly stable and efficient perovskite solar cells.

EN08.06.31
Enhanced Near-Infrared Photoresponse of Inverted Perovskite Solar Cells Enabled by Rational Design of Electron-Transporting Layer Chih-I Chen and Chu-Chen Chueh; National Taiwan University, Taiwan

Organic-inorganic hybrid perovskites solar cell (PVSC) has received worldwide attention in the past decade. Its power conversion efficiency (PCE) has struck to 24.2% from 3.8% since its first debut in 2009. Even though the perovskite materials possess exceptional semiconducting properties, such as ambipolar charge-transporting capability, low exciton binding energy, long carrier diffusion length, their generally light-harvesting range is limited in the visible-light region, from 300 nm to 800 nm, which engender great loss in spectral while illumination pass through the device. The enhancement in near-IR (NIR) region usually could be attained by composition engineering but the results were not significant, on the other hand, it could also be reached through device engineering but the researches mostly focused on conventional configuration. Herein, we describe a simple and accessible method to enhance the NIR photoresponse of inverted PVSC by rational design of electron-transporting layer.

In general, fullerene is the most commonly used ETL for inverted PVSCs. However, owing to its symmetric geometry, the light absorption of fullerene is quite weak. Recently, low bandgap non-fullerene acceptor (NFAs) with NIR light absorption has been vigorously develop in the field of organic photovoltaics. As inspired by this impressive progress, we herein conceive a study to enhance the NIR response of inverted PVSC by engineering the fullerene ETL with NFAs with NIR light absorption. Owing to the low bandgap, the NFA can form type II charge transfer with fullerene to dissociate the photoexcitation induced by NIR absorption. However, our result manifests that such binary blend is not sufficient to enhance the NIR photoresponse of derived inverted PVSCs. The ETL consisting of PCBM and NFA blend could not convert any near-IR photons into resulting photocurrent, as evidenced by the corresponding EQE spectrum. Intriguingly, we demonstrated a strategy to efficiently intercept the near-IR light and convert the photons into current through further modification of this hybrid ETL with NIR absorbing capability. As a result, the optimized near-IR ETL can enable its derived inverted PVSC to possess an extended photoresponse from visible region to 950 nm and present 40% EQE in the NIR region, contributing to 8.4% of the overall photocurrent (22.5 mA/cm²). Combined with the high Voc of 1.15 V and decent FF of 70%, an inverted PVSC with a high PCE of 18.1% was finally demonstrated. Our study unveils an effective approach to enhance the NIR photoresponse of inverted PVSCs through simple design of compatible charge-transporting layer.

EN08.06.32
Hyperspectral Photoluminescence Imaging of Spatial Inhomogeneities in Multi- Cation and –Anion Perovskite Absorbers Aslihan Babayigit1, Derese Desta1, Laura-Isabelle Dion2, Nicolas Rivas Rivas1, Frank
Renner¹, Koen Vandewal¹ and Hans-Gerd Boyen¹; ¹Hasselt University, Belgium; ²Photon Etc., Canada

Metal halide perovskites have witnessed a remarkable growth in efficiency that has yet to be recorded for any other photovoltaic technology to date (1). At the heart of these high performances lie exceptional material properties, which only in the recent years have started to be studied more profoundly alongside research efforts focusing on boosting the efficiency. An aspect attracting particular recent interest in this respect has been the significant impact of low fractional Cs substitution of the composition and the addition of sacrificial additives containing elements such as Rb, K and Na on the stability and/or performance of perovskite solar cells (2,3). Already clearly linked to effects such as halide homogenization in the light harvester, there are also strong indications that these compounds have an influence on crystallographic and phase intermediates of the soft and forgiving semiconductor (2,3,4). In an attempt to unravel the mechanism underlying the effect of these operations, this work studies the spatial photoluminescence of multi-cation and –anion perovskites by hyperspectral imaging. We demonstrate that sacrificial and substitutional compounds result in the elimination of distinct domains with varying intensities and emission maxima, which cannot be correlated to compositional inhomogeneities. Instead, we link this observation to effects inherent to the deposition method used to fabricate the absorber, and hypothesize that the observed results are due to strain effects in the semiconductor grains (5). In addition, we also elaborate on the stability of these PL inhomogeneities in terms of exposure to circumambient atmosphere, and reflect on their potential effects in corresponding devices.

Electronic Structure Analysis of an Organometallic Halide Perovskite via Photoemission Yield Spectroscopy in Air for Stability Study Daisuke Yamashita¹, Yoshiyuki Nakajima¹, Satoshi Uchida² and Hiroshi Segawa²; ¹Riken Keiki Co., Ltd, Japan; ²The University of Tokyo, Japan

An open counter [1] is a unique detector that can operate in air at atmospheric pressure to detect and count a small number of low-energy photoelectrons. Therefore, photoemission yield spectroscopy in air (PYSA) can be performed by employing an open counter as the detector [2]. PYSA has the unique advantage of measuring high energy-resolution and low photo-excitation energies in a non-vacuum environment. After the commercial model was released, it was used to analyze industrial materials, e.g., semiconductors, organic photoconductors, toners, organic light-emitting diodes, and magnetic disk drives. Furthermore, the successive change on the practical surfaces, such as fresh Al surface exposed to air [3], has been successfully observed.

PYSA measurement was performed as follows. UV light emitted from a deuterium lamp was monochromatized using a grating monochromator, which was then focused on the sample surface. The number of photoelectrons emitted from the sample surface was counted using an open counter.

In recent years, PYSA has been applied to measure halide perovskites [4, 5]. Last year, we proposed a novel PYSA measurement technique and examined the change in the threshold energy of photoemission, which corresponds to the first-ionization potentials, at approximately the phase transition temperature of CH3NH3PbI3 [6]. Here, we discuss the applicability of PYSA for evaluate the long-term stability of halide perovskites.

EN08.06.35
Spatial Correlation of Organolead Halide Perovskite Nanocrystals Photoblinking and Photodegradation by Single-Particle Photoluminescence Microscopy Juvinch R. Vicente\textsuperscript{1,1,2} and Jixin Chen\textsuperscript{1,1}; \textsuperscript{1}Ohio University, United States; \textsuperscript{2}University of the Philippines- Visayas, Philippines

Organolead halide perovskites (OHP) have emerged as a promising material for applications in photovoltaics, LEDs and light detectors. This group of materials offers the simplicity of wet-chemistry methods while keeping competitive optoelectronic properties. However, photodegradation of OHPs especially under ambient conditions and high intensity illumination has been a significant bottleneck for its commercialization. Although the actual mechanism for this detrimental phenomenon is still under debate, the role of surface defects has been proposed. Recently, the presence of these surface defects has also been associated to the stochastic photoblinking of OHP nanocrystals. Employing super-resolution localization methods, we were able to estimate the spatial distribution of these surface defects along a single OHP nanocrystal. We then deliberately expose the particles at elevated light intensity and ambient conditions and observe the spatial evolution of its photodegradation and correlated it with the estimated localization of surface defects.

EN08.06.36
Design of Structures in Lead Halide Perovskite Solar Cells by Optimizing Interfacial Charge Transfer and Transport Dynamics Yasuhiro Tachibana\textsuperscript{1,2}; \textsuperscript{1}RMIT University, Australia; \textsuperscript{2}Osaka University, Japan

Perovskite solar cells have been recognized as a newly emerging solar cell with the potential of achieving high efficiency with a low cost fabrication process. In particular, facile solution processed cell fabrication facilitated rapid development of optimum cell structure and composition. Over the last few years, the cell efficiency has exceeded 23%.

A typical perovskite solar cell employs a perovskite layer sandwiched by p-type semiconductor (such as spiro-OMeTAD, PEDOT or NiO) and n-type semiconductor (such as TiO\textsubscript{2}, ZnO or PCBM) layers. Following light absorption, an electron and a hole are separated at the perovskite film interface, and are collected at the back electrodes. Choice of the most suitable solar cell structure is crucial to improve the performance further. In this presentation, we will present parameters controlling charge separation and recombination dynamics at the perovskite interfaces employing a series of transient absorption and emission spectroscopies. Nanosecond transient emission spectroscopy (Vis-ns-TES) clarifies charge separation processes, while Vis-NIR submicrosecond-millisecond transient absorption spectroscopies (VisNIR-smm-TAS) identify charge separation efficiency and charge recombination rates. The mechanisms of interfacial charge transfer and recombination processes have been clarified. Correlation of the dynamics results with the solar cell performance will be discussed [1-4]. An optimum cell structure for methylammonium lead iodide (MAPbI\textsubscript{3}) perovskite sandwiched by TiO\textsubscript{2} and spiro-OMeTAD layers, among planar heterojunction, mesoporous structure and extremely thin absorber structure will be identified. The method to determine the best structure will be applied to a different type of semiconductor.

This work was financially supported by the JST PRESTO program (Photoenergy Conversion Systems and Materials for the Next Generation Solar Cells) and partly by JSPS KAKENHI Grants (16K05885) and (19H02813) and the Collaborative Research Program of Institute for Chemical Research, Kyoto University (grant number 2019-50), Japan. The author also acknowledges Australian Research Council (ARC) LIEF grant (LE170100235) and the Office for Industry-University Co-Creation, Osaka University, for the financial supports.

Hight throughput Fabrication of Efficient Perovskite Solar Modules and Tandem Solar Cells
Jinsong Huang; University of North Carolina at Chapel Hill, United States

The efficiencies of small-pixel perovskite photovoltaics have increased to well above 20%, while the question is whether fabrication methods can be transferred to scalable manufacturing process. Here we report a method of fast blading large area perovskite films at an unprecedented speed of 99 millimeter-per-second or higher in ambient condition by tailoring solvent coordination capability. Combining volatile non-coordinating solvents to Pb2+ and low-volatile, coordinating solvents achieves both fast drying and large perovskite grains at room temperature. The reproducible fabrication yields a record certified module efficiency with aperture area of 63.7 cm². The perovskite modules also show a small temperature coefficient of -0.13%/°C and nearly fully recoverable efficiency after 58 cycles of shading, much better than commercial silicon and thin film solar modules. The application of the coating method to perovskite/silicon tandem cells and will also be presented. We will answer the question whether the perovskite layers can be fabricated at the speed of silicon cells are produced in the regular production lines.

Correlating the Performance of Perovskite/Silicon Tandem Solar Cells with Their Nanostructure

Crystalline Si (c-Si) solar cells are driving the progression of renewable electricity generation technologies thanks to lowering costs and increasing efficiencies. One solution to maintain this cost-competitiveness on the long-term involves increasing efficiencies beyond the limit of c-Si by stacking a perovskite solar cell on a commercial c-Si one to form a photovoltaic tandem device. The tunable bandgap, soft processing conditions and high single-junction performance of perovskites indicate that this approach could upgrade c-Si solar cells to efficiencies >30% through a few extra process steps with low additional process costs.

For maximum photocurrent and compatibility with existing c-Si process flows, the perovskite solar cell should be deposited directly on the textured front side of the c-Si solar cell, a texture that improves light management in the c-Si. But this pyramidal texture imposes several microfabrication challenges as the perovskite absorber is typically deposited via solution processing, and is about one order of magnitude thinner than the height of the pyramids it needs to cover. Achieving a conformal deposition of all the layers on the top cell on this pyramidal texture and hence maximum performance requires a fine control over the layer formation to avoid pinhole formation.

In that regard, electron microscopy techniques, notably analytical transmission electron microscopy (TEM), can shed some light on the device nanostructure and its dependence on processing/operation conditions, guiding the development of devices. However, the fragile nature of perovskite solar cells complicates their preparation into thin cross-sections necessary for TEM observations and their analysis with high-energy electrons. This presentation will review artifacts that may occur during TEM sample preparation and observation, elaborate several strategies to identify and mitigate them, before discussing several topics correlating nanostructure and performance of perovskite single-junction and tandem solar cells. This contribution will present how electron microscopy data coupled with other techniques provide valuable inputs to guide the development of high-efficiency (>25%) tandems featuring textured n- and p-type c-Si solar cells1,2, notably by i) identifying optimal bottom cell contact nanostructures, ii) isolating crystallographic and chemical features enabling the recombination junction to quench shunts,2 iii) guiding
the removal of shunts running through the perovskite absorber on textured c-Si by adapting process conditions and iv) visualizing the dewetting of charge-selective layers during the crystallization of the perovskite solar cell on certain recombination junctions. In addition, degradation pathways triggered by reverse voltages (also investigated through TEM in situ biasing experiments) during long-term operation at maximum power point at various temperatures, or during damp heat tests (85°C/85% relative humidity) will be examined. These results highlight the dynamic nature of the perovskite nanostructure (ionic migration within the absorber and into the contacts, volatilization of species, crystallographic phase change/decomposition) depending on the external stimuli and its influence on the solar cell performance.

Towards Highly Efficient Monolithic Tandem Devices with Perovskite Top Cells Steve Albrecht1,2, Marko Jost1, Eike Köhnen1, Amran Al-Asghouri1, Lars Korte1 and Bernd Stannowski1; 1Helmholtz-Center Berlin, Germany; 2Technical University of Berlin, Germany

Integrating metal halide perovskite top cells with crystalline silicon or CIGS bottom cells into monolithic tandem devices has recently attracted increased attention due to the high efficiency potential of these cell architectures. To further increase the tandem device performance to a level well above the best single junctions, optical and electrical optimizations as well as a detailed device understanding of this advanced tandem architecture need to be developed. Here we present our recent results on monolithic tandem combinations of perovskite with crystalline silicon and CIGS, as well as tandem relevant aspects of perovskite single junction solar cells.

By selecting a front contact layer stack with less parasitic absorption and utilizing the p-i-n perovskite top cell polarity, a certified conversion efficiency of 25.0% for a monolithic perovskite/silicon tandem solar cells was enabled. Further fine-tuning of the stack optics as well as contact layers improved the efficiency to 26.0% (0.8 cm² area) and we present how especially the fill factor of highly efficient tandem solar cells behaves under current-mismatch conditions. In strong mismatch the FF of the tandem cell is enhanced which reduces the sensitivity of efficiency to spectral mismatch. Additionally, the introduction of light trapping foils with textured surfaces is presented together with the influence on texture position on lab performance and outdoor energy yield.

The monolithic combination of perovskite and CIGS was highly challenging up to now as the CIGS surface is rather rough. By implementing a conformal hole transport layer, an 21.6% efficient monolithic perovskite/CIGS tandem (0.8 cm² area) was realised. Absolute photoluminescence of the perovskite and CIGS sub-cells gives insights into the contributions to the tandem open-circuit voltage (Voc). To further improve the tandem efficiency, the Voc of perovskite top cells needs to be enhanced via reduction of non-radiative recombination at the interface between perovskite and the charge selective layers. This can either be done via proper interlayers or via fine-tuned charge selective contacts.

Recently we have shown that self-assembled monolayers (SAM) could be implemented as appropriate hole selective contacts. The implementation of new generation SAM molecules enabled further reduction of non-radiative recombination losses with Voc’s up to 1.19 V and efficiency of 21.2% for p-i-n perovskite single junctions with band gaps of 1.63 eV and 1.55 eV, respectively.

Efficient and Stable Wide-Bandgap Perovskite Solar Cells for Tandem Solar Cell Applications Yanfa Yan; University of Toledo, United States

Wide-bandgap (~1.7-1.8 eV) perovskite solar cells have attracted substantial research interest in recent years due to
their great potential to fabricate efficient tandem solar cells via combining with a lower bandgap (1.1-1.3 eV) absorber (e.g., Si, copper indium gallium diselenide, or low-bandgap perovskite). However, wide-bandgap perovskite solar cells usually suffer from large open circuit voltage ($V_{oc}$) deficits caused by small grain sizes and photoinduced phase segregation. We show that in addition to large grain sizes and passivated grain boundaries, controlling interface properties is critical for achieving high $V_{oc}$’s in the inverted wide-bandgap perovskite solar cells. We adopt guanidinium bromide solution to tune the effective doping and electronic properties of the surface layer of perovskite thin films, leading to the formation of a graded perovskite homojunction. The enhanced electric field at the perovskite homojunction is revealed by Kelvin probe force microscopy measurements. This advance enables an increase in the $V_{oc}$ of the inverted perovskite solar cells from an initial 1.12 V to 1.24 V. With the optimization of the device fabrication process, the champion inverted wide-bandgap cell delivers a power conversion efficiency of ~19% and sustains more than 72% of its initial efficiency after continuous illumination for 70 h without encapsulation. The improvement on performance of wide-bandgap perovskite subcells enables us to fabricate efficient and stable perovskite tandem solar cells.

Tuning the Composition of Metal Halide Perovskites and Passivating Their Surfaces for Tandem Applications

Michael D. McGehee1,2; 1University of Colorado, United States; 2National Renewable Energy Laboratory, United States

The record power conversion efficiency is 28 % for perovskite-silicon tandems and 23.2 % for perovskite-perovskite tandems. One of the challenges that must be overcome to achieve efficiency greater than 30% is to reduce the voltage loss in high bandgap perovskite cells and prevent light-induced phase separation. We have found that treating the surface of perovskites can dramatically reduce the extent of light-induced phase separation, which has interesting implications for how the process occurs. We have also developed new strategies for increasing the bandgap in perovskite compounds that have modest amounts of bromine. We have been able to make semitransparent high bandgap solar cells with greater than 20% power conversion efficiency that do not suffer from light-induced phase separation. These advances in combination with improvements in the atomic layer deposition of highly impermeable metal oxide contacts enable the fabrication of highly efficient and stable tandems.

Tracking Photo and Thermally Driven Halide Ion Movement in Metal Halide Perovskites

Prashant Kamat and Tor Elmelund; University of Notre Dame, United States

Halide ion mobility in metal halide perovskites plays an important role in determining the performance of perovskite solar cells. For example, the high ionic conductivity in MAPbI3 compared to the electronic conductivity along with high native ionic disorder leads to the trapping of the electronic carriers. The intrinsic ionic defects, specifically halide ion vacancies, often dictate the mobility of halide species within the perovskite film during the operation of solar cells. Whereas entropy of mixing explain the thermally activated mixing of halide ions to yield mixed halide perovskite, an opposite trend is observed when the mixed halide film is subjected to photoirradiation. This process, commonly referred as photoinduced phase segregation or halide segregation, yields Br-rich and I-rich perovskite domains. The interesting part is the total recovery when the film is left in the dark as thermal activation drives back to original composition. Formation of such Br-rich and I-rich domains severely affects the solar cell performance. The kinetic and thermodynamic arguments that explain the photoinduced halide segregation and dark recovery will be discussed.

2:00 PM EN08.08.02

Passivation Engineering for High Performance Perovskite Solar Cells

Damir Aidarkhanov1, Zhiwei Ren1,
The promising photovoltaic properties of organometallic halide perovskite based solar cells (PSCs) make it highly competitive with the existing solar technologies. Recently, the record power conversion efficiencies (PCEs) of 24.2 % for the single junction perovskite solar cell and 28 % for the monolithic perovskite/silicon tandem solar cell were reported. The rapid enhancement in device efficiency has attracted increasing attentions in the field of photovoltaics. Tremendous research efforts have been devoted to optimizing the performance of perovskite solar cells and increasing the device area to meet the criteria for future commercialization. Passivation engineering is an effective approach to enhance the stability and PCE of PSCs. In this work, we demonstrated effective passivation strategies for the bulk of mixed perovskite and the electron transport layer (ETL). Systematic experiments were conducted to investigate the electron transport materials (ETM) and their layer architecture. It is found that the SnO2 based ETM in a multilayer structure is superior in suppressing the $I-V$ hysteresis and enhancing the performance of PSCs due to the optimized morphology of the ETL and the passivation effects attributed to the presence of additional nanoparticles and thin films between the ETL/perovskite interface. The performance of PSCs can be further improved by incorporating a controlled amount of organic cross linker in the perovskite absorber. The experimental results obtained from photothermal thermal deflection spectroscopy, time resolved photoluminescence and scanning confocal microscopy show that an optimal amount of the organic cross linker can passivate the defect states in the bulk of mixed perovskite. However, excessive organic cross linkers will significantly lower the device performance of PSCs due to the generation of new defects and the insulating properties of the organic cross linker itself. A PCE of 19 % with negligible hysteresis can be achieved after careful optimizations of the perovskite absorber and material interfaces in PSCs. This work will provide useful information for the photovoltaic community to optimize the fabrication process of PSCs through the passivation engineering.

All-Vapor Processed Perovskite Thin Films by Close Space Vapor Transport Alexander Harding, Austin G. Kuba, Brian McCandless, Ujjwal Das, Babatunde Ogunnaike and William Shafarman; University of Delaware, United States

As the stability and efficiency of perovskite solar cells improve, methods for scaling laboratory performance to industrial production are increasingly sought after. Current efforts focus primarily on transferring the chemistry of spin-coating to high-throughput, continuous processes. However, perovskites are also compatible with vapor-processing, meaning that established thin film PV manufacturing methods could be used to address scale-up challenges. For instance, First Solar’s Vapor Transport Deposition (VTD) process has made CdTe the dominant thin film PV on the market; and VTD is particularly appealing for perovskites due to its high-throughput, dry processing and its highly efficient use of toxic material.

Here, an all-vapor process for CH$_3$NH$_3$PbI$_3$ perovskite deposition using close-space vapor transport (CSVT) is described, and its viability as a fabrication route is confirmed. The film is formed in a 2-step process with deposition of a PbI$_2$ precursor layer followed by its reaction in CH$_3$NH$_3$I vapor. A pilot C SVT reactor was designed and constructed with control of critical process variables including: source temperature, substrate temperature, system pressure, carrier gas flow rate, and the distance between the source and the substrate. As a result, a range of deposition rates, reaction rates, mass transport regimes, and morphologies are accessible which can be used to improve device performance.

Films of PbI$_2$ were deposited on CdS/ITO/SLG substrates in low vacuum at pressures ranging from 1 to 10 torr. CdS was chosen as the electron-selective contact due to its favorable band alignment with CH$_3$NH$_3$PbI$_3$ and its low-temperature, robust processing through chemical surface deposition. Temperatures, pressures, and deposition times were optimized for deposition of 200 nm films of PbI$_2$. At a source temperature of 260 °C, substrate temperature of 215 °C, and pressure of 1 torr, full coverage of the CdS substrates at the 200 nm target thickness was achieved after a 20 min deposition. Control of morphology and crystallinity in highly-oriented PbI$_2$ films was demonstrated, and their dependence on processing conditions will be described.

For the 2nd processing step, PbI$_2$ films were reacted with CH$_3$NH$_3$I vapor by CSVT to form CH$_3$NH$_3$PbI$_3$. 

Final Program 1/13/2020 808
Temperature was found to have a significant effect on the rate of reaction and control of film morphology. At 160 °C, complete conversion from PbI$_2$ to CH$_3$NH$_3$PbI$_3$ is achieved within 10 min, but the CH$_3$NH$_3$PbI$_3$ grains coalesce at this temperature, leaving the CdS substrate exposed in the form of large pinholes. On the other hand, at 100 °C reacted films are pinhole-free with full surface coverage, but they require 150 min for complete conversion.

While isothermal reactions at 100 and 160 °C produced single-phase perovskites, reactions with a temperature gradient between the source and substrate promoted the formation of uncharacterized secondary phases. A brief rinse in isopropanol removes these phases, leaving behind only single-phase tetragonal CH$_3$NH$_3$PbI$_3$. The structure and composition of these secondary phases are under investigation, but it is possible that the temperature gradient promotes CH$_3$NH$_3$I deposition which drives an alternate chemical reaction.

Devices with CSVT CH$_3$NH$_3$PbI$_3$ films were completed with spin-coated, hole-selective spiro-OMeTAD and evaporated gold back contacts, and a 12.1% efficient cell with $V_{OC} = 980$ mV, $J_{SC} = 21.9$ mA/cm$^2$, and FF = 56.6% was measured. This result demonstrates the viability of CSVT as an all-vapor processing method for perovskite solar cells.

Ingenious and Multifunctional Synthesis Approach of In:CuCrO$_2$ nanoparticles for Highly Performed Perovskite Solar Cells Wallace C. Choy$^1$, Boping Yang$^2$ and Dan Ouyang$^1$; $^1$University of Hong Kong, China; $^2$Yancheng Institute of Technology, China

When there is no clear study of doped ternary metal oxide for efficient hole transport layers (HTL), we propose the ingenious and multifunctional synthesis approach of In doped CuCrO$_2$ nanoparticles (NPs) HTL including simplifying the synthesis requirements, enabling doping and achievement treatment-free HTLs. To be more specific, we demonstrate an azeotropic promoted approach (APA) to synthesize In doped CuCrO$_2$ nanoparticles (NPs) [1]. Remarkably, compared with the conventional method for synthesizing CuCrO$_2$ NPs, the reaction time is dramatically shortened by 90% and the calcination temperature is lowered by one-third, which not only promote the high throughput production but also reduce power consumption and cost in synthesis. Equally important, we successfully dope Indium into CuCrO$_2$, which is fundamentally difficult to low temperature process. The In doping offers less d-d transition of Cr$^{3+}$ and p-type doping characteristics for improving the transmittance and conductivity of the hole transport layer (HTL) respectively. Interestingly, the In doped CuCrO$_2$ HTL with these improvements can be achieved by simple ambient condition process and exhibits thermal stability up to 200 °C, which is beneficial for realizing highly performed perovskite solar cells (PSCs). Our results show that PSCs with the power conversion efficiency (PCE) of 20.54 % has been achieved with higher short-circuit current density ($J_{SC}$) and fill factor (FF) than that of the control PSCs with pristine CuCrO$_2$ NPs. Meanwhile, the devices show good repeatability and photostability. Consequently, we demonstrate an effective approach for realizing efficient HTL from the synthesis of material all the way to film formation featuring with substantial simplification of in synthesis conditions of In doping CuCrO$_2$ NPs to treatment-free high-quality film process for favoring the practical applications of highly performed PCSs.

High Efficient and Stable Organic Inorganic Hybrid Perovskite Solar Cells by Modulating Triple B Cations Using Ge-Pb-Sn Gyu Min Kim and Tsutomo Miyasaka; Toin University of Yokohama, Japan

With the development of compositional engineering, the power conversion efficiencies (PCE) and air stabilities of organic-inorganic hybrid perovskite solar cells (OlHPs) have been greatly improved. Triple A cations of Cs, MA and FA are the most popular compositions used in OlHPs recording high PCEs over 22%. Different from the modulation of cations in A site, manipulation of cations in B site is relatively limited compared to the cations in A site due to the quite unstable properties of elements used in B site such as Ge and Sn. Recently, the use of Ge$_2$I$_4$ in perovskite solar cells was reported to improve the PCEs and efficiencies of cells. However, Ge-Pn or Ge-Sn systems
were mainly focused on inorganic based perovskite solar cells because of extremely poor stability of GeI$_2$ when organic cations in A site such as MA and FA are used, leading to poor electronic performances. We found out that the incorporation of MACl in the precursor significantly improves the solubility of GeI$_2$ in the precursors. Based on this fact, the triple B cations composed of Pb-Sn-Ge were used in OIHPs based on organic A cations composed of MA and FA. As a result, general optoelectronic properties were improved with high Jsc and Voc leading to superior PCEs.

4:15 PM EN08.08.06
Towards Industrialization of Perovskite Solar Cells Using Slot Die Coating Anand Verma$^1$, David Martineau$^2$, Jakob Heier$^1$, Rene Schneider$^1$, Frank Nuesch$^1$ and Toby Meyer$^2$; $^1$Empa, Switzerland; $^2$Solaronix, Switzerland

Perovskite solar cells are the fastest developing solar cell technology till time. In a short span of time, power conversion efficiencies exceeding 23% in laboratory cells were reported by different research groups, hereby challenging existing dominant photovoltaic technologies. The focus of PeroPrint and the follow up project Upero-fundied by the Swiss Federal Office for Energy is to develop perovskite solar cells with high efficiency, using industrially relevant printing and coating techniques. The layered architecture of perovskite solar cells, as well as the ability of raw materials to disperse and dissolve into inks, opens the doors for solution processing of the cells. On the other hand, printing and coating technologies are large area deposition methods, which can drastically reduce production costs, especially when performed under ambient conditions. This is contrary to existing industrial photovoltaic products, which rather employ energy and waste intensive manufacturing techniques, such as high-purity ingot growth or vacuum deposition. The latter techniques also require huge capital expenditure to get production plants up and running at a profitable scale, a domain where simpler printing and coating techniques could lower the entry barrier to production.

In this project, we were able to develop novel inks to efficiently slot die coat the full stack of carbon based monolithic perovskite solar cells (Glass/FTO/compact TiO$_2$, mesoporous TiO$_2$, mesoporous ZrO$_2$, carbon with infiltrated MAPbI$_3$ into the porous structure) with power conversion efficiencies exceeding 12% for a large area cell. Here we also demonstrate an inventive co-firing method to fabricate monolithic perovskite solar cells where only one high temperature step is required in comparison to four reported till time for this architecture, thus reducing the fabrication time from 14 hours to 3.5 hours. We also demonstrate high shelf-life of the slot die coated cells exceeding 1 year when stored under ambient condition without any encapsulation.

4:30 PM EN08.08.07
Thermal Stability and Degradation Mechanism of Halide Perovskites Arising from Interaction with Oxide Transport Layer Materials Sampreetha Thampr, Boya Zhang, Weijie Xu and Julia W. Hsu; The University of Texas at Dallas, United States

Long-term stability has been a key challenge towards commercialization of organic-inorganic metal halide perovskite solar cells despite their high-power conversion efficiency and low-cost. To enable improvements in stability, it is of paramount importance to understand the chemical processes that could trigger degradation and the associated reaction pathways within the perovskite as well as its interaction with other materials. To this end, we employ temperature programmed desorption (TPD) and Fourier transform infrared (FTIR) spectroscopy techniques to study the thermal stability and decomposition of organic halide precursors (e.g. methylammonium (MAX), formamidinium (FAX), X = I, Cl, Br) and halide perovskites by themselves, as well as when they are in contact with metal oxide materials used as transport layers. In our experiments, the powder sample is heated with a controlled rate at atmospheric pressure. The gases evolved during heating from desorption, reaction, or decomposition are carried using an inert gas to a mass spectrometer and FTIR connected inline with the furnace and are simultaneously analyzed. The composition of these released gases as a function of temperature enables direct deduction of the thermal processes and helps elucidate the reaction steps involved in the degradation mechanism. Using this approach, we determine that the decomposition of MAI (CH$_3$NH$_3$I) proceeds via the formation of CH$_3$I and NH$_3$ above 250 °C. However, when MAI is mixed with NiO, the decomposition temperatures lowers to 175 °C with release of CH$_3$NH$_2$ and H$_2$O. Although, both NiO and SmO$_2$ reacts with MAI, NiO is found to be more reactive, consistent with n-i-p devices with SnO$_2$ are more stable than p-i-n devices with NiO. Studies will also be performed on other halide precursors, halide perovskites, and other commonly used metal oxide transport layer materials. These studies provide fundamental knowledge that will facilitate the choice of suitable perovskite and transport layer materials and processing conditions to further engineering of perovskite solar cells with enhanced stability.
Clean Production of Plastic Perovskite Solar Cell from Aqueous Lead Nitrate Tzu-Chien Wei; National Tsing Hua University, Taiwan

Lightweight, plastic photovoltaic (PPV) devices are attractive renewable energy devices because they can be fabricated using high-throughput printing process and they enable the possibility to use solar power on curved surfaces. Generally, the power conversion efficiency (PCE) of a PPV is lower than that of its rigid counterpart, primarily owing to the limitations of the low thermal budget of plastic substrates. Apart from this problem, its flexibility is, ironically, another troublesome factor that causes PCE low due to insufficient light capture from its thin absorbing layer. Perovskite solar cells (PSCs) utilizing organometal halide perovskite absorber is considered a favorable candidate of PPV because of its unrivaled extinction coefficient, low exciton binding energy and low formation temperature. However, most published processes to deposit perovskite absorber involves the use of polar organic solvent such as DMF or DMSO, which is toxic and can not be vastly used in production scale. In the past few years, we devoted ourselves to develop a low-toxic process to fabricate high PCE PSC using only water as the primary solvent.

In this presentation, the journey of our efforts in this protocol and our targets in near future is shared. The conversion mechanism, morphology control and device engineering will be highlighted. Currently, we have achieved 16.5% plastic PSC using Pb(NO3)2/water as the starting material to prepare organometal halide perovskite layer.

Abnormal Aging and Recovery Processes in Perovskite Solar Cells with Metal Electrodes Dong Geon Lee1, Min-cheol Kim2, Shen Wang2, Byeong Jo Kim3,1, Sangwook Lee4, Shirley Meng2 and Hyun Suk Jung1; 1Sungkyunkwan Univ, Korea (the Republic of); 2University of California, United States; 3Uppsala University, Sweden; 4Kyungpook National University, Korea (the Republic of)

Perovskite solar cells (PSCs) have been rapidly improved in their energy converging performances, currently exhibiting up to 24.2 % of power conversion efficiencies (PCEs). Despite their great performances, they still suffer from various issues such as stabilities and scaling-up problems. PSCs struggle to maintain their performance owing to fast chemical decomposition or performing instability caused by hysteretic behavior or ion migration. Large-area perovskite film fabrication and cost problems of electrodes should be resolved for practical photovoltaic application. Among present problems, electrode selection is one of most important assignments in solving both hurdles for commercialization because the most popular metal electrodes, Au or Ag, are instable chemically and it is too much expensive to be used in mass production system, especially Au electrode. PSCs with Ag electrode performs low PCEs with low open circuit voltage and fill factor showing an s-shape kink in current density-voltage (J-V) curves at first. However, with aging time, the performance of PSCs recovers to the normal level and such abnormal performing instability can be a huge obstacle for commercial application of Ag electrode. The s-shape J-V curves are mainly attributed to inferior majority charge carrier extraction from the photo-absorbing area to the cathode or anode, however, the underlying reason for these phenomena, especially for the abnormal aging and recovery mechanism in PSCs with Ag electrode has not been elucidated at all. It is important to understand the origin of the s-shape J-V curves of PSCs with Ag electrode at early stage and the mechanism of aging and recovery phenomena with elimination of s-shape for securing the possible use of Ag electrode in commercialized PSCs. Here in this work, we present the different time-dependent performance change trends of PSCs with regard to metal electrodes (Au and Ag). PSCs with Ag electrode exhibit a clear s-shape J-V curves in early stage, however they recover to their best performance with 12 h of aging time. On the other hands, PSCs with Au electrode exhibit their best performance from the beginning. In order to clarify this abnormal aging and recovery process in PSCs with Ag electrode, we also investigate the time-dependent carrier dynamics alteration by photo-luminescence behaviors.
which proves the performance changes with aging time. By the measurement and simulation results, we are able to verify that the work function difference between Ag electrode and hole transport materials, Spiro-MeOTAD, induces a significant injection barrier for holes, and it clearly cause the formation and alleviation of the s-shape J-V curves in PSCs with Ag electrode. We finally address the potential of Ag electrodes for commercial use by demonstrating highly stable PSCs with Ag electrode for durations exceeding 350 h under light-illumination, which is close to the results of PSCs with Au electrode.

Advances in the Triple Mesoscopic Perovskite Solar Cells

Wenhao Zhang and Hongwei Han; Huazhong University of Science and Technology, China

Perovskite solar cells (PSCs) have attracted intensive attention from many researchers due to the excellent properties of perovskite materials and simple device fabrication process. Thanks to worldwide efforts, PSCs have achieved the most rapid development with certified efficiencies rising from 3.8% in 2009 to 24.2% in 2019. Different from mesoscopic structure or planar structure, the triple mesoscopic perovskite solar cells are based on a TiO₂/ZrO₂/carbon triple-layer mesoporous scaffold, acting as the electron transporting layer, spacer layer and counter electrode, respectively. All these functional layers are fabricated by screen printing along with subsequent sintering. Innovatively, the triple mesoscopic PSCs eliminate the use of noble metal electrodes and hole transport materials, which can simplify the fabrication procedures and reduce the fabrication cost. More impressively, the stability of PSCs with the triple mesoscopic structure is quite superior and different groups have confirmed it in recent years. Photostability of more than 1000 h in ambient air under full sunlight irradiation was first reported in 2014. Subsequently, stability of more than 10,000 h with zero loss in performances was obtained under controlled standard conditions in 2017. In addition, thermal stability of the triple mesoscopic PSCs is also excellent for they can maintain initial efficiency for over 1500 h during the 100°C thermal test in the dark. Based on these advantages, the triple mesoscopic PSCs have drawn lots of interest and become a competitive candidate for the new generation of photovoltaic technology. And a series of work have been performed to improve the performance of the triple mesoscopic PSCs, including perovskite modification, interface engineering, optimization of each functional layers, post-treatment and encapsulation. Up to now, the state-of-the-art power conversion efficiency of 15.77% has been obtained, exhibiting promising future of commercialization for the triple mesoscopic PSCs.

Comprehensive Investigation of Thermochemical Stability of Perovskite Layer and Perovskite Solar Cells with Zinc Oxide Electron Transport Layers

Wenjing Zhao, Dapeng Wang and Shengzhong (Frank) Liu; Shaanxi Normal University, China

In an efficient perovskite solar cell (PSC), the quality of the charge transport layers should be significantly considered. In case of the electron transport layer (ETL) materials, TiO₂ is a most commonly used inorganic semiconductor as ETL. However, due to the limitation of the intrinsic properties of TiO₂, it always suffers from high processing temperature, low electron mobility, and strong photocatalytic activity, resulting into the undesirable carrier recombination for TiO₂ based PSCs. Comparatively, zinc oxide (ZnO) is an alternative metal oxide ETL owing to its high electron mobility and comparable energy level as well as low temperature fabrication. In addition, ZnO films can be simply prepared through the various solution- or vacuum-based techniques, which is beneficial to the mass and low-cost production of photovoltaic devices. Although the solution processed ZnO-based PSCs have acquired the significant achievements, some problems still need to be settled for the future commercial applications. An important issue is the hydroxyl groups and/or residual acetate ligands remained on the solution-processed ZnO surface, which accelerates the chemical decomposition of the perovskite film during the fabrication processing. In comparison to various solution methods, magnetron sputtering technique is a traditional vacuum-deposition approach to form stoichiometry and morphology controlled metal oxide semiconductors at a desirable temperature. On the basis of sputtered ETLs-based normal or inverted PSCs, the thermochemical stability of the devices is rarely discussed. Most importantly, the sputtered samples contain few hydroxyl groups because the hydrogen-free ceramic target and working gases are used during the whole fabrication process, which effectively avoid the chemical decomposition of the perovskite layer and is beneficial to enhance the stability of the devices. Hitherto, the ETLs with various amounts of hydroxyl groups prepared by vacuum and solution methods are seldom considered. In this study, the thermochemical stability of the perovskite layer and PSCs on ZnO substrates containing the different amount of hydroxyl groups is investigated. To evaluate the chemical decomposition of the perovskite layer caused by the amount of hydroxyl groups remained on the interface of ZnO/perovskite films, ZnO films with
different amount of hydroxyl groups are prepared by magnetron sputtering and spin-coating methods. The sputtered ZnO film contains the negligible hydroxyl groups because the hydrogen-free working gases of argon and oxygen are introduced during the sputtering process. In case of the optimized deposition condition under Ar/O2 ratio of 1:4, the sputtered ZnO film shows larger grain size, bigger water contact angle, higher energy-level matching, better optical transmission, and higher conductivity in comparison with the spin-coated ZnO film. Moreover, the planar perovskite solar cells (PSCs) based on the sputtered ZnO electron transport layers (ETLs) yields an optimal power conversion efficiency of 17.22%, sharply outperforming that based on the spin-coated ZnO ETL (14.24%). More notably, the thermochemical stability of the device based on the sputtered ZnO ETL was also significantly improved.

EN08.09.04
Dual Function SBOET Glass Improves the Stability and Efficiency of Perovskite Solar Cell Jing Gou; Shaanxi Normal University, China

The performance of perovskite solar cells has been developing rapidly since 2009, the certified power efficiency has exceeded 24% in a few years. It has a very broad application prospect on basic research fields and new energy development, thus which has attracted great attentions. Ultraviolet radiation in solar spectrum is inevitable that can destroy the performance of perovskite solar cells in the same time. In order to solve this problem, we introduced photoluminescent glass in perovskite solar cells replacing traditional glass basement. The key point is SBOET photoluminescent glass, which can convert high-energy ultraviolet light to visible light for improving the stability and efficiency of perovskite solar cells. On the one hand, it can decrease the decomposition of perovskite material because less ultraviolet radiation can pass through SBOET glass. On the other hand, it can increase visible radiation by photoluminescence conversion. So that utilization of dual function SBOET glass can both improve stability and efficiency of the perovskite device.

EN08.09.05
Electric Field Induced Degradation in MA-Free Perovskite Solar Cells Erjin Zheng, Zhiyin Niu, Hao Dong, Gabriella A. Tosado and Qiuming Yu; University of Washington, United States

Small cation (Cs+ and Rb+) doped formamidinium lead triiodide (FAPbI3) is one of the most promising perovskite materials for solar cell applications because of the elimination of thermally unstable methylammonium (MA) cation and the reduced phase transition of FAPbI3 from photoactive α-phase to photo-inactive δ-phase. Comprehensive studies have been performed on the stability of small cation doped FAPbI3 perovskites with respective to oxygen, humidity, and temperature. However, the stability under the operational condition, such as applied electric bias and solar illumination, is equally important, yet has not been well studied.

In this work, we fabricated MA-free Rb0.05Cs0.10FA0.85PbI3 perovskite via hot casting and anti-solvent method. Diethyl ether and chlorobenzene were applied as the anti-solvent. Diethyl ether served as a better anti-solvent than chlorobenzene, yielding densely packed, uniform α-phase Rb0.05Cs0.10FA0.85PbI3 perovskite thin films confirmed by SEM and XRD. Perovskite solar cells with the structure of ITO/PEDOT:PSS/Rb0.05Cs0.10FA0.85PbI3/PC60BM/BCP/Ag exhibited an average PCE of 12.14% and a steady Jsc at the maximum power for 60 min. The PCEs of the devices, stored in N2 glove box, dropped to ~60% of the initial value over the first 15 days and retained the same level for the next 15 days with a testing interval of 3 days in these 30 days, and kept the same PCEs when tested in another 20 days later. No interfacial degradation was confirmed via light intensity- and effective voltage-dependent Jsc measurements. SEM images showed that the perovskite thin film still remained crystalline grains with clear grain boundaries over the entire cross-section. However, XRD patterns showed that small amount of photo-inactive δ-phase perovskite formed in the region right under the electrodes while the region in between electrodes remained photoactive α-phase, indicating the initial PCE drop is due to the δ-phase perovskite formation and electric-field plays an important role.

The impact of precursor preparation on the formation of phase pure Rb0.05Cs0.10FA0.85PbI3 perovskite was further investigated. Rb/CsPbI3 phase segregation occurred in the formation of Rb0.05Cs0.10FA0.85PbI3 perovskite thin film if the precursor solution was not well mixed before spin coating. While a higher average PCE of 13.23% and a steady Jsc at the maximum power for 60 min were achieved from the devices prepared with the unwell-mixed precursor solution, the devices exhibited an accelerated degradation and strong dependence on testing frequency, which means the exposure to the applied electric field. With the testing intervals of 3, 15, and 30 days, the PCE reduced to 8, 20, and 44% of the initial values, respectively. The perovskite under electrodes turned to yellow while in between electrodes were still black. No interfacial degradation was confirmed. The perovskite material degradation was investigated via SEM, which showed small pin holes in the cross-sectional area right under the electrode, and XRD,
which showed the significantly decreased α-phase peaks accompanied by the significantly increased δ-phase peaks. The perovskite in between electrodes, again, remained crystalline grains with clear grain boundaries and α-phase with trace δ-phase formation. We proposed that the electric field induced degradation via small cation migration between vacancies could be a possible mechanism. More experiments were conducted to verify this proposal. Furthermore, the possible reducing phase segregation methods were also proposed and experimentally tested. This work provides an insight on the selection of anti-solvent for making mixed-cation perovskite thin films, demonstrates the importance of precursor preparation to the operational stability of devices, reveals a perovskite solar cell degradation mechanism via the electric field driven phase segregation, and offers the means to reduce such phase segregation and to enhance perovskite solar cell stability.

EN08.09.06
Enhanced Water-Resistance of Perovskite Solar Cells by Grain Boundary Passivation with Polydimethylsiloxane-Woochul Kim, Yusin Pak and Gun Young Jung; Gwangju Institute of Science and Technology (GIST), Korea (the Republic of)

Organic-inorganic hybrid perovskite solar cells (PSCs) have attracted considerable attention due to their remarkable power conversion efficiency (PCE) that lately exceeds 22 %. However, stability issue remains regarding their use in real-life environments with the most urgent matter being their long-term stability under humid conditions. The hybrid perovskites are inherently vulnerable to water molecules, which can induce degradation of perovskite photoactive chemicals such as MAPbI3, FAPbI3. Therefore, to realize the commercial-level long-term PSC stability, the adsorption and infiltration of water into perovskite films must be minimized. Herein, it is demonstrated that polydimethylsiloxane (PDMS) introduced simultaneously during perovskite spin-coating is highly beneficial to passivate perovskite grains and adjacent grain boundaries (GBs). It promotes the formation of lead oxide (PbO) bonding that prevent a water-perovskite reaction and contributes to reducing a Pb defect density related to trap-assisted recombination. Owing to the reduced trap-assisted recombination, the best PDMS-passivated PSC exhibits a PCE of 16.16 %, FF of 70 % and $J_{sc}$ of 21.10 mA/cm². The photovoltaic performance of the PDMS-passivated PSC is notably enhanced compared to a reference PSC (without PDMS). Furthermore, the PDMS with abundant methyl moieties is hydrophobic, effectively limiting water infiltration into the perovskite film and PbO bonding formed by PDMS passivation can prevent catalytic reaction between Pb atoms and water molecules. Thus surprisingly, more than 90 % of the initial PCE (~15 %) is sustained after laboratory storage of 5000 h under 70 % relative humidity, while only 20 % of original PCE of reference PSC is retained after 2000 h under the same conditions. These results will pave the way for developing commercial perovskite optoelectronic devices.

EN08.09.07
Enhancement of Humidity Stability by Cation Engineering in Perovskite Solar Cells Bohyung Kim; UNIST, Korea (the Republic of)

Many organic cations in halide perovskites have been studied for their application in perovskite solar cells (PSCs). Most organic cations in the PSCs are based on protic nitrogen cores, which are susceptible to deprotonation. Here, a new candidate of fully alkylated cation (target cation) was designed and successfully assembled into PSCs with the aim of increasing humidity stability. To ensure promising photovoltaic performance of three-dimensional perovskites, trace amount of target cation was assembled into perovskite solar cells by using typical solution spin-coating method. From the results of the structural and morphology studies combined with XPS analysis, it was evident that the target cation was introduced in the grain boundaries and/or surface of perovskites without change in 3-D perovskite lattice, which resulted in the comparable photovoltaic performance (η ~ 19 %) of 3-D MAPbI3 under 100 mWm⁻² irradiation. Regarding the stability of perovskite film on moist, it was found that the generic feature of A-site cations in the form of ABX₃ perovskites significantly affected humidity stability of perovskites, with ammonium-based perovskites giving a poor moisture-tolerance. However, the target cation-driven perovskites showed a much more pronounced effect on the increase in humidity stability, which emphasizes a generic electronic difference between protic versus aprotic cation. From the point of view on the humidity stability, it should be added that not only hydrophobic alkyl (or aromatic) chain but also basicity of cations should be considered when engineering large cations for their use in perovskites. Based on the prominent photovoltaic performance and stability of target additive-driven PSCs, current additive is considered as logical cations for further design of 2-D, 3-D, or 2D/3D hybrid perovskite.
EN08.09.08
Evaluation of Durability of Organic-Inorganic Perovskite Compound Films II Yuki Fukazawa1, Masato Gocho1, Kazunori Ito1, Toshiya Kobayashi1, Ryusuke Umeda1 and Hironori Ogata1,2,3; 1Hosei Univ. Grad. Sch., Japan; 2Hosei University, Japan; 3Research Center for Micro-Nano Tech, Japan

In organic-inorganic hybrid solar cells using a lead halide-based perovskite compound as a light absorbing layer, improvement in durability is one of the major issues in practical use. Several studies have been reported on improving the durability of the perovskite layer. In particular, it have been reported that the stability of the compounds is enhanced by mixed crystal formation of lead halide perovskite compounds. In particular, it has been reported that stability is improved by mixing inorganic cations such as Cs and Rb with organic cations such as CH3NH3+ (MA+) and HC (NH2)2+(FA+) (1) (2). In addition, recently, it has been reported that energy conversion efficiency and stability are improved by mixing CH6N3+ as an organic cation (3), but these deterioration suppressing mechanisms have not been sufficiently elucidated yet. We are conducting research focusing on the durability mechanism of the perovskite layer with mixed cations and halide anions.

In this study, the effects of temperature and humidity on the crystal structure, morphology, charge transport properties and photovoltaic properties of the mixed perovskite compound films based on FAPbI 3-y Br self were systematically investigated. Furthermore, the results of evaluating the influence of the ratio of the inorganic cation (Cs or Rb) and the organic cations of the mixed perovskite compound thin film on the durability are also reported. Detailed results will be discussed on the conference.

EN08.09.09
Impacts of Secondary Phase on Performance of Formamidinium-Based Perovskite Solar Cells—Mechanisms and Solutions Linfeng Cai and Furong Zhu; Hong Kong Baptist University, China

Solution-processable perovskite materials have already been proven the potential for applications in optoelectronic devices, including solar cells, photodetectors, light-emitting diodes etc. Stability of the perovskite solar cells is particularly important for the eventual application. The formation of secondary phase in the complex perovskite active layer, typically with multiple ions, is one of the causes leading to the deterioration in the cell performance. In this work, we report our effort to understand the thermal stability of the solution-processed methylammonium- and bromine-free formamidinium-based perovskite (FA0.85Cs0.1Rb0.05PbI3) layers, and the relationship between the formation of secondary phase and long-term stability of the FA0.85Cs0.1Rb0.05PbI3-based perovskite solar cells. It shows that the emergence of secondary phase in the perovskite layer is closely associated with the storage time of the perovskite precursor solution. An obvious decrease in power conversion efficiency was observed when the secondary phase was formed in the perovskite active layer in the cells. The formation of the secondary phase in the perovskite active layer leads to an increase in charge recombination, due to the reduction in the built-in potential across the cell. The improved understanding of the formation mechanism of the secondary phase and the solutions to supress the formation of the secondary phase are the prerequisite for attaining high performing perovskite solar cells.

EN08.09.10
Influence of Guanidinium on the Stability and Performance of the Multi-Cation Perovskite Solar Cells Eunhwan Jung, Senol Oez, Feray Uenlue, Heechae Choi and Sanjay Mathur; University of Cologne, Germany

Here we present the preparation of solution processed mixed cation GAx(Cs0.05MA0.15FA0.8)1-xPb(I0.85Br0.15)3 (GA= guanidinium; MA= methylammonium; FA= formamidinium) organic-inorganic hybrid perovskite films and their incorporation into mesoporous perovskite solar cells by spin coating solution processing. We found that incorporation of GA into Cs, MA, and FA triple cation perovskite enables the formation of highly crystalline black phase perovskite which enhance charge carrier transfer and inhibits charge recombination at the perovskite/spiro-OMeTAD interfaces and therefore improves short-circuit current density of the device. Time-resolved photoluminescence (TRPL) data confirm a faster decay of the PL signal in the presence of the perovskite/spiro-OMeTAD with GA incorporation perovskite solar cell in comparison with triple cation perovskite solar cell. The effect of GA substitution was systemically investigated, and the 5% GAI was the optimum condition to achieve high performance perovskite solar cells. This study will provide a basic insight for the mixed-cation perovskite for the future energy harvesting applications.

EN08.09.11
Investigation of Air Stability in Different Perovskite Semiconductors Abhishek Kumar Chauhan, Pankaj Kumar
Organo-metal halide perovskite semiconductors have attracted especial attention of the entire photovoltaic community as they have shown excellent properties for photovoltaic applications. They have shown unprecedented improvement in their ability of converting solar energy into electricity from 3.8% in 2009 to certified 22.1% in 2016. Perovskite photovoltaic technology is considered to be the most cost effective technology and the devices are very thin, light weight and compatible to roll-to-roll fabrication on flexible substrates, making them mountable on any kind of building surfaces. Ease in band gap tuning of perovskite semiconductors have paved the path for overcoming the efficiency limitations in tandem structures. Scientist are applying perovskite semiconductors on the commercial solar cell technologies and c-Si/Perovskite tandem solar cells have already crossed 23% in monolithic architecture and 26% in mechanical stacking. Unfortunately perovskite semiconductors are very sensitive and lose their optical and electrical properties in the presence of moisture, oxygen, UV light and high temperature. Rapid degradation in perovskite semiconductors is keeping this technology away from the market. Application of stable perovskite semiconductors will provide the solar cells a longer stability. Keeping this objective in our mind we have synthesized a number of perovskite semiconductors by varying the composition of precursors and using double or triple cations along with different halides. Thin films of these perovskites were prepared via spin coating technique and subjected to different test conditions to investigate their stability and degradation mechanisms. The films were characterized by the important tools, used for understanding of degradation, like UV-vis absorption spectroscopy, scanning electron microscopy, optical microscopy, X-ray diffraction technique etc. From these studies we were able to identify the stable perovskite materials for stable solar cells and the results will be discussed in more detail during the conference.

EN08.09.12
Perovskite Solar Cell Operational Stability under Vacuum for Space Application Yan Jiang, Shih-Chi Yang, Stefano Pisoni, Thierry Moser, Fan Fu, Stephan Buecheler and Ayodhya N. Tiwari; Swiss Federal Laboratories for Materials Science and Technology, Switzerland

High power conversion efficiency,$^1$ high specific power (W/g) and stowed packing efficiency (W/cm$^3$),$^2$ low processing cost (US cents/kWh)$^3$ and high tolerance against space environmental threats (high energy and charged particle radiation)$^4,5$ makes perovskite solar cell (PSC) a promising candidate as space-based photovoltaics. However, vacuum causes outgassing of perovskite absorber,$^4$ raising concerns on its long-term reliability. In this work, we investigated how different pressure levels affect the operational stability of non-encapsulated PSCs with the state-of-the-art (SOA) architecture. Stability of PSCs decreases upon reducing the operational pressure while they are kept at the maximum power point (MPP) condition under 1 sun continuous illumination. By performing XRD, UV-Vis, SEM and SIMS measurements, we reveal the vacuum induced efficiency loss mechanism. In addition, we developed two PSC architectures that effectively delay/mitigate these vacuum induced detrimental effects. PSCs with one of the new developed device architectures show a low PCE loss rate of 0.007%/h in 1037 h at MPP condition under 50 mbar, equaling to a projected T$^0$ lifetime of 4750 h. The findings present in this study lay the foundations towards highly stable PSC structures for applications in low-pressure environment, as encountered in outer space.

EN08.09.13
Qualifying Cesium as a Stabilizer for Effective Perovskite Solar Cells Denice N. Feria$^1$ and Yu-Chiang Chao$^2$; $^1$Chung Yuan Christian University, Taiwan; $^2$National Taiwan Normal University, Taiwan
The rapid increase in global demand for energy paved the way for finding renewable and efficient energy source. With this, a cost-effective and environment friendly hybrid organic-inorganic lead halide perovskites have gained attention as an absorber layer for effective solar cells. The perovskite device performance is more efficient not only because of its distinct properties. But also, the flexibility of the perovskite material to be tuned in different structures to enhance its stability under ambient conditions. The process of interchanging cations to the perovskite material became a feasible route to further improve its efficiency which contributes to its fast development over the past years. By replacing Methylammonium (MA) cation to Formamidinium (FA) cation, it created a new perovskite structure that can be utilized for better device performance. A pristine FAPbI₃-based solar cells exhibited good characterizations and desirable device performance but its stability is inconsistent under ambient conditions. This can be attributed to the non-perovskite property of the FA cation which often exhibits during exposure to air and inappropriate fabrication process. Thus, in this study, creating a double or mixed cation perovskite solar cells (PSCs) were observed to solve the instability issue of HC(NH₂)₂PbI₃ /FAPbI₃ making it more photo and structurally-stable under environmental factors.

The idea of double cation PSC was done by incorporating small amounts of Cesium (Cs) in FA-based perovskite absorber layers. This incorporation pushed the photo-active black perovskite phase of FA-based solar cells which made it more suitable for the effective perovskite solar cell fabrication. The CsFA-based structure also avoids the phase transition of the perovskite material from perovskite to non-perovskite property. This PSC was enhanced both in its efficiency and stability under thermal and moisture exposure. With thorough investigation on the different techniques in PSC fabrication such as addition of poor solvent, delay time and annealing conditions, perovskite samples have shown more developed characterizations compared to the pristine FAPbI₃. Fabricated in different delay time conditions, the most stable photo-active black perovskite phase was detected from the structure, FA₀.₉ Cs₀.₁ PbI₃. Flat and smooth surface which has a full perovskite coverage and appropriate thickness were found from dark and bright optical images and scanning electron microscope (SEM) observations. Also, it contributed to the perovskite samples to have broader absorption and stronger photoluminescence that developed its device performance. Moreover, X-Ray Diffraction (XRD) patterns and its full-width half-maximum (FWHM) values showed that when a correct amount of Cesium was incorporated to the pristine FAPbI₃, a pure perovskite film with high crystallinity will be obtained. Because of these enhanced properties, the PSC exhibited an efficiency of 8.74% with good reproducibility. A stable device was also observed which is highly needed for fabricating an effective solar cell. As a whole, the perovskite solar cell in FA₀.₉ Cs₀.₁ PbI₃ demonstrated enhanced device properties over the FAPbI₃-based device on the influence of other variables. The observation in the fabrication techniques made the PSC to be structurally and thermally stable which were also useful for future experiments and large-scale applications.

EN08.09.14
Semi-Locked Tetrathienylethene as a Building Block for Hole-Transporting Materials—Toward Efficient and Stable Perovskite Solar Cells Chao Shen; East China University of Science and Technology, China

The construction of state-of-the-art hole-transporting materials (HTMs) is challenging regarding the appropriate molecular configuration for simultaneously achieving high morphology uniformity and charge mobility, especially because of the lack of appropriate building blocks. Herein a semi-locked tetrathienylethene (TTE) serves as a promising building block for HTMs by fine-tuning molecular planarity. Upon incorporation of four triphenylamine groups, the resulting TTE represents the first hybrid orthogonal and planar conformation, thus leading to the desirable electronic and morphological properties in perovskite solar cells (PSCs). Owing to its high hole mobility, deep lying HOMO level, and excellent thin film quality, the dopant-free TTE-based PSCs exhibit a very promising efficiency of over 20% with long-term stability, achieving to date the best performances among dopant-free HTM-based planar n-i-p structured PSCs.

EN08.09.15
Sn–Zn-Oxide Nanocomposites (TZO) Electron Transport Layers for Efficient and Stable Perovskite Solar Cells Nageh K. Allam; American University in Cairo, Egypt

Tin–zinc-oxide nanocomposites (TZO) with various Sn:Zn ratios were successfully fabricated and tested as electron transport layers (ETLs) in perovskite solar cells (PVSs). The fabricated nanocomposites showed good crystallinity, good contact between layers, good electrical conductivity, and favorable light absorption, resulting in an enhancement in the net efficiency of CH₃NH₃PbI₃ (MAP) based perovskite solar cells. The device made of TZO–
Sn0.05 as an ETL showed a maximum power conversion efficiency (PCE) of 17.81% with a short-circuit current density (Jsc) of 23.59 mA cm^{-2}, an open-circuit voltage (Voc) of 1 V, and a fill factor (FF) of 0.754. However, the ETL containing lower Sn ratios showed PCEs of 12.02, 13.80 and 15.86% for pure ZnO, TZO–Sn0.2 and TZO–Sn0.1, respectively. Meanwhile, the reproducibility of 30 fabricated devices proved the outstanding long-term stability of the cells based on TZO nanocomposites, retaining 85% of their PCE over 1200 h of operation. In addition, the incident photon-to-current efficiency (IPCE) exceeded 90% over the entire wavelength range from 400 to 800 nm. The current results suggest that our synthesized tin–zinc-oxide nanocomposite is an effective electron transport layer for efficient and stable perovskite solar cells.

EN08.09.16
Study of the Stability of Lead Halide Perovskite under Two Different Fluoropolymer Top Coatings Fatemeh Khorramshahi and Arash Takshi; University of South Florida, United States

In this work, two lead halide perovskite photodetector were fabricated by laser-assisted rapid fabrication method. A microchannel was engraved on an indium tin oxide (ITO) coated polyethylene terephthalate (PET) conductive flexible substrate using a CO2 laser source. The channels were filled by methylammonium lead halide perovskite (CH3NH3PbI3) using the capillary motion of perovskite precursor. CYTOP and the low-cost commercially available FluroPel were used as a top protective coating layer to suppress the decomposition of the perovskite channel. X-ray diffraction pattern (XRD) was used to measure the stability of the perovskite. Strong humidity resistant and self-healing behavior were observed in both devices. The performance of the two photodetectors was compared by measuring electrical and optical characteristics over time. This study will help in the low-cost fabrication of perovskite-based devices.

EN08.09.17
Concentrated Sunlight for Studying Bias-Dependent Stability of Perovskite Solar Cells Anoop K M1, Mark Khenkin1, Renjun Guo3, Eugene A. Katz1, Yulia Galagan3, Francesco Di Giacomo2, Stav Rahmany3, Lioz Etgar3 and Iris Visoly-Fisher1; 1Ben-Gurion University of the Negev, Israel; 2TNO-Solliance, Netherlands; 3The Hebrew University of Jerusalem, Israel

Perovskite solar cells have exhibited impressive power conversion efficiency, but to be considered for large scale commercial applications these cells have to be stable under operating conditions including exposure to sunlight, heat and electric bias. Here we present stability studies using concentrated sunlight, which allows rapid screening of the degradation parameters in the cells. Specifically, accelerated degradation studies to determine factors affecting degradation at different bias conditions were performed. Our experimental methodology allows independent control of sunlight intensity, the sample temperature and environment during the exposure. Stress testing of perovskite solar cells showed that faster degradation was found for cells held at SC under concentrated sunlight and on the initial stage of outdoor exposure. However, cells kept at short circuit (SC) showed better long-term stability compared to cells kept at open circuit (OC) upon real operational conditions. We also found that intensity was more important than dose for cells degradation at SC conditions, while dose was the determining factor at OC. This indicates that different degradation mechanisms are dominant at different degradation stages and under different bias conditions and that nano-scale understanding of degradation mechanisms is required to suggest ways to increase the device life-time.

EN08.09.18
Sunlight Concentration-Dependent Degradation of Perovskite Solar Cells Anoop K M1, Mark Khenkin1, Eugene A. Katz1, Yulia Galagan3, Francesco Di Giacomo2, Lioz Etgar3, Stav Rahmany3 and Iris Visoly-Fisher1; 1Ben-Gurion University of the Negev, Israel; 2TNO-Solliance, Netherlands; 3The Hebrew University of Jerusalem, Israel

Over the last few years, perovskites have emerged as promising photovoltaic materials because of their ease of fabrication and high power conversion efficiency. However, their long-term stability remains a major concern for their commercialization. Here we present stability studies using concentrated sunlight, which allows rapid screening of the degradation parameters in the cells. Studies conducted on dual cation perovskite solar cells revealed that there are two different degradation mechanisms being dominant at different exposure intensities. At 10 to 30 suns exposure, the PCE degradation behaved entirely...
different from that of 40 and 50 suns exposed samples. We have studied the mechanisms behind this PCE degradation with the help of photoluminescence mapping and by electrical measurements including photo-induced charge carrier extraction by linearly increasing voltage (photo-CELIV), transient photo-current and impedance, using the PAIOS instrument. PL mapping shows non-homogeneous degradation only at intensities of 40-50 suns, which is non-reversible, in contrast with that at lower sunlight concentrations. Electrical measurements showed that cell degradation up to 30 suns can be due to the generation of traps. The different acting degradation mechanisms indicate that accelerated stability testing using concentrated sunlight is limited to smaller sunlight concentrations.

EN08.09.19
Thermochemical Stability of Hybrid Halide Perovskites  Alessandro Senocrate1,2, Gee Yeong Kim1, Davide Moia1, Michael Graetzel1,2 and Joachim Maier1; 1Max Planck Institut for Solid State Research, Germany; 2École Polytechnique Fédérale de Lausanne, Switzerland

Hybrid halide perovskites (HOIHPs) have been extensively studied in recent years due to their potential use as light-harvester in photovoltaic devices. While the efficiencies of such devices pose no limitation to commercial applications, the severe lack of stability of the materials remains an important issue to be overcome. Indeed, HOIHPs are known to easily degrade under moderate thermal stress,[1] or upon oxygen[2] and/or light exposure.[3] Notably, recent calorimetric studies even suggested that, in agreement with DFT calculations,[5] some HOIHPs (MAPbI3 in particular and MAPbBr3 to a lesser extent) could be thermodynamically unstable[4] with respect to decomposition into their binary precursors. In contrast, other studies indicate the materials to be intrinsically stable.[1,6] Obviously these questions need to be unambiguously answered. In this contribution, we discuss the underlying thermodynamics of HOIHPs. We treat the intrinsic (vs temperature) and the extrinsic (vs oxygen) stability, as well as decomposition processes induced by light and applied bias. Intrinsically, we find the materials to be stable under standard conditions (albeit, in the case of MAPbI3, only marginally), and we also can assess the favourable degradation path upon heating. A strong tendency towards instability is expected under real conditions. Extrinsically, our considerations reveal a large tendency towards degradation of HOIHPs in the presence of oxygen, which is especially severe under real conditions. Notably, light itself can activate a relevant photodecomposition pathway.[7] We discuss these issues on a quantitative level, in conjunction with experimental observations of the degradation phenomena.

Thermomechanical Behaviour of Halide Perovskites  Srinivas K. Yadavalli, Zhenghong Dai, Yuanyuan Zhou and Nitin P. Padture; Brown University, United States

Organic-inorganic halide perovskite (OIHP) based solar cells have rapidly emerged as a promising photovoltaic technology because of fascinating optical and electronic properties of OIHPS. However, perovskite solar cells (PSCs) are extremely fragile and have cohesion energy values lower than that of even the organic solar cells. Also, the devices have multi-layered structures with functional layers possessing different thermal and mechanical properties. So, thermal cycles during device fabrication can induce macroscopic residual stresses in the OIHP film. The possibility of these stresses leading to different modes of film fracture (surface cracks, channelling cracks and interface cracks) is evaluated. The behaviour of the devices is also studied under externally applied stresses. The effect of interface modification on the cohesion energy of the devices is demonstrated, leading to more mechanically reliable PSCs. The OIHP film’s mechanical stability is evaluated by subjecting the films deposited on flexible substrates to high strains. The microstructural and the residual stress changes during a bending cycle are characterized to understand the mechanisms of failure. This brings insights to the fundamental aspects of the mechanical behaviour of OIHPS which is very likely to be critical inorder to emerge as a highly reliable solar cell technology.

Understanding Intrinsic Instability of Perovskite Solar Cells at Outdoor Operation Settings
Wenya Song1,2, Sownder Subramaniam1,2, Stijn Lammar1,2, Yinghuan Kuang1, Tom Aernouts1 and Jef Poortmans1,2,4; 1imec, Belgium; 2KU Leuven, Belgium; 3Delft University of Technology, Netherlands; 4Hasselt University, Belgium

Thin film solar cells based on organo-metal halide perovskite have reached efficiencies above 24%, promising to be part of next generation photovoltaics. However, one of the preconditions for its commercialization is performance stability. In recent years, extrinsic stability of perovskite solar cells (PSCs) has significantly improved due to better encapsulation. As a follow, increasing attention has been attracted towards the intrinsic stability of PSCs. In this regard, many PSCs have been reported to be stable for over 1000 hours under continuous illumination at constant temperature in inert environment. However, in real life outdoor operation solar cells undergo light-dark cycling and temperature variation due to day-night periods. Thus, it’s necessary to understand PSC performance changes due to these variable conditions.

Motivated by this cause, we have tracked the changes in the maximum power of PSCs in three scenarios progressively evolving from conventional laboratory settings to approximate diurnal outdoor settings, i.e. from continuous light at constant temperature to light-dark cycling with respective constant temperatures ending with light-dark cycling with temperature variation under light. Study shows that first and second scenarios do not significantly affect PSC performance, while the third scenario results in irreversible performance degradation. Based on analysis using numerical simulation and advanced electrical characterizations, we arrive at the understanding of this degradation with respect to defect dynamics.

To conclude, this work reveals the combination of day-night cycling and varying temperature causes PSC degradation, owing to the intrinsically unstable property of perovskite, i.e. defects generation and migration. Thus, this work further accents the necessity to control defects formation in polycrystalline perovskite films in order to achieve stable PSCs at outdoor operation settings.

EN08.09.22
Engineering Hybrid-Processed Metal-Halide Perovskites on Textured Interfaces for Perovskite/Silicon Tandem Solar Cell Applications
Erkan Aydin, Michele De Bastiani, Furkan H. Isikgor, Jiang Liu, Thomas G. Allen, Emmanuel Van Kerschaver and Stefaan De Wolf; King Abdullah University of Science and Technology, Saudi Arabia

In recent years, metal-halide perovskites (MHPs) have drawn significant attention as a new class of photovoltaic (PV) materials. In a short period after the first solid-state perovskite solar cells (PSCs) were reported, rapid progress followed, culminating recently in single junction devices with a reported power conversion efficiency (PCE) of 24.2%. The excellent optoelectronic properties of the MHPs together with their band gap tunability make them also promising for tandem solar cells. Considering their dominance in the current PV market, the marriage of the perovskite and crystalline silicon (c-Si) solar cells seems very promising for large scale deployment of the PSCs, potentially enabling >30 PCE in the near future.

Such an appealing concept comes nevertheless with some constraints in terms of device processing. Although MHPs processed using a variety of techniques, the community still widely relies on spin-coating, owing to its easy and cost-efficient employment in the lab. Several reports have been published utilizing spin-casted PSCs on ‘flat’ c-Si bottom cells achieving >25% PCE in a monolithic tandem configuration. However, micron-sized textured surfaces play a critical role in efficient light-coupling into c-Si solar cells. This is also true when used as bottom cells, ensuring thereby well-matched high photocurrents between the subcells. Moreover, the use of textured Si wafers is standard in existing c-Si solar cell processing lines, with little incentive to change this. Therefore, the development of the conformal and high-quality PSCs on such textured interfaces is the critical step towards the >30% PCE target. Solution-based techniques may have limitations to produce conformal layers on textured interfaces. However, ‘hybrid’ processing is very promising to this end, which requires first (co)evaporation of the inorganic part of the perovskite, followed by the conversion of this layer to the final perovskite structure by a solution-based technique, relying on the inter-diffusion of the halides. In hybrid processing, achieving high-quality perovskite absorbers depends on several critical parameters such as evaporation rate, film thickness, solution concentration, annealing temperature, ambient conditions (relative humidity), etc. In this study, we investigate the role of these parameters
and report the optimal processing conditions.
Non-optimized, the hybrid deposition method may suffer from the incomplete transformation of PbI₂; residual PbI₂ remains as a secondary domain at the interface, limiting device performance. We found that the porosity of the PbI₂ films is critical for their full conversion; notably, co-evaporation of CsBr together with PbI₂ enables this needed porosity with controlled Cs/Pb elemental ratio. To obtain fully converted perovskites, the solution concentration is another parameter which requires a good balance between film thickness and solution concentration. We found that a low concentration causes non-converted films, whereas a high concentration results in segregated phases and residual FAI on the surface of the films, which limits the device performance. Since the thermal evaporation is a directional deposition technique, the top of the pyramidal texture and deepest point of the valleys are always thicker than the flanks of the pyramidal texture. Increasing the number of such points results in poorly converted films.
With this motivation, we compared different pyramid sizes and found the optimal range. Finally, we looked into the different recombination junctions such as TCOs and nc-Si and correlated these results with shunt problems.
Overall, in this study, we deeply investigated critical processing parameters in hybrid processing of perovskite on textured interfaces by correlating these results with monolithic tandem solar cell performances. This study reveals the potential of the hybrid processing method for tandem applications and gives an insight into the further progress of the field.

EN08.09.23
Fabrication of Uniform Perovskite Films on 4-inch Textured Silicon Surface Using Sputtering and Chemical Vapor Deposition Process Jae-Keun Hwang¹, WonKyu Lee¹, Sang-Won Lee¹, Soohyun Bae¹, Solhee Lee¹, Yoonmook Kang²,¹, Hae-Seok Lee²,¹ and Donghwan Kim¹,²;¹ Korea University, Korea (the Republic of); ²KU-KIST Green School, Korea (the Republic of)

Perovskite solar cells (PSCs), reported for the first time in 2009, are experiencing rapid increase in efficiency from 3.81% at the initial efficiency to 24.2% at present, attracting many researchers with the next generation solar cells. Basically, CH₃NH₃PbI₃ perovskite films (PFs) can be fabricated through the synthesis of the precursor (ex:PbI₂) and CH₃NH₃I. One of the key factor for producing a highly efficient PSCs is to produce a uniform thin films on substrates.

One of the major research topic in the future of PSCs is commercialization strategy, and it is important to deposit thin films uniformly over a large area. However, it is expected that the conventional solution process will have a limitation in uniformly depositing PSCs on a large area. In order to fabricate a large-area PSCs, a method of depositing PFs through the vacuum process is required.

In addition, the vacuum process is also needed from the viewpoint of silicon/perovskite tandem solar cells, deposition of conformal PFs over silicon pyramids is limited by solution processes on textured commercial silicon substrates. For this reason, the silicon/perovskite tandem solar cell has been fabricated to have a flat structure at the front face so that a lot of reflection loss was generated. Recently, there has been a report on fabricating silicon/perovskite tandem solar cell with double-sided texture through evaporation process to reduce reflection loss and increase current density.

In this study, the PFs were fabricated by sputtering and chemical vapor deposition process which are widely used in commercial applications. Perovskite precursor were deposited by sputtering, followed by chemical vapor deposition process for phase converted into the PFs. The films were analyzed by X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM). A PSCs with glass/FTO/compact-TiO₂/CH₃NH₃PbI₃/spiro-OMeTAD/Au structure were fabricated. Finally, it was confirmed that the PFs were conformally deposited on the 4-inch textured silicon substrate. The uniformity of reflectance and thickness was higher than 86% and 92%, respectively. This fabrication processes of the PFs are expected to be applicable to silicon/perovskite tandem solar cells.

EN08.09.24
Optimization of Device Design for Low Cost and High Efficiency Planar Monolithic Perovskite/Silicon Tandem Solar Cells Chan Ul Kim, Jae Choul Yu, Eui Dae Jung, In Young Choi, Wonjin Park, Hyungmin Lee and Kyoung Jin Choi; UNIST, Korea (the Republic of)

Currently, various multi-junction solar cell structures are being studied to overcome the theoretical limitation of silicon solar cell. The III-V tandem structure can achieve high efficiency, but it can not be commercialized because of a high cost. In order to overcome this problem, research on perovskite / silicon tandem solar cell using a low cost perovskite solar cell which is rapidly emerging as a next generation solar cell is being conducted. However, most
hybrid tandem cell research is based on n-type heterojunction silicon cells, which occupy only a small fraction of the total solar market. Therefore, for commercialization, research on perovskite / silicon tandem solar cell based on PERC structure emerging as the mainstream of next-generation silicon solar cell and Al-BSF structure which is mainstream of silicon solar cell is essential.

Here, we have fabricated perovskite / silicon tandem solar cells by introducing Al-BSF structure and PERC structure. Optimized tandem cells based on Al-BSF structure, fabricated with a 310-nm-thick perovskite layer of (FAPbI3)0.8(MAPbBr3)0.2 and a hole transport layer of PTAA, have significantly increased efficiency of 21.19% compared to stand-alone 13.4% perovskite and 12.8% Si cells. Our tandem cell represents the highest efficiency increment among all monolithic perovskite / silicon tandem cells and the highest efficiency among monolithic perovskite / silicon tandem cells based on p-type homojunction silicon cell with Al back-surface field at the same time. The design rules suggested in this study can be applicable to different types of perovskite / silicon tandem cells as well. We believe that this approach opens up a pathway for the commercialization of perovskite solar cells with industry-standard monocrystalline Si solar cells as highly efficient monolithic tandem devices.

EN08.09.25
Perovskite and Quantum Dot Tandem Solar Cells with Optimized Semitransparent Middle Electrode Aneta H. Andruszkiewicz and Erik Johansson; Uppsala University, Ångström laboratoriet, Sweden

In recent years the significant effort has been made to develop new photovoltaic materials configurations and architectures, among which the considerable attention was drawn to tandem cells. It was theoretically proven that tandem configuration involving two or more solar cells has a great potential to overcome the Shockley-Queisser single-junction efficiency limit. Theoretical calculations predict that the combination of large band gap energy (~1.5 eV) material as top cell and low band gap energy (~1.0 eV) material as bottom cell can allow the conversion efficiency of around 30%. Among solution-processed photovoltaic materials, metal halide perovskites with their broad light absorption spectrum, tunable band gaps, long charge carrier diffusion, and low fabrication cost together with lead sulfide (PbS) colloidal quantum dots (QDs) with highly tunable band gap and strong infrared absorption, shows great opportunity to create such highly efficient tandem cells. However, the biggest challenge here is to incorporate the sensitive and unstable perovskite film into such tandem structure. Herein, I will demonstrate efficient solution-processed tandem solar cells using Methylammonium Lead Iodide (MAPbI3) Perovskite in the front cell and PbS QDs in the rear cell and discuss the progress on developing and optimizing semitransparent middle interlayer in such tandem solar cell configuration. Also, further strategies for improving this interlayer together with short overview of other challenges on how to provide even more complementary absorption will be discussed.

EN08.09.26
Sandwiched Gold Nanomesh Electrode for Ultrahigh Near-Infrared Transmittance for High-Efficiency Multijunction Perovskite Solar Cells Ziyu Wang; Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China

The crystalline Si-based solar cells have been dominating the ever-expanding global PV market with about 95% market share. With its highest cell efficiency of 26.6% reaching its theoretical limit, there is little hope to raise its performance by just device optimization within the single-junction cell architecture. As the PV market is so huge with its annual revenue in the order of trillion US dollars, even 1% cost reduction would mean net profit of billions of US dollars per year. Since efficiency increase is proven to be the most reliable means to reduce cost, it makes sense for industries like Hanergy and Shanghai Institute of Microsystem and Information Technologies to support us to develop the tandem cells with potential of significantly increased cell efficiency. There are two basic designs for the tandem cells: (1) two-terminal configuration in which the perovskite top-cell is deposited on the silicon bottom-cell; and (2) four-terminal design in which both the perovskite top-cell and the silicon bottom-cell are completed independently. For the first, in case the top-cell is degraded for any reason, the integrated tandem cell is affected by the same proportion. For the latter, if the perovskite goes bad for any reason, it can be simply removed from the integration and the silicon cell will work just fine. Considering that the silicon solar modules are so robust with product warranty of 25-35 years, and the perovskite solar cells are still in the research stage without any reliability data from the market, the 4-terminal cell design is therefore selected in the present work to not only taking the advantages of higher cell efficiency for reduced cost, but also minimized influence of uncertain reliability of perovskite on the silicon solar modules.
Semi-Transparent Perovskite Solar Cells with Two-Step InZnSnO Top Electrodes Deposited by Damage-Free Linear Facing Target Sputtering Sang-Hwi Lim\textsuperscript{1}, Jin H. Park\textsuperscript{1}, Han-Ki Kim\textsuperscript{1} and Seungju Nam\textsuperscript{2};
\textsuperscript{1}Sungkyunkwan University, Korea (the Republic of); \textsuperscript{2}Korea Electric Power Research Institute, Korea (the Republic of)

Recently, semi-transparent perovskite solar cells (PSCs) have been investigated as building integrated photovoltaics (BIPV) for next generation smart building. To realize semi-transparent PSCs, both anode and cathode electrodes have a high transparency and conductivity. However, unlike bottom anode electrodes prepared by typical sputtering, the preparation of top cathode electrode is very difficult because the semi-transparent PSC is severely damaged by irradiation of high energy plasma during the sputtering process. Here, we reported semi-transparent perovskite solar cells (PSCs) with InZnSnO (IZTO) top cathode prepared by two-step sputtering at room temperature. At first sputtering process, 30 nm thick IZTO top cathode was very slowly sputtered at a low DC power to minimize the direct plasma damage of PSCs. Then, thick IZTO top cathode was directly sputtered on the thin IZTO buffer layer to obtain high conductivity\textsuperscript{1} and transparency of the IZTO cathode electrode. LFTS-grown IZTO top cathode sputtered at an optimized condition has a sheet resistance of 20.95 Ohm/square and optical transmittance of 85.97% at wavelength 550 nm. In addition, we confirmed LFTS-grown IZTO top cathode has appropriate energy band structure as a top cathode for semi-transparent PSC by using ultraviolet photoelectron spectroscopy (UPS). The semi-transparent PSCs with LFTS-grown IZTO top cathode has comparable power conversion efficiency (PCE) of 14.08% to PCE(16.46%) of reference opaque PSC with Ag top cathode. Similar PCE value of the semi-transparent PSC prepared by LFTS indicates that the LFTS is a promising thin film process to make IZTO top cathode on the PSCs without plasma damage which was easily found in typical DC or RF magnetron sputtering of TCO top cathode in semi-transparent PSCs.

Subcells Characterization of Highly Efficient Perovskite-Based Tandem Solar Cells Jae Hyun Park, Ik-Jae Park, Su Geun Ji and Jin Young Kim; Seoul National University, Korea (the Republic of)

The tandem solar cells based on perovskite top cells are attracting significant interest due to its high conversion efficiency and decent stability.[1,2] The theoretical calculation shows that the combination of a top cell with a large bandgap energy (1.5–1.7 eV) and a bottom cell with a low bandgap energy (1.0–1.1 eV) can lead to a conversion efficiency higher than 40%. Given that the bandgap energy of most commercial single junction solar cells is around 1.1 eV, the perovskite solar cell with a bandgap energy around 1.6 eV must be a very promising candidate for the top cell of tandem solar cells.

Although the efficiency of the perovskite-based tandem solar cells is rapidly increasing, the accurate characterization of their photovoltaic/electrical properties is quite tricky due to their monolithic device structure. We have recently demonstrated that the photovoltaic/electrical properties of the highly efficient (~24%) perovskite-Si tandem solar cells and each subcell can be accurately characterized using a 3-terminal characterization platform.[3] where we used subcell EQE spectra for precise current matching. In this presentation, the concept of 3-terminal characterization platform and how we utilized it for developing highly efficient perovskite-Si tandem solar cells will be introduced. In addition, some of our recent studies focusing on the unique photovoltaic/electrical properties of each subcell in the monolithic tandem solar cells such as the effect of the subcell illumination on the electron dynamics and the effect of the current mismatching on the photovoltaic properties will be discussed.

Carbon-Based Electrode Engineering Boosts the Efficiency of All Low-Temperature Processed Perovskite Solar Cells Sisi He, Longbin Qiu, Luis K. Ono and Yabing Qi; Okinawa Institute of Science and Technology Graduate University, Japan
Using carbon to function as both hole transport layer (HTL) and back contact electrode in perovskite solar cells (PSC) can significantly lower the cost, improve the device stability and expand applications to flexible substrates [1]. The interface between HTL and the perovskite layer which is the only effective hole extraction interface in this device is expected to have a significant impact on the device performance [2]. Besides the effective HTL, a high open-circuit voltage (Voc) of carbon-based PSCs is also key to achieving high performance. One of the reasons responsible for the low Voc in carbon electrode-based PSC devices is the energy level mismatch between the carbon electrode (e.g., graphite, carbon black) and the perovskite film (e.g., CH$_3$NH$_3$PbI$_3$ (MAPbI$_3$), CH(NH$_2$)$_2$PbI$_3$, CH$_3$NH$_3$PbBr$_3$) [3]. In this work, we develop an elaborate process to engineer carbon paste to optimize the properties of carbon electrodes and the perovskite/carbon interface to fabricate all low-temperature processed carbon electrode-based lead halide perovskite solar cells. In addition, the low-temperature coating process is fully compatible with large scale and continuous fabrication. Carbon electrode-based flexible solar cells can be also fabricated on flexible conductive substrates thanks to the low-temperature process and their compatibility with printing processes.

Engineering an Open-Air Process Window for Rapid Spray-Plasma Fabrication of Stable, Highly Reproducible Perovskite Solar Cells William J. Scheideler, Nicholas Rolston, Austin Flick, Oliver Zhao, Justin Chen, Jinbao Zhang and Reinhold H. Dauskardt; Stanford University, United States

Hybrid metal halide perovskite solar technology poses exciting global potential for terawatt-level generation and penetration of solar energy into new markets such as transportation and lightweight wireless devices. However, large area scaling and operational reliability remain formidable challenges hindering commercialization. High-throughput open-air fabrication methods such as spray coating and printing could offer low capital-expenditure routes to continuous manufacturing of perovskites, but understanding and overcoming ambient factors such as relative humidity (RH) has been a persistent challenge for achieving high performance and device stability.

In this work, we present moisture-immune open-air spray-plasma processing of high-performance double cation perovskite solar cells that leverages solvent engineering and dual source annealing to precisely control film drying kinetics. Rapid plasma curing and air blade drying of perovskite films (< 100 ms) at elevated substrate temperatures > 100 °C and high processing speeds (>20 cm/s) afford immunity to ambient moisture ingress even under high humidity conditions (up to 50% RH). Our study of the influence of precursor composition, processing speed, and perovskite plasma curing kinetics on film morphology and crystallinity, as well as solar cell performance, allows a generalizable correlation of micron-scale morphologies with photovoltaic efficiency.

This detailed understanding of open-air perovskite processing allowed fabrication of highly reproducible planar inverted Cs$_{17}$FA$_{83}$Pb(Br$_{17}$I$_{83}$)$_3$ cells with stabilized PCE > 16 %, fill factors as high as 78 %, and standard deviation < 1.5% absolute PCE among independent batches fabricated from 25%-50% RH. Importantly, these devices are processed exclusively by scalable methods (no spin coating), utilizing spray deposited inorganic NiO hole transport layers to complete a highly photostable cell architecture that retains 98% of initial PCE over the course of 5•10$^4$s of maximum power point tracking under illumination. This combination of rapid open-air processing methods with an efficient and highly stable multiple cation perovskite composition can offer a viable path towards module upscaling.

EN08.09.31
Flexible Perovskite Solar Cells via Gravure Printing toward Roll-to-Roll Manufacturing Young Yun Kim¹, Tae-Youl Yang¹, Riikka Suhonen², Antti Kemppainen² and Jangwon Seo¹; ¹KRICT (Korea Research Institute of Chemical Technology), Korea (the Republic of); ²VTT Technical Research Centre of Finland, Finland

Perovskite solar cells (PSCs) have been of great interest due to the inherent superior optoelectronic properties of organometallic halide perovskite itself, such as high absorption coefficient, long carrier diffusion length, ambipolar charge transport and solution-processability. Over 24 % of power conversion efficiency (PCE) have been achieved recently for PSCs by virtue of composition engineering, optimization of interlayer, and defect management. Aside from the high PCE, flexibility and light-weight are the most unique and promising characteristics of PSCs. To utilize
such advantages the PSCs, the fabrication of large-area PSCs via scalable deposition process is prerequisite. The several successful demonstrations of scalable production of PSCs have been reported by blade, slot-die, and inkjet coating, yielding uniform perovskite films with a high quality. Nevertheless, the direct printing of the desirable layer with arbitrary shape and size at a relatively high deposition speed remains a great challenge for flexible PSCs. In this presentation, we will present the fabrication of all-printed PSCs with a n-i-p structure on flexible substrates using gravure printing, which is a roll-to-roll compatible deposition method enabling a realization of the desirable image pattern. The successful formation of Methylammonium (MA)-based perovskite layer is demonstrated by gravure printing using the one-step method employing printing and successive antisolvent-bathing process. The SnO2 and Spiro-OMeTAD as electron- and hole-transporting layer are also gravure-printed. As a result, the all-printed PSCs showed a PCE of 17.2% in reverse scan and a stable power output over 1000 s. [1] For a better performance, Formamidinium (FA) based, multi-cation perovskite films are prepared by gravure printing. Eco-friendly and efficiently extracting antisolvent is newly suggested so as to successfully form a uniform FA-based perovskite layer and extend the process to roll-to-roll scale. Consequently, gravure-printed cells exhibited PCE of over 18% for table-top printing and over 15% for partial roll-to-roll process, respectively. Furthermore, the gravure-printed perovskite layers fabricated by the two-step method via mediator extraction treatment (MET) will be discussed in this presentation. [2]

High-Performance, Stable and Flexible Perovskite Solar Cell for Wearable Photovoltaic Systems Janak Thapa, Sai Nithin Reddy Kantareddy, Noor Titan Putri Hartono, Ian Mathews, Sanjay Sarma, Ian Marius Peters, Shijing Sun and Tonio Buonassisi; Massachusetts Institute of Technology, United States

Perovskite solar cells (PSCs) show great promise as an emerging photovoltaic technology (PV) because of their low cost and relative ease of manufacturing. In a previous study, we demonstrated the application of flexible solar cells for wireless systems, using them as external power sources for radio-frequency identification (RFID) sensors [1]. Traditionally, the performance of PSCs deposited on plastics is inferior to their on-glass counterparts, both in terms of efficiency and stability. We, therefore, performed a diagnostic study to determine the key performance limiting factors and understand the root-cause of the performance drop. Our results identified shunting effect as a major contributor for low efficiency in flexible cells. Hence, we performed process optimization through cleaning, etching, morphology control and chemical doping, and achieved an improvement in efficiency from 10% to over 13% in an ongoing process. We evaluated the device stability via an accelerated aging test in our in-lab stability chamber and performed a comparative study on the degradation mechanisms of PSCs deposited on glass and plastics, respectively. Our study shows significant improvement in the performance of flexible PSCs and contributes to the development of flexible PSCs for wearable technologies, such as solar-powered RFID.

EN08.09.33
Large-Scale Deposition of Copper (I) Thiocyanate Hole Transport Material for Use in Perovskite Solar Cells Lokeshwari Mohan1,2, Martyn McLachlan1 and Joe Briscoe2; 1Imperial College London, United Kingdom; 2Queen Mary University of London, United Kingdom

Copper (I) thiocyanate (CuSCN) is an optically transparent, wide bandgap (3.4-3.9 eV), p-type semiconductor used in organic and perovskite solar cells. In comparison to other hole transporting materials (HTMs), CuSCN is economically favourable and comparable in performance, with efficiencies for hybrid organic-inorganic metal halide perovskite solar cells exceeding 20% [1].

Current research involves several solution-processable methods such as spin coating, spray coating and doctor blading. This study reports the first ever deposition of CuSCN via aerosol assisted chemical vapour deposition (AACVD). AACVD is a scalable ambient-pressure technique with low processing costs and simple reactor design. An added advantage is the flexibility over material choice due to the process being dependent on the solubility of the precursor, rather than the volatility as in conventional chemical vapour deposition techniques [2].
The study involves deposition of CuSCN using three different solvents: dipropyl sulfide, diethyl sulfide and ammonium hydroxide. For each CuSCN/solvent combination, deposition temperature, concentration of solution and amount of precursor solution deposited were varied. CuSCN films produced by diethyl sulfide solvent were further optimised by studying the growth characteristics. CuSCN films deposited via AACVD were compared to films produced by conventional spin coating methods. Scanning electron microscopy (SEM), atomic force microscopy (AFM), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and ultraviolet-visible spectroscopy (UV-Vis) were used to determine morphological, structural and optical information.

Using the optimised conditions, AACVD CuSCN was incorporated into a working methylammonium lead iodide perovskite solar cell. Addition of interlayers, different electron transport layers and device architectures were explored to determine structure with highest performance. Studies into the solar cell performance allowed further understanding of the less well-known CuSCN HTM. Solar cells were tested under AM 1.5 and a champion efficiency of 10.44% was achieved, which represents the first ever working solar cell using AACVD CuSCN.

EN08.09.34
Laser Scribing of Organometal Halide Perovskite Solar Cells for See-Through Module Fabrication David Hwang¹, Zhen Wang¹, Seungkuk Kuk¹ and Jeung-hyun Jeong²; ¹State University of New York at Stony Brook, United States; ²Korea Institute of Science and Technology, Korea (the Republic of)

Organometal–halide perovskite solar cells (PSC) have attracted attention by its unprecedented rise in device efficiency. However, the PSCs were mostly tested for the unit cell of small area. Therefore, it is important to upscale to solar modules that provide desired voltage and power output. Laser scribing technology, proven for the conventional thin film solar cell fabrication process, can be effectively extended for PSC module fabrication. The P1 scribing to isolate the transparent bottom electrode layer is essentially identical to the conventional laser scribing task. However, the P2 laser scribing to expose the bottom electrode for serial interconnect with the minimal contact resistance has been recognized as a challenging process; it is important to develop reliable single-step P2 process removing necessary stack of films, e.g., including hole blocking layer, without damaging bottom electrode, depending on the PSC material architectures selected. Although the P3 laser scribing to isolate the top electrode layer has been assumed to be less difficult, close examination of possible electrical shunt and/or unwanted damage of underlying structures are required. On the other hand, the P4 laser scribing to fabricate see-through patterns should minimize electrical shunt and/or degradation of surrounding structures with high optical transmissivity or visuality. Current study will focus on addressing the aforementioned challenges by exploring the optimal PSC laser scribing parameters based on pico- and nano- second lasers of various wavelengths from ultraviolet to visible and near-infrared, illuminated both from film and substrate sides. Relevant mechanisms and further improvement plans will be also discussed based on the measured module performance in conjunction with morphological, compositional, optical and spectroscopic characterization results.

EN08.09.35
Engineering of the Back Contact between PCBM and Metal Electrode for Planar Perovskite Solar Cells with Enhanced Efficiency and Stability Shaobing Xiong and Qinye Bao; East China Normal University, China

The cathode interface plays a critical role in achieving high-performance fullerene/perovskite planar solar cells, governing the charge extraction and transport behaviors between the perovskite layer and the electrode. However, there is a high energy mismatch between PCBM and the commonly used metal cathode electrode aluminum (Al) and silver (Ag), severely restricting the electron extraction at the contact and therefore leading to poor device performance. [1]

Herein, organic dyes, Isatin and Isatin-Cl, which are abundant, cheap, air stable, and easy to modify in terms of their chemical structure, are introduced at the back contact PCBM/Al as a cathode modification interlayer due. [2] It is revealed that the Isatin interlayers facilitate electron transport/extraction and suppress electron recombination, attributed to the formation of negative dipole potential steps and the passivation of the interfacial trap density. The
average power conversion efficiencies of the resulting devices are significantly improved by 11% from 17.68 % to 19.74%, with an enhancement in all device parameters including short-circuit current, open-circuit voltage and fill factor. The hysteresis index is found to disappear. In addition, such interlayer enhances device stability under ambient conditions compared to the control devices due to suppression of moisture-induced degradation of the perovskite films. Our findings provide a comprehensive understanding of the engineering of the back contact between PCBM and the metal electrode to improve efficiency and stability of perovskite solar cells.

EN08.09.36
Analyzing the Reactivity of Surface Ligands with MAPbI3 Films and Their Influence on Photoluminescence, Stability and Photovoltaic Performance
So Min Park, Ashkan Abtahi and Kenneth R. Graham; University of Kentucky, United States

Surface ligand treatment provides a promising approach to passivate defect states and improve the photoluminescence quantum yields (PLQY), charge-carrier mobilities, material and device stability, and photovoltaic (PV) device performance of organic metal halide perovskites (OMHPs). Numerous surface treatments have been applied to OMHP thin films and shown to passivate defect states and improve the PLQY and PV performance of OMHPs, but it is not clear which surface modifiers bind to the surface and to what extent. As surface ligands have the potential to passivate defect states, alter interface energetics, and manipulate material and device stability, it is important to understand how different functional groups interact with the surfaces of OMHP thin films. In this study, we investigate a series of ligand binding groups and systematically probe the stability of the bound surface ligands, how they influence PL properties, film stability, and PV device performance. We observe phosphonic acids (PAs) form reasonably stable surface bonds, whereas carboxylic acids (CAs) and thiols do not. Trichlorosilane (SiCl3) groups react rapidly and lead to thicker surface layers that restrict charge transfer at the perovskite/electron transport layer (ETL) interface. Ammonium salts react rapidly to displace the methylammonium cations, thus resulting in less control over formation of only a surface layer. Despite the fact that we do not detect thiol or CA binding with XPS measurements, both of these surface ligands lead to increased PL intensity and increased stability. Furthermore, toluic acid treatment of MAPbI3 based inverted PV devices results in an improved power conversion efficiency from 16.5% to 19.3%.

Chemomechanical Effect of Cutting Fluid Affects Ductile Mode Material Removal in Slicing Silicon Wafers for Photovoltaics
Arkadeep Kumar1,2 and Shreyes Melkote2; 1Lawrence Berkeley National Lab, United States; 2Georgia Institute of Technology, United States

Mechanical strength of crystalline silicon wafers sliced by diamond wire sawing process depends on the surface and subsurface damage (in form of microcracks) caused by material removal processes. The type and the extent of damage depends on material removal being ductile or brittle. In this work we investigated the chemo-mechanical effect of cutting fluid on material removal mechanisms in single crystal silicon by scribing experiments, which simulates the material removal mode of industrial diamond wire slicing process. We show experiments between of scribing single crystal silicon in dry and in presence of water-based cutting fluids. Our results show more ductile material removal of silicon in presence of the cutting fluid – such chemomechanical effect of fluid on silicon has not been reported in literature, and provide new ways of reducing surface and subsurface damage in silicon wafers.

EN08.09.38
Effect of Polycrystalline Silicon on Wear of Diamond In Scribing
Arkadeep Kumar1,2 and Shreyes Melkote2; 1Lawrence Berkeley National Lab, United States; 2Georgia Institute of Technology, United States

Multi-crystalline silicon (mc-Si) is cheaper than single-crystalline silicon and hold promise of delivering affordable photovoltaic energy. However, manufacturing process of multi-crystalline silicon wafers by slicing with diamond wire sawing faces challenges of reduced efficiency with increased consumption of the diamond abrasives on the wire. We simulate the cutting process by fundamental scribing or scratch experiments with diamond on single and multi-crystalline silicon substrates. We used two tips of same geometry conical diamond indenters, and monitored the wear of diamond by microscopy and radius of curvature measurements, apart from contact forces for mc-Si
versus single-crystal silicon. We found that the forces are higher for diamond contacting for mc-Si, and corresponding increase in tip radius being higher in mc-Si versus single-crystal silicon, due to higher stresses and wear of the tip. We found the fracture surfaces of diamond show micro-fracture and blunting from high resolution scanning electron microscopy and confocal microscopy. Stress induced phased transformation of diamond along with compressive residual stresses were measured using Raman spectroscopy for difference in silicon material structure. We explain the results using material inhomogeneity of multi-crystalline silicon for increased wear of diamond cutting the material, compared to single crystal silicon.

SESSION EN08.10: Perovskite Solar Cell—2D, Stability, Nanostructures

Two Dimensional Organic-Inorganic Perovskite from Nanostructures to Solar Cells Lioz Etgar; Hebrew University, Israel

Perovskite is a promising light harvester for use in photovoltaic solar cells. In recent years, the power conversion efficiency of perovskite solar cells has been dramatically increased, making them a competitive source of renewable energy. This work will discuss new directions related to organic inorganic perovskite and their applications in solar cells. In low dimensional systems, stability of excitons in quantum wells is greatly enhanced due to the confined effect and the coulomb interaction. The exciton binding energy of the typical 2D organic-inorganic perovskites is up to 300 meV and their self-assembled films exhibit bright photoluminescence at room temperature. *In this work we will show the dimensionality in the perovskite structure. The 2D perovskite structure should provide stable perovskite structure compared to the 3D structure. The additional long organic cation, which is added to the perovskite structure (in the 2D structure), is expected to provide hydrophobicity, which will enhance the resistivity of the perovskite to humidity. Moreover we will demonstrate the use of 2D perovskite in high efficiency solar cells.

* Organic-inorganic halide perovskite is used mainly in its “bulk” form in the solar cell. Confined perovskite nanostructures could be a promising candidate for efficient optoelectronic devices, taking advantage of the superior bulk properties of organo-metal halide perovskite, as well as the nanoscale properties. In this talk, I will present our recent progress related to the synthesis and characterization of perovskite NPs - i.e. Inorganic and hybrid organic-inorganic NPs. New nanostructures such as: NRs and NWs will be presented and the introduction of other cations such as Rb will be shown.

9:00 AM *EN08.10.02
Crystal Orientation Drives the Interface Physics at 2/3-Dimensional Hybrid Perovskites Marine E. Bouduban1, Valentin I. Queloz1, Valentina Caselli2, Kyung Taek Cho1, Ahmad R. Kirmani1, Sanghyun Paek1, Cristina Roldan Carmona1, Lee Richter1, Jacques E. Moser1, Tom J. Savenije2, Mohammad K. Nazeeruddin1 and Giulia Grancini1; 1EPFL, Switzerland; 2Delft University of Technology, Netherlands; 3National Institute of Standards and Technology, United States

Combining halide perovskites with tailored dimensionality into two/three-dimensional (2D/3D) systems has revealed a powerful strategy to boost the performances of perovskite photovoltaics (PVs). Despite the recent advances, a clear understanding on the intimate link between interface structure and physics is still missing, leading so far to a blind optimization of the 2D/3D PVs. Here, we reveal the impact of 2D/3D crystal alignment in driving the interface charge-recombination dynamics. The 2D crystal growth and orientation is manipulated by specific fluorination of the phenethylammonium (PEA), used here as the organic cation backbone of the 2D component. By means of time-resolved optoelectronic analysis from femto- to microsecond, we demonstrate a static function of the 2D as electron barrier and homogeneous surface passivant, together with a dynamical role in retarding back charge recombination. Our results reveal a crucial dependence of such beneficial effect with the 2D crystal orientation, leading to enhanced open circuit voltage (V_{OC}) if 2D lies parallel on the 3D. Such findings provide a deep
understanding and delineate precise guidelines for the smart design of multi-dimensional perovskite interfaces for advanced PV and beyond.

9:15 AM EN08.10.03
From 2D to 1D Electronic Dimensionality in Halide Perovskites with Stepped and Flat Layers Using Propylammonium as a Spacer
Justin M. Hoffman1, Xiaoyang Che2, Siraj Sidhik3, Xiaotong Li1, Ido Hadar4, Jean-Christophe Blancon5, Hisato Yamaguchi6, Mikael Kepenekian7, Claudine Katan8, Jacky Even9, Constantinios Stoumpos1, Aditya D. Mohite3 and Mercouri G. Kanatzidis1; 1Northwestern University, United States; 2Université de Rennes, France; 3Rice University, United States; 4Los Alamos National Laboratory, United States

Two-dimensional (2D) hybrid halide perovskites are promising in optoelectronic applications, particularly solar cells and light emitting devices (LEDs), and for their increased stability compared to 3D perovskites. Here, we report a new series of structures using a propylammonium (PA+) cation which results in a series of Ruddlesden-Popper (RP) structures with the formula (PA)2(MA)n-1PbnI3n+1 (n = 3, 4) and a new homologous series of “step-like” (SL) structures where the PbI6 octahedra connect in both a corner- and face-sharing motif with the general formula (PA)2m+4(MA)m-2Pb2m+1I7m+4 (m = 2, 3, 4). The RP structures show a blue-shift in bandgap for decreasing n while the SL structures have an even greater blue-shift. DFT calculations show that, while the RP structures are electronically 2D quantum wells, the SL structures are electronically 1D quantum wires with the chains of corner-sharing octahedra “insulated” by blocks of face-sharing octahedra. These blocks form an additional lateral carrier confinement barrier that prevents any significant electronic coupling across the face-sharing octahedra and results in 1D electronic dimensionality. Dark measurements for RP crystals show high resistivity perpendicular to the layers but a lower resistivity parallel to them. The SL crystals have varying resistivity in all three directions, confirming both RP and SL crystals’ utility as anisotropic electronic materials. The RP structures show strong photoresponse and are utilized in solar cell devices. Solar cells were made with n = 3 using “hotcasting” and solvent engineering methods giving an efficiency of 7.04% (average 6.28 ± 0.65%) with negligible hysteresis.

9:30 AM EN08.10.04
Uniformly Arranging Different-n-Value Nanoplates for Developing Highly Efficient Quasi-2D Perovskite Solar Cells
Jia Zhang1, Jiajun Qin2, Miaosheng Wang1, Yujie Bai2, Han Zou1, Hengxing Xu1, Jong K. Keum4, Haomiao Yu5 and Bin Hu1; 1University of Tennessee, United States; 2Fudan University, China; 3University of Strasbourg, France; 4Oak Ridge National Laboratory, United States; 5Beijing Jiaotong University, China

Quasi-2D perovskites are inevitably formed with multi-layer nanoplates of different n values. Normally, the nanoplates are vertically arranged from small-n-value to large-n-value structures between bottom and top surfaces in quasi-2D perovskite films, forming a common approach to facilitate charge transfer for developing high-performance optoelectronic devices. Here, we report a different strategy of uniformly arranging different-n-value nanoplates (PEA2MAn-1PbnI3n+1) between bottom and top surfaces in quasi-2D perovskite films to generate high-performance solar cells by introducing vacuum poling treatment right after spin-coating of precursor solution. By mechanically peeling off the monolayers of nanoplates with our delicate scotch-tape method while monitoring the photoluminescence (PL), we un-ambiguously show that our vacuum poling method can create the uniform dispersion of different-n-value nanoplates between bottom and top surfaces in quasi-2D perovskite films, as compared to the conventional ordered dispersion of nanoplates from n = 1 to n = 5 prepared without vacuum poling treatment. The transient absorption (TA) measured through bottom and top surfaces show that the efficient carrier transfer occurs within 10 ps from small-n-value nanoplates to large-n-value nanoplates under uniform dispersion, presenting an efficient carrier extraction mechanism. The PL dynamics indicate that uniformly arranging different-n-value nanoplates leads to small-n-value and large n-value nanoplates functioning as passivation agents and light-emitting centers with significantly enhanced PL intensity and lifetime. Moreover, the record-high fill factor (FF) of 82.4 % was realized with the power conversion efficiency (PCE) of 18.04% (Voc = 1.223V and Jsc = 17.91 mA/cm2), showing an extremely efficient carrier extraction occurring in the quasi-2D perovskite device (ITO/PTAA/quasi-2D perovskites/PC61BM/PEI/Ag) based on this new strategy. Therefore, uniformly arranging different-n-value nanoplates offers a new materials engineering strategy to enhance carrier transfer and extraction for developing high-performance quasi-2D perovskite solar cells.

All-Organic CsPbI₃ Perovskite for High Efficiency Photovoltaics Yong Wang, Taiyang Zhang and Yixin Zhao; Shanghai Jiao Tong University, China

The all-inorganic lead halide perovskite without volatile component would be a promising alternative candidate for high efficiency photovoltaics. However, the all inorganic CsPbI₃ with most suitable band gap face the challenges of low room temperature phase stability and relative low efficiency. To enhance the performance and stability of all-inorganic CsPbI₃ perovskite, the 2D/3D configuration especially the (110) oriented 2D perovskite component was introduced to stabilize the α-CsPbI₃. The (110) oriented 2D based on EDAPbI₄ help stabilize α-CsPbI₃ to achieve up to >11% efficiency. Impressively, the Cs cation in CsPbI₃ would not ion exchanged with organic cation, which is significantly different from the hybrid and a signal for the promising cation stability of inorganic perovskite. Therefore, a facile organic cation surface termination approach was developed to significantly enhance the stability and performance of α-CsPbI₃ solar cell with >15% efficiency. The bifunctional stabilization of CsPbI₃ with gradient Br doping and organic cation termination finally improve the efficiency of CsPbI₃ perovskite solar cells to a record value of 17% with enhanced stabilities.

10:45 AM EN08.11.02
High Efficiency 16.37% of Cesium Bromide-Passivated All-Inorganic CsPbI₂Br Perovskite Solar Cells Yuqing Zhang, Cuncun Wu and Bo Qu; Peking University, China

Recently, the all-inorganic CsPbI₂Br perovskite attracts increasing attention owing to its outstanding thermal stability and suitable bandgap for optoelectronic devices. However, the substandard power conversion efficiency (PCE) and large energy loss ($E_{\text{loss}}$) of CsPbI₂Br perovskite solar cells (PSCs) caused by the low quality and high trap density of perovskite film, still limit the application of devices. Herein, we utilize the post-treatment of evaporating cesium bromide (CsBr) on top of perovskite surface to passivate the CsPbI₂Br/hole-transporting layer interface and reduce $E_{\text{loss}}$. The results of micro zone photoluminescence indicate that the evaporated CsBr gathered at grain boundaries of CsPbI₂Br layers and Br-enriched perovskites (CsPbIₓBr₃₋ₓ, x<2) are formed, which can provide protection for CsPbI₂Br. Therefore, the gaps between crystal grains are filled up and the recombination loss of the all-inorganic CsPbI₂Br PSCs is reduced accordingly. The champion device exhibits the high open-circuit voltage and PCE of 1.271 V and 16.37%, respectively. To the best of our knowledge, it’s the highest PCE among all-inorganic CsPbI₂Br PSCs reported so far. In addition, the stability of CsPbI₂Br PSCs is effectively improved by CsBr passivation and the device without encapsulation can retain 86% of its initial PCE after storage of 1368 hr, which is beneficial to the practical application.

11:00 AM EN08.11.03
Straining to be Black—On the Thermal Unequilibrium of Metastable Perovskite Thin Films Julian A. Steele, Johan Hofkens and Maarten Roefraers; KU Leuven, Belgium

The all-inorganic CsPbI₃ perovskite offers the prospect of a more stable alternative to hybrid organic-inorganic perovskites. Unfortunately, like many other polymorphic perovskite systems, the metastability of its high-temperature black phase (l) stands in the way of realizing room-temperature (RT) stable optoelectronic devices. It is of interest to find ways to shift the energetics of CsPbI₃, in order to secure RT black phase formation over its yellow non-perovskite phase (2). In this presentation, we outline the role of glass substrate clamping and biaxial strain (induced by the large thermal expansion mismatch) to realize RT stable black-phase CsPbI₃ thin films. Employing synchrotron-based grazing incidence wide angle X-ray scattering with extremely fast acquisition time (~0.1 s), we track the introduction of crystal distortions and texture formation within black CsPbI₃ thin films as they are cooled from annealing temperatures. The thermal stability of black CsPbI₃ thin films are vastly improved by the strained interface, a response verified by ab initio thermodynamic modelling. This contribution introduces substrate clamping as an important parameter in the rational design of stable RT black inorganic halide perovskite thin films.

High-Stability All-Inorganic Perovskite Solar Cells  Jia Liang and Jun Lou; Rice University, United States

Hybrid organic-inorganic halide perovskite solar cells (PSCs) have attracted a great deal of attention as they show promises toward the development of next generation solar cells, with the highest power conversion efficiency (PCE) reaching 24%. However, these types of PSCs, such as PSCs based on methylammonium lead iodide (MAPbI3) or formamidinium lead iodide (FAPbI3), exhibited poor stability against moisture and heat. Moreover, hole transport materials (HTMs) in these traditional PSCs (Spiro or PTAA) are very expensive and need some additives to improve their mobility. In order to overcome these disadvantages, we develop all-inorganic PSCs based on CsMX3 (M = Pb, Sn, In; X = I, Br, Cl) and low-cost carbon films. First, we employed CsPbBr3 as the absorb layer in the all-inorganic PSC, which showed excellent stability even under environmental stress and without any encapsulation. However, because the bandgap of CsPbBr3 was 2.3 eV, the light absorption for CsPbBr3 was only up to ~540 nm, which led to the low PCE. As CsPbI3 possesses a smaller bandgap (1.7 eV) than CsPbBr3, CsPbI3-based all-inorganic PSCs are subsequently developed. However, they still exhibited lower PCEs because of the existence of defects and poor stability. Therefore, in our recent work, we engineered the defect densities in CsPbI3, and a new all-inorganic perovskite material, CsPbI3:Br:InI3, was prepared. This new perovskite retained the same bandgap as CsPbI3, while the intrinsic defect concentration has been largely suppressed. Moreover, it can be prepared under extremely high humidity atmosphere thus a glovebox was not required. By completely eliminating the labile and expensive components in traditional PSCs, the all-inorganic PSCs based on CsPbI3:Br:InI3 and carbon electrode exhibited the PCE and open-circuit voltage as high as 12.04% and 1.20 eV, respectively. More importantly, the encapsulated all-inorganic PSCs based on CsPbI3:Br:InI3 demonstrated excellent stability in air for more than two months, while those based on CsPbI3 can just survived a few days in air. The progresses reported here open the door for all-inorganic PSCs with long-term stability under harsh conditions, making practical application of the PSC with high performance a real possibility.

Highly Efficient CsPbBr2 Perovskite Solar Cells—Interface Modification and Heteroatom Substitution  Kai Wang1, Waqas Siddique Subhani1 and Shengzhong (Frank) Liu1,2; 1Dalian Institute of Chemical Physics, China; 2Shaanxi Normal University, China

The state-of-the-art organic-inorganic halide perovskite solar cells (PSCs) have scored tremendous achievements as reflected by the highest power conversion efficiency (PCE) skyrocketing to over 24.2% in just a few years.[1] Nevertheless, the long-term stability of the hybrid perovskite inherited from its organic moiety remains a major hurdle preventing it from commercialization. For further development of PSCs, a more robust inorganic cesium halide perovskite (CsPbX3, X = I or Br) without a fragile organic component and possessing a range of spectacular advantages, including superb thermal stability (> 300 °C) and high electron mobility, is considered to have more potential than the organic-inorganic hybrid material. As such, it is extremely crucial to design inorganic perovskite-based solar cells possessing both excellent photovoltaic performance and outstanding stability. Among the shared inorganic perovskite employed in PSCs, CsPbBr2 is considered a feasible material for tandem solar cells after balancing the band gap and stability of the inorganic perovskite. Nevertheless, the performance of CsPbBr2 PSCs has lagged behind that of other analogs, far from its highest theoretical efficiency. In general, the inferior performance is attributed to substantial interface recombination and non-radiative recombination within the perovskite.

Accordingly, we report a facile interface modification strategy for inorganic PSCs, wherein a low-cost lanthanide halide, SmBr3, is incorporated to modify the TiO2/CsPbBr2 interface.[2] Apart from its effects at the interface, SmBr3 can diffuse into the perovskite layer and induce a blocking layer with a gradient energy band gap. Therefore, SmBr3 interface modification can not only optimize the charge transfer process and restrain interface recombination, but also suppress the non-radiative recombination within the perovskite material. Finally, the devices with SmBr3 interface modification yield a high PCE of 10.88%.

In addition, Ba2+ was doped in CsPbBr2 to suppress the inside non-radiative recombination.[3] Ba2+ with large radius can result in an undesired tolerance factor less than 0.8, but strikingly, the Ba2+-doped CsPbBr2 has beneficial
morphology and excellent crystallinity as well as suppressed carrier recombination. Compared with the control sample, Ba\(^{2+}\) doping boosts the device efficiency from 8\% to 10.5\%. This finding indicates that the perovskite films are tolerant to Goldschmidt-rule-deviating homovalent heteroatoms, extending the substitution engineering of inorganic perovskite.

Effective Strategies to Improve the Performance and Operational Stability of Perovskite Solar Cells

M Ibrahim Dar; University of Cambridge, United Kingdom

Over a span of a decade, perovskite solar cells have evolved as a promising photovoltaic technology by displaying a meteoric rise in the power-conversion efficiencies. However, it is equally important that the performance of perovskite solar cells sustains under operating conditions over a long period of time. Therefore, their stability under different conditions such as illumination, humidity, and thermal stress needs to be thoroughly investigated. It is well known that the stability problems of perovskite solar cells arise from the degradation of the light-absorbing and/or charge extraction layers and the deterioration of various interfaces across the solar cell. We have employed three main strategies to develop better perovskite-based devices that are not only efficient but also stable. We have investigated the interfaces on both sides of the hole transporting material (HTM) i.e., perovskite absorber/HTM and HTM/back contact interface in a solar cell device to mitigate the catastrophic stability issues associated with perovskite solar cells. We explored three main strategies including employing all-inorganic charge extraction layers [1]. This has led to the CuSCN hole extraction layer based devices with stabilized efficiencies exceeding 20\%. Another strategy involves using highly water-repellent wide bandgap perovskite layer inserted between the 3D light-harvesting perovskite film and HTM. This approach combines the suitable properties of 2D layer (ultrahydrophobicity, improved interfacial hole extraction, enhanced operational stability under humid conditions) enabling perovskite solar cells with 3D/2D architecture with efficiencies exceeding 22\% [2]. The third strategy is to introduce electrochemically stable or inert layers, which, respectively, facilitate or allow the transport of holes, either in between perovskite and hole transporting layer or in between hole conductor and metallic back contact [1, 3]. It is worth emphasizing that these approaches not only allowed us to realize high efficiencies but also outstanding stability under operational conditions for perovskite solar cells. In my presentation, important fundamental insights gained through various structural, morphological, and spectroscopic characterization techniques directly impacting the performance and stability of perovskite solar cells will be discussed.

**Stability of Perovskite Solar Cells—Molecular Design and Defects Passivation**  
Songyuan Dai, Molang Cai and Yong Ding; North China Electric Power University, China

The photovoltaic efficiency of perovskite solar cells (PSCs) has remarkably developed, while poor stability is a huge barrier for the commercialization of PSCs. The strategies to enhance stability are portrayed in terms of moisture and illumination endurance of photoactive layer as well as defects at interfaces of different layers. Here we effectively improve the stability of perovskite solar cell by molecular design and defects passivation. Firstly, the quasi 2D molecular with several ammonium salts are design for enhance the hydrophobic properties of photoactive layer. The halogen functional groups are further introduced to improve the poor charge transport with high-quality perovskite films with better crystallization. The optimal 2D PSCs exhibit high efficiency of 20.08% as well as retain 92% initial PCE after aging at 50 ± 5% relative humidity for 2400 h. Moreover, the defects of photoactive layer are reduced by controlling the growth and nucleation of perovskite film and adding passivation additives. The C60/TiO2 bilayer were employed to gain intimate contact between the ETL and perovskite, which results in an enhanced perovskite crystallization and a reduced charge recombination at the interface. The bilayer-based PSC shows outstanding stability, retaining 83% and 90% of its initial performance after 312 h UV irradiation and 1000 h exposure to ambient air, respectively.

**Enhancing Electron Diffusion Length in Narrow-Bandgap Perovskites for Efficient Monolithic Perovskite Tandem Solar Cells**  
Zhenhua Yu, Zhibin Yang and Jinsong Huang; University of North Carolina at Chapel Hill, United States

Developing multijunction perovskite solar cells (PSCs) is an attractive route to boost PSC efficiencies to above the single-junction Shockley-Queisser limit. However, commonly used tin-based narrow-bandgap perovskites have shorter carrier diffusion lengths and lower absorption coefficient than lead-based perovskites, limiting the efficiency of perovskite-perovskite tandem solar cells. We discover that the charge collection efficiency in tin-based PSCs is limited by a short diffusion length of electrons. Adding proper additive into tin-perovskite precursors reduce the background free hole concentration and electron trap density, yielding a long electron diffusion length of 2.72±0.15 µm. It increases the optimized thickness of narrow-bandgap perovskite films to 1000 nm, yielding exceptional stabilized efficiencies of 20.2% and 22.7% for single junction narrow-bandgap PSCs and monolithic perovskite-perovskite tandem cells, respectively. This work provides a promising method to enhance the optoelectronic properties of narrow-bandgap perovskites and unleash the potential of perovskite-perovskite tandem solar cells.

2:15 PM EN08.12.03  
**High-Efficiency Solution-Processed Perovskite—Colloidal Quantum Dot Tandem Solar Cells**  
Afshal Manekkathodi1, Bin Chen2, Junghwan Kim1, Benjamin Scheffel2, Yi Hou2, Maksud Saidaminov2, Oleksandr Voznyy2, Vinod Madhavan1, Abdelhak Belaidi1, Sahel Ashhab1 and Edward H. Sargent2; 1Hamad Bin Khalifa University (HBKU), Qatar; 2University of Toronto, Canada; 3Photo-electronic Hybrids Research Center, Korea Institute of Science and Technology, Korea (the Democratic People's Republic of)

Multi-junction solar cells composed of complementary absorber layers with appropriate bandgaps offer avenues to improve the AM1.5 power conversion efficiency (PCE) beyond the Shockley-Queisser (SQ) limit of single-junction solar cells. In particular, PV technologies based on low-temperature solution processing have attracted interest in the pursuit of low-cost, flexible, and lightweight solar cells. Solution-processed perovskite/perovskite tandem solar cells have achieved significant progress in recent years. However, face a fundamental limitation on the path to reaching their full tandem potential due to the lack of efficient low-temperature processed IR back solar cell technology. Perovskite:colloidal quantum dot (CQD) hybrid tandems offer a route to overcoming this limitation. PbS CQDs are desirable for third-generation solar cell technology, owing to their superior photoelectric properties, facile bandgap tunability, and low-temperature solution-processability. The band gaps of CQDs can reach 0.5 eV providing a path to harness photons in the near to deep infrared region of the solar spectrum, beyond the capacity of crystalline silicon and perovskites. Here we report a solution-processed four terminal (4T) tandem solar cell composed of a perovskite front cell and a PbS CQD back cell, with a PCE exceeding 21% and a stabilized efficiency of 20%. This is the highest reported PCE of the perovskite/CQD tandem solar cell to date, and it surpasses the performance of
both the perovskite and the CQD single junction double-pass solar cells. We developed a dielectric-metal-dielectric (DMD) electrode to enable semi-transparent perovskite solar cells that combine enhanced transmittance and conductance for record-performing front cells. The DMD structure is designed to have high IR transmittance by optimizing the thickness of top dielectric oxide based on the zero-reflection condition in the optical admittance diagram. As a result, we achieved an increase of 25% in IR transmittance, and this enabled us to take advantage of CQDs as IR absorbers and boost the photon collection beyond the capacity of prior solar cells. The semi-transparent perovskite solar cell has a best PCE of 19.0% and a stabilized efficiency of 17.5%. The back cell is fabricated based on the IR PbS CQD absorber layers that is complementary to the IR transmittance characteristic of semi-transparent perovskite solar front cell for the optimized 4T tandem performance. The CQD:perovskite 4-terminal tandem is designed by mechanically stacking the 1.15 eV PbS-CQD solar cell as the back cell to the semi-transparent perovskite (1.63 eV) front cell. The EQE measurements of 1.15 eV and 0.95 eV CQD absorbers showed high EQE values at the exciton peaks; which indicates that the solar cells have an excellent IR charge collection efficiency from light harnessed beyond the perovskite absorption at ~750 nm. The short circuit current of the filtered CQD solar cell were ~6 mA/cm2 after filtering the perovskite front sub-cell. The Voc of the device is only marginally reduced, while a small increase in the fill factor is obtained. In the 4T measurement of the CQD solar cell, for the best performing cell, we were able to get a filtered PCE of 2.11%. Together with the 19.02% efficiency of the perovskite front cell, this gives 21.13% efficiency for the tandem device. Significant progress could be achieved in this perovskite:CQD tandem device in future, with concurrent advances in the light management in the perovskite sub-cell and IR charge collection techniques in the CQD sub-cell. Solution-processed hybrid tandem photovoltaics combining these two emergent PV technologies open the possibility to realize not only high-efficiency solar cells with substantial reductions in the cost of solar electricity but also next-generation flexible photovoltaic (PV) devices.

2:30 PM EN08.12.04
Efficient and Stable Monolithic All-Perovskite Tandem Solar Cells Renxing Lin1, Ke Xiao1, Chunfeng Zhang1, Edward H. Sargent2 and Hairen Tan1; 1Nanjing University, China; 2University of Toronto, Canada

Combining wide-bandgap and narrow-bandgap perovskites to construct monolithic all-perovskite tandem solar cells offers avenues for the continued increase in photovoltaic power conversion efficiencies (PCEs). However, the actual efficiencies of all-perovskite tandem solar cells today are diminished by the subpar performance of narrow-bandgap subcells. Here we report a strategy to reduce Sn vacancies in mixed Pb-Sn narrow-bandgap perovskites. We increase thereby the charge carrier diffusion length in narrow-bandgap perovskites, and we obtained a PCE higher than 20% for 1.2-eV narrow-bandgap solar cells. We then developed a recombination junction that avoids sputtered transparent-conductive-oxide and takes advantage instead of robust and compact recombination layer processed via atomic layer deposition. We fabricated monolithic all-perovskite tandem solar cells with PCEs beyond 23%. The tandem solar cells retained 90% of their performance after more than 400 hours of operation at the maximum power point under full one-sun illumination.

Materials and Process Issues in Facilitating Commercialization of Perovskite Solar Cells Hyun Suk Jung; Sungkyunkwan University (SKKU), Korea (the Republic of)

All solid-state solar cells based on organometal trihalide perovskite absorbers have already achieved distinguished power conversion efficiency (PCE) to over 24% and further improvements are expected up to 25%. Now, the research on perovskite solar cells has been moving toward commercialization. To facilitate commercialization of these great solar cells, some technical issues such as long-term stability, large scale fabrication process, and Pb-related hazardous materials need to be solved. Also, exploitation of flexible solar cell is of great importance for commercialization in niche markets. This talk is dealing with our recent efforts to facilitate commercialization of perovskite solar cells. For examples, we introduce a recycling technology of perovskite solar cells, which covers the regeneration process of Pb contained perovskite layer as well as recycling process of Au electrodes and transparent conducting oxide glass. Also, simple fabrication technologies for large scale perovskite module is going to be introduced. Finally, recent interesting results regarding ultra-flexible perovskite cells will be discussed in terms of stress analysis.
Improved Performance of Printable Perovskite Solar Cells with Bifunctional Conjugated Organic Molecules
Yue Hu and Yaoguang Rong; Huazhong University of Science and Technology, China

The past few years have witnessed a rapid evolution of hybrid organic-inorganic perovskite solar cells (PSCs) with both low cost and boosted high power conversion efficiency (PCE) over 22%. Despite the achievements, MAPbI$_3$ suffers from inherent instability over ambient operation conditions due to the low formation energy of the material itself and the high hydrophilicity of the organic cations. Efforts such as developing novel device architectures as well as exploring novel materials have been tried to improve the device stabilities. Among them, the two-dimensional (2D) perovskites that are crafted using bulkier alkylammonium cations in place of methylammonium exhibit appealing environmental stability. However, the insulating alkylammonium spacer cations hinder charge transport and limit the efficiencies of the devices based on such perovskites. In this scenario, an exploration of alternative yet effective organic spacer cations that increase the charge transfer is imperative to enhance the efficiency.

Herein, we design such an alternative bi-functional conjugated cation AB. We report the first time the incorporation of AB in 2D/3D perovskites and its implementation on solar cells. The use of bi-functional conjugated cations enhances significantly the performance of the cells, reaching a highest power conversion efficiency of 15.6% with improved stability. The efficiency remained around 90% of the initial value after 100 h continuous illumination, much more stable than MAPbI$_3$ perovskite. By comparing this cation with a mono-functional cation and a bi-functional non-conjugated cation with similar structure, we found that the bi-functional conjugated cation not only benefits the growth of perovskite crystals in the mesoporous network, but also facilitates the charge transport. Our approach helps explore new rational designs of cations in perovskites.

Carrier Lifetimes of >1 μs in Sn-Pb Perovskites Enable Efficient All-Perovskite Tandem Solar Cells
Jinhui Tong and Kai Zhu; National Renewable Energy Laboratory, United States

All-perovskite–based polycrystalline thin-film tandem solar cells have the potential to deliver efficiencies of >30%. However, the performance of all-perovskite–based tandem devices has been limited by the lack of high-efficiency, low–band gap tin–lead (Sn–Pb) mixed-perovskite solar cells (PSCs). We found that the addition of guanidinium thiocyanate (GuaSCN) resulted in marked improvements in the structural and optoelectronic properties of Sn–Pb mixed, low–band gap (~1.25 electron volt) perovskite films. The films have defect densities that are lower by a factor of 10, leading to carrier lifetimes of greater than 1 microsecond and diffusion lengths of 2.5 micrometers. These improved properties enable our demonstration of >20% efficient low–band gap PSCs. When combined with wider–band gap PSCs, we achieve 25% efficient four-terminal and 23.1% efficient two-terminal all-perovskite–based polycrystalline thin-film tandem solar cells.

Low-Bandgap 1.2 eV Tin-Lead Perovskite Solar Cells and All-Perovskite Tandem Solar Cells with Improved Device Stability
Jeremie Werner$^{1,2}$, Rohit Prasanna$^{1,2}$, Giles Eperon$^2$, Tomas Leijtens$^4$, Eli J. Wolf$^{1,2}$, Daniel J. Witter$^{1,2}$, Caleb C. Boyd$^{1,2}$, Luca Bertoluzzi$^3$, Axel F. Palmstrom$^2$, Sean Dunfield$^{1,2}$, Maikel F. Van Hest$^2$, Glenn Teeter$^2$, David T. Moore$^2$, Joseph J. Berry$^2$ and Michael D. McGehee$^1$; $^1$University of Colorado Boulder, United States; $^2$NREL, United States; $^3$Stanford University, United States; $^4$Swift Solar, United States

All-perovskite tandem solar cells have the potential to reach high efficiency but still suffer from limited stability. While a large effort of the community has been focused on improving the efficiency and stability of wide-gap (E$_g$>1.5eV) perovskite solar cells, Tin-based low-gap (E$_g$=1.2eV) perovskites still have a large room for improvement, especially in terms of stability, hindered by potential problems of Tin oxidation and improper charge selective contacts.

We will present our latest development on designing the Tin-Lead perovskite absorber composition and deposition conditions to reach high efficiency and high stability in tandem configuration. The growth conditions of the absorber are adapted to yield smooth, compact and large grained films. Then, we will discuss the crucial role of the hole selective contact in the efficiency/stability compromise. Several hole transport materials are under investigation. In particular, we will show low gap cells that can maintain >95% of initial efficiency after 1000hrs at 85°C, in air with no encapsulation. This can be achieved by eliminating the commonly used hole transport layer PEDOT:PSS and use instead the band bending effect existing at the ITO/perovskite heterojunction [1]. Further adapting an ALD-
deposited barrier and sputtered TCO layer for the Sn/Pb perovskites can improve the device environmental stability. Overall, Tin-Lead perovskite solar cells having a bandgap of ~1.25 eV will be presented with >16% efficiency and improved light, thermal and environmental stability. We will also present our progress at integrating these low gap cells into efficient and stable all-perovskite tandem solar cells. In that respect, a new perovskite tandem structure in substrate orientation will be introduced and discussed at the conference, including its potential for easier industrial penetration and lower module fabrication costs.

4:30 PM EN08.12.09
High-Resilience Compounds Enabling Monolithic Perovskite-Si Tandem Solar Cells Exceeding 27% Efficiency Yen-Hung Lin and Henry J. Snaith; University of Oxford, United Kingdom

Hybrid organic-inorganic metal-halide perovskites stand out as obvious candidates for solar energy generation and photovoltaic applications owing to their much-heralded material property trio: remarkable absorption coefficients, long-lived photocarriers and tuneable bandgaps. After the first introduction of the solid-state device architectures in 2012,1,2 tremendous efforts from both academia and industry have been devoted to research fundamental properties of metal-halide perovskites as well as to advance relevant photovoltaic technologies. Power conversion efficiency (PCE) of perovskite solar cells has since continued to soar over the past years. This skyrocketing progress has reflected on a recent record breaking PCE over 24% certified for perovskite single-junction cells, fast-approaching the performance offered by incumbent crystalline-silicon (c-Si) technologies.3 Such rapid development of perovskite photovoltaics has directly led to their emergence in the hope of preventing natural resource depletion as well as mitigating global climate change. Among the applications of perovskite photovoltaics pioneered so far, perovskite-Si tandem solar cells that feature two sub-cells operating in their optimised absorption spectrum appear to be one of the most promising photovoltaic technologies to achieve remarkable energy conversion efficiency in a cost-effective manner. The latter is largely thanks to the simplicity and versatility of metal-halide perovskite material processing.4

In this contribution, we will present high-durability metal-halide perovskite compounds enabled by a series of additives. Our approach allows ultra-high-longevity perovskite solar cells to sustain an aggressive ageing condition that combines high-strength light and heat. With numerous material and spectroscopic characterisation techniques, we will shed light on the mechanism and factors that could eventually help perovskite solar cells to resist extreme environmental conditions. Integrating our high-resilience compounds into monolithic two-terminal perovskite-Si tandem solar cells has led to a 27% PCE, surpassing the highest recorded efficiencies for single-junction c-Si solar cells. Our demonstration represents a significant advancement that validates the approach of using perovskite-Si tandem configurations to ultimately enhance the absolute performance of market-dominating Si-based photovoltaics.5,6

Efficient and Stable Printable Mesoscopic Perovskite Solar Cells Yaoguang Rong, Yue Hu, Zhengyang Fu, Yanjun Guan and Da Li; Huazhong University of Science and Technology, China

Perovskite solar cells (PSCs) have attracted much attention in the past several years due to the ever-increasing power
conversion efficiency (PCE) and simple fabrication process. Particularly, we developed a printable triple mesoscopic architecture for PSCs, which uses carbon electrodes instead of traditional noble metals and can be fabricated with screen printing process. Through optimizing the material systems, modifying the interfaces, and diversifying the device structures, the efficiency of such printable triple mesoscopic PSCs has increased from the initial ~6% in 2013 to ~18% in 2019. Besides the lower material cost and simpler fabrication process, printable triple mesoscopic PSCs also have shown promising stability under various conditions, such as high temperature (85 °C), continuous illumination (AM1.5G), and outdoor conditions. In 2018, we enlarged the cell area to module level (3600 cm2) and installed a power system for outdoor exposure.

Dynamical Transformation of Two-Dimensional Perovskites with Alternating Cations in the Interlayer Space for High-Performance Photovoltaics
Ya L. Zhang¹, Sheng Z. Liu¹,² and Kui Zhao¹; ¹Shaanxi Normal University, China; ²Dalian Institute of Chemical Physics, China

The two-dimensional (2D) perovskites stabilized by alternating cations in the interlayer space (ACI) define a new type of structure with different physical properties than the more common Ruddlesden–Popper counterparts. However, there is a lack of understanding of material crystallization in films and its influence on the morphological/optoelectronic properties and the final photovoltaic devices. Herein, we undertake in situ studies of the solidification process for ACI 2D perovskite (GA)(MA)nPbnI3n+1 (n=3) from ink to solid-state semiconductor, using solvent mixture of DMSO:DMF (1:10 v/v) as the solvent and link this behavior to solar cell devices. The in situ grazing-incidence X-ray scattering (GIWAXS) analysis reveals a complex journey through disordered sol−gel precursors, intermediate phases, and ultimately to ACI perovskites. The intermediate phases, including a crystalline solvate compound and the 2D GA2PbI4 perovskite, provide a scaffold for the growth of the ACI perovskites during thermal annealing. We identify 2D GA2PbI4 to be the key intermediate phase, which is strongly influenced by the deposition technique and determines the formation of the 1D GAPbI3 byproducts and the distribution of various n phases of ACI perovskites in the final films. We also confirm the presence of internal charge transfer between different n phases through transient absorption spectroscopy. The high quality ACI perovskite films deposited from solvent mixture of DMSO:DMF (1:10 v/v) deliver a record power conversion efficiency of 14.7% in planar solar cells and significantly enhanced long-term stability of devices in contrast to the 3D MAPbI3 counterpart.

EN08.13.02
In Situ Grain Boundary Modification via Two-Dimensional Nanoplates to Remarkably Improve Stability and Efficiency of Perovskite Solar Cells
Xuejie Zhu; Shaanxi Normal University, China

Even though a record efficiency of 24.2% has been achieved in organic–inorganic hybrid perovskite solar cells, their stability remains a critical issue, which greatly depends on the morphology of perovskite absorbers. Herein, we report a practical grain boundary modification to remarkably improve the humidity and thermal stability by gradually growing in situ two-dimensional nanoplates between the grain boundaries of perovskite films using phenylethylammonium iodide (PEAI). The experimental results show that PEAI nanoplates play a critical role in stabilizing perovskite thin films by reducing the moisture sensitivity and suppressing phase transition at the grain boundaries. In addition to the significant improved ambient stability, the grain boundary modification by PEAI can effectively suppress the nonradiative charge recombination at grain boundaries. As a result, the efficiency of perovskite solar cells is up to 20.34% with significant humidity and thermal stability.

EN08.13.03
MACI Doping for High-Performance ACI Perovskite Solar Cells Tao Luo¹, Yalan Zhang¹, Kui Zhao¹ and Shengzhong (Frank) Liu¹,²; ¹Shaanxi Engineering Lab for Advanced Energy Technology, School of Materials Science and Engineering, Shaanxi Normal University, China; ²Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China

Organic–inorganic perovskite structured compounds recently have emerged as attractive materials in the photovoltaic fields due to their exciting optical properties and easy syntheses, as well as exceptional structural and optical tunability. Recently, we have reported a layered two-dimensional (2D) perovskite with an alternating cation of C(NH₂)₃(CH₃NH₃)₃Pb₃I₁₀ (ACI) (n≥3) in the interlayer space by anti-solvent engineering with an efficiency of 14.7%. Based on the previous work, we further improved the quality and stability of the film by using CH₃NH₃Cl (MACI) as additive, and achieved a record efficiency of 18.48% for low-dimensional perovskite. In addition, the optimized device retained approximately 90% of the original PCE after 60 days at 30% relative humidity (RH) at ambient condition, and 80% of the original PCE after 65 hours at 80 °C without any encapsulation. This work will be useful to achieving more desirable outcomes and increase in photovoltaic performance.

EN08.13.04 Structure-Photophysics-Function Relationship of Quasi-2D Perovskite Solar Cells Chengbin Fei, Meng Zhou, Julio Sarmiento and He Wang; University of Miami, United States

Quasi-2D perovskite has higher stability and easier tunability compared with conventional 3D organic-inorganic hybrid perovskite. Tuning the phase distribution according to the device structure is necessary. We manipulate the structure of quasi-2D perovskite film and probe how the structure affects the solar cell device performance and stability. To better understand the structure-function relationship, we utilize femtosecond laser spectroscopy to study photophysics of different structures.

The addition of a small amount of hydrophobic cation of large size into 3D perovskite can improve both efficiency and stability. We find that the propylammonium is the most effective by comparing a family of different cations. The cations of large size preferentially segregate at the grain boundaries and surface, verified by transient absorption and reflection spectroscopy. Such passivation enhances device efficiency up to 20.1% and improves both device and precursor stabilities. The efficiency of devices with treatment only decreases by ~3% after 600 hours under low (10-15% RH) and high humidity (45–50% RH). (J. Mater. Chem. A, 2019, DOI:10.1039/C9TA01755K)

We also manipulate the phase purity and vertical distribution of quasi-2D perovskite. Ethyl acetate is utilized as antisolvent to tune the vertical phase distribution and the direction of carrier transfer is reversed accordingly. CH₃NH₃Cl and dimethyl sulfoxide are used to control the phase purity. These phenomena are proved by transient absorption spectroscopy. We find that solar cell performance is more sensitive to phase purity than vertical phase distribution. (Solar RRL, 2019, 3, 1800359)

EN08.13.05 Chlorine Doping for Black γ-CsPbI₃ Solar Cells with Stabilized Efficiency beyond 16% Kang Wang¹, Zhiwen Jin² and Sheng Z. Liu¹; ¹Key Laboratory of Applied Surface and Colloid Chemistry, Ministry of Education; Shaanxi Key Laboratory for Advanced Energy Devices; Shaanxi Engineering Lab for Advanced Energy Technology; School of Materials Science & Engineering, Shaanxi Normal University, China; ²School of Physical Science and Technology & Key Laboratory for Magnetism and Magnetic Materials of the Ministry of Education, Lanzhou University, China

Although the solar cells based on the α-CsPbI₃ presents very impressive power conversion efficiency, it suffers from insufficient crystalline structure stability even in ambient condition. Herein, the black orthorhombic γ phase based CsPbI₃ is successfully fabricated with its performance further optimized by doping chlorine ions. It is found that the chlorine incorporation improves crystallization dynamics for favorable surface morphology and crystalline orientation. In particular by doping 3 mol% chlorine into the CsPbI₃ film, its trap density is minimized with enhanced black phase stability and much improved thin film characteristics, including conductivity, electron and hole mobilities. Consequently, the solar cell efficiency is increased to as high as 16.07%. More importantly, the PCE of the optimized device shows only 0.45% degradation after continuous light soaking for 200 h. It retains as much as 94% of its initial PCE even after being exposed in air (relative humidity of 20%-30% at 25 °C) for 60 days.
Fabrication and Characterization of All-Inorganic Lead Halide Perovskite Films

Ryusuke Umeda1, Kazunori Ito1, Masato Gocho1, Toshiya Kobayashi1, Yuki Fukazawa1 and Hironori Ogata1,1,2; 1Hosei University, Japan; 2Research for Micro-Nano Technology, Japan

In recent years, perovskite solar cells that can be easily manufactured at low cost by solution processing have achieved high energy conversion efficiency exceeding 24%. Halide perovskites of an ABX3 structure [A=CH3NH3+(MA), HC(NH2)2+(FA), Cs+; B=Pb2+, Sn2+; X=I-, Br-, Cl-] are used photovoltaic materials. In perovskite solar cells, a perovskite compound containing methylammonium or formamidinium, which is an organic cation is widely used as a photoactive layer because it exhibits high energy conversion efficiency, but its durability against heat and moisture is low.

It has been reported that thermal resistance is improved by using an inorganic cation such as an alkali metal instead of an organic cation. In addition, it has been reported that the CsPbX3 thin film using cesium as an inorganic cation changes in band gap energy and durability due to mixed crystallization of halide ions. Furthermore, it has been reported that CsPbX3 thin film causes a structural change δ phase which is non perovskite phase by moisture, which is a problem for practical use.

In this study, the effects of temperature and humidity on the crystal structure, morphology and charge transport properties and durability of several kinds of CsPbX3-yX'y thin films with different proportions of halide ions (X and X') were systematically investigated. Detailed experiment results will be presented.

Fabrication of High-Efficiency Planar CsPbBr3 Perovskite Film Solar Cells by One-Crucible Thermal Evaporation of PbBr2 and CsBr

Juan Li, Rongrong Gao, Fei Gao, Xin Wu, Jie Lei, Haoxu Wang, Jianbo Li, Xiaodong Hua, Hao Liu and Shengzhong (Frank) Liu; Shaanxi Normal University, China

It is promising to improve the stability of organic–inorganic hybrid halide perovskite solar cells by using all-inorganic perovskite materials. Herein, a facile one-crucible single-source vacuum thermal evaporation (VTE) approach is developed, which is used to evaporate two different melting points materials CsBr (630 °C) and PbBr2 (370.6 °C) to deposit high-quality inorganic CsPbBr3 perovskite films. Molar ratio of PbBr2 to CsBr in their mixture in the crucible is a key factor influencing the stoichiometry, structure, photoelectrical and photovoltaic properties of the CsPbBr3 films. The other important factor is the thickness of the CsPbBr3 films. High-quality CsPbBr3 films with good uniformity and compact and large grains are prepared. Planar CsPbBr3 perovskite solar cells are fabricated giving a high power conversion efficiency of 8.65%. The fabricated CsPbBr3 solar cells exhibit a good stability in air without encapsulation. This study opens up the possibility to deposit multi-element compound thin films by facile single-source VTE of different melting points materials.

Graded Bandgap CsPbI2+xBr1-x Perovskite Solar Cells with a Stabilized Efficiency of 14.4%

Hui Bian, Zhiwen Jin and Shengzhong (Frank) Liu; School of Chemistry and Chemical Engineering, China

All-inorganic perovskite shows great potential for photovoltaic applications due to its excellent solar cell performance and atmospheric stability. Herein, CsPbI2Br1-x perovskite solar cell with a graded bandgap is explored using CsPbBrI2 and CsPbI3 quantum dots as component cells. Four strategies were pursued to boost the device performance. First, CsPbI2Br film was fabricated as the main absorber, with the component cell showing remarkable power conversion efficiency (PCE) as high as 13.45%. Second, by Mn2+ substitution, SCN- capping and [(NH2)2CH]+ treatment, stable and high-mobility CsPbI3 QDs film was attained. Third, a halide-ion-profiled heterojunction was designed at the CsPbBrI2/CsPbI3 QDs interface to achieve proper band edge bending as graded bandgap for improved carrier collection. Finally, the CsPbI3 QDs layer was optimized in the graded bandgap structure to achieve maximum overall light harvesting. As a result, the device achieved PCE with 14.45%. This is the highest efficiency ever reported for inorganic perovskite solar cells.

High Efficiency Inorganic CsPbBrI2 Perovskite Solar Cell via Iodine Salts Optimized Interface

Jingru Zhanag and Shengzhong (Frank) Liu; School of Materials Science & Engineering, China

The inorganic CsPbBrI2 perovskite has attracted ever-increasing attention for its outstanding optoelectronic
properties and ambient phase stability. However, to achieve high power conversion efficiency (PCE), it is imperative to minimize recombination at interface between the CsPbBrI₂ and the hole-extraction layer (HEL) for maximized carrier extraction efficiency. Herein, we developed the AI treatment to provide a general method for optimizing the interfacial properties. In our present work, quantum-dots (QDs) were firstly used to form dimension-graded heterojunction structure with the CsPbBrI₂ perovskite bulk film for optimized energy alignment in the solar cell (PSC) structure. Then, we ventured to conduct interface engineering by post treatmentment of the CsPbBrI₂ perovskite film with a series of A-site cation based iodine salts (AI, where A = formamidinium (FA⁺), methylammonium (MA⁺), ethylenediamine (EDA⁺), phenylethylammonium (PEA⁺) or n-butylammonium (BA⁺)) to achieve further improved device performance. In the applied QDs/film structure, an ultra-thin iodine-ion-enriched perovskite layer was formed on the top of CsPbBrI₂ film, and QDs surface were proved capped with AI after AI salt post-treated. We found such a phenomenon leads to proper band edge bending, decreased surface defects, and high-quality QDs modified layer. As a consequence, these changes proved effectively decreased recombination loss with improved hole extraction efficiency. More specifically, the FAI treated device yields an ultra-high PCE of 14.12% which positioning above the best reported PCE for CsPbBrI₂ PSCs to date. We believe such strategy should have significant potential for future applications in other optoelectronic devices.

EN08.13.10
High-Voltage CsPbBr₃-Based Fully Inorganic Planar-Type Perovskite Solar Cell Youhei Numata¹ and Tsutomu Miyasaka²; ¹The University of Tokyo, Japan; ²Toin University of Yokohama, Japan

Up to now, the best conversion efficiency of perovskite solar cells (PSCs) has reached over 23%, which is approaching to theoretical limit, and therefore, not only high efficiency, but also development of related technologies and new applications such as flexible device, module, lead-free material, high voltage, X-ray detector, and power source for IoT device are focused as next targets of researches. Recently, Cs-based all inorganic perovskite solar cells are energetically developed due to their high thermal stability. CsPbX₃ (X = I, Br and their mixture) perovskites possess wide band gap compared to the FA and MA-based perovskites, enabling to obtain high-voltage PSCs. Unfortunately, a-phase of iodide-rich CsPbX₃ perovskites such as CsPbI₃ and CsPbI₂Br is unstable under ambient condition, because of too small Cs ion size to form 3-D cubic perovskite structure at room temperature. Therefore, various effort to stabilization of the a-phase is devoted. On the other hand, reports of pure bromide, CsPbBr₃ is increasing because of high phase stability and high open-circuit voltage (VOC) up to 1.6 V. We focused on CsPbBr₃ and developed a fully inorganic planar-type PSCs using TiOX compact layer and a carbon-based electrode. Because of very poor solubility of the CsPbBr₃ perovskite in any solvent (maximum less than 0.5 mM for DMF and DMSO), the CsPbBr₃ film is commonly prepared sequential deposition method; a precursor PbBr₂ film was treated with CsBr solution. The CsBr treatment is repeated four times to perfectly convert the PbBr₂ to CsPbBr₃ perovskite. However, because of no TiO₂ mesoporous scaffold, CsPbBr₃ film converted on the TiOX CL became very rough and there are many pinholes due to low adhesion power between perovskite and TiOX surface. To obtain pinhole-free and high-quality perovskite film, we modified a recipe of precursor solution and CsBr treatment procedure, and obtained pinhole-free CsPbBr₃ film on the TiOX CL by CsBr treatment once. Furthermore, by passivation of surface of the TiOX CL, VOC of up to 1.5 V was obtained.

EN08.13.11
In Situ Structural and Optical Studies of Phase Transformations of CsPbI₃ from Atomic Scale to Macroscopic Properties Jose Marquez Prieto¹, Pascal Becker¹, Justus Just², Hampus Nässström¹, Chen Li³,⁴, Thomas Unold¹ and Roland Mainz²; ¹Helmholtz Zentrum Berlin, Germany; ²Lund University, Sweden; ³Max Planck Institute for Solid State Research, Germany; ⁴University Antwerpen, Belgium

Understanding the phase transitions in inorganic halide perovskites is crucial to increase the stability of solar cells and to allow possible application of these materials in thermochromic solar cells and phase-change based optoelectronic devices [1, 2]. Here we present a combination of several in-situ techniques to reveal the phase transformation relations between the α, β and γ (black) perovskite phases and the δ (yellow) non-perovskite polymorph in thin films. Structural changes were tracked as a function of relative humidity (RH) and temperature by in-situ X-ray diffraction with a liquid-metal jet X-ray source. We find that at room temperature, the transition from the γ-black to the δ-yellow phase is exclusively triggered by the % of RH whereas O₂ is not involved in the mechanism. The transformation is preceded by an expansion of the unit cell volume of the perovskite phase
Spectrally filtered in-situ optical microscopy reveals that this transformation does not affect the grain structure. An intermediate state is observed, where the optical transmission at 700 nm is significantly reduced, suggesting a pseudo-amorphous state during the atomic reordering.

For a detailed understanding of the atomic motion during the phase transitions we also studied the conversion from the yellow non-perovskite to the black-perovskite polymorph during in-situ heating using scanning transmission electron microscopy (STEM) revealing the transition from the δ- to the α-phase with atomic resolution where a layered structure is observed as intermediate.

EN08.13.12
Pb-Bi Binary Metal Absorber Layer for Stability Enhancement in Perovskite Solar Cells Jin Huang1,2; 1Shanxi Normal University, China; 2Shanxi University of Science &Technology, China

A lead-bismuth (Pb-Bi) binary metal based perovskite film is successfully fabricated and applied as absorber layer to enhance the stability of perovskite solar cells (PSCs). Unlike the Pb-only perovskite-based device, the Pb-Bi binary metal perovskite based one shows better tolerance to humidity and oxygen. High power conversion efficiency (PCE) of 11.1% is obtained for the PSC. Noticeably, the PCE only reduced by 15% under atmospheric humidity of 30% in four weeks. An electron-only device also shows reduced trap states. The improved stability and PCE is ascribed to higher quality perovskite film with less trap states and smaller series resistance (Rs) in the device.

EN08.13.13
Perovskite Solar Cell towards Lower Toxicity—A Theoretical Study of Physical Lead Reduction Strategy Yifan Zheng; Peking University, China

The huge performance enhancements of the organometal halide perovskite solar cells (OHPSCs) have appealed enormous attention within recent ten years. Although the rapid growth of the device power conversion efficiency (PCE) has attained over 24%, the contamination of health-hazardous components still holds back its sustainable applications. To reduce the lead usage, many groups have tried chemical lead reduction solutions: substituting the lead by other group 14 metal elements to realize the low-lead OHPSCs. Unfortunately, neither the PCE nor the stability, low-lead OHPSCs all lag far behind the state-of-the-art conventional lead-based OHPSCs. In this work, we present a physical lead reduction (PLR) concept by reducing the perovskite film thickness to restrict the perovskite hazard risk with minor scarification in device performances. Through the simulation of transfer matrix model, we theoretically demonstrated that by introducing the optical space layer, the device PCE could maintain 96% of the original maximum value while attenuating the perovskite film thickness to one-third. This means that the usage of lead can be reduced by ~70% with PLR concept, which could have broad appeal as a new lead reduction strategy towards high performance OHPSCs.

EN08.13.14
Rapid Architecture-Specific Toxicity Screening of Lead-Based Emerging Thin-Film Photovoltaics Nicole Moody1, Dasol Yoon2, Anna Johnson1, Dak B. Dou1, Vladimir Bulovic1 and Mounig G. Bawendi1; 1Massachusetts Institute of Technology, United States; 2Wellesley College, United States

While lead-based perovskite and quantum dot (QD) solar panels are rapidly approaching the technological maturity for widespread commercialization, their environmental impacts and end-of-life disposal requirements have been largely uncharacterized. Here we present the United States Environmental Protection Agency Toxicity Characteristic Leaching Procedure (TCLP) as a means of rapidly characterizing the human and environmental health impacts of laboratory-scale solar cells and their resulting disposal requirements. We employ the TCLP to screen the toxicity and regulatory requirements of perovskite solar cells on various substrates, revealing increased lead leaching and potentially higher disposal costs for perovskite solar cells on lightweight, flexible substrates compared to heavier, rigid ones. We also use the TCLP to guide the development of a lower-toxicity manufacturing method for lead sulfide (PbS) QD solar cells. By developing a new solution-phase QD ligand exchange method that employs tetrabutyl ammonium iodide (TBAI) as the source of ligands, we maintain high device performance while reducing the total lead content in the synthesis byproducts by nearly 250 times and the total volume of solvents used.
by 80% compared to previous methods that employ lead halides. TCLP analysis reveals that QD solar cells made with this ligand exchange method leach less lead than the EPA limit, and as a result are unlikely to cause environmental harm during end-of-life disposal in municipal landfills. Further, the TBAI ligand exchange method offers significant cost savings compared to previous lead-halide-based methods, reducing synthesis costs by more than 70%. By using the TCLP to obtain architecture-specific toxicity information of lab-scale devices, we are able to design new solar technologies with low environmental risk.

EN08.13.15
The Phase Segregation in CsPbI2Br Inorganic Perovskite Solar Cells Haoxu Wang, Fei Gao and Shengzhong (Frank) Liu; Shaanxi Normal University, China

The rapid development of organic-inorganic hybrid and all-inorganic pervoskite materials have drawn widely attention in energy field. Within a decade, the PCE of perovskite solar cells has exceeded 24.2% from 3.8%. With such a promising commercialization potential, the perovskite solar cells still have many problems to be solved, such as poor ambient stability, heavy metal toxicity and expensive additives. Herein, we fabricated high performance CsPbI2 solar cells and studied the phase segregation mechanism of CsPbI2 thin films.

In this work, we explored the CsPbI2 thin films and solar cells fabrication via dual-source thermal evaporation. A best device performance up to 7.4% was gained through adjustment of molar ratio, substrate temperature, annealing temperature and annealing time. The device performance decay in ambient with 25%-35% relative humidity is less than 10% for 30 days. And two different methods to prepare the CsPbI2 thin films and solar cells were compared. The advantage of dual-source thermal evaporation was proved by superior quality and performance of CsPbI2 thin film and solar cells. Furthermore, the mechanism of the intrinsic phenomenon of phase segregation in CsPbI2 thin films was demonstrated via EDX characterization. Due to different formation energy, the I atom is intended to be replaced by Br atom spontaneously during power injection from external thermal source such as annealing process. The phase segregation is intrinsic characteristics of CsPbI2 thin films which will not be eliminated completely.

EN08.13.16
All-Inorganic Cesium Tin Halide Perovskite for Photodetector Junhua Shen; Rensselaer Polytechnic Institute, United States

Inorganic halide perovskite materials have attracted wide attention for optoelectronic applications due to its high mobility, long diffusion length and outstanding visible light harvesting performance. However, there are two major challenges for industrial applications, stability, and toxicity. By introducing environmental benign element Tin (Sn), toxicity problem could be addressed. Compared with divalent Sn-based perovskite which must be handled in an inert condition, tetravalent Sn-based perovskite materials are stable in ambient condition.

In this work, we demonstrate a novel solution processed all-inorganic perovskite Cs2SnI6 with excellent optoelectronic properties. At room temperature, the solution processed Cs2SnI6 photodetectors are sensitive to red-light(650nm), exhibiting a high detectivity. These Sn-based devices possess good linearity photo-response, and their optoelectronic performance is comparable to most of the all inorganic perovskite photodetectors. Our results indicate that with proper synthesis and device construction, lead-free inorganic perovskite materials are promising for stable, low-cost, environmentally-benign and high-performance photodetectors.

EN08.13.17
Humidity Controlled Fabrication of Methylammonium Lead Iodide and Spiro-OMeTAD Layer for High Efficiency Perovskite Solar Cells Junyeong Lee, Jiyoon Nam, Changgyun Kim, Kyudong Kim and Sungjin Jo; Kyungpook National University, Korea (the Republic of)

Perovskite solar cells (PSCs) have advanced intensively over the last few years and have reached in 24.2% power conversion efficiency (PCE). Because the achievement of high efficiency is enough for commercial applications, the stability and scalability issues have attracted attention for the potential commercialization of PSCs. However, when exposed to moisture, methylammonium lead iodide (MAPbI3), which is used as the active layer of PSCs, decomposes into methylammonium iodide (MAI) and lead iodide (PbI2), thereby degrading the device performance. For this reason, PSCs have to be fabricated under humidity-controlled environments. Recently, it is reported that the humidity plays an important role in the crystallization of the MAPbI3 and MAPbI3 fabricated in ambient conditions has had a higher performance than that coated at low humidity. Thereafter, studies
were conducted to fabricate the MAPbI₃ layer at various humidities, and it has been shown that when moisture is absorbed, the adjacent grain merges and the grain size increases. However, while the Spiro-OMeTAD material that is often used as a HTL has the property of absorbing moisture like MAPbI₃, few studies have reported on Spiro-OMeTAD coated at various humidities.

In this report, we investigate the tendency of characteristic changes when both Spiro-OMeTAD and MAPbI₃ were fabricated at relative humidity (RH) 20%, 40%, 60%, and 80%. As a result, PSCs fabricated at RH 60% showed PCE 15.5%, which is higher than the PCE 12.9% fabricated at RH 20%. We demonstrated that MAPbI₃ is more critical for the PCE of PSCs than Spiro-OMeTAD when we deposited MAPbI₃ and Spiro-OMeTAD separately under different humidity conditions. In this regard, the amount of PbI₂ produced by the humidity condition was characterized by employing an X-ray diffractometer and an ultraviolet–visible spectrophotometer. The surface morphology of the MAPbI₃ image were obtained by a scanning electron microscope and the charge lifetime of the MAPbI₃ surface was analyzed by steady-state photoluminescence (PL) and time-resolved PL. In this result, we can confirm that the efficiency increases when all experimental processes were performed in ambient condition at RH 60%. We expect this to be useful for commercialization because the fabrication of PSCs in ambient environment does not require expensive equipment to maintain low humidity.

EN08.13.18

Large Single-Crystal Grains for Highly Efficient Integrated Back-Contact Perovskite Solar Cells Teng Ma and Ayumi Hirano; Tohoku University, Japan

The perovskite solar cells (PSCs) have been attracting great attention due to their promising high performance and low fabrication cost. Researchers have put a huge amount of effort to optimize the bulk and interfaces of perovskite layer in the PSCs to achieve high power conversion efficiency (PCE) and high stability at the same time. As a result, the PCE of PSCs has increased from 3.8% to 24.2% in only 10 years. However, as the internal quantum efficiency of the PSCs approaching 100%, the space left for further optimization is getting smaller. Previously, by using numerical simulation methods, we have demonstrated that the performance of the PSCs could be improved by 11% by replacing the widely-used sandwich structure with an integrated back-contact (IBC) structure. However, the reported PCEs of the IBC-PSC are still lower than that of their sandwich-PSC counterparts.

Here, based on our simulation and experiment results, we propose that the grain boundary is one of the main factors limiting the performance of IBC-PSCs. In IBC structure, since the photo-generated charges need to travel laterally through a longer distance than that in a sandwich structure, if the distance of the electrodes is larger than the grain size, the charges might have to cross several grain boundaries to reach the electrode, resulting in a high recombination possibility. To reduce grain boundaries in the charge transporting path, we adopt a unique method to form a uniform perovskite layer with large single crystal grains as large as 50 µm. In the fabricated IBC devices, most of the adjacent electrodes were connected by a single crystal of perovskite material. The performance of the IBC-PSCs was therefore significantly improved due to the reduced grain boundaries.

Probing Perovskite Crystal Quality to Drive Process Development for Flat and Textured Perovskite Solar Cells Peter Fiala1, Florent Sahli1, Ricardo Z. Razera1,2, Jeremie Werner1,3, Fan Fu1,4, Terry C. Yang1, Daniel Jacobs1, Beat Ruhstaller5,6, Quentin Jeangros1 and Christophe Ballif1; 1Ecole Polytechnique Federale Lausanne, Switzerland; 2Instituto de Física, Brazil; 3University of Colorado Boulder, United States; 4Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; 5Fluxim AG, Switzerland; 6Zurich University of Applied Sciences, Switzerland

In the field of perovskite thin-film solar cells (PSC), the formation of the perovskite absorber via hybrid thermal evaporation / spin-coating processes represents an important step towards large-area deposition methods and potential industrial feasibility, while also enabling deposition on textured substrates. One caveat of this hybrid method is that it requires two physically separate layers of precursors to interdiffuse and crystalize, forming the perovskite absorber. This interdiffusion is complex, and many process parameters influence the resulting perovskite
crystal quality and associated interfaces. In turn, these material qualities strongly affect the photovoltaic performance of the fabricated PSC. Directly measuring the perovskite material quality would be an ideal shortcut to drive process development without the need to make large numbers of full devices. In this work, photo-thermal deflection spectroscopy (PDS), atomic force microscopy (AFM), and X-Ray diffraction (XRD) measurements were used to investigate material quality in perovskite films formed via a hybrid evaporation/spin-coating process. Specifically, the temperature, dew point, and anneal time of the interdiffusion process were investigated. This led to insights about the crystal quality and stoichiometry of the perovskites, which was shown to directly link back to PSC performance, with efficiency gains of over 3% absolute. However, verification by PSC production revealed that these metrics (PDS, AFM, XRD) did not tell the whole story of the interdiffusion process. The remaining effects were attributed to modification of the perovskite layer interfaces. Further investigations into this phenomenon will be discussed at the conference.

The understanding of this hybrid fabrication method was then applied to PSC deposited on textured substrates. In theory, PSC employing a textured absorber interface could eschew the optical losses typical of thin films via improved light management. As our hybrid method allows for perovskite deposition on textured surfaces, textured PSC development focused more on optimization of the substrate texture. Along this route, we first performed optical ray-tracing simulations using AFM scans of textured surfaces formed by KOH-etched silicon (c-Si) wafers, as demonstrated in our previous publications. Optimal BZO and c-Si textured surfaces were then used to fabricate PSC in the p-i-n architecture, with the perovskite layer deposited via the optimized hybrid method. Demonstrated PSC verified the trends predicted by simulation, with increased short-circuit current density (JSC) and removed interference fringes from external quantum efficiency curves. However, improved optical performance and JSC are not the only factors relevant to the overall performance of our PSC. Optimization of the full device and the impact of textured interfaces on other device parameters will be discussed at the conference.

EN08.13.21
Record Efficiency Stable Flexible Perovskite Solar Cell Using Effective Additive Assistant Strategy Feng Jiangshan; Shaanxi Normal university, China

Even though the power conversion efficiency (PCE) of rigid perovskite solar cells is increased to 22.7%, the PCE of flexible perovskite solar cells (F-PSCs) is still lower. Here, a novel dimethyl sulfide (DS) additive is developed to effectively improve the performance of the F-PSCs. Fourier transform infrared spectroscopy reveals that the DS additive reacts with Pb2+ to form a chelated intermediate, which significantly slows down the crystallization rate, leading to large grain size and good crystallinity for the resultant perovskite film. In fact, the trap density of the perovskite film prepared using the DS additive is reduced by an order of magnitude compared to the one without it, demonstrating that the additive effectively retards transformation kinetics during the thin film formation process. As a result, the PCE of the flexible devices increases to 18.40%, with good mechanical tolerance, the highest reported so far for the F-PSCs. Meanwhile, the environmental stability of the F-PSCs significantly enhances by 1.72 times compared to the device without the additive, likely due to the large grain size that suppresses perovskite degradation at grain boundaries. The present strategy will help guide development of high efficiency F-PSCs for practical applications.

EN08.13.22
Stable High Efficiency Two-Dimensional Perovskite Solar Cells via Cesium Doping Xu Zhang1,2; 1Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China; 2University of Chinese Academy of Sciences, China

Two-dimensional (2D) organic–inorganic perovskites have recently emerged as one of the most important thin-film solar cell materials owing to their excellent environmental stability. The remaining major pitfall is relatively poor photovoltaic performance in contrast to 3D perovskites. In this work we demonstrate cesium cation (Cs+) doped 2D (BA)2(MA)3Pb4I13 perovskite solar cells giving power conversion efficiency (PCE) as high as 13.7%, the highest
among reported 2D perovskite based devices. In addition, it has excellent humidity stability. The enhanced efficiency is attributed to perfectly controlled crystal orientation, increased grain size of 2D planes, superior surface quality, reduced trap-state density, enhanced charge-carrier mobility and charge-transfer kinetics. To our surprise, the Cs+ doping yields superior environmental stability and humidity tolerance. The device doped using 5% Cs+ degrades only ca. 10% after 1400 hours exposure in 30% relative humidity (RH), and exhibits significantly improved stability under heating and high moisture environment. Our results provide an important step toward air-stable and fully printable low dimensional perovskite as a next-generation renewable energy source.

EN08.13.23
Interfacial Chemical States, Reactivity and Stability of Antifluorite Cesium Titanium Bromide, Cs₂TiBr₆
Jocelyn Mendes¹, Weiran Gao², Alexander D. Carl¹ and Ronald L. Grimm¹; ¹Worcester Polytechnic Institute, United States; ²Massachusetts Institute of Technology, United States

Cesium titanium bromide, Cs₂TiBr₆, has attracted research interest as a semiconductor due to its ~1.8 eV band gap, which makes it desirable for forming tandem junctions with silicon. However, little is known about the surface of the material. To ascertain stability of the material in ambient air we conducted controlled air exposure experiments, and to determine the reactivity and basicity of interfacial halides, we reacted the surface with a series of Lewis acids. X-ray photoelectron spectroscopy (XPS) established correct synthesis, effects of atmospheric exposure, and surface coverage of Lewis adducts. Powder X-ray diffraction (pXRD) quantified the effects of atmospheric exposure to the crystal over time. Temperature programmed desorption (TPD) quantified bond strengths of resulting Lewis adducts. The presence of Lewis adducts at the surface of Cs₂TiBr₆ demonstrated consistent loss of cesium bromide on the surfaces and surface exposure to ambient air resulted in rapid surface oxidation. These results elucidate the reactivity of the chemical states on Cs₂TiBr₆ surfaces, and future routes through which interfacial reactivity may be used to improve atmospheric stability.

EN08.13.24
Lead-Free Double Perovskite Cs₂AgBiBr₆ Quantum Dots Excited State Interactions and Solar Cell Applications Junsang Cho¹ and Prashant Kamat¹,²; ¹Radiation Laboratory, University of Notre Dame, United States; ²University of Notre Dame, United States

Lead-free double perovskites of Cs₂AgBiBr₆ wherein two divalent Pb²⁺ cations are substituted by one monovalent Ag⁺ cation and one trivalent Bi³⁺ cation, respectively, are considered as potential candidates for developing materials for perovskite solar cells. We have now prepared 8—10 nm diameter Cs₂AgBiBr₆ nanocrystals using a hot-injection method and investigated their excited state properties. In addition, we have also probed the excited state interactions of double perovskite quantum dots (QDs) with various metal oxides (TiO₂, ZnO, SnO, and ZrO₂) and established the electron transfer kinetics between the two. Spin-coated QD films were annealed (at 225 °C) to obtain bulk double perovskite films. UV-vis absorption, high resolution SEM images, and X-ray diffraction have been employed to track the transformation of QDs to bulk films. The annealed films can be directly employed in the fabrication of solar cell architecture: FTO/c-TiO₂/m-TiO₂/Cs₂AgBiBr₆/Spiro-oMeTAD/Au. The double perovskite solar cells show relatively low solar energy conversion efficiency (less than 1.0 %) with Jsc of 0.40 mA/cm² and Voc of 0.65 V. Understanding of nanocrystal growth mechanism and correlation between the grain size and solar cell efficiency is important for improving the efficiency of double halide perovskite for solar cells.

EN08.13.25
Lead-Free Perovskite (-Like) Solar Cells Qiaohui Zhang, Cuncun Wu and Lixin Xiao; Department of Physics, Peking University, China

Organic-inorganic hybrid perovskite solar cells (SCs) have emerged as one of the most promising contenders to traditional silicon solar cells, due to their active layers outstanding photoelectric properties, such as appropriate direct bandgap, balanced high carrier mobility and long carrier diffusion length, the identified power conversion efficiency (PCE) has reached to 24.2 %. But the toxic lead, a key component in the archetypical light harvesting material, is a large obstacle to commercialization.

Double perovskite Cs₂AgBiBr₆ has emerged as a promising optoelectronic material due to its excellent physics and photoelectric properties. We first reported double perovskite planar heterojunction SC with a high quality Cs₂AgBiBr₆ film, fabricated by a low-pressure assisted solution processing method under ambient conditions, which presents a highest PCE of 1.44 %. Moreover, we reported highly efficient and stable self-powered ultraviolet and
deep-blue photodetector based on Cs$_2$AgBiBr$_6$/SnO$_2$ heterojunction with two responsivity peaks at 350 and 435 nm, which is suitable for ultraviolet-A (320–400 nm) and deep-blue light detecting. A high responsivity of 0.11 A/W at 350 nm and a quick response time of less than 3 ms are obtained, which is significantly higher than other semiconductor oxide heterojunction based UV-detectors. More importantly, the stability is significantly better than most of the hybrid perovskite photodetectors reported so far. Its photocurrent shows no obvious degradation after more than six months storage in ambient condition without any encapsulation. Consequently, the utilization of Cs$_2$AgBiBr$_6$ film is a practical approach for high performance, large-area lead-free perovskite photodetector application. The low toxicity and high stability of this double perovskite active layer make it very promising for practical application. For mechanism, we found that photogenerated carriers in Cs$_2$AgBiBr$_6$ film are separated at Cs$_2$AgBiBr$_6$/SnO$_2$ heterojunction interface by its build-in field, which is very important for the future double perovskite based optoelectronic device structure design.

Silver bismuth iodide (Ag–Bi–I) as an environmentally friendly semiconductor with suitable band gap and high stability has been regarded as a potential photovoltaic material, while the reported mesoscopic devices all showed poor open circuit voltage ($V_{oc}$) of 0.5–0.6 V. We reported silver bismuth iodide-based solar cells with a planar heterojunction structure of “ITO/SnO$_2$/AgBiI$_4$/PTAA/Au” by a solution method. Li-TFSI additive (2 wt %) was added into the AgBiI$_4$ precursor and induced a fully covered pinhole-free morphology. The readily coordinated organic component, TFSI$^-$, was proven to play a role of assisting the film growth. The optimal device could achieve a $V_{oc}$ of 0.82 ± 0.01 V and PCE up to 2.50 ± 0.20 %, much higher than the one without Li-TFSI of 0.66 ± 0.02 V and 1.67 ± 0.09 %. Moreover, we fabricated AgBiI$_4$ SC with a thicker absorber film, which could even have a record $V_{oc}$ of 0.88 V, but the depressed $J_{sc}$ implied its limited carrier diffusion length. In addition, the double layer devices with a structure of “ITO/SnO$_2$/AgBiI$_4$/Au” or “ITO/AgBiI$_4$/PTAA/Au” showed the carrier separation occurred in the interface of SnO$_2$/AgBiI$_4$. Above results pointed out the significance of film quality improvement and interface charge extraction in further research.

Lead-Free Tin Halide Perovskite Material and Interface Energetics and Iodide Diffusion Into Electron Transport Layers

Alex M. Boehm and Kenneth R. Graham; University of Kentucky, United States

Halide perovskites have generated tremendous interest as low-cost semiconductors for optoelectronic applications such as photovoltaics. The bulk of work surrounding halide perovskites has centered around Pb-based perovskite derivatives; however, recent years have seen a rise in Pb-free perovskites which are less harmful and more environmentally friendly. In this regime the leading alternative to Pb is Sn, which has successfully been used in photovoltaics to achieve over 9% power conversion efficiency. The further development of Sn based perovskite photovoltaics necessitates a firm understanding of the material properties and the ways in which tin derivatives differ from their lead counterparts. One key property is the energetic structure of Sn-based perovskites and the energetic alignment of their transport states with those in adjacent layers. Herein lies an issue where current literature regarding the valence and conduction band energies cannot reach consensus even for formamidinium tin iodide (FASnI$_3$), the most popular tin-based composition, for which reported ionization energies (IEs) already span a range greater than 1 eV. Using low energy ultraviolet and inverse photoelectron spectroscopy, we find the IE and electron affinity (EA) to equal 5.3 and 3.9 eV for FASnI$_3$. In addition, we observe that the amount of tin(II) fluoride, a nearly ubiquitous additive employed to reduce tin oxidation, shifts these energetics by hundreds of meV. Further, we find that short air exposures (<1 minute), synonymous with sample transfer, result in minimal changes to IE, EA, and PV performance, whereas longer exposure times (5-10 minutes), analogous of a sample measurement in air, shows changes of hundreds of meV in both IE and EA as well as degradation of device performance. At the interface between FASnI$_3$ and C60 we detect migration of iodide from the perovskite into the fullerene and the formation of a surface dipole. Additional fullerene derivatives are examined to elucidate the prevalence of iodide migration and the impacts on energy level alignment with the perovskite and photovoltaic performance. Finally, surface modifiers are explored to prevent iodide diffusion out of the perovskite layer. These results are important for understanding the electronic structures of tin-based perovskites, how interface energetics influence charge extraction in perovskite photovoltaics, and minimizing iodide diffusion is critical to improving stability.

EN08.13.27
Research Pertaining to Fabricate Efficient Tin/Lead Perovskite Solar Cells

Gaurav Kapil$^1$, Takeru Bessho$^1$, Takumi Kinoshita$^1$, Qing Shen$^2$, Taro Toyoda$^2$, Takurou N. Murakami$^2$, Takashi Minemoto$^2$, Hiroshi Segawa$^1$ and Shuzi Hayase$^2$; $^1$The University of Tokyo, Japan; $^2$University of Electro-Communications, Japan; $^3$National Institute of Advanced Industrial Science and Technology, Japan; $^4$Ritsumeikan University, Japan
Tin-lead (Sn-Pb) perovskite exhibits an ideal band gap (1.2 eV-1.4 eV) to achieve higher power conversion efficiency (PCE) than pure Pb based PSCs [1]. However, being a low band gap material and prone to oxidation of Sn²⁺ to Sn⁴⁺, Sn-Pb solar cells exhibit low open circuit voltage (Voc) [2,3]. To increase the Voc, a spike structure strategy was reported by our group, Voc of 0.75 V and PCE of 17.6% were obtained [2]. To further improve Voc, in this work we will demonstrate that by decreasing the strain in the Sn-Pb perovskite lattice, Voc more than 0.80 V can be obtained. Also, we will show that with the change in conducting glass substrate, i.e by selecting a conducting glass with better IR transmittance, short circuit current density (Jsc) more than 30 mA/cm² can be obtained. The methodology discussed in the work can direct to PCE of more than 20%

Cs⁺ added triple cation-based Sn-Pb perovskites, (CsxFA₁₋ₓSnI₃)₀.₅(MAPbI₃)₀.₅, were prepared. Voc was improved from 0.76V to 0.81V with the addition of optimized amount of Cs⁺. This observation was well supported by the decrease of lattice strain at the optimized concentration of Cs⁺. In the work, we will discuss in detail about the characterization techniques such as X-ray diffraction (XRD), UV-Vis spectroscopy, Trap density measurement by Thermally stimulated current (TSC) measurements, etc, which led to the conclusive discussions regarding the optimized precursor for Sn-Pb PSCs.

Strain relaxation in Sn-Pb PSCs was reported which led to the increase in Voc more than 0.80 V. It was demonstrated that better transmittance of conducting glass in infrared region can increase Jsc of Sn-Pb PSCs more than 30 mA/cm². Furthermore, PCE of more than 20% can be achieved in the case of Sn-Pb PSCs despite of oxidation problem. Also, the results obtained in the work encourage implementation of Sn-Pb PSCs as a low band gap solar cell in tandem solar cells.

Role of Water Vapor in the Thermal Deposition of MAPbI₃ Ke Wang, Benjamin Ecker and Yongli Gao; University of Rochester, United States

Organometal halide perovskites have received a lot of attention in recent years as an efficient light absorbing material for use in a solar cell, where the device efficiency has reached 24.2% in early 2019. Compared to traditional silicon solar cells, the perovskite thin films can readily be made in a lab environment with techniques such as spin coating, blade coating, and thermal vapor deposition. In particular, thermal deposition is well-known for its ability to grow highly uniform perovskite thin films, often times with fewer defects and a more ideal chemical stoichiometry than films grown by solution-based techniques. The interactions of the prototypical perovskite precursors, lead iodide (PbI₂) and methylammonium iodide (MAI), while in the vapor phase and their depositions are poorly understood, despite their role they play in perovskite film growth. Herein, we observed the partial pressure changes of the perovskite precursors in the vapor phase with a residual gas analyzer, and each precursor was individually evaporated in a vacuum chamber which was continually pumped by a turbomolecular pump. No increase in the MAI partial pressure was observed during the MAI evaporation and this suggested that it was not evaporating as a whole compound, but rather it was dissociating into several other species including CH₃NH, CH₃NH₂, and HI.

Surprisingly, residual water vapor was also observed to behave differently in the two different individual evaporation. During the MAI evaporation, the water vapor pressure was reduced and this indicated that the water vapor was being consumed either by MAI or MAI dissociation products. This was not observed during the evaporation of PbI₂ or the heating of an empty tungsten boat used as a control investigation. This was surprising as the water vapors initial pressure was 5*10⁻⁷ torr, and such a low amount of water vapor was not expected to influence the depositions. In literature, it had previously been thought that MAI depositions were problematic due to a low sticking coefficient. However, this work suggests that the MAI’s and its dissociation component’s vapor pressures in previous investigations may have unknowingly also been reduced due to residual water vapor in the vacuum growth chambers. This reduction effect of the MAI related vapor pressures may play a critical role in the initial deposition of MAI films, and subsequently, any deposition of perovskite thin films by vapor deposition.

Rubidium-Dopped Cs₂AgBiBr₆ Double Perovskite Solar Cell Zehao Zhang, Cuncun Wu, Duo Wang, Ganghong Liu, Qiaohui Zhang, Wei Luo, Xin Qi, Xuan Guo, Yuqing Zhang, Yinan Lao, Bo Qu, Lixin Xiao and Zhijian Chen; Peking University, China
Cs$_2$AgBiBr$_6$ has received great attention as an emerging double perovskite material. Some researches shown that the performance of the double perovskite material can be improved by doping other elements, but there is no report about solar cell with doping. We demonstrate Rb$^+$ doping in Cs$_2$AgBiBr$_6$ can effectively increase the current and PCE of the device. Doping Rb$^+$ can effectively modify the perovskite to reduce the density of defect states, while the absorption of long-wavelength is strengthened. We also found the optimizing ratio of Cs$^+$ and Rb$^+$ is 9:1. The device with (Cs$_{0.9}$Rb$_{0.1}$)$_2$AgBiBr$_6$ achieves a maximum PCE of 1.52% and an ultra-high FF of 0.788 with the planar structure. And the average PCE is nearly 15% higher than the devices with Cs$_2$AgBiBr$_6$. However, excessive Rb$^+$ would lead to formation of Rb$_3$Bi$_2$Br$_9$, that means the degradation of the double perovskites.

EN08.13.30
Metal Encapsulation of Scalable Perovskite Devices for Operation Under High-Moisture Environments

Virgil Andrei, Robert L. Hoye, Shahab Ahmad, Michael De Volder, Richard H. Friend and Erwin Reisner; University of Cambridge, United Kingdom

Research in perovskite photovoltaics (PV) has witnessed a tremendous development over the last decade, as leaps in efficiency and stability were achieved by improvements in the device architecture. Progress in the charge selective layers led to better charge collection and band alignment, whereas development of multiple cation mixed halide perovskite phases resulted in robustness beyond 500 h under harsh environmental conditions.[1,2] Yet, the broad commercialization of perovskite PV panels has remained an elusive goal, as issues remain regarding the modules’ scalability and their long-term moisture- and air-sensitivity.

While typical stability tests employ high ambient humidity and elevated temperatures to accelerate device degradation, it must be pointed out that real-life module operation involves device soaking, mechanical stress and temperature changes, as experienced by a solar panel under say a heavy rain. Accordingly, the investigation of device robustness when submerged in aqueous, potentially corrosive electrolyte solutions may provide a more realistic benchmark for evaluating encapsulation strategies.

In this contribution, we introduce photoelectrochemical (PEC) device testing as a way to evaluate encapsulation methods, which are employed for perovskite PV devices of different sizes. Accordingly, we will focus on the recent advances in solar cell encapsulation achieved using a thin layer of Field’s metal (FM), a low melting InBiSn alloy.[3,4,5] The metal layer has a dual function, as protective barrier and electrical contact, which can act as an electronic interface to a surface-bound catalyst for PEC applications. In particular, the FM encapsulation demonstrates an advantage for the J-V characterization of larger single pixel perovskite solar cells, which can be straightforwardly employed as hydrogen-evolving photocathodes after electroless deposition of a platinum nanoparticle catalyst.[5] In this respect, we will also place special focus on the scalability of FM encapsulated solar cells, highlighting the interplay between device performance and serial resistance losses for single pixel perovskite PV devices of sizes of up to 10 cm$^2$.

In this context of photoelectrochemical benchmarking, we will also give a brief introduction to the basic principles of solar-fuel research and its advantages in terms of simultaneous energy production and storage,[6] showcasing our recent progress in the development of perovskite-BiVO$_4$ PEC tandem devices for unassisted water splitting.[5] Taking our current progress on 300 cm$^2$ large scale BiVO$_4$ panels into account,[7] we envision rooftop PEC devices by combining the BiVO$_4$ photoanodes with perovskite photocathodes of matching sizes. In the context of commercial applications, we will further address the potential of lowering down the overall device costs by appropriate choice of components.

Photonic Curing to Increase Throughput in Halide Perovskite Solar Cell Fabrication

Weijie Xu1, Trey Daunis1, Robert T. Piper1, Juan Carlos S. Batres1,2, Shubham R. Patil1, Kurt Schroder1 and Julia W. Hsu1; 1The University of Texas at Dallas, United States; 2Universidad Autónoma Metropolitana, Mexico; 3NovaCentrix, United States

Halide perovskite solar cells (PSCs) have leap-frogged many photovoltaic systems in the past decade due to their excellent optoelectrical properties and solution-processability. Meanwhile, metal oxide (MO) transport layers have been shown to exhibit better stability, lower cost, and more tolerant processing parameters than their organic counterpart, leading to a promising path towards PSC commercialization. However, the bottleneck to high-throughput manufacturing of PSCs is the thermal annealing step in both the perovskite active layer and the MO transport layer, especially for mixed-cation perovskite materials and sol-gel MO films, which both require long thermal annealing time and high temperature. Conventional thermal annealing methods are not conducive to high-throughput manufacturing of large area PSCs because they translate to hundreds of meters long annealing tools and tremendous energy consumption due to the heat loss. In this work, we explored photonic curing as a rapid thermal annealing technique to replace conventional thermal annealing for both the bottom MO transport layer and the perovskite layer. Photonic curing, which is often used to sinter conductive nanoparticles on flexible substrates, delivers intense pulsed light on a sample within ~1ms. The absorption of light by the precursor film can increase its temperature by several hundreds of degrees within a short time window while minimizing heating of the substrate due to overall low energy. Thus, it is suitable for plastic substrates that can only be processed at low temperatures, e.g. PET. In addition, many photonic curing parameters—pulse length, pulse shape, pulse rate, energy per pulse, and number of pulses—can be optimized to process different materials due to their different light absorption coefficients and thermal properties. Our p-i-n PSCs are fabricated on PET/ITO substrates using NiOx as the hole transport layer. We spin coat and photonic cure NiOx sol-gel precursor films and perovskite precursor films sequentially. The materials’ properties, including optical absorption, crystallinity, surface morphology and roughness, and work function, as well as device performance are compared for films processed by photonic curing vs. conventional thermal annealing. We also compare the processing time and cost between photonic curing and hot plate annealing to demonstrate photonic curing as a potential candidate in high-throughput manufacturing of halide PSCs.

Showerhead-Assisted Chemical Vapor Deposition of Perovskite Films for Solar Cell Application

Simon Sanders1, Dominik Stümmler1, Pascal Pfeiffer1, Jan Seidel1, Jonas Gerber1, Gintautas Simkus1,2, Michael Heuken1,2, Andrei Vescan1 and Holger Kalisch1; 1RWTH Aachen University, Germany; 2AIXTRON SE, Germany

Organic-inorganic halide perovskite solar cells have shown a rapid increase of performance with a maximum power conversion efficiency (PCE) up to 24.2 % in 2019, making these devices promising alternatives to those of established solar cell technologies. Besides the toxicity of the commonly used Pb-based compounds, the lack of deposition tools for large areas is one of the major challenges for the commercialization of perovskite photovoltaics. Chemical vapor deposition (CVD) is an appealing choice because it furthermore features high purity and superior process control.

In this work, we present a custom-developed showerhead-based perovskite CVD tool as well as novel low-vacuum (total pressure 10 hPa) CVD processes to fabricate dense perovskite films by simultaneous deposition of the precursors from the gas phase. We employ an organo-halide compound (CH3NH3I (MAI)) and a metal halide (either PbI2 or BiI3 as a non-toxic alternative) to obtain either MAPbI3 or (MA)3Bi2I9 (MBI) perovskite layers on a typical solar cell anode stack (glass / FTO / compact TiO2 / mesoporous TiO2, substrate size 2.5 cm x 2.5 cm). The thermally sublimated precursors are transported via N2 carrier gas (500 sccm) through the heated showerhead. The carrier gas flow is spread homogeneously enabling deposition on large-area substrates. Condensation and reaction of the precursors occur on the temperature-controlled substrate. A quartz crystal microbalance (QCM) is used to determine the deposition rates, usually between 3 and 7 nm/min for perovskite growth. For morphological, structural and optical characterization of fabricated layers, scanning electron microscopy (SEM), X-ray diffraction (XRD) and absorption measurements are performed. To obtain stoichiometric perovskites, we analyze the impact of the deposited-volume ratio between MAI and PbI2/BiI3 (adjusted by the QCM rates). In case of the Pb-based perovskite, an excessive supply of MAI (volume ratio MAI/PbI2 > 5) was found to be responsible for the formation of the
dihydrate perovskite phase \((\text{CH}_3\text{NH}_3)_4\text{PbI}_6\cdot2\text{H}_2\text{O}\) (XRD reflex at 11.3 °, measured in ambient air), leading to fast degradation of the perovskite layer. Providing the right amount of MAI during deposition (volume ratio between 2 and 4) results in stoichiometric perovskite films without any residues of the precursors (XRD spectrum perfectly matches the calculated pattern). We fabricated dense layers with thicknesses of 400 nm, exhibiting a cubic morphology with grain sizes of 200 nm.

For the MBI perovskite, a volume ratio of 5 was found to be sufficient for a complete conversion of BiI₃. Depositions with MAI/BiI₃ volume ratios exceeding 5 do not exhibit XRD peaks which can be assigned to either MAI or a perovskite hydrate. Obviously, the simultaneous deposition of BiI₃ and MAI has a self-limitation for MAI incorporation, still leading to the formation of stoichiometric MBI. Furthermore, we investigated the influence of the substrate temperature and layer thickness on film properties. Decreasing the substrate temperature from 88 to 50 °C leads to a more rounded grain morphology. The size of the crystallites scales to some extent with the layer thickness. Large grains up to 500 nm diameter are formed for a film with 225 nm layer thickness. The MBI films were implemented in non-inverted solar cell structures (Spiro-MeOTAD / Au contacts on top) with a maximum PCE of 0.016 %. Most likely, higher efficiencies can be achieved by optimizing the device architecture as the mesoporous TiO₂ matrix is not penetrated by the perovskite film. Finally, we deposited and characterized dense MBI films on large-area FTO substrates (12 cm x 9 cm), demonstrating the high degree of homogeneity. The formation of dense perovskite layers combined with the versatility and scalability of the process render this technology to be an auspicious candidate for commercial large-area production.

EN08.13.33
Upscale of Perovskite Solar Cells—Impacts of Drying Processes on Growth Mechanisms and Layer Properties of the Absorber

Sophie Bernard¹,²,³, Sébastien Jutteau¹,², Frédéric Sauvage³ and Jean Rousse³¹,², IPVF, France; ²EDF R&D, France; ³UPJV, France

For the past few years, perovskite solar cells have known a tremendous development among photovoltaic technologies. Since 2012, their performances rapidly increased from 2% to 24.2% efficiency. Nonetheless, most of the research occurs on lab scale substrates with an active area in the range of 0.1 cm². One challenge for the future of perovskite solar cells is the device up-dimensioning to modules, larger than 1 m². To do so, it first requires a better understanding and a good control of nucleation and growth mechanisms, but also the development of large scale fabrication processes, including deposition and drying methods.

Fabrication of a thin film on large-scale by solution coating is very demanding. To address this issue, various techniques have been previously developed, such as blade-coating, screen printing or slot-die coating [1]. However, none of this processes have achieved the small-scale performances yet. For now, the best efficiency for slot-die coated perovskite reached 18% [2] on lab-scale cell and 10.1% for a 160 cm² module [3]. To enhance the performances, it is necessary to deeply understand the influence of coating processes and drying methods.

First, we noticed that DMF/NMP offer a larger window coating, which can be optimized for slot-die systems. In fact, NMP get a similar coordination potential with PbI₂ than DMSO, usually used in spin coating solutions, but evaporate slower. Varying NMP ratio in DMF solvent mix allowed us to investigate different crystallization mechanisms in order to fit upscale conditions. Moreover, depending on NMP ratio, it is possible to enhance perovskite film coverage. Then, using an ideal DMF/NMP ratio, we developed a vacuum aspiration protocol. Inspired by X.Li and al.’s work on VASP (Vacuum flash-assisted solution process) for small scale spin-coated perovskite solar cells [4], we adapted this technology for 5x10 cm² slot-die coated perovskite layers. We studied different temperature and pressure conditions for quench and annealing stages in order to get an efficient and repeatable drying process.

On another hand, we studied several perovskite ink compositions. Besides solvent variation, it is possible to add different additives and surfactants to control adducts formation, making it more compatible with a slot-die coating system. We focused our work on FACs perovskite, excluding methylammonium cation. We adjusted the solid content and the ink formulation to improve uniformity, thickness and crystallization rate.

Through this work, we aim to demonstrate the influence of drying method on the absorber properties and how it is possible to control it to achieve high quality perovskite layers by slot-die system. We plan to transfer this achievements on mini-modules, with slot-die coated perovskite absorber.
EN08.13.35
P-type Conductors for Reducing Defect Density and Improving Stability in Invert Perovskite Solar Cells Lin Li; Huazhong University of Science and Technology, China

Perovskite solar cells (PSCs) are one of the most promising photovoltaic technology. However, lead perovskites face long-term instability issues under stimuli of heat, oxygen, moisture, electric field and light irradiation. Here we incorporate a series p-type organic conductors as additives in perovskite layer, increasing the device efficiency and markedly improving the long-time device stability. We close by positing organic conductor, reduce the defect density on the perovskite surface, by tying up both halide-rich antisites and undercoordinated lead center. After optimization, the carrier recombination lifetime was increased and the boost efficiency of 20.4% inverted perovskite solar cells was obtained. The thermal stability of the PSCs with passivation was evaluated, in which the devices were heated to 85°C inside a N2-filled glove box. there is almost no PCE reduction for the perovskite-conductor device after being heated for 24 hours.

EN08.13.36
Hydrophobic Perovskite Based on an Alkylamine Compound for High Efficiency Solar Cells with Improved Environmental Stability Mi Hee Jung; Sejong University, Korea (the Republic of)

Hybrid quasi-two dimensional perovskites (2D) have attracted significant scientific interest, because they have demonstrated excellent light absorbing materials in photovoltaic devices. However, the quasi-2D perovskites still perform poorly in high humidity, even though they have exhibited greatly improved stability compared to their three-dimensional (3D) counterparts. This is the biggest obstacle for the practical implementation and commercial viability of perovskite solar cells. Herein, we used hexylamine (CH3(CH2)4CH2NH2, HA) for a quasi-2D, HA(CH3NH3)n-PbnI3n+1 (n = 1, 2, 3, 4) perovskite, which has had sufficient long alkyl chain to maintain the chemical stability of perovskite. As the number of layers of quasi 2D HA(CH3NH3)n-PbnI3n+1 perovskites was increased, it exhibited an appropriate band gap as a light absorber to be applied to solar cells. The perovskite solar cell based on the 2D HA(CH3NH3)n-PbnI3n+1 perovskites showed an excellent power conversion efficiency of 5.90% with a short circuit current density of 13.61 mA cm⁻¹, an open circuit voltage of 0.72 V, a fill factor of 60.10%, and stability with solar cells to ambient air. The long alkyl chain of the hexylamine cation prevented degradation of the solar cell from the atmosphere with passivation of the perovskite films due to its high hydrophobic property. This investigation highlights the role of the organic cation to maintain the quality of the perovskite film and provides a critical solution for the poor stability of perovskites in ambient air.

EN08.13.37
Stacking of Layered Halide Perovskite from Incorporating a Diammonium Cation into Three-Dimensional Perovskites Mi Hee Jung; Sejong University, Korea (the Republic of)

Quasi two-dimensional (2D) layered perovskites have been emerging as promising candidates for a photovoltaic cell because they exhibit intrinsic stability and a higher tunability of optical properties compared to three-dimensional (3D) perovskites. However, since most 2D perovskites have bulkier groups as an organic space group, it will inevitably have a van der Waals gap between the inorganic layers, and their crystal growth directions orientate in a lateral direction. It also interrupts carrier transport across the conducting inorganic layer in the solar cell. Here, we presents the new homologous 2D layered perovskites, (HA)(A)n-PbnI3n+1, where HA stands for the histammonium ((C5N3H11)2+) as a diammonium cation, and A stands for methylammonium (CH3NH3+) or formammonium (HC(NH2)2+). Since the ditopic HA have diammonium cation, it connects the inorganic slabs stacked in the vertical direction. The inorganic layer is stacked on the other layer to form a layered structure, which results in rigid and stable structures. These materials (1.46 eV for (HA)(FA)n-PbnI3n+1 and 1.80 eV for (HA)(MA)n-PbnI3n+1) have significantly lower band gaps than the HAPbI4 (2.20 eV). Compared to the pure 2D and 3D perovskites, these perovskite have a longer electron lifetime due to the vertical crystal structure and show improved environmental...
stability for the perovskite solar cell application

**EN08.13.40**  
**A Chemically Inert Bismuth Interlayer Enhances Long-Term Stability of Inverted Perovskite Solar Cells**  
Chen Rui; Huazhong University of Science and Technology, China

Highly efficient and low-cost halide perovskite solar cells (HPVKSCs) are regarded as one of the most promising photovoltaic technologies to realize commercialization in the near future. However, the long-term stability of HPVKSCs under real working conditions, involving stresses from moisture, heat, light, and the electric field, is still a challenge that must be addressed. The irreversible degradation of HPVKSCs can be mainly attributed to three phenomena: (1) volatilization of the organic components in organic–inorganic hybrid perovskites, especially for the benchmark methylammonium lead triiodide (MAPbI3) under thermal aging conditions above 85°C, (2) permeation of external H2O/O2 and its induced degradation of perovskites, and (3) reactions between the normally used metal electrodes and halogens from the perovskites during prolonged operation. For the last two issues, especially the third one, their resolutions are largely related to the essential properties of the interfacial layers (i.e., morphologic pin-hole free, chemical resistivity to H2O/O2 and halides), which could act as robust permeation barriers to block the undesired processes. If the interfacial layers are permeable or have pin-holes, sufficient separation between the perovskites and electrode metals cannot be achieved, and the corrosive reaction could be fast.

Here, we demonstrate a facile processing strategy for highly stable HPVKSCs with the structure FTO/Li+-doped NiMgLiO/Perovskite (PVK)/PCBM/BCP/Bi/Ag by introducing the compact Bi interlayer. The devices and films were characterized by photoluminescence (PL), scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), time of flight secondary ion mass spectrometry (ToF-SIMS), etc., which demonstrate that the Bi interlayer acts as a robust penetration barrier that blocks the unfavorable external molecules from diffusing into the devices and suppresses the diffusion of ions between the metal electrode and the perovskites. As a result, our unencapsulated MA-HPVKSCs retain 88% of their initial efficiency after being maintained in the dark in ambient air without humidity control for 6000h. During long-term light soaking or thermal aging at 85°C in the dark, the devices with Bi interlayers are considerably more stable than devices without Bi. This Bi-interlayer strategy is easily scalable and highly repeatable and may pave the way to the future practical application of large-area and highly stable HPVKSCs.

**EN08.13.41**  
**Inorganic Halide Perovskite Single Crystal—Growth Mechanism, Structural and Optical Properties**  
Sovesh Mohapatra, Naveen K. Tailor and Soumitra Satapathi; Indian Institute of Technology, India

Lead halide semiconductors with a perovskite crystal structure and APbX3 stoichiometry [A = Cs+; X = I−, Br−, Cl− or mixtures thereof have recently turned into the most strongly considered category of inorganic optoelectronic materials. These materials are now widely utilized in light-emitting diodes, lasers, photo-detectors as well as in X-ray and gamma-ray (γ-ray) detectors. In these applications, large single crystals (SCs) grown by precursors solutions of perovskites are mostly utilized because of low trap density and less grain boundary. Therefore, the rapid emergence of halide perovskite based single crystalline materials for a wide variety of as mentioned applications has drawn much research attention in recent years. Many efforts have been made in optimizing their macroscale device performance by improving material processing and device fabrication and over the last few years. But, to fully obtain and understand the intrinsic characteristics of perovskites, a variety of high-quality single-crystalline materials are genuinely necessary.

In our present study, we have reported the 3mm size lead free perovskite single crystals grown by the slow cooling method. The synthesis, crystal growth, and detailed structural and optical characterization have been carried out by Optical microscopy, FESEM, EDXA, single crystal XRD, UV-Vis, PL, and TCSPC. The synthesized single crystals have orthorhombic structure and Pnma space group and the corresponding lattice parameters and reciprocal lattice parameters are calculated. Moreover, symmetry operators in the crystal, hkl values, linear absorption coefficient and reciprocal lattice pattern of the synthesized single crystals have been calculated. Transmission microscope and FESEM images have shown clearly the single crystalline morphology and EDXA have shown the stoichiometry matching by means of elemental analysis of the crystals. The I-V characteristics of this lead-free perovskite single crystals are also discussed.
Grain Size Increase of MAPbI₃ Perovskite via Hot-Casting Technique for PV Application with Enhanced Efficiency

Jasmine Li¹, Aidan York², Yuchen Zhou¹, Yifen Yin¹ and Miriam Rafailovich¹; ¹Fairview High School, United States; ²Kellenberg Memorial High School, United States; ³Stony Brook University, United States

Perovskite solar cells (PSCs) demonstrated fast-raising power conversion efficiency (PCE) in past couple years. However, one of the problems associated with PSCs is the formation of small sized grains with large density of grain boundaries (GB) and defects within the perovskite layer, which largely results from the conventional post annealing method used in perovskite layer preparation. To promote crystalline quality and reduce GB density, we utilized a so-called “hot-casting” technique, in which the perovskite precursor solution and substrate are preheated at a relatively high temperature before spin-casting. This allows annealing and spin-casting to occur at the same time, prolongs the grain growth time, and as a result, enhances the crystal quality. Therefore, PSCs made by hot-casting can have promoted PCE by growing large crystal grains and decreasing defects/traps.

We compared the morphology and crystalline structure of perovskite layer and PV performance of corresponding devices prepared via conventional post annealing versus the hot-casting. We observed in scanning electron microscope (SEM) images that hot-casted samples produced an average grain size of 11.40 μm, nearly 60 times greater in size than the average grain size of 194 nm obtained for the post annealing method. Furthermore, we observed in atomic force microscopy (AFM) images that hot-casted perovskite demonstrated a canyon-like crystal growth due to such vigorous growth that neighboring grains collided at the edges, forming a uniform, fully covered, and highly crystalline film with micron sized grains; in contrast, perovskite made by post annealing produced a film with much smaller and nanosized grains. We also used x-ray diffraction (XRD) to confirm that hot-casting generated perovskites possessed the tetragonal crystal phase, same with the sample made by post annealing method; in fact, hot-casting enhanced the crystallinity of perovskite, which exhibited stronger XRD peak intensity than the conventional ones. Most notably, PV performance tests demonstrated a PCE increase of ≈15% when using hot-casting, from 12.2% prepared conventionally to 13.9% prepared via hot-casting. Thus, hot-casting has demonstrated to be an effective method to increase PCE of PSCs through the grain size management. Ion Diffusion and Surface Moisture-Induced Degradation Behaviors in Halide Perovskite Using Molecular Dynamics Simulations

Huanhuan Zhou¹, Mingchao Wang², Jingfan Wang¹ and Shangchao Lin³; ¹Florida State University, United States; ²Monash University, Australia; ³Shanghai Jiao Tong University, China

Organic-inorganic hybrid perovskites, such as the prototypical methylammonium lead iodide (CH₃NH₃PbX₃ or MAPbX₃, X=I-, Br-, Cl-), have emerged as promising light absorbers in photovoltaic (PV) cells or as emitters in light-emitting diodes (LEDs). However, they generally suffer from moisture instability, which limits the long-term use of perovskite-based devices in ambient environment and impedes the rapid commercialization. In this work, we have studied the ion diffusion and surface moisture-induced degradation behaviors for two types of perovskites: 3D MAPbI₃ and 2D MAPbBr₃. In order to greatly decrease the ion dissociation rate and improve the moisture stability, we have applied molecular dynamics (MD) simulations and first-order reaction kinetics theory to model the ion dissociation process and estimate the associated free energy barrier with and without ligand passivation. We design 3D MAPbI₃ and 2D MAPbBr₃ structures with ligand-passivated surfaces by replacing MA cations with ligands composed of long-chain alkyl-ammoniums. Ligands with different chain lengths, such as CH₃(CH₂)₇NH₃⁺ (n=7), and under different surface coverages (σ = 25%, 50%, 75%, 100%), are considered here. We discover that ligand passivation can greatly help 3D MAPbI₃ and 2D MAPbBr₃ perovskites protect MA cations on the surface due to the much higher dissociation energy barriers of these ligands compared to that of MA cations. For I anions, ligand passivation can also shield them from water contacts, except for long-chain ligands, such as CH₃(CH₂)₇NH₃⁺ (n=7) at full surface coverages (σ = 100%), due to the reduced dissociation free energy barriers of long-chain ligands. As an interesting finding, the reduced dissociation free energy barriers for long-chain ligands at high surface coverages could be explained by their larger tendencies to micellize, which serves as additional driving force for their dissociation. Additionally, water contact angle simulations have also been performed for 3D MAPbI₃ perovskites to compare the hydrophobicity of different ligand-passivated surfaces and verify that the surface moisture stability of 3D MAPbI₃ surface has been improved by the ligand passivation technique. We also observe suppressed and anisotropic ion diffusion in 2D MAPbBr₃ perovskites due to the layered ligand phase sandwiched by the PbI₂ crystals, which resembles an organic-inorganic superlattice. This work significantly motivates future experimental
efforts in designing new surface ligands to improve the moisture stability of halide perovskites.

Stability Enhancement of Perovskite Solar Cells Using Mixed Cation/Halide Perovskite Ethan Eisenberg¹, Jack Cox², Yuchen Zhou³, Yifan Yin³ and Miriam Rafailovich³; ¹George W. Hewlett High School, United States; ²South Side High School, United States; ³Stonybrook University, United States

Within the last decade, perovskite (PVSK) has emerged as a solar cell material rivaling those of silicon and quantum dots due to their increasing power conversion efficiency (PCE). PVSK serves as the active layer within a planar solar cell and have the common hybrid organic inorganic halide structure ABX3. The increasing efficiency of these cells can be attributed to several optoelectronic characteristics such as a high absorption coefficient, tunable bandgap and ambipolar carrier transport. However, PVSK is limited because the ABX3 classic structure is unstable. The most common ABX3 structure is methylammonium lead iodide (MAPbI3). The organic cation of methylammonium (MA) is hygroscopic, causing the cell to degrade under conditions of moisture, heat, oxygen, and light [3]. To reduce degradation and enhance efficiency, Cs and formamidinium (FA) cations and Br halide are introduced to create a mixed cation/halide structure CsFAMAPbIxBr1-x. The combination of these cations and halides can allow for increased stability and optoelectronic performance by reducing transformation into a photo inactive delta phase, while maintaining the preferable bandgap produced by the FA structure.

Pervious research studies have used different pure PVSK compounds such as CsPbI3 or FAPbI3 to either prevent degradation or to optimize absorption. However, due to the existence of inactive phases, these materials suffer from structural instability. Furthermore, studies that have observed mixed structures that do not include FA (CsxMA1-xPbI3 for example) can exhibit lower efficiencies due to a bandgap increase. This study tries a combination of Cs, FA, MA, and Br with a spin-coating method to optimize both efficiency and stability of the cell. One-step spin coating was used to prepare the PVSK film. PbI2, MAI, CsI, FAI, and PbBr2 at a molar ratio of 1:0.7:0.15:0.15 were placed in a mixed solvent of DMF and DMSO (8:2). Titanium dioxide was spin coated onto FTO substrates and annealed to form the electron transport layer (ETL). The precursor PVSK solution was then deposited via spin coating and chlorobenzene was applied onto the surface as an anti-solvent for crystal generation. Spiro-OMeTAD was coated as a hole transport layer (HTL) and physical vapor deposition (PVD) was used to add the gold electrodes.

UV-Visible Spectroscopy indicated that the changing of the cation/halide component did not influence the absorption of the photoactive layer. Scanning electron microscopy (SEM) morphology results showed increased grain size for the mixed PVSK. Atomic force microscopy showed correspondent morphologies to SEM results, but with an increase in roughness, which is within acceptable range. Moreover, XRD results implicated that the mixed PVSK had two possible crystal phases (α and phases) compared to the single peak of (110) of MAPbI3 PVSK, while only the cubic α phase is photoactive. Therefore, the mixed PVSK layer was annealed at various conditions to optimize the cubic alpha photoactive phase. This is because the partial phase segregation can lead to increased recombination at Iodine rich centers, and would therefore hinder PCE. After the optimization, results revealed that at a temperature of 120 Celsius and a time of 10 minutes allowed for the preferable crystallization of the mixed PVSK with a strong alpha peak and negligible delta phase. Furthermore, the PCE measurement indicated the mixed PVSK has higher PCE, probably due to increased grain size. The moisture and heat stability tests (XRD) revealed enhanced structural stability against excessive heat, supporting that the mixed structure can successfully generate better performance and enhance the durability. (We acknowledge support from the Louis Morin Charitable Trust and NYS Department of Economic Development.)

127I NQR Study of Methylammonium Lead Iodide MAPbI3 YoHan Kim, BeomJe Jo and Moohee Lee; Konkuk University, Korea (the Republic of)

The single crystals of methylammonium lead iodide (MAPbI3) CH3NH3PbI3, which recently draws much research interest as light-harvesters in dye-sensitized solar cells because of the high photovoltaic efficiency and the structural flexibility for all solid-state devices, were prepared by the solution growth method and characterized by 127I NQR (nuclear quadrupole resonance) techniques. 127I NQR spectrum, linewidth, spin-spin relaxation rate 1/T2, and spin-lattice relaxation rate 1/T1 were measured as a function of temperature down to 70 K to microscopically understand the iodine dynamics associated with the ionic conductivity. As temperature decreases, 127I NQR frequency slightly increases from ~ 82 MHz at room temperature and then disappears around 180 K with the rapidly increasing linewidth. At lower temperatures, the NQR signal appears again with the fast increase of resonance frequency but
the narrowed linewidth remains almost same. The spin-echo signal is observed below 120 K and $1/T_2$ decreases quickly at low temperatures. $1/T_1$ increases down to 180 K, below which it starts to decrease. Based on these NQR data, we conclude that the iodine dynamics change significantly around 180 K.

EN08.13.47
Moisture Induced Structural Degradation in Methylammonium Lead Iodide Perovskite Thin Films Panteha Toloueiinia, Hamidreza Khassaf, Alireza Shirazi-Amin, Anne Mirich, Chris Monteleone and Steven L. Suib; University of Connecticut, United States

Methylammonium lead iodide (CH$_3$NH$_3$PbI$_3$, MAPbI$_3$) belongs to the group of organic-inorganic halide perovskite (OIH) that exhibit exceptional electrical and optical behavior for photovoltaic applications. However, its structural and chemical stability and robustness remain a challenge in order to be considered a feasible active material in optoelectronic devices. Therefore, it is crucially important to understand mechanisms by which MAPbI$_3$ undergoes chemical degradation under operating conditions such as a relatively humid environment. We use dark pulse discharge measurements and current-voltage (I–V) variations of MAPbI$_3$ under different moisture levels to investigate the nature of structural degradation in (OIHs). We show that while relatively low levels of humidity (RH<65%) have limited impact on structural stability, exposure to higher levels of moisture results in the formation of PbI$_2$ and CH$_3$NH$_3$I which fundamentally change the charge transport phenomenon in MAPbI$_3$. Our findings suggest an explanation of the ongoing debate on the presence of a critical level of humidity that triggers irreversible structural transformation that leads to full degradation of MAPbI$_3$.

SESSION EN08.14: Perovskite Solar Cell—High Efficiency
Session Chairs: Shuzi Hayase, Shengzhong (Frank) Liu and Selina Olthof

Understand the Stability Limitation of Perovskites and Strategies to Enhance the Stability Jinsong Huang; University of North Carolina at Chapel Hill, United States

The efficiencies of small-pixel perovskite photovoltaics have increased to well above 20%, while the question is whether fabrication methods can be transferred to scalable manufacturing process. Here we report a method of fast blading large area perovskite films at an unprecedented speed of 99 millimeter-per-second or higher in ambient condition by tailoring solvent coordination capability. Combining volatile non-coordinating solvents to Pb$^{2+}$ and low-volatile, coordinating solvents achieves both fast drying and large perovskite grains at room temperature. The reproducible fabrication yields a record certified module efficiency with aperture area of 63.7 cm$^2$. The perovskite modules also show a small temperature coefficient of -0.13%/°C and nearly fully recoverable efficiency after 58 cycles of shading, much better than commercial silicon and thin film solar modules. The application of the coating method to perovskite/silicon tandem cells and will also be presented. We will answer the question whether the perovskite layers can be fabricated at the speed of silicon cells are produced in the regular production lines.

8:30 AM *EN08.14.02
Surface Passivation for Efficient Perovskite Solar Cells Jingbi You; Chinese Academy of Sciences, China

It is known that the $V_{OC}$ of solar cells are strongly related to the defects recombination in the bulk or on the surface of absorber layer. Solution processed perovskite film is usually polycrystal, which contains substantial structural disorder such as grain boundary defects, crystallographic defects. Although it was theoretically predicted that most of the defects formed in perovskite layer could be shallow defects, several experimental results still showed that the suppression of defects in the solution-processed perovskite films are very critical for further enhancing the performance of PSCs toward their thermodynamic limits. Surface is the place where the defects could be easily formed, passivation of the surface defects is always the most important tasks in any type of solar cells. In PSCs, several efficient surface passivation methods have been adopted previously. Recently, we developed an organic halide salt phenethylammonium iodide (PEAI) for post-treatment of mixed perovskite to suppress the surface
defects of perovskite polycrystal film for efficient solar cells. We find that the PEAI can form on the perovskite surface and results in higher efficiency cells by reducing the defects and suppressing non-radiative recombination. As a result, planar PSCs with a certificated efficiency of 23.32% (Quasi-steady-state) are obtained. More recently, we have pushed the efficiency of PSCs beyond 24%.

Application of 2D Materials in Fabrication of Efficient and Stable Perovskite Solar Cells Mohammad Mahdi Tavakoli and Jing Kong; Massachusetts Institute of Technology, United States

Organic-inorganic perovskite materials, due to their excellent optoelectronic properties and low-cost processing have attracted many research groups nowadays. These materials with ABX₃ crystal structure (A: cesium (Cs), methylammonium (MA) or formamidinium (FA), B: Pb or Sn, and X: Cl, Br or I) have been a good candidate for the fabrication of highly efficient perovskite solar cells (PSCs) with a certified power conversion efficiency (PCE) of 24.2%. Interfacial engineering is one of the effective strategies for improving the efficiency and stability of PSCs. In this regard, combination of two-dimensional (2D) materials with PSCs would be so effective to improve the photovoltaic properties of devices. Here, we study the applications of monolayer graphene synthesized by chemical vapor deposition (CVD), MoS₂, and BN in the perovskite architecture. We considered graphene as top and bottom electrodes in the device and found that this would be a great way to replace metal electrode such as gold and fabricate efficient semi-transparent PSCs. Based on graphene as a top electrode in CsPbI₃ QDs PSC, we achieved a PSC with power conversion efficiency (PCE) of 6.8%, which is slightly lower than the reference cell (9.6%). Additionally, by tuning the thickness of the active layer, a PSC with PCE of 4.95% and average visible transmittance (AVT) of 53% is demonstrated, indicating the potential of CsPbI₃ QDs for the fabrication of semi-transparent devices applicable in windows.

Moreover, we employed MoS₂ as an electron transporting layer (ETL) in the PSCs and a PSC with PCE of 18% was achieved with this architecture, indicating the potential of 2D materials in the PSCs. In addition to the above study, we considered BN monolayer as an interface layer in inverted PSC device. Based on this modification, we improve the open circuit voltage (Voc) and stability of the PSCs drastically. Based on this modification, a PSC with PCE of over 20% was achieved.

Stable and Efficient Perovskite Solar Cells by Thiophene-Based 2D Perovskite Functionalization Albertus Adrian Sutanto¹, Nikita Drigo¹, Inés García Benito¹, Valentin I. Queloz¹, Kyung Taek Cho¹, Giulia Grancini² and Mohammad K. Nazeeruddin¹; ¹École polytechnique fédérale de Lausanne, Switzerland; ²University of Pavia, Italy

Hybrid metal halide perovskite materials have become a leading technology in the photovoltaic scene since its first application in solar cells in 2009. The power conversion efficiency (PCE) of perovskite solar cells (PSCs) has been reached from 3.8 to 24.2% in the past ten years. Compositional tuning, i.e., by substituting the anions or cations, and interface functionalization have been the key to the breakthrough of the device performances. However, the state-of-art device performance is, so far, achieved by employing three-dimensional (3D) perovskite materials as the light absorber. The major drawback in using 3D perovskites is the poor stability against moisture, which hinders the widespread application of this technology. On the other hand, two-dimensional (2D) perovskite materials have demonstrated superior stability compared to the 3D counterparts. However, 2D perovskites have limited light-harvesting ability, resulting in low PCE. Combining 2D and 3D into a new hybrid 2D/3D has been a popular alternative to boost both device efficiency and stability. In this work, we design and employ a family of thiophene-based organic cations, as building blocks for layered two-dimensional (2D) perovskites. The 2D layer functionalizes the interface between the optimized triple-cation (formamidinium (FA), methylammonium (MA), and cesium) lead halide perovskite layer and the organic hole transporting material (HTM) employed in n-i-p solar cells configuration. As an immediate result, the functional 2D interlayer actively improves device performances by significantly improving the long-term device stability by retaining up to 90% of the initial efficiency after continuous illumination and delivering efficiency of >20%. In parallel, the thiophene-based 2D capping layer reduces the commonly observed current voltage hysteresis behavior to a great extent.

9:30 AM EN08.14.05
Surface Tailoring and Passivation for Both Enhanced Efficiency and Stability of Perovskite Solar Cells
Shangshang Chen and Jinsong Huang; University of North Carolina at Chapel Hill, United States

Lead halide perovskites have drawn extensive research attention due to their excellent optoelectronic properties and remarkable performance in photovoltaic devices. The power conversion efficiency of perovskite solar cells has already reached over 24 %, surpassing those of mainstream thin film photovoltaic technologies like CdTe and CIGS. Despite these encouraging progresses, perovskite solar cells still suffer from poor stability owing to their vulnerability to oxygen, moisture and light.

It has been demonstrated that the degradation of perovskite initializes from the defective surface and grain boundaries, due to the higher reactivity of defects site, making them vulnerable to be attacked by moisture and oxygen.[1] Therefore, the passivation of these defects is imperative for the commercialization and large-scale production of this photovoltaic technology.

Here we present a simple strategy via the in-situ conversion of surface perovskite to water-insoluble lead salts, which exhibits dual effects: 1) passivate the surface defects and thus enhance the power conversion efficiency to over 21 %; 2) the formation of compact surface lead salt layer exhibits good resistance to hazardous stimuli under ambient atmosphere and light irradiation. Consequently, our encapsulated devices show excellent stability after operation at maximum power point under simulated AM 1.5G irradiation for over 1000 hours at 65 °C.

Ultrafast Thin-Film Perovskite Solar Cells Exian Liu¹, Kai Zhu² and Jianbo Gao¹; ¹Clemson University, United States; ²NREL, United States

To reveal the device physics of solar cells, various photoconductivity approaches such as time-resolved microwave photoconductivity (TRMC), time-of-flight (TOF), and photo charge extraction by linearly increasing voltage (CELIV) are used in-situ. However, their time resolution is within the range of couple nanoseconds to microsecond due to the device structure, resulted in that the carrier dynamics study is dominated by trapping states, rather than trapping-free phenomena. Therefore, it remains a challenge to study in-situ solar cells in an ultrafast fashion.

In this report, we use a more than 20 % perovskite thin film solar cell as a test-bed, and integrated them into an ultrafast photocurrent spectroscopy with sub-40 ps time resolution to study the carrier dynamics from the sub-40 ps to couple microseconds. We address the evolution of carrier dynamics such as relaxation, recombination, transport, and trapping.

10:30 AM *EN08.14.07
New Nanostructures, Interfaces and Crystallization Modes for Efficient and Stable Perovskite Solar Cells Shihe Yang; Peking University Shenzhen Graduate School, China

Nanostructures, interfaces and active layer crystallization are critical to the functioning of the new generation solar cells. The hybrid organic/inorganic halide perovskite solar cells have emerged as among the most competitive photovoltaic technologies of the future thanks to their superb and rapidly improving power conversion efficiencies (PCEs). For realistic deployment of the perovskite photovoltaic technology in large scale, however, device stability has become more and more important issue of the day. I will update our recent work on the development of high-efficiency and high-stability perovskite solar cells. First, we have developed a new hole transport material by embedding an ultra-low concentration of gold nanoparticles into a NiO film, significantly boosting the performance of the p-i-n perovskite solar cells. Second, by incorporating an ultrathin ferroelectric oxide PbTiO₃ layer between the electron transport material and the halide perovskite, we are able to significantly increase both PCE and stability of the perovskite solar cells. Finally, we discovered that a large excess of cesium iodide induces spinodal decomposition of CsPbI₂Br perovskite films, and these films could also be made into high performance perovskite solar cells. Implications of these results on the future development of perovskite solar cells will be discussed.
Compared with silicon-based solar cells, organic-inorganic hybrid perovskite solar cells (PSCs) possess a distinct advantage, i.e., its application in flexible field. However, the efficiency of flexible device is still lower than that of rigid one. Firstly, we found that dense perovskite film can be obtained with the help of N-methyl-2-pyrrolidone (NMP) by low pressure assisted method (LPAM). In addition, CH$_3$NH$_3$Cl (MACl) as the additive could preferentially form MAPbCl$_{3-x}$I$_x$ perovskite seeds to induce perovskite phase transition and crystal growth. Finally, by using FAI-PbI$_2$-NMP+x%MACl as the precursor, i.e., ligand and additive synergetic process (LASP), FA-based perovskite film with large grain size, high crystallinity and low trap density was obtained on a flexible substrate in ambient due to the synergetic effect, e.g., MACl could enhance the crystallization of the intermediate phase of FAI-PbI$_2$-NMP. As a result, a record efficiency of 19.38% in flexible planar PSCs was achieved by using FAI-PbI$_2$-NMP+15%MACl as the precursor, and it could retain about 89% of its initial PCE after 230 days without encapsulation in ambient. The PCE retained 92% of the initial value after 500 bending cycles with a bending radii of 10 mm. Our results show a robust way to fabricate highly efficient flexible PSC.

Perovskite solar cells are approaching silicon photovoltaic counterparts in performance, but mostly on a small area. To commercialize this low-cost technology, scalable fabrication is one of the main challenges to be addressed, for both perovskite active layers and charge transport layers [1]. For large-area, uniform and high-quality perovskite deposition, we have developed industry compatible hybrid chemical vapor deposition (H-CVD) to deposit MAPbI$_3$, FAPbI$_3$, and C$_x$FA$_{1-x}$PbI$_3$ films with high quality for solar cells/modules [2-5]. In this talk, I will focus on fully scalable perovskite solar modules with high-geometric fill factor by a further optimized hybrid chemical vapor deposition process and scalable sputtering deposition of electron transport layer SnO$_2$ [6-7]. With optimized interface structure between SnO$_2$ and C$_x$FA$_{1-x}$PbI$_3$, 10 cm x 10 cm solar modules showed a designated area efficiency approaching 10% with a geometric fill factor greater than 90%. We show that H-CVD is capable of fabricating large-area and high performance perovskite solar modules.

References:

The past ten years have witnessed the booming development of perovskite solar cell (PSC) with efficiency exceeding 24%, which is recognized as a superstar in photovoltaic research fields. However, the stability issue still limits their further development and commercialization. One of the main factors which lead to the instability issue is the ion diffusion between metal electrodes (Ag or Au) and perovskite absorbers. Carbon nanotubes have attracted tremendous attention with merits of low cost, outstanding electrical and mechanical properties, great chemical stability as well as large-area fabrication. Aiming at improving the long-term stability and reducing the fabrication cost of PSCs, we have devised several high-performance PSCs based on cross-stacked superaligned carbon nanotube
electrodes (CSCNT). Via subtly optimizing the device architecture and chemically modifying the CNT electrodes, we have significantly enhanced the photovoltaic performance and stability of CNT based PSCs under multi-environment. We first modify CNT with iodine and polyethylenimine (PEI) for regular HTM-free PSCs and inverted planar PSCs, respectively. Devices show better photovoltaic performance than that of the pristine CNT based ones owing to the enhanced charge transfer. Then we successfully construct inverted PSCs with all inorganic charge transport layer based on SnO$_2$@CNT electrode and obtain a champion power conversion efficiency (PCE) of 14.3% and 10.5% on the rigid and flexible substrate, respectively. Meanwhile, devices retain 88% of their original PCE aging at light illumination in air or thermal treatment in N$_2$ for 550 h. Finally, we design all-carbon-electrode based flexible PSCs with graphene as anode and CNT as cathode with a best PCE of 11.9%. Our devices show outstanding stability and durability under continuous light soaking in air for 1000 hours or bending cycles over 2000 times, retaining ca. 90% of their original PCEs respectively. Considering the increasing efforts dedicated to developing low-cost and stable energy conversion devices, the promising efficiency, flexibility, and long-term stability of CNT based PSCs clearly reveal sufficient compatibility. In addition, we have successfully developed a perovskite-thermoelectric tandem cell, which promotes the device PCE up to 23.2%.

Hysteresis-Free, Stable and Efficient Solution-Processed Perovskites Solar Cells by Hybrid Perovskites Co-Crystallized with Polymers

Hybrid perovskite materials have emerged as attractive alternatives for cost-effective solar cells. Impressive device performance has been realized through generic interface engineering. However, approaching hysteresis-free, stable and efficient solution-processed perovskites solar cells has remained a significant fundamental challenge. In this study, we report a strategy that utilizes polymer to anchor the counter ions in the perovskite lattices to suppress the formation of point defects, reduce the migration of ions/vacancy and to facilitate crystal growth in a more thermodynamically preferred orientation. Systematical investigations indicate that polymer indeed form hydrogen bonds at the crystal interface, which reduce the formation of kinetically-driven point defects, minimizes charge carrier recombination and maintains the sharp distribution of the density of states. As a result, un-encapsulated perovskite solar cells by novel hybrid perovskites thin film exhibit efficient, hysteresis-free characteristics and a decent device lifetime after being operated in air with 50% relative humidity in comparison to the reference perovskite solar cells by pristine hybrid perovskites thin film. Our studies demonstrate that development of hybrid perovskite materials crosslinked with polymers is one option to approach hysteresis-free, stable and efficient solution-processed perovskite solar cells.

Narrow Band Gap Perovskite Solar Cells Containing Sn

Perovskite solar cells in which metal halide perovskite layers are used as light harvesting materials are gaining much attention because of the high efficiency although these solar cell can be prepared by low temperature printing technology. The efficiency of Pb-perovskite solar cells with more than 1 cm$^2$ is 20.9% which became close to those of inorganic multi-crystalline solar cells such as MC-Si, CIGS, and CdTe. In small cells with less than 1cm$^2$, the efficiency of 24.2% has just been reported for the perovskite solar cells. Conventional perovskite solar cells consisting of Pb have band gap of 1.5-1.6 eV and can harvest the light in the visible region up to 850nm. According to Shockley-Queisser limit, light harvesting layer with 1.2-1.4 eV band gap gives the highest efficiency. Mixed metal PbSn perovskite materials have a narrow band gap of around 1.2 eV. Therefore, mixed metal SnPb perovskite solar cell is expected to give higher efficiency than Pb-perovskite solar cells. In addition, the narrow band gap solar cell is useful for bottom cells for all perovskite tandem solar cells. When SnPb mixed metal perovskite solar cells was firstly reported by us, the efficiency was around 4%. However,
the efficiency has been enhanced gradually and recently efficiency higher than 20% has been reported by several groups including our Lab. How the efficiency was enhanced will be discussed in the presentation1-3. The conventional perovskite layer consists of Pb ions. Therefore, the perovskite solar cells have to recover completely, for which a new business model is needed such as CdTe solar cells. In addition, the use of Pb ions is limited by the law such as RoHS directive in Europe. From this view point, there is a strong request for Pb-free perovskite solar cells solar cells. Bismuth halide compounds such as Cs$_3$Bi$_2$I$_9$, MA$_3$Bi$_2$I$_9$ Ag$_3$BiI$_6$, AgBiI$_3$, Cs$_2$AgBiBr$_6$, antimony halide compounds such as Rb$_3$Sb$_2$I$_9$, titanium halide compounds such as Cs$_2$TiBr$_6$, and copper halide compounds such as MA$_2$CuI$_4$ have been reported to replace lead. However, the solar cell efficiency based on these materials were less than 5% and was not satisfactory. Among all lead-free perovskite materials, Sn-based perovskite is one of the most promising candidates as the light harvesting layer for Pb-free PSCs, because they have perovskite structure similar to Pb perovskite. The efficiency has been enhanced to 10% by several research groups including us, however, the efficiency is not still satisfactory, when compared with Pb-perovskite. The cause of the low efficiency and how the efficiency will be enhanced is discussed4-7. In addition, wide gap perovskite solar cells needed for all perovskite tandem cells will be reviewed including our results on Pb-perovskite consisting of Ge ion6.

Suppression of Surface Recombination in Tin-Halide Perovskite Solar Cells via Lewis Base Post-Treatment
Muhammad Akmal Kamarudin1, Daisuke Hirotani2, Kengo Hamada3, Kohei Nishimura1, Qing Shen1, Taro Toyoda1, Satoshi Ikubo2, Takashi Minemoto3, Kenji Yoshino4 and Shuzi Hayase1,2; 1The University of Electro-Communications, Japan; 2Kyushu Institute of Technology, Japan; 3Ritsumeikan University, Japan; 4Miyazaki University, Japan

Tin perovskite solar cells (PSCs) show the most promise to replace the more toxic lead-based perovskite solar cells. However, the efficiency of tin-based PSCs falls short of that of lead-based PSCs by a large margin, as a result of low open-circuit voltage (Voc). This is due to the tendency of Sn$^{2+}$ to oxidize into Sn$^{4+}$ in the presence of air together with the formation of defects and traps caused by the fast crystallization of tin perovskite materials. Here, we performed post-treatment of tin perovskite layer with Lewis base to suppress the recombination reaction in tin halide PSCs resulting in efficiencies more than 10 %, which is the highest reported efficiency to date for pure tin-halide PSCs. The Voc increased by as much as 0.1 V with optimum concentration of the Lewis base. Upon analyzing the X-ray photoelectron spectroscopy and impedance spectroscopy data, we came to the conclusion that the amine-group bonded the under-coordinated perovskite, passivating the dangling bonds and defects resulting in suppressed charge carrier recombination. This also has the effect of prolonged lifetime and higher charge carrier mobility. Our findings will provide the groundwork for improving the efficiency of pure tin halide PSCs to compete with that of lead-based PSCs by simple post-treatment with organic molecules.

2:15 PM EN08.15.03
Rudorffites as Alternatives for Solution Processed Lead Halide Perovskite Solar Cells
Feray Ünlü1, Ashish Kulkarni2, Sanjay Mathur1 and Tsutomu Miyasaka2; 1Institute of Inorganic Chemistry, University of Cologne, Germany; 2Graduate School of Engineering, Toin University of Yokohama, Japan

Inorganic-organic hybrid lead halide perovskite solar cells have attracted tremendous research attention due to rapid rise in power conversion efficiency (PCE) from merely 3.8% to 24.2% within 10 years. Such rise in PCE is attributed to exceptional optoelectronic properties such as long charge carrier diffusion length, low exciton binding energy, ambipolar charge mobility, tunable narrow bandgap. Despite of these advantages, one of the major problems encountered with this new technology, apart from structural and chemical stability, is the toxicity associated with heavy metal lead. Among various metals explored, bismuth-based perovskite materials provide promising optoelectronic properties and can be processed from solution using a variety
of wet chemical deposition techniques and additives. In our research, we focused on different various bismuth-based perovskite materials having zero dimensional to higher dimensional networks and investigated their optical, morphological and photovoltaic properties. Interestingly, we could observe, that by increasing the bismuth halide network dimensionality, the power conversion efficiency could be improved. This increase in solar cell performance could be achieved by introducing monovalent noble metals. The incorporation of these monovalent cations lead to 3D networking of Bismuth halides, resulting in rudorfitte structure.

Stable and Efficient Tin-Based Halide Perovskite Solar Cells via Defects Passivation Min Chen, Yuanyuan Zhou and Nitin P. Padture; Brown University, United States

The state-of-the-art high efficiency perovskite solar cells (PSCs) contain lead and organic cations in the perovskite light-absorber. However, lead-toxicity and intrinsic instability of these PSCs are major hurdles in the path towards the commercialization of PSCs. While there has been effort towards replacing lead cation with less toxic cations, typical lead-free PSCs still suffer from the low power-conversion efficiency (PCE) and poor stability to ambient. Herein, we have utilized a defects passivation strategy in Sn-based perovskite materials, and realized PSCs with a promising PCE of up to 10%. Furthermore, the defects passivation via native oxides passivation layer or 2D phase passivation result in superior air-stability of Tin-based perovskite solars within 1000-hours continuous operation under one-sun illumination. Thus, this work provides a new avenue for the design and development of high performance and stable Sn-based PSCs.

The Challenges of Printable Mesoscopic Perovskite Solar Cells Hongwei Han; Huazhong University of Science and technology, China

Over the past few years, organic–inorganic hybrid perovskites have attracted significantly attention as light absorbers in efficient photovoltaics. While impressive power conversion efficiencies exceeding 24% have been attained within a period of only a few years, concerns have been raised about the viability of this class of photovoltaics as a scalable and long-term reliable energy source. In our group the printable perovskite solar cells were developed with triple mesoscopic layers1. The conjugated or non-conjugated bifunctional molecules were introduced into the perovskite materials to enhance their stability and efficiency2-4. The results indicated that the interface engineering plays a key role of directing the crystal formation and growth during the infiltration and precipitation of the perovskite within the mesoporous oxide scaffold. The fully printable mesoscopic perovskite solar cell presents no obvious decay within over 1000h light soaking and high efficiency of more than 18%. The crystals of the perovskite films are reconstructed by post-treating with methylamine gas and allows the regeneration of the photodegraded PSCs via the crystal reconstruction and the PCE can recover to 91% of the initial value after two cycles of the photodegradation-recovery process5-8. Meanwhile, the characterization of the mesoscopic perovskite solar cells under the UV light soaking condition was performed. A 110 m2 mesoscopic perovskite solar system was exhibited. These results offer a promising prospect for its commercial application.

References
Solution processing of organic-inorganic metal halide perovskites represents a major advantage for low-cost solar cell fabrication. However, scalable processes must be developed in place of spin-coating in order to successfully commercialize the technology. Slot die and ambient spray coating have emerged as alternatives, but like spin-coating, these methods require lengthy anneals that pose significant challenges for inline high-speed fabrication.

In this work, we fabricate all of the perovskite, charge transport, and barrier layers in open air with scalable processes. Using a p-i-n planar architecture, we first spray coat an aqueous NiO hole transport layer that demonstrates improved efficiency and fill factor relative to a spin coated organic NiO precursor. A double cation perovskite film consisting of Cs$_{0.17}$FA$_{0.83}$Pb(Br$_{0.17}$I$_{0.83}$)$_3$—a composition with excellent thermal and photostability—is then formed using the Rapid Spray Plasma Processing (RSPP) method, where films are sprayed and immediately exposed to a plasma at an ultrafast linear processing rate $> 10$ cm/s. The combination of reactive species (ions, radicals, metastables, and photons) and convective thermal energy produced by the plasma rapidly transfer energy to the perovskite-precursor solvate, enabling the growth of efficient and mechanically robust perovskite films in seconds with no post-annealing necessary.

A fiber laser (1064 nm) and CO$_2$ laser (10.6 μm) are used for the respective P1 and P2 scribes to create a monolithic, series-interconnected module. Module design is optimized for the RSPP process to achieve $>70\%$ Geometric Fill Factor. After completion of the module, an organosilicate barrier film is deposited with RSPP to improve thermal and environmental stability in addition to providing protection from thermal degradation of the perovskite during encapsulant lamination. A stabilized value of 12.4% PCE was achieved after 1000 s illumination in air for a 12.5 cm$^2$ series-connected module with six subcells and a module $V_{oc} > 6.2$ V. Additionally, encapsulated modules with in-situ barriers demonstrate validated reliability and retain $>80\%$ of their initial PCE after 500 hours of indoor (damp heat testing at 85 °C) and outdoor (full spectrum illumination) ageing tests.

The commercial application of perovskite based thin film photovoltaic technology requires highly efficient large area devices. A high drop in power conversion efficiency of 40%rel. is observed when comparing record solar cells of 0.1 cm$^2$ aperture area with the best 100 cm$^2$ modules. As Li et.al reported in Nature review in 2018, perovskite based TFPV still have higher upscaling loss than any other PV technology. Recently, with better understanding of perovskite crystallization dynamics, module efficiencies of 17% on 17 cm$^2$ and 12.6% on 355 cm$^2$ have been achieved.

Upscaling losses going from cell to module can be grouped into four types of losses: sheet resistance, interconnection resistance, inactive area and layer inhomogeneity loss. In order to achieve high performance upscaled devices, we process and analyze devices up to 156 cm$^2$, using techniques such as spin coating, blade and slot die coating. We employ integrated circuit-based simulation techniques, as well as electrical and optical
characterization methods including J-V measurements, transmission line measurement, luminescence imaging, thermography and electron spectroscopy to analyze each of the loss mechanism separately.

As a result, we identify specific process optimization steps that should be undertaken in order to minimize each performance loss, including module design, laser interconnection patterning, optimizing deposition method used, improving processing conditions and solvent engineering. Following an ideal process implementation, the relative upsaling losses going from cells to modules could decrease to 5 %, making large area perovskite modules with 20 % power conversion efficiencies a reality.

High-Throughput Vapor Transport Deposition of Organic-Inorganic Perovskite Films Anurag Panda, Ella Wassweiler and Vladimir Bulovic; Massachusetts Institute of Technology, United States

Development of large-area high-throughput deposition techniques is necessary to successfully commercialize perovskite solar cell technology. Vapor transport deposition (VTD) is one such potential technique that uses a carrier gas to transfer sublimed salts from source to substrate, where they react to form perovskite films. Unlike vapor thermal evaporation, during VTD the material deposition rate is decoupled from material temperature allowing for high throughput deposition. During the VTD process there is also independent control of chamber pressure and deposition rate, parameters which can be tuned to change the film crystallization kinetics. Similar to thermal evaporation, VTD allows for precise thickness control and eliminates hazardous solvents from device fabrication, allowing for facile growth of complex multi-layer device structures such as tandem solar cells. The high throughput deposition coupled with low vacuum operation reduces capex requirement for VTD deposition tools, and has already led to commercialization of the technique for CdTe and organic semiconductor materials manufacturing.1

In our work, through the use of a custom-built VTD setup2 we study perovskite film formation via co-evaporation of lead iodide and methylammonium iodide (MAI). We find that control of MAI degradation during vapor transport and its deposition rate is a critical challenge that needs to be overcome. We describe design parameters and deposition conditions necessary to incorporate undegraded MAI into the methylammonium lead iodide film. We describe numerical simulation of material diffusion and gas flow necessary to narrow the design parameter space. We study the impact of substrate temperature and carrier gas flow rate on film formation kinetics by examining metrics such as photoluminescence, x-ray diffraction, morphology, as well as device efficiency. Through this systematic study we demonstrate VTD to be a viable new deposition tool for large-area high-throughput deposition of perovskite solar cells.

Theoretical Investigation of Halide Perovskites for Solar Cell and Optoelectronic Applications Su-Huai Wei;
Beijing Computational Science Research Center, China

Halide perovskites such as CH3NH3PbI3 have recently emerged as promising materials for low-cost, high-efficiency solar cells. The efficiency of perovskite-based solar cells has increased rapidly, from 3.8% in 2009 to more than 23% recently by modifying material compositions and engineering cell architectures and defect properties. The emergence of high efficiency perovskite solar cells can be attributed to the intrinsic properties that distinguish them from conventional semiconducting solar cell absorber materials. However, despite the enormous progress of the perovskites in solar cell applications, challenges are still standing in their way to large-scale commercial applications, including their poor long-term stability, which could be partially attributed to the intrinsic thermodynamic instability of CH3NH3PbI3 and related materials, and the toxicity of Pb, currently used in halide perovskite based solar cells with high power conversion efficiencies. Recently, various approaches have been proposed to overcome these bottlenecks, including defect control, alloying, as well as atomic transmutation. In this talk, I will discuss some of our recent theoretical investigations on ordered and disordered halide perovskites to understand their material properties and provide theoretical insights and possible solutions to the usage of halide perovskites for solar cell and other optoelectronic applications.

Persuasive Evidences for Hyperfine Interaction in Halide Perovskite Bulk Single Crystals Alyssa Kostadinov,
Arthur Shapiro, Yahel Barak, Shahar Zuri, Ellenor Geraffy and Efrat Lifshitz; Technion–Israel Institute of
Technology, Israel

Halide perovskite materials are at the forefront of scientific and technological interest in the last decade, due to their extraordinary physical properties and their indisputable performance in solar cells, and in other opto-electronic applications. The most studied halide perovskite has the chemical formula APbX3 (A = methylammonium, formamidinium, Cs; X = I, Cl, Br) prepared as bulk single crystals, thin films or nanostructures. Those were characterized by their long carrier diffusion length, unity emission quantum efficiency, tolerance for defects, anharmonicity, reduced elastic stiffness, strong carrier-phonon coupling and polaron formation. However, spin properties were investigated only to a lesser extent, albeit, they may be of a paramount importance in the control of
the optical properties of halide perovskites, thus demands further exploration. Most recent years studies uncovered the occurrence of a Rashba effect, related to the existence of an exotic spin-orbit field which split both valence and conduction band in k-space into two valleys, symmetrically spaces away from a Brillouin point with opposing спин helicity, hence dictating spin selective recombination.\(^1\)\(^2\) Other studies explored the g-factor of photo-generated carriers, as well as the carrier spin relaxation time (T\(_1\) ~ 1nsec) and dephasing time (T\(_2\) ~ 80 psec).\(^3\)\(^4\)

The current work reports magneto-optical measurements of MAPbBr\(_3\) high quality single crystal where the observation brought about for the first time, a strong evidence for the existence of an Overhauser effect, viz., occurrence of coupling between a photo-generated carrier' spins and nuclei spins, the last related to the existence of neutral absence isotopes. A photo-generated carrier applies a local field on nuclear spins via hyperfine interactions and induces their mutual alignment. Then, the effective magnetic field created by the nuclei acts back on a carrier, affecting its polarization and the helicity of a recombination emission. The effective nuclear field may enhance or suppress a Zeeman and Rashba fields. The current work exploited the counter balance between the Rashba, Overhauser and a Zeeman field. A follow up of the exciton emission intensity or its circular polarization versus strength of an external magnetic field, revealed a special trend corroborating the occurrence of an Overhauser field < 0.2 Tesla. Furthermore, the Rashba field is pronounced as a non-Zeeman behavior, as well as by occurrence of uniform ordering of exciton fine structure. The study discovered a dominant route causing de-coherence of carrier's spin, with significance impact on the perovskites use in quantum information or memory devices.

**Halide Perovskites as a Polymorphous Network with a Distribution of Local Motifs** \textit{Alex Zunger}; University of Colorado, United States

While octahedral tilting or B atom displacements as a single repeated structural motif are well known in perovskites, we find that removing the standard restriction to such a minimal unit cell size in total energy structural optimization, leads in some perovskites to the formation of a ‘polymorphous network’, manifesting a \textit{distribution of different tilt angles and different B-atom displacement in different octahedra}. Such systems cannot be described crystallographically by a small, repeated unit cell, and were generally described as thermally disordered compounds, modelled by high temperature molecular dynamics via time-dependent dynamic motions with entropy-driven disorder. What is different about the polymorphous network for the cubic halide perovskite FASnI\(_3\) (where FA\texttextsuperscript{=CH(NH\textsubscript{3})\textsubscript{2}}) is that the \textit{distribution of local motifs emerges already from the (density functional) minimization of the static, T=0 internal energy of a large supercell}, constrained to have the global cubic lattice vectors. This a-thermal distribution represents a correlated set of displacements and is very different from the time-dependent uncorrelated entropic thermal disorder calculated by MD, or from the single sharp monomorphous values of these deformation parameters . This distribution of local motifs is also different from the periodically repeated ordered double-potential well models that address anharmonic polar fluctuations. The existence of such a polymorphous distribution is easy to miss using standard energy minimization protocols (such as those based on following gradients to the nearest local minimum) but is revealed once one initially applies a \textit{random} atomic displacement (“nudge”) off the cubic sites and explores lower symmetries in the minimization process. These polymorphous networks represent a different paradigm in understanding cubic halide and oxide perovskites. Our finding suggests that the widely discussed single formula unit cubic Pm-3m structure of halide perovskites does not really exist, except as a macroscopically averaged fictitious structural model. Because X-ray diffraction has a rather long coherence length, such polymorphous systems were often fit in structure refinement models by a macroscopically averaged (“\textit{fictitious monomorphous}”) cubic Pm-3m unit cells. Significantly, compared to the monomorphous assumption, we show here that the cubic polymorphous network (i) fits much better the observed Pair Distribution Function (PDF), which probes the local environment. (ii) a significantly lowering of calculated total energies, by \textit{~70-150 meV/f.u.}, and (iii) up to 300% larger band gaps, on account of the reduced level repulsion afforded by larger octahedral tilting and rotations. Thus, (iv) the band gap renormalization energy (~200 meV) is now closer to experiment relative to the values computed with respect to the band gap of the monomorphous model (390-640 meV). (v) Use of the polymorphous structure leads to the reversal of the predicted sign of the mixing
enthalpies of the solid solutions from negative (ordering-like; not seen experimentally) to positive (experimentally observed phase-separating), in better agreement with observations. (vi) Remarkably, despite the existence of a distribution of motifs, the calculated band structure (unfolded to the primitive Brillouin zone from the supercell) shows sharp band edge states and a correspondingly fast rise of the absorption spectrum, and leads to a broad and slow rising absorption tail. Finally, relative to the monomorphous case, (vii) polymorphous networks have a much larger (by ~50%) calculated dielectric constant, where the ionic contribution now dominates the electronic contribution as expected from near ferroelectrics. The polymorphous approximant could thus serve as a useful practical structure to use with standard band structure approaches to predict properties, replacing the fictitious monomorphous structures. In collaboration with Xingang Zhao, Zhi Wei and Gustavo Dalpian.

Impact of Structural Dynamics on Optoelectronic Properties of Halide Perovskites—Insights from Theory
David Egger; Technical University of Munich, Germany

Halide perovskites (HaPs) are highly promising materials for a range of optoelectronic devices. HaPs are also very interesting scientifically because of the unusual structural dynamics that occur in the material. These include the appearance of complex structural disorder and sizable nuclear anharmonic effects already at room temperature, which challenge our basic understanding of coupling between nuclear vibrations and optoelectronic properties in a semiconductor.

In this talk, I will present our recent explorations of the consequences of the unusual structural phenomena in HaPs for their optoelectronic properties. Theoretical calculations based on density functional theory, molecular dynamics, and tight-binding modeling will be used to examine the impact of structural dynamics on pertinent device-relevant observables. Consequences of the structural dynamics and anharmonicity in HaPs will be discussed for the charge-carrier mobility, Urbach energy, and defect energetics. It will be shown that the impact of the unusual structural dynamics on the optoelectronic properties of HaPs cannot be neglected when understanding these materials microscopically and designing new functional compounds.

11:00 AM EN09.01.06
Determining the Changes in Electronic Structure of Lead and Tin-Based Perovskites—A Combined Experimental and Theoretical Approach
Selina Olthof1, Ines Schmidt1, Shuxia Tao2 and Geert Brocks2;3; 1University of Cologne, Germany; 2Eindhoven University of Technology, Netherlands; 3University of Twente, Netherlands

In recent years, the interest in halide perovskites rose at a rapid pace due to their tremendous success in the field of photovoltaic while other fields, like light emitting diodes, show great potential as well. One intriguing property of this material class is the wide tunability of the band-gap that can be induced by changing the perovskite composition. While changes in band gap are regularly reported, it is unclear how the respective conduction and valence band positions change and what the underlying origins of these changes are. Knowing the band positions is however crucial for device design, i.e. ensuring efficient charge transport across the various interfaces.

In this talk, I will discuss recent findings regarding the variations in ionization energy and electron affinity, covering the complete library of lead and tin based halide perovskite systems. [1] Using a combination of photoelectron spectroscopy, density functional theory, and a tight binding model we are able to reliably extract the relevant energy level positions. Furthermore, we are able to explain the origin of these changes based on changes in hybridization strength, atomic level positions, and lattice distortion.

The Bandgap Bowing Behavior and Its Origin in Perovskite-Inspired Lead-Free Cs3(Bi,Sb)2(I,Br)9Alloys
Anuj Goyal1,2, Shijing Sun3, Noor Titan Putri Hartono3, Tonio Buonassisi3 and Vladan Stevanovic1,2; 1Colorado School of Mines, United States; 2National Renewable Energy Laboratory, United States; 3Massachusetts Institute of
Lead-based hybrid organic-inorganic perovskite photovoltaic materials have been the focus of much research in recent years because of their low fabrication cost and extremely high photoconversion efficiencies. Inspired by the rapid rise in efficiencies of lead based perovskite solar cells and the environmental concern of the heavy metal content, lead-free alternatives are attracting increasing attention. Perovskite-inspired materials with 0D and 2D crystallographic structure with the formula A3B2X9, where A is the monovalent cation (methyl ammonium MA, formamidinium FA, Rb, or Cs), B is the metal cation (Sb and/or Bi), and X is the halide anion (I, Cl and/or Br), have recently attracted the attention of the researchers looking for the next lead-free material. Recently, dual-site alloys Cs3(Bi1-xSbx)2(I1-yBr y)9 exhibiting a transition between 0D to 2D crystal structures and a non-linear bandgap tunability, have been synthesized. The discovery of non-linear bandgap behavior (bandgap bowing) in this series has opened up a new pathway to achieve lead-free all-inorganic perovskites for multi-junction solar cells. However, compared to their lead-based counterparts, the origins of the bandgap bowing in these systems are not yet understood. In this study, we employ detailed first-principles DFT calculations to model Cs3(Bi,Sb)2I9, Cs3(Bi,Sb)2Br9, Cs3Sb2(I,Br)9, Cs3Bi2(I,Br)9 systems to better understand the pathways to reduced bandgaps in dual-site alloys, as well as to systematically decouple the structural and chemical origins to the bandgap bowing. Our results suggest that bandgap bowing is caused by mixing at the B-site and that the non-linearity in the bandgap exists regardless of the crystallographic dimensionality of the alloy. With better understanding of the bandgap behavior we aim to tailor these lead-free perovskite-inspired mixed systems to achieve optimum optoelectronic properties.

Pressure-Induced Carrier Recombination in Halide Perovskite Light-Emitting Diodes

Young-Kwang Jung1, Mayami Abdulla2, Samuel D. Stranks2 and Aron Walsh1,3; 1Yonsei University, Korea (the Republic of); 2University of Cambridge, United Kingdom; 3Imperial College London, United Kingdom

Metal halide perovskites have been widely studied for light-emitting applications (LEDs) [1-2], as well as photovoltaics [3-4] showing drastic increase in efficiencies due to their unique opto-electronic properties. The control of non-radiative losses in the active perovskite layer is still one of limiting factors that diminishes the efficiency of devices below their theoretical performance limits. Recently, it has been shown that lattice strain present in halide perovskites correlated with non-radiative electron-hole recombination [5]. To prove the concept, we systematically investigate how volumetric strain affects the atomic and electronic structure, charged native point defect concentration, and luminescence properties by combining state-of-the-art simulations and experiment. Our first-principles density functional theory (DFT) calculations including relativistic effects show enhanced Rashba splitting and Schottky vacancy defect disorder under compressive pressure, while experiments of perovskite LEDs under hydrostatic pressure display a pronounced decrease in photoluminescence peak position and intensity under compressive pressure. The combination of theory and experiment provide a unified model of pressure-induced recombination in these soft semiconductors.

Ni Doping in CsPbX₃ Nanocrystals via Post-Synthesis Anion-Cation Co-Exchange

Arthur Shapiro¹,²,³, Markus W. Heindl⁴, Faris Horani¹,²,³, Meir H. Dahan⁵, Matan Menahem⁶, Yaron Amouyal⁵, Omer Yaffe⁶ and Efrat Lifshitz¹,²,³ ; ¹Technion–Israel Institute of Technology, Schulich Faculty of Chemistry, Israel; ²Technion–Israel Institute of Technology, Solid State Institute, Israel; ³Technion–Israel Institute of Technology, Russell Berrie Nanotechnology Institute, Israel; ⁴Technical University of Munich, TUM Department of Chemistry, Germany; ⁵Technion–Israel Institute of Technology, Department of Materials and Interfaces, Israel; ⁶Weizmann Institute of Science, Israel

In the last decade perovskite nanocrystals (NCs) burst into the consciousness of the scientific community as a new class of semiconductors and became the material class at the forefront of research efforts. Particularly, the topic of doping arose in recent years, involving doping or alloying by magnetic ions, which induced changes in the optical and magnetic properties.

In this work a novel dynamic cation exchange strategy driven by a simultaneous anion exchange was implemented¹ to incorporate Ni²⁺ ions into CsPbBr₃ perovskite nanocrystals² at room temperature and ambient conditions. Ni is especially interesting as a dopant, as it combines an electron spin of S=1, a lack of nuclear spins (with the exception of ⁶¹Ni with a low natural abundance of < 1%) and relatively weak spin-orbit coupling compared to Pb. Magnetic dopants in semiconducting materials induce spin-exchange interactions with the host carrier's spins, mostly leading to a giant magnetization within the host lattice. The lack of spin-orbit and nuclear spin coupling of the Ni dopants should preserve this giant magnetization and consequently the carrier's spin coherency for a length of time. Long spin coherence time is the holy-grail of spin-based devices.

The present work describes a thorough investigation of the doping mechanism into perovskite nanocrystals and characterization of the produced structures and composition, using electron microscopy and spectroscopic techniques. The doping of CsPbBr₃ NCs with Ni²⁺ ions was carried out using ion exchange procedures, involving post-treatment with either NiCl₂, PbCl₂, PbBr₂ or NiBr₂ precursors at room temperature. The reaction with NiCl₂ was utilized for the anion-cation co-exchange in order to achieve a uniform Ni incorporation into the lattice, and the use of all other reagents was dedicated to control experiments. The results indicate the essential need for co-exchange of cation and anion, enabling integration of Ni²⁺ ions with a concentration from < 1% to about 12%. The observations revealed a uniform distribution of the Ni ions across the nanocrystals. Moreover, the nanocrystals exhibit improved luminescence quantum yields beyond those of the non-doped CsPbCl₃ and CsPbBr₃. The observations were corroborated by a theoretical density functional theory calculation, confirming that the exchange of Ni is energetically favorable.

hybrid perovskite semiconductors. Using combinations of scanning-probe, electron backscatter diffraction (EBSD), and time-resolved photoluminescence microscopy and spectroscopy, we explore the microscopic origins of non-radiative recombination in both archetypal methylammonium lead tri-iodide (MAPI), and more advanced mixed-cation perovskites. Using EBSD, we image local grain orientation and strain, and correlate surface strain with increased non-radiative recombination in MAPI. We explore the interface between the perovskite and various common charge extraction layers, combining experiment and simulation to show that surface recombination at the charge extraction layers is a limitation in current perovskite solar cell architectures. Finally, we explore alternative passivation and extraction layers to propose ways to more routinely approach the theoretical voltage limits in perovskite photovoltaic using scalable process chemistry.

2:00 PM *EN09.02.02
Characterization of Electronic and Ionic Transport in Halide Perovskites by Multi-Dimensional Luminescence Imaging
Laurent Lombez1,2,3, Adrien Bercegol1,4, Stefania Cacovich1, Olivier Fournier1,4, Daniel Suchet1,2, Jean Rousset1,4, Jean-Francois Guillemoles1,2 and Daniel Ory1,4; 1IPVF Institut Photovoltaïque Ile de France, France; 2CNRS-IPVF, France; 3LPCNO, France; 4EDF R&D, France

The excellent photovoltaic performance of halide perovskites goes along with a high photoluminescence yield (PL) that makes them suitable for a wide range of photonic devices and various optoelectronic applications, such as photodetectors, lasers and light emitting diodes. However, due to the complexity of the materials and the related devices, often traditional macroscopic characterisation tools are not able to unveil the physical processes underlying the working principles of the solar cells, especially the transport properties. Indeed, electronic as well as ionic transport are still under investigation. Here we quantify electrons, holes and ions transport and investigate the mutual impact of both transport mechanisms.

To do so, we used innovative characterisation methods that combine hyperspectral imaging system (HI) and a time-resolved fluorescence imaging (TR-FLIM) set-ups. We employed these optical techniques to study lateral transport of charge carriers in hybrid perovskites and probe a large variety of transport parameters (diffusion length, mobility, lifetimes…) which are often cross-linked. Photonic transport is also observed. Besides, measuring the local variations of time resolved luminescence in the nanosecond scale under lateral electric bias allows a direct access to charge carrier collection and transport properties for each kind of charge carrier –electrons and holes-. At long time scale such experiment allows to probe the ionic transport, especially associated with iodine species. It is confirmed when looking at spectrally resolved images where we can monitor ionic transport a part of the electronic transport and see the impact of the ions migration on the material properties. More precisely, the iodine seems to affect the band structure and locally modify the bandgap; it also degrades the local quasi Fermi level splitting (i.e. the internal bias).

The novel experimental approach, can thus image and quantify the transport mechanisms occurring within the material, providing new insights on these complex transport phenomena.

2:30 PM EN09.02.03
Understanding Phase Stability by In Situ X-Ray Diffraction in Mixed A-Site Halide Perovskite Active Layers
Laura T. Schelhas1, Zhen Li2,3, Jeffrey A. Christians4, Anuj Goyal5, Paul Kairys5, Steven Harvey2, Donghoe Kim2, Kevin Stone1, Joseph Luther2, Kai Zhu2, Vladan Stevanovic5 and Joseph J. Berry2; 1SLAC National Accelerator Laboratory, United States; 2National Renewable Energy Laboratory, United States; 3Northwestern Polytechnical University, China; 4Hope College, United States; 5Colorado School of Mines, United States

Hybrid organic-inorganic perovskite photovoltaic materials have been the focus of much research in recent years due in part to their extremely high photoconversion efficiencies[1] and also their ability to be synthesized by solution processing. These materials crystallize in the perovskite, AMX₃ crystal structure where A is the monovalent cation (methyl ammonium, MA, formamidinium, FA, Rb, and/or Cs), M is the metal cation (Pb²⁺), and X is the halide anion (I⁻, Cl⁻, and/or Br⁻). As the field has progressed, formulations of halide perovskite solar cells (PSC) have evolved from the simple MAPbI₃ to more complex alloys, e.g. RbCsMAFA-perovskite.[2] With these more complicated formulations understanding the operation and stability of these materials becomes more challenging.
For example, it is important to understand the geometric constraints and so-called “tolerance factors” when formulating new mixed phases in order to target stable structures.[3] Additionally, the composition and phase homogeneity across the film can also influence device performance.

In this study we present results using operando X-ray characterization techniques previously developed by our groups coupled with standard laboratory device measurements.[4] Using this operando technique we are able to monitor the crystal structure by X-ray diffraction (XRD) of the PSC in full device stacks during operation. Here, we explore the phase stability of mixed A-site PSCs of the form X\(\text{PbI}_3\) where \(X = \text{FA}, \text{Cs}, \text{and/or MA}\). Simultaneous JV and XRD measurements on devices are measured in both inert and humid (~50% relative humidity) conditions, at room temperature for up to 15 hours. Here we observe degradation pathways for these mixed A-site formulations which result in phase segregated films in some formulations and greater stability in others. To explain the experimentally observed mixing and de-mixing in these systems, we present a hypothesized framework developed using complementary first-principles calculations of mixed A-site halide perovskites. This is then validated using in-situ X-ray diffraction and spatially resolved time of flight secondary ion mass spectrometry. With greater understanding of the structural stability of these alloys we aim to inform well-tuned alloy formulations targeting long term stability in devices.

References
Impedance spectroscopy is a non-destructive characterization technique that has been used for the characterization of perovskite solar cells since the beginning of this technology. Impedance spectroscopy is a characterization method in the frequency domain that allows to decouple physical processes with different characteristic times at the working conditions i.e. under illumination and applied bias. However, different models and interpretation have been employed to explain the impedance measurements. Despite the huge potentiality of this technique for the characterization of perovskite solar cell a complete model of impedance for this kind of cells applicable in all the conditions and configuration has been elusive for the moment. Undoubtedly, the combined action of electron and holes and ions in perovskite solar cell is at the base of the complex behavior observed in this kind of devices. In this presentation, we compare the well know dye sensitized solar cells with the perovskite solar cells highlighting similarities and differences, and studying the evolution from the former to the later. In addition the interest of impedance characterization of different types of perovskite optoelectronic devices is discussed.

Band Structure and Electronic Properties of Lead Halide Perovskites from Photoemission Studies

Photovoltaic devices based on halide perovskites with outstanding optoelectronic properties have exhibited tremendous progress in performance. To understand the origin of these properties comprehensively, detailed knowledge on the underlying electronic band structure is required. Here, we present complementary results from low-energy electron diffraction (LEED), angle-resolved photoelectron spectroscopy (ARPES), and density functional theory (DFT) calculations for CH3NH3PbBr3 and CH3NH3PbI3 single crystals. For both, sharp LEED patterns corresponding to the (001) surfaces of CH3NH3PbBr3 and CH3NH3PbI3 were observed together with well-resolved, dispersive valence band (VB) features. Noteworthy, the LEED patterns of CH3NH3PbI3 reveal a coexistence of the cubic and tetragonal phase at the sample surface already at room temperature. From ARPES, we determined a bandwidth of ~1.0 eV and of ~1.3 eV along the X-R direction in CH3NH3PbI3 and CH3NH3PbBr3 single crystals, respectively. In good agreement with results from DFT calculations, the hole effective-mass, mh*, with values as small as 0.18 m0 (CH3NH3PbI3) and 0.25 m0 (CH3NH3PbBr3) were found. Furthermore, the fundamental differences between linear and logarithmic methods in determining the VB onset are discussed and addressed, revealing the fact that logarithmic method is more preferable to determine the VB onset for perovskite systems.[1,2] In addition, surface photovoltage effect (SPV), which has so far hardly been discussed in this context, is found to play significant effect in photoemission studies. We provide evidence that due to the presence of surface band bending, not only visible light but also UV light, as used in ultraviolet photoemission spectroscopy (UPS), induces substantial SPV (over 700 meV) in four modern perovskites. Given such effect, the conflicting energy levels as probed by UPS can be better rationalized.[3] Within the framework laid out here, the consistency of relating the energy level alignment in perovskite-based photovoltaic and optoelectronic devices with their functional parameters is substantially enhanced.

Metal halide perovskites present ideal properties for both light absorbing and light emitting devices. Despite their promising optoelectronic properties and the progress made over the last decade, perovskites still display instabilities when exposed to environmental stresses such as moisture, oxygen, bias, temperature, and light [1]. Here, we present our ongoing study of the fundamental science surrounding this dynamic behavior, typically detrimental for optoelectronics. Our first focus is the impact of humidity cycling on charge carrier recombination through the use of in situ micro-photoluminescence (micro-PL) [2, 3]. Here, we consider a set of four benchmark compositions based on Cs$_x$FA$_{1-x}$Pb(I$_y$Br$_{1-y}$) known for their superior stability and suitability for tandem photovoltaics, where Cs varies between 10-17% and Br within 17-38%. Each of the films is exposed to identical relative humidity (rH) treatments (<5%, 15%, 35%, 55%, and <5% rH) while the luminescence is simultaneously monitored to understand the changes to the optical response. While all samples considered exhibit an increase in overall PL emission upon reaching 35% rH, their luminescence response bifurcates at 55% rH, when the 17%-Br samples sustain their previous enhancement but those containing 38%-Br display a marked reduction in light emission. After returning to a low humidity ambient, all compositions present PL hysteresis dependent on the Br/Cs ratio. The irreversibility of the luminescence after the humidity cycle is due to surface-limited degradation leading to the formation of additional trap states. Next, we evaluate the water-driven recombination dynamics in the prototypical MAPbI$_3$ and MAPbBr$_3$ compositions, capturing light emission every ~1 s as the films undergo multiple humidity cycles. Our results indicate that water modifies I-containing material quickly, with abrupt increases in emission when the film is first exposed to water (~30% rH), and as the film returns to a low moisture environment. Contrastingly, the Br samples are less affected by water, and require high humidity (>50% rH) for a modest luminescence enhancement. Given the dynamic behavior of the I-based films, we investigated the impact of excitation wavelength on light emission. Surprisingly, the energy of the incident photons is anticorrelated with the area contained within the rH-PL loop. Based on their absorption depth, shorter wavelength photons create electron hole pairs more likely to nonradiatively recombine at the new, near-surface defects created through our controlled moisture-induced degradation. Inspired by our wavelength-dependent PL measurements, we also measured the voltage dynamics across dark-light-dark cycles for both the MAPbI$_3$ and MAPbBr$_3$ compositions through the use of a Kelvin probe and a wavelength tunable light source [4]. While the I-containing film shows a wavelength-independent trend in voltage decay, the Br-containing sample exhibits a 10x slower wavelength-dependent voltage relaxation that displays an exponential trend across the range of 405-605 nm. The slower voltage process is associated with the MAPbBr$_3$ lattice constant that increases resistance to ion migration back to equilibrium under dark conditions relative to MAPbI$_3$. The methods employed above can be extended to include the other environmental stressors (temperature and bias) and are material independent, easily applied to other critical compositions, such as lead-free variants. Finally, we will discuss the use of machine learning to understand the impact of the environmental parameters on perovskites recovery [1].

Ultrafast Dynamics in Metal-Organic Halide Perovskites Revealed by Soft X-Ray Spectroscopy
Regan Wilks¹, Axel Erbing², Golnaz Sadoughi³, Evelyn Handick¹, David E. Starr¹, Monika Blum⁴, Frank Meyer⁶, Dirk Hauschild⁷, Wanli Yang⁴, Lothar Weinhardt⁵, Clemens Heske⁵, Henry J. Snaith¹, Michael Odelius² and Marcus Bär¹,³,⁸; ¹Helmholtz Zentrum Berlin, Germany; ²AlbaNova University Center, Stockholm University, Sweden; ³University of Oxford, United Kingdom; ⁴Lawrence Berkeley National Laboratory, United States; ⁵University of Nevada, Las Vegas, United States; ⁶Julius-Maximilians-Universität Würzburg, Germany; ⁷Karlsruhe Institute of Technology, Germany; ⁸Helmholtz-Institute Erlangen-Nürnberg for Renewable Energy, Germany

CH$_3$NH$_3$PbI$_3$ perovskite layers on compact TiO$_2$ have been investigated using nitrogen and carbon K-edge x-ray
emission (XES) and absorption (XAS) spectroscopy. These techniques, and their combination in Resonant Inelastic X-ray Scattering (RIXS), probe the organic component of the metal-organic compounds and can be used to examine the local partial density of occupied and unoccupied states. The measured spectra are strongly influenced by ultrafast (femtosecond-scale) proton dynamic effects, as modelled using ab initio molecular dynamics combined with density functional theory calculations of the electronic structure. The dynamic effects at the organic component are very similar to what has been observed in comparable molecules in solid, liquid, and gas phase experiments [1-3], and can be well understood by comparing and contrasting with reference materials. The spectral signature and related dynamic effects are influenced by the interaction of the organic and inorganic components of the material. Experimentally, it is also shown that the organic portion of the perovskite is quickly and strongly influenced by radiation damage, with soft x-rays from a third-generation synchrotron light source undulator causing significant degradation of the material on the time scale of a few seconds. The degradation mechanisms will be discussed in terms of their influence on experimental studies, as well as in terms of the general decomposition of metal-organic perovskite materials.

Interfacial Hole Injection Dynamics in Organohalide Perovskite Probed by Femtosecond Tabletop Extreme Ultraviolet Spectroscopy Aastha Sharma, Max Verkamp and Josh Vura-Weis; University of Illinois at Urbana-Champaign, United States

Hybrid organic-inorganic halide perovskites, such as methylammonium lead iodide (CH₃NH₃PbI₃) have emerged as potential hot-carrier (HC) solar cell materials. Despite rapid progress in device performances, the feasibility of HC injection in hybrid perovskites before carrier cooling is not fully understood. One experimental challenge is the difficulty in using optical methods to independently measure electron vs hole dynamics. We have shown that extreme ultraviolet (XUV) spectroscopy in the 40 to 80 eV energy range measures Iodine 4d→5p transitions and provides separate and distinct signals for valence band and conduction band dynamics. We use this technique to measure the rate of electron and hole injection into charge collection layers such as TiO₂, NiO and Co octaethylporphyrin after visible light excitation of the perovskite layer. The intense 3p→3d absorption, also in the XUV energy range, provides a unique spectroscopic fingerprint of the transition metal electronic structure with distinct peak changes corresponding to photoinduced oxidation state changes. The tabletop instrument uses high-harmonic generation to produce 15 femtosecond XUV probe pulses, enabling us to observe both carrier cooling and charge injection on the femtosecond to picosecond time scales.

SESSION EN09.03: Poster Session I: Fundamental Materials Properties and Advanced Characterization of Halide Perovskites I
Session Chair: Ross Kerner

Rationalizing the Impact of B-Site Metal Additives and Their Spatial Incorporation in Halide Perovskites Xueying Li¹, Yanqi Luo¹, Moses Kodur¹, Rishi Kumar¹, Martin V. Holt¹, Zhonghou Cai² and David P. Fenning¹; ¹University of California, San Diego, United States; ²Argonne National Laboratory, United States

Leveraging their structural and chemical flexibility, halide perovskites have shown significant optoelectronic performance and stability improvements over the last several years with addition of alkaline metals (e.g. Cs, Rb and K) to the major organic A-site constituents (methylammonium and formamidinium). More recently, several studies
have shown improved film quality and solar cell performance with addition of cations targeting B-site incorporation. However, the spatial distribution and actual incorporation of B-site cations has yet to be firmly established. To understand the distribution of these potential dopants and their local effects on optoelectronic properties, we use a combination of X-ray nanofluorescence to probe the elemental composition and nano-diffraction to identify changes in the local crystal structure. We pair these with correlative microscopic evaluations of optoelectronic quality via photoluminescence mapping and E-beam induced current measurements. We thus develop relationships between local chemistry, grain size, crystal quality, and optoelectronic enhancement to identify the impacts of a range of metal cations. This new information on the distribution of cations targeting B-site incorporation rationalizes the wider composition space available to tune the properties of halide perovskite materials.

EN09.03.02
TlBr and Tl2AgBr3 Nanocrystal Synthesis Timothy Siegler, Yangning Zhang, Tushti Shah, Mokshin Suri and Brian A. Korgel; The University of Texas at Austin, United States

We have become interested in the addition of thallium to halide perovskites, both in A-site and B-site substitutions. Cs2AgTlBr6 (CATB) double perovskite for example offers the lowest band gap in the halide perovskite family of materials with a direct band gap of 0.95 eV in single crystals. Additionally, thallium halides have applications in radiation detectors due to their high mobility and high average atomic number. Controlling the Tl oxidation state is one of the challenges facing the synthesis of these nanocrystals. For instance, we have found that Tl3+ readily reduces to Tl+ under most reaction conditions. Here, we report progress on thallium bromide nanocrystal chemistry and have developed chemical routes to cubic CsCl-type TlBr and trigonal dolomite-type Tl2AgBr3 nanocrystals. TlBr nanocrystal synthesis involves hot injection of trimethylsilyl bromide (TMSBr) into a thallium (III) acetate solution in octadecene, oleic acid, and oleylamine at 70 °C. Tl2AgBr3 nanocrystals are synthesized using the same reaction conditions with a both thallium (III) acetate and silver (I) acetate in the precursor solution. The nanocrystals are uniform with diameters between 10 and 15 nm. The Tl2AgBr3 nanocrystals exhibit an indirect band gap of 3.1 eV and a direct band gap of 3.7 eV. This is the first report of Tl2AgBr3 nanoparticle synthesis and the first characterization of the band gap of Tl2AgBr3. TlBr has a direct band gap of 3.05 eV, consistent with bulk band gap of TlBr in literature. We were able to assemble face centered cubic (FCC) superlattices of the TlBr and Tl2AgBr3 nanocrystals. The size of the TlBr nanocrystals could be varied by changing the reaction temperature, with smaller (~5 ± 3 nm) TlBr nanocrystals formed at higher reaction temperatures (110 °C).

EN09.03.03
Solvent Engineering for All-Inorganic CsPbIBr2 Perovskite Photodetectors Ting Zhang, Feng Wang and Shibin Li; University of Electronic Science and Technology of China, China

Photodetectors, which can convert light signals into electrical signals, are important opto-electronic devices in imaging, optical communication, biomedical/biological sensing. Currently, most of the commerical photodetectors are based on traditional inorganic semiconductors, such as Si, ZnO, GaN and InGaAs, which require expensive vacuum equipment. In recent years, organic-inorganic halide perovskites have drawn great attention and been a very promising candidate for opto-electronic applications due to their outstanding physical properties, including strong light absorption, low exciton binding energy, long carrier lifetime and low charge recombination rate. Here, through optimizing the film quality via precursor solvents and posttreatment process, high performance flexible photodetectors based on all-inorganic cesium lead halide perovskite (CsPbIBr2) are demonstrated. The device show a high response speed (rise time and decay time are 170 and 250 μs, respectively.), a large light on/off ratio of 105 upon illumination with 520 nm light, high specific detectivity (~1011 Jones). Moreover, the flexible photodetectors exhibit outstanding long-term environmental stability after being kept in ambient air for one month. The results demonstrate a great potential for the application of CsPbIBr2 perovskite in opto-electronic detection, and provide a promising route to enhance the film quality and achieve high performance.

EN09.03.04
Directly-Generated Acetate Ions Enable Efficient and Stable Surface Management of CsPbI3 Perovskite Quantum Dots for Improved Solar Cell Performance Jigeon Kim¹², Younghoon Kim¹, Changsoon Choi¹ and Min Jae Ko²; ¹Dague Gyoungbuk Institute of Science and Technology, Korea (the Republic of); ²Hanyang University, Korea (the Republic of)

Fully-inorganic CsPbX3 (X=Cl, Br, I) perovskite quantum dots (PQDs) are receiving much attention as a
photoactive semiconductor in various optoelectronic devices because of their excellent opto-electrical and photophysical features resulting from the intrinsic properties of lead halide PQDs such as size- and composition-tunable optical bandgap, high absorption coefficient, narrow emission, high photoluminescence quantum yield, and high charge-carrier mobility. Recently, CsPbI$_3$ perovskite quantum dot (CsPbI$_3$-PQD) solar cells have shown the best device performance in the field of colloidal quantum dot (CQD) solar cells, achieved by methyl acetate (MeOAc) and formamidinium iodide treatments for enhanced electronic coupling within CsPbI$_3$-PQD solids. MeOAc treatment for CsPbI$_3$-PQDs generates acetate ions, which substitute for the oleates (act as insulators) on the surface of CsPbI$_3$-PQDs, as a result of MeOAc hydrolysis. However, the by-products, which are formed during the hydrolysis of MeOAc, induce the cubic-phase lattice distortion, nanocrystal aggregation and undesired surface traps. Herein, we demonstrate a new surface management strategy for CsPbI$_3$-PQDs, which removes the oleates more effectively without any side effects. In this strategy, a solution of sodium acetate (NaOAc) in MeOAc directly releases acetate ions minimizing the hydrolysis of MeOAc. This approach improves the electronic coupling in CsPbI$_3$-PQD solids, by preservation of their nanocrystal size and minimization of surface trap states. As a result, the NaOAc-treated CsPbI$_3$-PQD solar cells showed a power conversion efficiency (PCE) of 13.3% (higher than a 12.4% of a lead nitrate-treated control device) by only the development of surface management of CsPbI$_3$-PQDs without the aid of antireflective coating layer. In addition, this performance is comparable to a PCE 13.4% of the previously reported best performance of CsPbI$_3$-PQD solar cells, which use an antireflective coating layer.

EN09.03.05
In Situ GIXRD Study of Two-Dimensional Organohalide Perovskite Quantum Wells Junwei Xu$^{1,2}$, Maged Abdelsamie$^{1,2}$, Haipeng Lu$^3$, Kai Zhu$^3$ and Michael F. Toney$^{1,2,3}$; $^1$SLAC National Accelerator Laboratory, United States; $^2$Stanford University, United States; $^3$National Renewable Energy Laboratory, United States

Two-dimensional (2D) layered organohalide perovskites form natural “multiple quantum wells” have emerged as more intrinsically stable materials for solar cells than conventional three-dimensional (3D) halide perovskites (such as MAPbI$_3$, CsPbI$_3$, et al). This is because long organic spacers are inserted between perovskite slabs which can stabilize the structure. The organic ligands are bonded to the perovskite sheet with hydrogen bonds and to each other with van der Waals interactions. It has been demonstrated that the diversity of spacer organic cations greatly impacts the tunability of 2D organohalide perovskites in structural dimensionality as well as optoelectronic properties. Initial work has shown that 2D layered perovskite based solar cell is able to work stably over 46 days in the air with high humanity, however, it has a relatively low power conversion efficiency (PCE) comparing to that of its 3D counterpart. The major reason is attributed to poor charge transport property of the insulating organic spacers. Although the recent finding suggests that the undesired charge loss in the 2D perovskite structure could be overcome by tuning the crystalline orientation, the underlying crystallization kinetics mechanism is largely unexplored. It thus requires enormous work to establish a fundamental understanding of crystallization and factors related to this process, which eventually contributes to the improvement of carrier transport in the 2D perovskite thin films and photovoltaic devices. In our study, synchrotron based in-situ GIXRD technique was used to study crystallization dynamics of 2D perovskite films during fabrication and learn how the length of the organic spacers (PMA, PEA, PPA, PBA) influence the orientation of crystallites. We investigated a fundamental understanding of 2D perovskite crystallization during spin-coating and thermal annealing, which will develop as a guideline for the fabrication of the highly crystallized, oriented, and stable 2D perovskite films.

EN09.03.06
Increasing Exciton Spin Lifetimes in Layered Hybrid Perovskites by Lattice Symmetry Modification Sean Bourelle$^1$, Tanja Schmitt$^2$, Nathaniel J. Tye$^1$, Thomas Winkler$^1$ and Felix Deschler$^{1,3}$; $^1$University of Cambridge, United Kingdom; $^2$Universität Heidelberg, Germany; $^3$Technische Universität München, Germany

2D metal-halide perovskites are self-assembled quantum well structures with excellent optoelectronic properties and strongly-bound excitonic states. In these systems, strong spin-orbit coupling and the presence of crystal lattice asymmetry leads to a Rashba type band splitting. We show that the crystal lattice space group and symmetry in layered metal-halide perovskites can be controlled by halogen para-substituents. We report the synthesis and ultrafast electronic state dynamics of layered benzylammonium lead iodide perovskites (4-XC$_3$H$_7$CH$_2$NH$_3$)$_2$PbI$_4$ with X = H, F, Cl and Br. We will present x-ray diffraction and second-harmonic generation experiments from which we extract information on the symmetry of the crystal structure. We demonstrate that the fabricated materials are non-centrosymmetric 2D Ruddlesden-Popper metal-halide perovskites with layer number n=1. Using circularly polarised broadband transient absorption spectroscopy (CTA) we track the spin-polarised populations of the optically active
Exciton species on ultrafast timescales and present how the modification of the 2D perovskite crystal structure leads to a significant enhancement of the exciton spin lifetime.

EN09.03.07
Microfluidic Studies of Anion Exchange Reactions of Inorganic Perovskite Quantum Dots Kameel K. Abdel-Latif, Robert W. Epps, Corwin Kerr, Christopher Papa, Felix Castellano and Milad Abolhasani; North Carolina State University, United States

Inorganic perovskite quantum dots (IPQDs) have demonstrated remarkable success as a more energy-efficient alternative to well-studied metal chalcogenide QDs, and are attracting attention from the energy and chemical industries for a wide range of applications including photovoltaic devices, LED displays, and solar-enabled organic synthesis (photocatalysis). The facile bandgap tunability at room temperature through anion exchange reactions, high photoluminescence quantum yield, and relatively high defect tolerance, differentiate IPQDs from the other colloidal semiconductor nanocrystals. Despite the groundbreaking advancements of IPQDs in the field, their unique ionic nature (different than metal chalcogenide QDs) require new colloidal synthesis routes and surface chemistries. Conventionally, batch synthesis methods are utilized to synthesize, screen, and optimize solution-processed QDs. However, the massive reaction parameter space associated with IPQDs, in combination with the inherent mass and heat transfer challenges of batch methods, necessitate the utilization of material- and time-efficient synthesis methods for fundamental and applied studies of IQPDs. In this work, we develop and utilize a modular microfluidic platform for accelerated in-situ studies of IPQDs anion exchange reactions with minimum reagent consumption. The developed flow synthesis platform enables precise process control of halide exchange reactions, isolating reaction kinetics from precursor mixing rates in a gas-liquid segmented flow system. Utilizing the modular microfluidic strategy, we study in detail the effects of halide composition, ligand ratios, and halide salt source across reaction (residence) times ranging from 0.5 to 90 s. Capitalizing on the wealth of the systematic studies of anion exchange reaction, enabled by the developed time- and material-efficient strategy, we postulate a three-stage reaction mechanism for the homogeneous IPQDs halide exchange reaction. We complement our in situ findings of IPQDs anion exchange reactions with off-line material characterization techniques, gleaning new insights on the overall understanding of the anion exchange reaction network. The results of our kinetic studies of IPQDs halide exchange reactions in combination with the versatility and performance efficiency of the developed modular microfluidic platform, enable on-demand synthesis of IPQDs with a desired bandgap (composition) for targeted applications in optoelectronics and energy technologies.

EN09.03.08
Optical, Thermal and Crystallographic Studies of a Highly Stable New Hybrid Perovskite Material Based on Tetraethylphosphonium Iodide as Alternative Organic Cation and Bismuth Iodide Diana F. Garcia-Gutierrez1, Sylvain Bernes2, Edgar Gonzalez-Juarez1, Domingo Ixcoatl Garcia Gutierrez1,3 and Eduardo M. Sanchez-Cervantes1; 1Universidad Autónoma de Nuevo León, Mexico; 2Benemérita Universidad Autónoma de Puebla, Mexico; 3Centro de Innovación, Investigación y Desarrollo en Ingeniería y Tecnología, Mexico

Nowadays the study of MAPbX (X=Halide I, Cl or Br) perovskites’ properties is common in the race for having high efficiency and stable solar cells based on these promising materials. The poor stability in the environment of solar cells made with MAPbI3 has received great attention from researchers, and, on the other hand, there is also a necessity to find lead-free alternatives. One of the alternatives explored to solve the stability problem proposes to replace the organic cation MA for a hydrophobic one; on this regard, phosphonium salts possess this characteristic and they have been used as ionic liquids, so they also have high ionic conductivity as well. In parallel, bismuth and antimony compounds have been studied to replace the lead in the perovskite structure; in most cases, these lead-free solar cells display lower efficiencies, nonetheless showing improved stability at ambient and working conditions. Moreover, the properties of these lead-free perovskites make them excellent candidates to be used in tandem solar cells or other kind of optoelectronic applications, such as light emitting diodes. Conversely, these new materials, in many cases, are not reported in the literature, nor in the materials data bases, hence it is required to perform thorough studies to measure and understand their characteristics and properties. In this work, single crystals of BiI3-tetraethylphosphonium iodide were obtained by the supersaturation method; this is a new, stable and highly luminescent hybrid perovskite. These (EtP)3Bi2I9 single crystals have displayed thermochromic properties and the single crystal XRD studies have shown that they possess a tetragonal crystalline structure with a space group I42-d and unit cell dimensions of $a = b = 27.42$ Å and $c = 13.72$ Å. Based on the results obtained for this new perovskite,
tetraethylphosphonium iodide proves to be a promising candidate as an alternative organic cation in the solution of the instability problem. Finally, optical characterization results of the (EtP)$_3$Bi$_2$I$_9$ perovskite show it can be useful in many optoelectronic applications, such as light emitting diodes, photodetectors and tandem solar cells.

**EN09.03.10**

**Structural Design of Two-Dimensional Lead Halide Hybrid Perovskites for Optoelectronics**

Xiaotong Li$^1$, Weijun Ke$^1$, Peijun Guo$^2$, Justin M. Hoffman$^1$, Ido Hader$^1$, Mikael Kepenekian$^3$, Claudine Katran$^4$, Jacky Even$^4$, Richard Schaller$^2$, Konstantinos Stoumpos$^2$ and Mercouri G. Kanatzidis$^1$; $^1$Northwestern University, United States; $^2$Argonne National Laboratory, United States; $^3$Institut des Sciences Chimiques de Rennes, France; $^4$FOTON, France; $^5$University of Crete, Greece

Two-dimensional (2D) halide perovskites exhibit excellent potential for optoelectronics because of their outstanding physical properties and structural diversity. Although the optical properties are mainly decided by the inorganic parts, the structures are significantly influenced by the shape and size of the spacer cations. Despite the large amount of recent new 2D perovskite reports, there is no existing rule that can predict the structures of the perovskites before the synthetic experiments. To achieve this, we carefully design our experiments by changing one factor of the organic cation at a time to assess the role each may play. We start with primary diamines NH$_2$C$_{m}$H$_{2m}$NH$_2$ ($m = 4−9$), using both solution and solid-state grinding method, we get the series (NH$_3$C$_{m}$H$_{2m}$NH$_3$)(CH$_3$NH$_3$)$_{n-1}$Pb$_n$I$_{3n+1}$ ($m = 4−9$ / $n = 1−4$), where $m$ represents the carbon-chain number and $n$ equals layer-thickness number. Even when the carbon-chain length is as short as $m = 4$, the structures are still closer to the Ruddlesden−Popper (RP) phase. If the primary diamines are replaced by cyclic diamines, the uncommon Dion-Jacobson (DJ) phase can be achieved. Furthermore, when aromatic diamines are utilized instead of the aliphatic ones, fine tuning of the structures can provide better insight for what kind of cations can template the rare DJ phase. Fabrication of photovoltaic devices using these materials shows promising solar cell performances. By using smaller 3-aminopyrrolidinium cation, more unique (110)-oriented perovskites can be synthesized. The highly distorted structures give rise to white-light emission at room temperature. By rational design of the structures for 2D perovskites, we may achieve the optimal properties ideal for their optoelectronic applications.

**EN09.03.11**

**The Interplay Between Free Charges and Traps in Organic and Inorganic Semiconductors**

Artem Musiienko$^1$, Jindrich Pipek$^1$, Petr Praus$^1$, Mahshid Ahmadi$^2$, Eduard Belas$^1$ and Bogdan Dryzhakov$^2$; $^1$Charles University, Czechia; $^2$The University of Tennessee, Knoxville, United States

Organometallic halide perovskites (OMHPs) have recently undergone a remarkable development as highly efficient optoelectronic materials for a variety of applications particularly solar cells, light emitting diodes and photodetectors. To fully use the potential of OMHPs, several important challenges must be overcome. One of these challenges is the understanding and control of their defect structures. The available data from multiple research studies suggest that trap-assisted recombination exists in OMHPs despite their large carrier lifetimes, which makes these materials highly attractive, and this has resulted in the perovskite boom over the last decade. Conventional spectroscopy faces serious obstacles in OMHPs due to their low defect concentrations and capture cross section, and therefore the electronic structure of such semiconductors remains poorly understood. Currently, such understanding is limited, restricting the power conversion efficiencies of OMHP solar cells from reaching their Shockley–Queisser limit. In more mature semiconductors like Si, the knowledge of defects is one of the major factors in successful technological implementation. This knowledge and its control can make a paradigm shift in the development of OMHP devices.

The detection of shallow and deep traps is extremely challenging due to non-radiative nature of electrical transitions which cannot be studied by photoluminescence measurements. Moreover, as a result of the low activation energy, shallow traps cannot be detected by thermal emission methods. Here, we report on a deep level and shallow levels defects parameters and their effect on the free charge transport properties of the single crystalline methylammonium lead bromide (MAPbBr$_3$) perovskite for the first time. The transport properties of single crystal MAPbBr$_3$ are investigated by Time of Flight (ToF) measurements at several biases. These measurements are further fitted by Monte Carlo simulation allowing us the detection of parameters of energy states in the band gap. The analysis of charge carrier transport by ToF and MC simulation explain the long hole carrier lifetime and memory effect in MAPbBr$_3$ devices. Here, our studies provide strong evidence for deep levels in OMHPs and open a richer picture of the role and properties of shallow levels in MAPbBr$_3$ single crystals as a system model for the first time. The presented electrical and charge transport properties are crucial for informing the processing conditions towards the
elimination of these defects as was done for classical inorganic semiconductors. The deeper knowledge of the electronic structure of OMHPs could open further opportunities in the development of more feasible technologies.

EN09.03.12
Chiral 2D Perovskites with a High Degree of Circularly Polarized Photoluminescence Jiaqi Ma and Dehui Li; Huazhong University of Science and Technology, China

Chiral materials are of particular interest and have a wide range of potential applications in life science, material science, spintronic and optoelectronic devices. Two-dimensional (2D) hybrid organic-inorganic lead halide perovskites have attracted increasing attention. Incorporating the chiral organic ligands into the layered lead-iodide frameworks have been suggested for achieving the chirality transfer in 2D perovskites, so that the pure 2D perovskites with strong chirality exhibit CD. Meanwhile, 2D perovskites that possess the merits of both chiral materials and perovskites can realize circularly polarized light (CPL) emission and detection and thus would be promising materials for many imaging applications including biomedical, optical and spintronic devices. Nevertheless, the study of chiral pure 2D perovskites is still in its infancy. Here we report on the strong CPL emission and sensitive CPL detection in the visible-wavelength range in pure chiral ($R$/$S$-MBA)$_2$PbI$_4$ (MBA = C$_6$H$_5$C$_2$H$_4$NH$_2$) 2D perovskites, which are successfully synthesized with a needle shape and millimeter size by incorporating the chiral molecules. The chiral 2D perovskites ($R$-MBA)$_2$PbI$_4$ and ($S$-MBA)$_2$PbI$_4$ exhibit an average degree of circularly polarized photoluminescence (PL) of 9.6% and 10.1% at 77 K, respectively, and a maximum degree of the circularly polarized PL of 17.6% is achieved in ($S$-MBA)$_2$PbI$_4$. The degree of circularly polarized PL dramatically decreases with increasing temperature, implying that the lattice distortion induced by the incorporated chiral molecules and/or temperature-dependent spin flipping might be the origin for the observed chirality. Finally, CPL detection has been achieved with decent performance in our chiral 2D perovskite microplate/MoS$_2$ heterostructural devices. The high degree of the circularly polarized PL and excellent CPL detection together with the layered nature of pure chiral 2D perovskites enables them to be a class of very promising materials for developing and exploring spin associated electronic devices based on the chiral 2D perovskites.

EN09.03.13
Impact of Processing Strategies on Phase Evolution of Cs$_x$FA$_{1-x}$PbI$_3$ Perovskite Solar Cells—In Situ Monitoring of Crystallization Pathways During Film Formation Maged A. Abdelsamie, Junwei Xu and Michael F. Toney; Stanford University, United States

Organo-metal-halide perovskites have gained tremendous attention as potential materials for photovoltaics, demonstrating efficiencies approaching the best silicon solar cells. Many approaches have been adopted to manipulate perovskite formation including anti-solvent processing, compressed-gas treatment, and post-deposition thermal annealing, where films can be deposited using different coating techniques such as spin-coating or blade-coating. Understanding the role of processing strategies on crystallization pathways is of crucial importance as crystallization strongly affects the perovskite film microstructure, its stability, and devices performance. Moreover, crystallization pathways become more complicated for perovskites with a mixed stoichiometric mixture such as Cs$_x$FA$_{1-x}$PbI$_3$ due to the thermodynamic and kinetic competition to form secondary phases. Herein, using time-resolved x-ray scattering, we investigate the film formation of Cs-FA-containing perovskites with stoichiometry [Cs$_0.15$FA$_{0.85}$PbI$_3$]$_{in situ}$ during spin coating, blade coating, and the subsequent post-deposition thermal annealing, while different processing approaches such as anti-solvent [chlorobenzene (CB)] and compressed-gas (N$_2$) treatments were applied during film casting. We show how different processing routes affect the competition between the formation of the non-perovskite δ-phase and perovskite α-phase during film formation. When either anti-solvent or compressed-gas treatment is used, both δ-phase and α-phase are induced during casting, with the δ-phase more dominant in the as-cast film. However, each approach works with different mechanisms; while anti-solvent induces immediate crystallization from the bulk wet film, applying compressed N$_2$ works by depleting volatiles from the top-surface leading to surface-induced crystallization that occurs after reaching supersaturation. When neither treatment is applied, the as-cast film is mostly amorphous with little non-perovskite δ-phase formation. In addition, we show the evolution of phases during thermal annealing. Our results reveal that, for the non-treated films, crystallization of perovskite α-phase occurs predominantly from amorphous phase rather than δ-phase to α-phase transformation during thermal annealing. However, direct phase transformation of δ-phase to α-phase is more dominant for CB- and N$_2$- treated films, while perovskite crystallization occurs from an initially ordered film compared to non-treated films. Furthermore, our findings reveal that using blade-coating promotes completely different crystallization pathways than spin-coating,
while solvothermal direct crystallization of perovskite α-phase occurs predominantly, leading to overcoming the non-perovskite δ-phase formation without the need for post-deposition thermal annealing. Our work highlights the importance of real-time investigation of film formation which can provide an in-depth understanding of the mechanisms of perovskite formation and help to establish processing-microstructure-functionality relationships.

**Exciton Dynamics in Perovskite Nanocrystal-Based Heterostructures** En-Ping Yao, Bernhard Bohn, Yu Tong, He Huang, Lakshminarayana Polavarapu and Jochen Feldmann; Ludwig-Maximilians-Universität München, Germany

Solution-processable perovskite nanocrystals (NCs) are gaining increasing interest in the field of photovoltaics because of their enhanced stability compared to their thin-film counterparts. However, charge transfer dynamics in perovskite NC based light-harvesting systems are not well understood. By applying femtosecond differential transmission (DT) spectroscopy we investigate the photoinduced charge transfer from inorganic perovskite CsPbBr₃ NCs to the fullerene derivative phenyl-C₆₁-butyric acid methyl ester (PCBM) for two fundamentally different architectures, namely layer-by-layer heterostructures as well as blend structures. Varying the thickness of the NC layer on top of the PCBM in the layer-by-layer heterostructure, an exciton diffusion length of 290 ± 28 nm for CsPbBr₃ NC is extracted. The diffusion process is followed by an ultrafast exciton dissociation (within 200 fs) at the CsPbBr₃ NC/PCBM interface. In blend structures an overall faster charge transfer process is observed. Furthermore, photoconductivity measurements on a blend structure-based photodetector reveal an effective charge extraction from the active layer resulting in a high photosensitivity. DT measurements on this blend structure including adjacent electron- or hole-transport layers give insight into the extraction process and suggest a certain degree of phase segregation, which assists the charge collection.

**Epitaxial Growth of Soft Perovskites and the Hidden Carrier Dynamics** Jie Jiang¹², Yiping Wang¹, Zhizhong Chen¹, Jing Feng² and Jian Shi¹; ¹Rensselaer Polytechnic Institute, United States; ²Kunming University of Science and Technology, China

High-temperature vapor phase epitaxy (VPE) has been proved ubiquitously powerful in enabling high-performance electro-optic devices in III–V semiconductor field. A typical example is the successful growth of p-type GaN by VPE for blue light-emitting diodes. VPE excels as it controls film defects such as point/interface defects and grain boundary, thanks to its high-temperature processing condition and controllable deposition rate. In this talk, we will present single-crystalline high-temperature VPE soft halide perovskite thin film as a unique platform on unveiling previously uncovered carrier dynamics in inorganic halide perovskites. With VPE, hot photoluminescence and nanosecond photo-Dember effect are revealed in inorganic halide perovskite. These two phenomena suggest that inorganic halide perovskite could be as compelling as its organic–inorganic counterpart regarding optoelectronic properties and help explain the long carrier lifetime in halide perovskite. The findings suggest a new avenue on developing high-quality large-scale single-crystalline halide perovskite films requiring precise control of defects and morphology.

**EN09.03.16**

**Efficient Perovskite Solar Cells by Hybrid Perovskites Incorporated with Heterovalent Neodymium Cations** Xiong Gong; Univ of Akron, United States

Recently, hybrid perovskite materials have emerged as attractive alternatives for realizing cost-effective efficient perovskite solar cells. To date, impressive efficiency has been realized from the state-of-the-art solar cells through generic interface engineering and film morphological manipulation of perovskite active-layer in macroscopic scale. To further boost the efficiency of perovskite solar cells, microscopically tuning optoelectronic properties of hybrid perovskite materials represents a promising direction. In this study, we report efficient perovskite solar cells by a novel hybrid perovskites material that is incorporated with heterovalent neodymium cations (Nd³⁺). As compared with pristine hybrid perovskite materials, Nd³⁺-doped hybrid perovskite materials possess superior film quality with highly reduced trap-states, significantly enlarged charge carrier lifetimes, dramatically enhanced and balanced charge carrier mobilities. As a result, planar heterojunction perovskite solar cells by Nd³⁺-doped hybrid perovskite materials exhibit highly reproducible power conversion efficiency of 21.15% and significantly suppressed photocurrent hysteresis. These findings open a new window of tuning the optoelectronic properties of hybrid
perovskite materials and boosting the device performance of perovskite solar cells.

**EN09.03.17**

**Ultrafast Probe at the Interfaces of Solar Energy Conversion Materials**

Xihan Chen, Matthew C. Beard and Kai Zhu; National Renewable Energy Lab, United States

Solar energy represents one of the most important renewable energy sources. It can be converted to electricity and chemical fuels by photovoltaics and photoelectrochemical devices. The efficiency of solar energy conversion is governed by ultrafast carrier dynamics at solar energy conversion material interfaces. To understand such interfaces and develop next generation of solar energy conversion devices, ultrafast spectroscopic probes are needed. By developing transient reflectance spectroscopy to monitor the surface carriers that are within ~ 10 nm of the surface emerging solar cell materials, crucial parameters such as surface recombination and carrier diffusion are determined. Our results indicate the formation of 2D layered structure on Sn based perovskite solar cell surfaces that could effectively reduce surface recombination by 10-fold and increase carrier diffusion length to 2.5 μm.

**EN09.03.18**

**Why are Hot Holes Easier to Extract than Hot Electrons from Methylammonium Lead Iodide Perovskite?**

Ibrahim Dursun, Partha Maity, Jun Yin, Bekir Turedi, Ayan A. Zhumekenov, Kwang Jae Lee, Omar A. Mohammed and Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

The power conversion efficiency of light harvesting devices is limited by the rapid thermalization of charge carriers that are photoexcited with energies above the bandgap of the absorbing material. As these so-called ‘hot’ carriers are difficult to collect, their cooling places an upper bound on the available photon energy that a given solar cell may utilize. Recently, studies on hot carriers in methylammonium lead iodide (MAPbI$_3$) perovskite have noted that they cooldown at an appreciably slower rate than carriers in other photovoltaic materials. However, the relaxation rate is still rapid in absolute terms, and hence, their capture and collection (before relaxing to the band edge) have not been shown so far. **Here we demonstrate and explain the efficiency of hot carrier extraction from MAPbI$_3$ using TiO$_2$ and Spiro-OMeTAD as an electron transporting layer (ETL) and hole transporting layer (HTL), respectively, via real-time observation of the carrier dynamics with femtosecond transient absorption spectroscopy and supported by density functional theory (DFT) calculation.** Time-resolved experiments establish that a quasi-equilibrium distribution of the hot carriers is directly populated upon excess-energy excitation of the pristine perovskite. This quasi-equilibrium distribution of hot carriers while not appreciably affected by the presence of TiO$_2$, is virtually absent in the presence of Spiro-OMeTAD, which is indicative of efficient hot hole extraction at the interface of MAPbI$_3$. DFT calculations predict that deep energy levels of MAPbI$_3$ exhibit electronically delocalized character, causing a strong overlap with the localized charge of the valence band of Spiro-OMeTAD lying on the surface of MAPbI$_3$. Consequently, the hot holes could be easily extracted from the deep-energy levels of MAPbI$_3$ by the HTL. These findings reveal the origins of efficient hot hole extraction in perovskites and offer a practical blueprint for optimizing interlayers of perovskite solar cells in order to enable hot carrier utilization.

**EN09.03.19**

**Low-Temperature-Gradient Crystallization for Multi-Inch High-Quality Perovskite Single Crystals for High Performance Photodetectors**

Yunxia Zhang$, Yucheng Liu$ and Shengzhong (Frank) Liu$; $1Shaanxi Normal University, China; $2Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China

With their excellent optoelectronic properties, the practical application of single-crystalline organolead halide perovskite materials is limited by the lack of a method to prepare high quality perovskite single crystals in large dimension. Herein, we report our development of a low temperature-gradient crystallization (LTGC) method for high-quality CH$_3$NH$_3$PbBr$_3$ (MAPbBr$_3$) perovskite single crystals with lateral dimension as large as two inches. The theoretical analysis suggests that a small temperature gradient should be used to restrain the growth condition, particularly the solution concentration, within the optimal single-crystal-growth (OSCG) zone. The solubility curve as a function of temperature reveals a sharp turning point at 60 °C, across which the first-order solubility derivative (dC/dT) shows very different behaviors: below this temperature, the dC/dT changes dramatically as the temperature increases, while above this temperature, the dC/dT enters a plateau where further temperature change has little effect on the derivative, meaning that one can attain both a substantial crystal growth rate and crystallization yield below this temperature. Utilizing this discovery, a MAPbBr$_3$ single crystal as large as 47 × 41 × 14 mm is obtained with high quality via the LTGC method. The single crystal exhibits the best optoelectronic quality among all MAPbBr$_3$
materials reported in the literature, including the best trap state density, mobility, carrier lifetime, and diffusion length. These superior optoelectronic properties are further transferred into a high-performance planar photodetector. The device exhibits high operational stability, high external quantum efficiency (13.453%), excellent detectivity as high as $8 \times 10^{13}$ Jones, and a fast response speed as quick as 15.8 µs.

EN09.03.20
Crystal Phase Control toward the Perovskite Superlattice Solar Cell Satoshi Uchida, Naoyuki Shibayama, Koichi Tamaki, Keishi Tada, Miwako Furue, Ludmila Cojocaru and Hiroshi Segawa; 1The University of Tokyo, Japan; 2University of Freiburg, Germany

Recently organic–inorganic halide perovskite solar cell have great attention for its high performance together with easy production and wide variety of the process & flexibility of substrate materials. The power conversion efficiency has already reached over 23% in 2019 much beyond another solar cells such as CIGS or amorphous Si. The further performance still looks promising toward the Shockley–Queisser limit at around 30%. For that purpose, physical chemistry understanding based on the crystallography must be essential to design the good light harvesting, good charge separation and good charge transfer. Recently we reported the scientific revelation that the crystal phase of thin film CH$_3$NH$_3$PbI$_3$ consists of the mixture of tetragonal phase and cubic phase. They are about 15-20 nm well crystallized domain and randomly oriented in high resolution TEM analysis. Furthermore, multi stack sequence such as tetra-cubic-tetra resulted to form the superlattice with d-spacing 10.989 Å (2θ=8.03° for CuKα). Such a superlattice may act beneficial for good charge separation & charge transfer that are well known property as a Type II superlattice. To make more efficient performance, the crystal phase control with some different approaches were examined as below.

(1) High pressure post treatment by cold isostatic pressing (CIP)
(2) Photo-flash rapid curing
(3) Crystal growth under the high voltage electrostatic field
Here in this research the results of advantage-disadvantage will be discussed.

EN09.03.21
On the Proximity of Formamidinium-Centered States in Formamidinium-Doped Methylammonium Lead Iodide and Formamidinium Lead Iodide Sergei Manzhos and Giacomo Giorgi; 1Institut National de la Recherche Scientifique, Canada; 2University of Perugia, Italy

Organic-inorganic halide perovskite (OIHP) materials beyond the classic methylammonium lead iodide (MAPI) are actively researched for use in perovskite solar cells (PSC) and perovskite-based light emitting diodes (PLED). Specifically, the use of other inorganic cations such for formamidium (FA) has been reported to be advantageous, in particular in PLED. While the minimum of the conduction band (CBM) and the maximum of the valence band (VBM) of OIHPs are typically dominated by states due to the inorganic sub-lattice (such as PbI), it was recently suggested (PCCP 2019, 21, 8161) based on cluster calculations of FA-doped MAPI that FA-centered states may be close to the CBM (with fractions of an eV). This could have significant effect on electronic properties, as such states could be occupied (forming neutral FA species) by photoexcitation (in PSC) or electron injection (in PLED).

Here, we compute ab initio the properties of bulk and nanoclusters of FAPI and compare them to those of FA-doped MAPI. We consider the effects of van der Waals interactions and of the choice of the functional (GGA or hybrid) on the bandstructure. We observe FA-centered states in proximity to the CBM and a strong nanosizing effect whereby FA-centered states may fall through the CBM of the PbI sub-lattice in small nanoparticles. The results suggest that one indeed should consider effects of FA-centered states in OIHP using formidium either as a dopant or as majority cation (FAI).

EN09.03.22
Quantitative Measures of Contact Selectivity and Interfacial Recombination of Spiro-OMeTAD-Modified Solar Cell Contacts and the Role of Li-TFSI Kira Egelhofer and Mark Lonergan; University of Oregon, United States

An ideal solar cell contact collects either the electron or hole with no energy loss while perfectly rejecting the other carrier. Nonideal charge transfer at the interface between absorber and contact can severely limit the efficiency of solution-processed solar cells like perovskites. Interfacial layers (IFLs) such as 2,2',7,7'-tetrakis(N,N-di-p-methoxyphenylamine)-9,9'-spirobiﬂuorene (spiro-OMeTAD) are frequently used to help improve charge transfer...
and therefore efficiency. However, the field lacks systematic methods of studying how IFLs impact efficiency due to a few key challenges. These include separating interface phenomena from bulk processes, separate quantification of contact selectivity and interfacial recombination, and measuring the effects of operando solar cell function on charge transfer. Our work seeks to address these challenges to answer lingering questions about IFLs. For example, there are mixed reports concerning whether the selectivity or recombination of spiro-OMeTAD-modified contacts is more influential in determining solar cell characteristics (primarily $V_{oc}$). It is well known that the addition of Li-TFSI (lithium bis(trifluoromethane)sulfonimide, a common additive) facilitates the oxidation of spiro-OMeTAD in air, effectively $p$-doping the film and shifting the Fermi level down. This shift would intuitively increase the hole selectivity of the contact and should therefore increase the $V_{oc}$. However, the $V_{oc}$ of perovskite cells decreases with increased Li-TFSI concentration. Because increased interfacial recombination theoretically decreases $V_{oc}$, recombination could be more influential in determining $V_{oc}$ than the selectivity. However, there are no quantitative reports of the selectivity or recombination of spiro-OMeTAD-modified contacts, which this study seeks to address.

To do so we use the silicon interdigitated back-contact solar cell as a tool to experimentally measure the selectivity and recombination. Additionally, we use numerical simulation to extract the corresponding exchange current densities ($J_{ex}$) as charge transfer parameters for both electrons ($J_{en}$) and holes ($J_{hp}$). We find that spiro-OMeTAD IFLs both with and without 25 mol% Li-TFSI strongly affect both the selectivity (defined as $J_{en}/J_{hp}$) and recombination (defined as $(J_{en}J_{hp})^{1/2}$) of gold contacts. Neat spiro-OMeTAD causes gold to become two orders of magnitude less hole selective while the addition of Li-TFSI causes it to become three orders of magnitude more hole selective (a five order of magnitude increase from neat). Neat spiro-OMeTAD causes the recombination to go down by six orders of magnitude while the presence of Li-TFSI causes it to go down by five orders of magnitude (an order of magnitude increase compared to neat). Recall that reported perovskite $V_{oc}$s go down with increasing Li-TFSI concentration; a decrease in hole selectivity or an increase in recombination would cause this to occur. We find that both the hole selectivity and recombination increase upon addition of Li-TFSI indicating that the recombination change dominates decreases in $V_{oc}$. We emphasize that only by measuring both selectivity and recombination can we definitively come to this conclusion. We also observe that when the solar cell using spiro-OMeTAD-modified gold as the hole selective contact is operated in the power quadrant, the recombination decreases and the hole selectivity increases. From these results we conclude that changes to the selectivity and recombination properties of spiro-OMeTAD-modified contacts contribute to hysteretic behavior in perovskite solar cells. Our methods of studying charge transfer at spiro-OMeTAD interfacial layer-modified solar cell contacts shed light on the complex interplay between contact selectivity, recombination, and solar cell parameters. These insights will help the field engineer target interfacial layers for improved perovskite and other solution-processed solar cell efficiency.

**EN09.03.23**

**Two-Dimensional Lead Halide Perovskites Incorporating Long Straight Chain Aliphatic Ammonium Ions—Crystal Structure, Optical Properties and Ferroelectricity**

Eugenia S. Vasileiadou, Qing Tu, Shiqiang Hao, Daniel Friedrich, Ido Hadar, Ioannis Spanopoulos, Christopher Wolverton, Vinayak Dravid and Mercouri G. Kanatzidis; Northwestern University, United States

Herein, we present a new family of bilayered lead bromide perovskites, incorporating long chain aliphatic alkylammonium cations as the organic spacer between the inorganic sublattices with formula $(C_{m}H_{2m+1}NH_{3})_{2}(CH_{3}NH_{3})Pb_{2}Br_{7}$ (m = 6–8). Structural characterization by single-crystal X-ray diffraction demonstrates uniaxial expansion of the stacking axis of the studied perovskites, as the length of the alkylammonium cation increases. Differential scanning calorimetry was used to study the reversible phase transitions of the reported bilayered 2D perovskites. The semiconducting properties of the materials were examined by UV-Vis absorption and photoluminescence (PL) emission measurements. The studied compounds have a similar absorption spectra that are typical of layered perovskites, with an absorption edge around 2.85 eV and an excitonic peak above the bandgap. PL at room temperature displays a strong narrow emission, close to the energy value of the excitonic peak in the absorption spectra. The band structure of the materials was calculated based on density functional theory (DFT), which affirms that the materials are direct band gap semiconductors. Film fabrication demonstrates that the layered perovskites can successfully be cast into thin films through the hotcasting technique. Switching spectroscopy-piezoresponse force microscopy (SSPFM) on thin films shows polarization switching, indicating ferroelectric behavior along with the non-centrosymmetric structures of the materials. Thus, tuning the spacer cation of the 2D hybrid lead bromide perovskite structure by incorporating long-chain alkylamines, provides a platform to combine ferroelectricity with the excellent optical properties and stability of layered perovskites for fundamental and applied studies.
Thermoelectric Properties of Lead-Free Halide Perovskites Solar Cells Tianjun Liu and Oliver Fenwick; Queen Mary University of London, United Kingdom

Halide perovskites have emerged as promising candidates for photovoltaics and light-emitting diodes. Recently, promising thermoelectric performance has been reported for single nanocrystals of a halide perovskite, but there is not yet a good understanding of how thermoelectric performance can be optimised in these materials, especially in thin films where a diverse range of structures and morphologies are accessible. In this presentation I will report a record thermoelectric figure of merit (ZT) for halide perovskites, using the example of CsSnI3 thin films. This result is in part due to the ultralow thermal conductivity of our films (0.38 W/mK at room temperature), as well as high electrical conductivity enabled by self-doping of the films through controlled Sn oxidation. I will also discuss the potential role of mixed-halide films in developing these materials further. Finally, charge and phonon transport mechanism in CsSnI3 thin films will be discussed, which would be helpful for improving its air stability and further photovoltaic applications.

Direct Measurement of Exciton Diffusion in Two-Dimensional Ruddlesden-Popper Perovskites Michael Seitz and Ferry Prins; Universidad Autonoma de Madrid, Spain

There is an increasing interest in two-dimensional (2D) Ruddlesden-Popper perovskites for solar harvesting as a result of their superior chemical stability as compared to their bulk counterparts.1,2 Both purely 2D and blends of 2D/3D phases have already been successfully employed in solar cells with reported efficiencies of >18% and >22%, respectively.3,4 With this increasing technological relevance of 2D perovskites, it is essential to understand the physical processes that govern their opto-electronic performance. Particularly, the reduced dimensionality in 2D perovskites results in excitonic excited states, dramatically modifying the dynamics of charge collection. While charge carrier dynamics in bulk systems is increasingly well understood, a detailed understanding about the spatial dynamics of excitons in 2D perovskites is lacking.5

Here, we present the direct measurement of the intrinsic diffusivities and diffusion lengths of excitons in single crystalline 2D perovskites using time-resolved microscopy.6 This technique allows us to follow the temporal evolution of a diffraction limited exciton population with sub-nanosecond resolution, revealing the spatial and temporal exciton dynamics.7 Using the versatility of perovskite materials, we study the influence of the organic spacer, the halide and cation composition, as well as the dimensionality (n = 1 and 2) on the diffusion dynamics of excitons in 2D perovskites. We find that changes in these parameters can lead to differences in diffusion lengths of up to two orders of magnitude. Our results provide important insights into the spatial exciton dynamics in 2D perovskites and yield clear design rules for more efficient 2D perovskite solar cells and light emitting devices.

Overcoming the Large Exciton Binding Energy in Two-Dimensional Perovskite Nanoplatelets by Attachment of Strong Organic Electron Acceptors Ferdinand C. Grozema1, María C. Gélvez-Rueda1, Magnus B. Fridriksson1, Rajeev K. Dubey1, Wolter F. Jager1 and Ward van der Stam2;1, Delft University of Technology, Netherlands; 2University of Utrecht, Netherlands

Two-dimensional perovskites are an emerging new class of materials with potential application in a broad range of opto-electronic devices. These materials are formed by layers of inorganic metal-halide octahedrals separated by large organic cations. The organic cations improve the stability and give a large freedom to tune the opto-electronic properties. However, the organic cations used so far act only as a dielectric non-conductive layer that contributes to the large exciton binding energy of these materials. This large binding energy limits their application in opto-electronic devices in which efficient charge carrier separation is required (such as solar cells, photo-detectors and photo-catalysts). In order to achieve charge separation, we consider the replacement of non-functional organic cations by a strongly electron accepting moiety.

We have explored the introduction of functional organic chromophores theoretically by density functional theory calculations and show that it is possible to introduce conjugated molecules that have a significant effect on the electronic structure. Strong electron acceptors or donors lead to conduction band or valence band edges that are localized on the organic part of the materials. This could lead to enhanced charge separation.

To test this idea experimentally we have introduced strongly electron accepting perylene diimide (PDI) molecules in 2D CsPbBr3 nanoplatelets as a model system for 2D perovskites. We show by ultrafast transient absorption and fluorescence that photoexcitation of these perovskite nanoplatelet:PDI conjugates leads to fast quenching of the fluorescence, fast decay of the bleach of the nanoplatelets and the appearance of a photoinduced absorption feature specific for the PDI anion. This latter feature unequivocally shows that the fluorescence quenching is due to electron transfer to the PDI molecules. Finally, we show by time-resolved microwave conductivity (TRMC) measurements that this charge transfer leads to long-lived hole conduction (tens of microseconds) in the two-dimensional perovskite nanoplatelets. This opens up a new synergistic approach, where the properties of two-dimensional perovskites can be tuned for specific device applications by introduction of strong functional dyes in the organic component of the material.

Multi-Modal Techniques Linking Carrier Behavior with Material Properties in Halide Perovskites Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites are generating enormous excitement for their use in high-performance yet inexpensive optoelectronic applications. Nevertheless, a number of fundamental questions about these materials still remain and need to be answered to push devices to their theoretical performance limits. For example, we still know very little about the specific nature of the defects leading to trap states, carrier recombination pathways or anisotropies of carrier diffusion.

In this talk, I will present a number of new techniques we are developing to try to address these open questions in 2D and 3D halide perovskite semiconductors. These techniques focus on understanding charge carrier behavior, including recombination, trapping and diffusion, and how these properties link to chemical and material properties. I will present a high-resolution luminescence microscopy technique employing two-photon excitation to allow us to visualize and time-resolve carrier diffusion in three-dimensions, revealing anisotropic and depth-dependent carrier diffusion properties. Furthermore, we link the local luminescence properties to high-resolution crystallographic and chemical properties using synchrotron nano-probe X-Ray beamlines and low-dose scanning electron diffraction measurements. Through these measurements, we start to reveal the nature of the defects associated with local non-radiative power losses and heterogeneous diffusion and provide guidelines about how we can ultimately eliminate these unwanted loss pathways and homogenize carrier diffusion.
Excitons and Polaron in Hybrid Perovskite

Paulina Plochocka; LNCMI, France

Organic and inorganic metal halide perovskites have emerged in recent years as revolutionary semiconductor materials for lighting and energy harvesting applications. Many of their fascinating properties originate from the fact that metal-halide perovskites should be classed as crystalline liquids rather than hard semiconductor materials. In this talk I will discuss excitons and polaron in perovskites.

I will start by describing the exciton fine structure splitting in semiconductors, which reflects the underlying symmetry of the crystal and quantum confinement. Since the latter factor strongly enhances the exchange interaction, most work has focused on nanostructures. Here, we report on the first observation of the bright exciton structure splitting in a bulk semiconductor crystal, where the impact of quantum confinement can be specially excluded, giving access to the intrinsic properties of the material. Detailed investigation of the exciton photoluminescence and reflection spectra of a bulk methylammonium lead tribromide single crystal reveals a zero magnetic field splitting as large as 200 µeV. The observed splitting can be understood in the exciton picture combined with symmetry considerations.

Next I will discuss the formation of the polaron, which is the result of the exciton – phonon coupling. The polaron formation is made in evidence by observation of the exciton effective mass enhancement. In the end I will describe some optical properties of a very new system: hollow perovskites, which exhibit optical properties of the excitons in 3D and quantum confinement regime.

On the Relation between Photoluminescence Quantum Efficiency, Minority Carrier Lifetime and Quasi-Fermi Level Splitting in Perovskite Solar Cells

Thomas Unold1, Martin Stolterfoht2, Christian Wolff2, Pietro Caprioglio2, Jose Marquez Prieto3, Dieter Neher2 and Thomas Kirchartz3; 1Helmholtz-Zentrum Berlin, Germany; 2University Potsdam, Germany; 3Forschungszentrum Juelich GmbH, Germany

The open-circuit voltage ($V_{OC}$) is currently considered to be the main limitation on the path to approach the radiative (Shockley-Queisser) efficiency limit in hybrid perovskite-type solar cells. The $V_{OC}$ is determined by recombination processes in the solar cell including bulk, interface and/or contact recombination.[1] Under ideal conditions the open-circuit voltage approaches the internal quasi-Fermi level splitting (QFLS), which may be estimated by measuring the external photoluminescence quantum yield (PLQY) and the absorption properties.[2] The PLQY and quasi-Fermi level splitting can also be estimated through time-resolved photoluminescence (TRPL) measurements, if the radiative recombination constants and photon recycling are taken into account properly.[3] A survey of the literature shows that the reported PLQY values for given open-circuit voltages sometimes vary by orders of magnitude which is difficult to reconcile from a theoretical perspective. In this contribution, we show that careful consideration of the above points leads to a consistent picture of the interrelation between the QFLS, PLQY and TRPL lifetime. Finally we discuss possible sources of error in the analysis and how to cross-check data.

How Charge Carrier Transport through Ferroelastic Twin Boundaries in Halide Perovskite?

Xun Xiao1, Wenhao Li2, Yanjun Fang3, Rashid Zia1 and Jinsong Huang1,3; 1University of North Carolina at Chapel Hill, United States; 2Brown University, United States; 3University of Nebraska–Lincoln, United States

Grain boundaries (GBs) have been established to play a vital role in determining the power conversion efficiency of organic-inorganic halide perovskite (OIHP) thin film solar cells. As a special category of GBs, ferroelastic twin boundaries (TBs) are recently discovered to exist in both CH$_3$NH$_3$PbI$_3$ thin films and single crystals (SCs), however their impact on the carrier transport and recombination in OIHP materials remains unexplored. Here, using the
scanning photocurrent microscopy, we have demonstrated the uniform distribution of electric field across the TBs in OIHP SCs as long as the influence of the crystal surface is well suppressed through surface passivation, suggesting that the TBs have little influence on the carrier transport across them. Also, the photoluminescence (PL) imaging and the spatial-resolved PL intensity and lifetime results confirm the electronic benign nature of the TBs, in strong contrast to regular GBs that will block the carrier transport and also behave as the non-radiative recombination centers. Our observations reveal the fundamentally different role of TBs and GBs played in carrier transport of OIHP materials, which will provide insights into the performance improvement of the OIHP based optoelectronic devices.

9:45 AM EN09.04.06
Exploiting Localized Charge Accumulation in Alloyed Perovskites for Highly Efficient Luminescence Sascha Feldmann1, Stuart Macpherson1, Satyaprasad P. Senanayak1, Mojtaba Abdi-Jalebi1, Jasmine P. Rivett1, Guangjun Nan2, Richard Ciesielksi3, Achim Hartschuh3, Emilie Ringe1, Richard H. Friend1, Henning Sirringhaus1, Michael Saliba4, David Beljonne5, Samuel D. Stranks1 and Felix Deschler1; 1University of Cambridge, United Kingdom; 2Department of Physics, China; 3Ludwigs-Maximilian-Universität München, Germany; 4University of Fribourg, Switzerland; 5Université de Mons, Belgium

Metal-halide perovskites have emerged as excellent solution-processable semiconductors for optoelectronic applications such as solar cells and light-emitting devices. Substitution of the monovalent cations has advanced luminescence yields and device efficiencies. Here, we control the cation alloying to push optoelectronic performance through alteration of the charge carrier dynamics in mixed-halide perovskites. In contrast to single-halide perovskites, we find high luminescence yields for photo-excited carrier densities far below solar illumination conditions. Using time-resolved spectroscopy we show that the charge-carrier recombination regime changes from second to first order within the first tens of nanoseconds after excitation in these films. Supported by temperature-dependent microscale-mapping of the optical bandgap and chemical composition, electrically-gated transport measurements and first-principles calculations, we demonstrate that spatially-varying energetic disorder in the electronic states causes local charge accumulation, creating photo-doped regions, which unearths a strategy for efficient light emission at low charge-injection in solar cells and LEDs.

Perovskite Solar Cells—Improving Device Efficiency and Stability and Understanding Optoelectronic Processes Henry J. Snaith and Yen-Hung Lin; University of Oxford, United Kingdom

Perovskite solar cells continue to gain momentum in research and gain in efficiency, and multijunction perovskite solar cells offer a roadmap to performance levels well beyond that possible with single junction silicon or other thin-film technologies. Operational stability is an area which is critical for any PV technology, and even more so for perovskites, which are dissimilar to conventional semiconductors in a number of ways. I will present different approaches we have adopted to improving the efficiency, and fundamental stability of the perovskite absorber materials and devices, and highlight degradations which can occur in the bulk of the perovskite absorber materials and induced by the charge extraction heterojunction. I will give further insight into what factors influence stability, and how to mitigate degradation. Beyond stability, I will highlight how moving from a single absorber layer, to a multijunction cell should lead to much higher efficiencies, and I will show experimental realisation of progress along such a roadmap, including record perovskite-on-silicon PV cells. Beyond research, I will highlight our progress towards manufacturing scale-up through the technology company, Oxford PV Ltd., and key challenges which need to be overcome to deliver an industrialised perovskite PV technology.

Strong Light-Matter Interactions in Hybrid Perovskites Madeleine Laitz1, Dane W. deQuilettes1, Jude Deschamps1, Roberto Brenes1, Inés García Benito2, Giulia Grancini2, Keith A. Nelson1 and Vladimir Bulovic1; 1Massachusetts Institute of Technology, United States; 2École Polytechnique Fédérale de Lausanne, Switzerland
State-of-the-art perovskite materials demonstrate photoluminescence quantum efficiencies (PLQE) above 90% due to low non-radiative recombination rates and unparalleled defect tolerance. The optoelectronic properties that have allowed perovskites to emerge as a leading active layer material in high efficiency thin film photovoltaics (PVs) – high absorption coefficient, high PLQE, solution processability, chemical tunability – simultaneously situate perovskites to function superbly as a coherent quantum material. In this work, we explore perovskites as a platform for strong light-matter coupling to sustain all-optical operations. Though light is weakly interacting, it is possible to form interacting quasi-particles, called exciton-polaritons, that have characteristics of both light and matter. Traditionally, polaritons have been studied at cryogenic temperatures in all-inorganic semiconducting materials (e.g. GaAs heterostructures). In this work, we study the room-temperature formation of exciton-polaritons with large Rabi splittings in semiconductor microcavities, using solution-processed 2D perovskites as self-assembled quasi-quantum well structures for the active layer. Polariton formation is probed by angle resolved reflectivity and photoluminescence measurements through a k-space imaging setup. The polariton-polariton interaction strength is explored by the confinement of photo-generated exciton-polaritons via modifications to the potential environment of the microcavity, presenting opportunities to study room-temperature Bose-Einstein condensation. The realization of facilely-fabricated room-temperature exciton-polaritons has the potential to revolutionize a wide range of devices, from PVs to low-threshold lasers to all-optical switches.

Free-Electron Screening and Mahan Excitons in MAPbI₃ from First Principles Theoretical Spectroscopy
Joshua A. Leveillee and Andre Schleife; University of Illinois at Urbana-Champ, United States

An unusual combination of low exciton binding energy and strong optical absorption renders hybrid organic-inorganic perovskites interesting candidates for efficient absorber materials in next-generation solar cells. This interesting behavior triggered numerous studies to better understand excitonic effects, e.g. in MAPbI₃. In experiment, exciton binding energies in this material range from as high as 62 meV to as low as 2 meV. At the same time, a line shape of the absorption edge similar to that of GaAs was reported, with no clear excitonic peak and a binding energy potentially less than 10 meV at room temperature. In contrast, cutting-edge first-principles simulations based on the Bethe-Salpeter framework seem to consistently overestimate exciton binding energies.

In this work, we use density-functional and many-body perturbation theory to study atomic geometries, electronic structure, and optical properties of MAPbI₃ and find good agreement with earlier results and experiment. Electronic band structures and gaps are predicted using Hedin’s $GW$ approximation, including the spin-orbit interaction. We account for free electrons within our first-principles theoretical spectroscopy and specifically study their impact on the electron-hole interaction. This allows us to conclude that additional screening due to free electrons can explain consistently smaller exciton binding energies, compared to those in the material without free electrons. Furthermore, we also observe that the absorption line shape in MAPbI₃ with free electrons strongly resembles that of the spectrum without free electrons up to high free-electron concentrations. Interestingly, our simulations show that this unexpected behavior can be explained by formation of Mahan excitons. These dominate the absorption edge and we show that this makes this material robust against free-electron induced changes of the optical absorption that are observed in other semiconductors.

Illuminating Charge Transfer at the Interfaces of Perovskite Solar Cells
Robert J. Westbrook¹,², Weidong Xu¹, Tracey Clarke², James R. Durrant¹ and Saif Haque¹; ¹Imperial College London, United Kingdom; ²University College London, United Kingdom

Perovskite solar cells (PSCs) have set themselves apart from their dye-sensitized (DSSC) and organic (OSC) predecessors, with impressive efficiencies at 24%. Despite the key role that charge transport layers (CTLs) have played in this success, researchers are still debating the importance of parameters that govern charge transfer at the PSC interfaces, namely: (i) the interfacial energy offset, $\Delta E$ between the perovskite and CTL; (ii) CTL structure; and (iii) intrinsic perovskite properties.

This talk will detail our progress in developing a complete picture of electron/hole transfer at PSC interfaces using a combination of time-resolved spectroscopy and device work.² Specifically, we will first outline our observation of highly efficient (>75%), nanosecond charge transfer to CTLs at remarkably low values of $\Delta E$ (<0.1 eV). We will also show that careful selection of CTLs with electron-donating functional groups can slow interfacial recombination by passivating surface traps, as has been previously observed with Lewis bases, inert polymers and
other molecules. Remarkably, the resulting coordination between the perovskite and CTL produces a 3-fold enhancement in charge transfer yield. Finally, we will discuss the impact of such passivation on device stability. This novel insight into the charge separation mechanism in PSCs goes some way to explaining the success of triarylamines (e.g., PTAA, PTPD) as HTLs in such systems and has important implications for the design of next-generation CTLs.

The Evolution of Ultrafast Carrier Dynamics In Situ Perovskite Optoelectronic Devices Kanishka Kobbekaduwa1, Exian Liu1, Pan P. Adhikari1, Yuanyuan Zhou2, Wanyi Nie3, Kai Zhu4 and Jianbo Gao1; 1Clemson University, United States; 2Brown University, United States; 3Los Alamos National Laboratory, United States; 4National Renewable Energy Laboratory, United States

Although significant progresses have been made toward to optoelectronics application including solar cells, large color gamut LEDs, photodetectors, and X-ray detectors, the fundamental understanding of ultrafast carrier dynamics of organic-inorganic perovskite materials remains unclear. The ultrafast dynamics, which reveals some novel physical phenomena such as hot carrier cooling, phonon bottle-neck effect was widely studied by ultrafast optical spectroscopies, which include pump-probe transient absorption (transmission, reflection, time-resolved THz, optical Kerr effect, and the most popular time-resolved photoluminescence (TRPL). However, it remains a challenge to study the perovskite optoelectronic devices in-situ in an ultrafast fashion.

In this talk, we use an ultrafast photocurrent spectroscopy with sub-25 picosecond time resolution to reveal the evolution of ultrafast carrier dynamics from sub-25 ps to microsecond in-situ perovskite solar cells and photoconductors. We address the basic questions of carrier photogeneration, recombination, transport, trapping, in addition to directly extracting carrier mobility, lifetime, and the property of trap states such as density, energy level, and capture cross-section.

SESSION EN09.05/EN08.05: Joint Session: Perovskite Solar Cell—A 10-Year Anniversary
Session Chairs: Shengzhong (Frank) Liu and Philip Schulz

Prospects of Perovskite PV Research Based on All-Inorganic Absorbers and New Dopant-Free Carrier Transporters Tsutomu Miyasaka; Toin University of Yokohama, Japan

This year, we are celebrating 10 years of perovskite solar cell (PSC). Since our first discovery of PSC in 2009, enormous efforts have been put into different aspects of PSCs and the progress has been incredibly fast on all fronts. While preparing a comprehensive review1 on the background, on-going R&Ds, and future direction of PSC research recently, we realized that, although efficiency level has gone beyond 24%, PSCs face serious challenges of practical stability and durability required for industrialization. Although compositional engineering of perovskites by mixing different cations and anions, using modulator molecules and mixing 2D and 3D structures have doubtlessly improved the stability of perovskites against heat and moisture, use of organic moieties still remain a challenge to improve the stability further. Intrinsic stability of the perovskite crystal structure and robust properties of carrier transport materials are going to be the keys to the long term durability of the device. In this respect, use of all-inorganic perovskite materials and combination with dopant-free carrier transport materials are highly desired. We have conducted some work in this direction which includes stabilization of CsPbI3 black phase 2 and use of dopant-
free hole transport materials (HTMs). Dopant-free HTMs combined with all-inorganic perovskites have yielded sufficiently high efficiency of 15%. Intrinsic thermal stability of the device was improved without using diffusible dopants. In our collaboration with JAXA, stability of perovskites was investigated in space environment for satellite applications. Here, organic cations in perovskite such as methyl ammonium are instable under exposure to vacuum and high temperatures >100°C. Perovskite materials demonstrate its high stability against exposure to high energy particle radiations (proton and electron beams) up to dose of $10^{15}$ particles/cm$^2$ due to use of thin absorber films that can avoid accumulation of particles and also exhibit defect tolerant nature. The lecture will also introduce our current efforts in making PSCs based on both lead and lead-free perovskites, and future perspectives of perovskite photovoltaics.

Stabilizing Halide Perovskites—Self-Repair, Defects and Sealing David Cahen$^{1,2}$; $^1$Weizmann Institute of Science, Israel; $^2$Bar-Ilan University, Israel

Halide Perovskites (HaPs) present a remarkable case of just stable (against decompositon into binaries) compounds that can function as active component for PV, light-emission and radiation detection, all demanding functions, over time periods that seem incompatible with their free energy of formation (again, from the binaries). Actually, the Achilles heel of the materials is their surface, true to Pauli's famous dictum, because of the law of mass-action: as long as the system remains a hermetically close one, it can withstand the onslaught of electronic carriers and photons. Add to that that it are to a large extent the interfaces that make the devices function (again following a famous dictum, this time from Kroemer) and.. those are made with surfaces. Thus, what might appear esoteric materials chemistry and physics issues, are highly relevant for device design. In principle, apart from the remarkable self-healing ability (known to some extent also for CIGS) this is not new as nearly every (inorganic) semiconductor material that we use today went through the process of taming its surfaces to get control over interfaces made with them. In this talk I will, depending on developments in the half year between abstract writing and presentation, present data on the self-healing and (de)stabilization processes of HaPs and put their behaviour in perspective with respect to some other semiconductors, to arrive at insights that should be useful to device design and building.

Molecular Dopants on Metal Halide Perovskite Surfaces—What Do We Learn? Antoine Kahn, Fengyu Zhang, Scott Silver, Joseph C. Hamill, Nakita K. Noel, Barry P. Rand and Lynn Loo; Princeton University, United States

Surfaces of metal halide perovskites (MHP) present an interesting set of questions and challenges that are only beginning to be addressed, namely the existence, origin, density and energy of electronic surface gap states. MHP surfaces are prone to ion diffusion and chemical reactions, and to degradation under various environmental conditions and probing tools, all of which likely induce some density of electronic gap states. In sufficient density, these states affect the electronic structure and optoelectronic performance of all MHP interfaces and devices. There is currently no consensus on potential profile and occurence of band bending in perovskite films, from substrate to surface. Available data point to a strong dependence of these profile on the nature and surface potential of the substrate on which the films are fabricated, and on the perovskite processing conditions. Limits in Fermi level excursion have been observed and also point to some low density of (surface or bulk) gap states.[1] To address some of these issues, several groups have started to use organic molecular dopants (reductants and oxidants), as “gentle” probes of the electronic occupation and density of surface states, and as modifier agents of these states. [2,3] This talk describes our recent investigations of the interaction between molecular reductants (mostly [RuCp*Mes]$_2$) and oxidants (Mo(tfd)$_3$ and derivatives) and surfaces of 3D MHPs CsPbBr$_3$ and FA$_x$MA$_{1-x}$Pb(I$_y$Br$_{1-y}$)$_{3}$, and the 2D Ruddlesden-Popper phase BA$_2$PbI$_4$. Using a combination of electron spectroscopies and contact potential measurements, we determine the sign and magnitude of surface photovoltage occurring at these free surfaces, and the extent of surface energy level shifts resulting from charge exchange with the molecular dopants. We also show evidence obtained via photoemission spectroscopy of a density of (surface) filled states above the valence band maximum of FAPbBr$_3$ following electron bombardment, and of MAPbI$_3$, likely due to the presence of DMSO in the precursor solution. The role of surface doping in changing the occupation of these states will be discussed.
Semiconducting metal-halide perovskites present various types of chemical interactions which give them a characteristic fluctuating structure sensitive to the operating conditions of the device, to which they adjust. This makes the control of structure-properties relationship, especially at interfaces where the device realizes its function, the crucial step in order to control devices operation. In particular, given their simple processability at relatively low temperature, one can expect an intrinsic level of structural/chemical disorder of the semiconductor which results in the formation of defects.

Here, first I will summarize our understanding of the nature of defects and their photo-chemistry, which leverages on the cooperative action of density functional theory investigations and accurate experimental design. Then, I will show the correlation between the nature of defects and the observed semiconductor instabilities. Instabilities are manifested as light-induced ion migration and segregation, eventually leading to material degradation under prolonged exposure to light. Understanding, controlling and eventually blocking such material instabilities are fundamental steps towards large scale exploitation of perovskite in optoelectronic devices. By combining photoluminescence measurements under controlled conditions with ab initio simulations we identify photo-instabilities related to competing light-induced formation and annihilation of trap states, disclosing their characteristic length and time scales and the factors responsible for both processes. We show that short range/short time defect annihilation can prevail over defect formation, happening on longer scales, when effectively blocking undercoordinated surface sites, which act as a defect reservoir. Finally, based on such knowledge, I will discuss different synthetic and passivation strategies which are able to stabilize the perovskite layer towards such photo-induced instabilities, leading to improved optoelectronic material quality and enhanced photo-stability in a working solar cell.

The surface of hybrid perovskites plays a crucial role in the performance and stability of optoelectronic devices, as it strongly influences the recombination rate of excited charge carriers. Recently, it has been reported that molecular ligands such as benzylamine are capable of significantly reducing the surface trap state density in thin films. Here I will report on the mechanism that governs the surface passivation of hybrid perovskites by benzylamine. To this end, we developed a versatile approach to investigate the influence of benzylamine passivation on the well-defined crystal surface of freshly cleaved methylammonium lead tribromide single crystals. We show that benzylamine is capable of permanently passivating surface trap states in these single crystals, resulting in enhanced photoluminescence intensities and charge carrier lifetimes. Additionally, we show that exposure of the perovskite surface to benzylamine leads to replacement of the methylammonium cations by benzylammonium, thereby creating a thermodynamically more stable two-dimensional perovskite $(BA)2PbBr4$ on the surface of the 3D crystal. This conversion from a 3D to 2D perovskite drives an anisotropic etching of the crystal surface, with the $\{100\}$ planes being most prone to etching.

The Photo-Responsive Transfer Property of Perovskite Materials  
Weili Yu; Chinese Academy of Sciences (CAS), China

The fields of photovoltaics, photodetection and light emission have seen tremendous activity in recent years with the advent of hybrid organic-inorganic perovskites. Yet, there have been far fewer reports on the photo-responsive transfer property of perovskite materials. The lateral and interfacial transport requirements of transistors make them particularly vulnerable to surface contamination and defects rife in polycrystalline films and bulk single crystals. Here, we demonstrate a spatially-confined inverse temperature crystallization strategy which synthesizes micrometre-thin single crystals of organometal trihalide perovskite with sub-nanometer surface roughness and very low surface contamination. The photo-responsive transfer property of perovskite materials were investigated and record, room-temperature field-effect mobility in both p and n channel devices were reported, with $10^4$ to $10^5$ on-off ratio and low turn-on voltages. This work paves the way for integrating hybrid perovskite crystals into printed, flexible and transparent electronics.

Tailoring Vertical Phase Distribution for High Open-Circuit Voltage and Performance in Quasi Two-Dimensional Perovskite Solar Cells  
Tiefeng Liu and Yinhua Zhou; Huazhong University of Science & Technology, China

Organic-inorganic hybrid perovskites ABX₃ have emerged as revolutionary solar absorbers with power conversion efficiencies rapidly increasing from 3.8% in 2009 to 24.2%. However, perovskite solar cells suffer from poor long-term stability, especially the moisture. Hydrophobic cations such as aliphatic alkylammonium and aromatic alkylammonium have been used to improve the resistivity to moisture, leading to the formation of the quasi 2-dimensional perovskites (A₁)₂(A₂)ₙ₋₁B₂X₃n+1 (where A₁ is large-size bulky organic cation and A₂ is Cs, methylammonium or formamidinium).

Different from their 3D counterparts, previous reports have shown that the fabricated quasi-2D perovskite films are actually a mixture of multiple perovskite phases with different n values instead of a homogeneous perovskite phase with an identical n value. These multiple phases are arranged spontaneously along the direction perpendicular to the substrate from small-n to large-n (from substrate side to the top surface of films). Vertical phase distribution plays an important role in the quasi-2D perovskite solar cells. So far, the driving force and how to tailor the vertical distribution of layer number (n) have been not discussed.

In this work, we report that the vertical distribution of n in the quasi-2D perovskite films deposited on PEDOT:PSS is different from that on glass substrate. The vertical distribution of n could be explained by the sedimentation equilibrium because of the colloidal feature of the perovskite precursors. But the addition of acid will change the precursors from the colloid to solution that therefore changes the vertical distribution. A self-assembly layer of 4-bromobenzenediazonium tetrafluoroborate covalently anchored onto the PEDOT:PSS induces the appearance of desired vertical distribution. The quasi-2D perovskite solar cells (n = 4) with the surface anchoring layer display a higher open-circuit voltage of 1.11 V and a higher efficiency of 13.74% comparing to the reference quasi-2D perovskite cells. The enhanced performance is attributed to the faster charge transport and lower trap densities.

EN09.06.03  
Oriented Attachment as the Mechanism for Microstructure Evolution in Chloride-Derived Hybrid Perovskite
**Thin Films with Enhanced Photovoltaic Performance** Wen Liang Tan¹, Yen Yee Choo¹, Wenchao Huang¹, Xuechen Jiao¹, Jian-feng Lu¹, Yi-Bing Cheng¹,² and Chris McNeill¹; ¹Monash University, Australia; ²Wuhan University of Technology, China

Hybrid organic-inorganic perovskites with appealing opto-electronic properties have attracted significant interest for photovoltaic application. The use of chloride (Cl⁻)-containing precursor species to induce improved perovskite thin-film microstructure and improved optoelectronic properties is well-established. However, the mechanism for the formation of perovskite films with highly textured, micron-sized grains in the presence of Cl⁻ remains elusive. Using synchrotron-based, in situ two-dimensional grazing incidence wide-angle X-ray scattering (GIWAXS) complemented by scanning electron microscopy (SEM) imaging, we present an oriented attachment mechanism via mineral bridge formation for the microstructural evolution of chloride-derived perovskite films. We have identified the crucial role of the oriented chlorine-containing intermediate phase as the mineral bridge, which templates the reorientation of primary, nanoscale perovskite grains followed by fusion into a uniaxial oriented monolithic grain. The resulting perovskite films exhibit micron-sized grains with preferential orientation of the tetragonal (110) direction perpendicular to the substrate with improved solar cell efficiency. Further device physics analysis also shows that highly textured perovskite films exhibit improved charge transport across the interface between the perovskite (110) crystal facet and charge transporting layers (CTLs). Our findings pave the way for rational microstructural design of chloride-derived perovskite films and highlight control of perovskite grain orientation for further exploration of the relationship between perovskite thin film microstructure and photovoltaic properties.

**Simple Method to Screen New Hole Transport Materials with Organic Small Molecules for Perovskite Solar Cell Application by First Principles** Eunhwan Jung, Feray Uenlue, Alexander Moellmann, Heechae Choi and Sanjay Mathur; University of Cologne, Germany

Perovskite solar cells (PSCs) have attracted considerable attention due to their outstanding power conversion efficiency (PCE) as high as 24.2%. A conventional PSC consists of electrode, hole transport material (HTM), electron transport material (ETM), and a conductive substrate. HTMs, among them are of importance component for high performance PSCs due to their efficient hole extraction, transportation, and blocking the electron transfer to the electrode. The major concern for HTMs is the materials used, especially spiro-OMeTAD which may be prone to degradation. Therefore, developing novel HTMs to replace spiro-OMeTAD is required to enhance the stability and efficiency of PSCs. Here, we present DFT calculations combined with the Marcus theory to investigate the electronic and charge transport properties of porphyrin-based HTMs and device performance containing these materials. Based on the calculated highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy level of reference molecules, we screened molecules which can be suitable alternatives to spiro-OMeTAD. Among them, tetraphenylporphyrin (TPP) shows the most promising properties which are relatively low HOMO and high LUMO energy level that facilitate comparably high open-circuit voltage and low reorganization energy and high transfer integral ensuring high hole mobility. TPP was synthesized and utilized as a HTM in solar cell device. Interestingly, the PCE of TPP was shown to be comparable to that of spiro-OMeTAD. Here we proposed new strategy to develop novel organic small molecules as HTMs by DFT calculation for stable and efficient PSCs and showed TPP may become one of promising alternatives to spiro-OMeTAD.

**EN09.06.05**

**Relationship between the Nature of Monovalent Cations and Charge Recombination in Metal Halide Perovskites** Katelyn Dagnall¹, Benjamin J. Foley¹, Joshua Choi¹ and YingZhong Ma²; ¹University of Virginia, United States; ²Oak Ridge National Laboratory, United States

In this study, the effect of the monovalent cation on monomolecular and bimolecular recombination rate constants in halide perovskites (HaPs) was investigated. Based on ultrafast optical measurements on HaP thin films with consistent morphology and trap site densities, our results reveal a key insight: the monovalent cation plays a different role in monomolecular and bimolecular recombination mechanisms; indicating that this remarkably customizable optoelectronic material may be more tunable than previously thought.

**EN09.06.06**

**Understanding Methylamine-Induced Phase Transitions in Hybrid Perovskites and Their Impact on Film Quality and Composition** Jonathan K. Meyers, Lorenzo Serafin and James F. Cahoon; University of North
Lead halide perovskites (LHPs) continue to rise with promise for efficient optoelectronic applications including photovoltaics. A wide variety of deposition techniques and treatments have been developed for LHPs with the goal of improving crystallization and thus efficiency and stability. Of particular interest to us is the exposure of perovskite films to methylamine gas. Such treatment has been shown to liquefy the film and dramatically decrease grain boundary defects in the treated film, especially at elevated temperatures. To better understand this reaction, we applied in-situ UV-visible spectrophotometry in controlled conditions of temperature and methylamine gas pressure to obtain a quantitative phase diagram highlighting solid, solid intermediate, and liquid phases. In this presentation, we discuss the impact of forcing crystallization along paths through this phase diagram in a unique system with no foreign solvent. Additionally we stress the importance of the liquid-substrate interaction as evidenced by contact angles measured between liquid perovskite and various substrates. Lastly, we extend these findings and methods to the two-dimensional system of butylammonium lead iodide and demonstrate controllable partial conversion. These insights may lead to more rational tuning of crystal quality, grain size, and hybrid 3D/2D properties.

EN09.06.07
Defect Tolerance in All-Inorganic Halide Perovskite PV Materials Chen Ming and Yi-Yang Sun; Shanghai Institute of Ceramics, Chinese Academy of Sciences, China

The success of halide perovskites has often been attributed to their defect tolerance. While there have been a number of studies showing that intrinsic defects in organic-inorganic hybrid halide perovskites tend to exhibit shallow defect levels only, whether such a conclusion can be extended to pure inorganic perovskite semiconductors is still an open question. In particular, in the past several months, pure inorganic perovskite solar cells have been demonstrated to achieve appealing efficiency (~17%). In this work, we systematically investigate the intrinsic defects in representative halide perovskites. We will present the results obtained with hybrid density functional including spin-orbital coupling (SOC) effect using large supercells with an aim of concluding the existence of defect tolerance based on the state-of-the-art computational technique. Several possible origins of the defect tolerance, including the SOC, the unusual bonding nature of the band edge states and the competition between ionicity and covalency will be discussed.

EN09.06.08
Pressure-Induced Crystallization of Halide Perovskites for High-Performance Photodetector Do Hyung Chun and Jong Hyeok Park; Yonsei University, Seoul, Korea (the Republic of)

Thanks to numerous studies focusing on enhancing performances of organic-inorganic halide perovskite (OIHP)-based photoelectronic devices, the impressive improvements have been reported. Representatively, since the emergence of OIHP-based photovoltaics in 2012, the powerconversion efficiency (PCE) of OIHP-based photovoltaics exceeds 24% nowadays. As strategies to enhance performance, compositional, interfacial engineering and developing novel deposition methods are utilized. However, as growth in the PCE has stagnated by 20%, another method is required for tuning intrinsic properties of OIHPs to ultimately overcome the hurdles, which block the way toward commercialization.

In this work, we suggest pressure-induced crystallization process as a technique for improving performance of OIHP-based photoelectronic devices by engineering intrinsic properties of OIHPs. As high-quality OIHP films can be fabricated with annealing anti-solvent washed intermediate-state, we exerted pressure during crystallization process with nanostructured polymer molds. By pressing OIHP films during annealing, nanostructures of OIHP films are controlled. By pressing the pre-crystallized film with intaglio nanohole-arrayed polyurethaneacrylate (PUA) molds, nanopillar structure emerges on the surface of OIHP films. Because of the aligned surficial nanostructure of OIHP films, light scattering effect was observed on the surface of OIHP films, which are induced by photonic crystal effect. Also, nanopillar arrays were clearly observed with scanning electron microscopic (SEM) and atomic force microscopic (AFM) images.

With nanopillar-structured OIH films, we developed 2-terminal photoconductors to confirm improved photoelectronic characteristics after the process. Firstly, we measured current-voltage (I-V) characteristics of devices employing OIH films, which exhibited increased photocurrent and decreased dark current and responsivity and detectivity are enhanced by an order. Furthermore, motivated by the fact that pressure-induced crystallization process contributes to improve OIH film quality, we analyzed trap-density and electrical properties with conductive AFM (c-AFM) and revealed that trap-density of film was reduced and electrical conductivity was
significantly enhanced. In conclusion, we fabricated a nanopillar structure on the surface of OIHP film through applying simple soft imprinting technology and confirmed the advantages of the process by investigating photophysical properties of films. Considering that the process we suggested can be conducted with low cost and high reproducibility, the pressure-induced crystallization process can be a promising solution that can overcoming recent stagnation in terms of OIHP-based device performance.

EN09.06.09
Fabrication of Cesium Lead Bromide Thick Films with Closely-Packed Columnar Crystals and High Carrier Mobility by Using a Mist Deposition Method Yuki Haruta, Takumi Ikenoue, Masao Miyake and Tetsuji Hirato; Kyoto University, Japan

X-ray imaging is an important technique used for medical imaging and the nondestructive inspection of industrial products. Highly sensitive X-ray detectors which enable X-ray imaging at low dose are strongly required to reduce the risk of cancer. Lead halide perovskites (APbX₃; A = CH₃NH₃⁺, Cs⁺, X = Br⁻, I⁻) are promising candidates for X-ray detectors due to their excellent physical properties including high absorption coefficients, high carrier mobility, and long carrier diffusion length. Y. C. Kim et al.[1] achieved CH₃NH₃PbI₃-based X-ray imaging devices with the high sensitivity of up to 11 μC mGy⁻¹ cm⁻² which is at least ten times as high as the sensitivities achieved with currently used amorphous selenium or thallium-doped cesium iodide detectors. W. Wei et al.[2] reported Si-integrated CH₃NH₃PbBr₃ single crystals for highly sensitive X-ray imaging with the sensitivity of 25 μC mGy⁻¹ cm⁻². The biggest problem of organic-inorganic hybrid perovskites, which is partly composed of an organic cation such as CH₃NH₃⁺, is instability to heat and moisture. To solve this problem, replacing the organic cation by Cs⁺ has been proposed[3]. For X-ray imaging, fabrication of thick CsPbBr₃ films over a large area is required. However, previous methods such as spin-coating are not applicable to the fabrication of CsPbBr₃ films with the thickness of more than 10 μm. Therefore, we are working on the fabrication of thick CsPbBr₃ films by using a mist deposition method. This method is good at large-area film fabrication[4]. In addition, this method seems to have potentials for the increase of film thickness by repeating fabrication process because a precursor solution is atomized and the mist is injected to the pre-heated underlying film, resulting in fast solvent-evaporation and the growth of the film without remarkable dissolution damages.

In this conference, we report the fabrication of thick CsPbBr₃ films with the thickness of 100 μm. The influence of substrate temperature and deposition rate on the orientation of CsPbBr₃ films were mainly investigated. At optimized fabrication conditions, the obtained CsPbBr₃ thick films were composed of columnar crystals and had high carrier mobility of 28 cm² V⁻¹ s⁻¹, which is comparable to that for single crystals.

EN09.06.10
The Role of the Substrate in Perovskite Precursor Thermal Evaporation Deposition Benjamin Ecker, Ke Wang and Yongli Gao; University of Rochester, United States

The energy level alignment that occurs at the interfaces in planar-hetero structured perovskite photovoltaic devices strongly influences the charge transport across the interface, and thus plays a crucial role in overall device performance. To directly observe the energy level alignment requires pristine homogeneous surfaces that are free of contamination including adventitious carbon. Coevaporation offers the ability grow perovskite thin films insitu, and the method involves thermally evaporating the perovskite precursors such as PbI₂ and CH₃NH₃I. Some early reports have shown that the perovskite film formation and stoichiometry are problematic at ultralow coverages when the film is just starting to form, often times it was reported that there was excess PbI₂ and a deficiency in CH₃NH₃I. Using photoemission spectroscopy, we investigated the perovskite precursors PbI₂ and CH₃NH₃I on gold and highly oriented pyrolytic graphite (HOPG) surfaces. Results show that the nature of the surface and the deposition conditions can strongly influence the film formation. Excessive iodine observed in the initial evaporation stages appears to be substrate dependent, and this may influence the overall energy level alignment.

EN09.06.11
Experimental and Computational Investigation of Sulfur-donor Solvents for Hybrid Organic-Inorganic
Perovskite Processing Oluwaseun Romiluyi; Johns Hopkins University, United States

The ability to be processed in solution, provides Hybrid Organic-Inorganic Perovskite (HOIP)-based solar cells a unique cost advantage over existing technologies for materials like silicon, chalcogenides or III-Vs. However, while the morphology of the final crystalline thin film is known to be heavily influenced by solvent selection, these effects remain poorly understood. Further, experimental routes to study the nucleation and early stage growth of these materials are limited in resolution and scope. In contrast, molecular simulation models and techniques have a significant role to play in this endeavour by providing exquisitely detailed thermodynamic and kinetic information that help uncover how solvent-solute interactions influence the formation of moieties that will ultimately nucleate and grow into thin films. These moieties chiefly include haloplumbate complexes (PbX2\(^{-}\)-PbX\(_6\)\(^{4-}\), where X = Cl, Br, or I). Experimental metrics like the Gutmann Donor Number (DN) have previously been used to predict the formation of these complexes in solution. It has been suggested that higher DN solvent environments limit the formation of higher order haloplumbate complexes (PbX\(_2\)\(^{-}\)-PbX\(_6\)\(^{4-}\)) and delay the nucleation of the perovskite crystal from solution, leading to desirable final film properties. Now, utilizing Density Functional Theory (DFT), we have suggested a DN cut-off value as a solvation threshold to guide the selection of solvents for HOIPs processing. This cut-off predicts whether the formation and distribution of lower order haloplumbates (PbX\(_2\)-PbX\(_4\)\(^{2-}\)) are preferred in certain solvent environments over undesirable, higher order haloplumbate complexes (PbX\(_2\)-PbX\(_4\)\(^{2-}\)). We identified this solvation threshold by comparing the enthalpic preferences of halide complexation to Pb\(^{2+}\) center against the surrounding solvent molecules. Our results identified a range of solvent environments, based on their DN values, that favour solvent coordination to the Pb\(^{2+}\) center over halide ions (Cl\(^{-}\), Br\(^{-}\), and I\(^{-}\)), limiting the rate of nucleation and Pb-X coordination in these solutions. It was revealed that higher DN solvents are required to outcompete halides for complexation to Pb\(^{2+}\) in chloride rich solutions than in solutions rich with bromide and iodide ions, following an electronegativity trend. This predictive model can be used to guide the selection of solvents for specific lead halide environments (PbCl\(_2\), PbBr\(_2\), or PbI\(_2\)) to optimize for an improved final film morphology.

Two-Dimensional Lead-Free Inorganic-Organic Hybrid Systems—Structural and Optical Tunability in (R-NH\(_3\))\(_2\)CuX\(_4\) Madhu Bochalya and Sunil Kumar; Indian Institute of Technology Delhi, India

Two-dimensional inorganic-organic (2D-IO) hybrid systems are Ruddlesden-Popper phase-like materials which can be tailor-synthesized to achieve desired and tunable thermoelectric, optoelectronic and multiferroic properties. The lead-free inorganic-organic hybrids are the demand of the day for real life applications. Much importantly, these 2D-IO hybrids are easy to synthesize and have shown excellent structural and chemical stability against heat, humidity, temperature and external environment conditions as compared to other inorganic-organic hybrid counterparts. We have investigated tunability in the structural and optical properties of solution processed lead-free 2D-IO hybrids, the (C\(_{12}\)H\(_{25}\)NH\(_3\))\(_2\)Cu(Cl\(_{1-x}\)Br\(_x\))\(_4\) and (C\(_6\)H\(_9\)C\(_2\)H\(_4\)NH\(_3\))\(_2\)Cu(Cl\(_{1-x}\)Br\(_x\))\(_4\) systems. (C\(_{12}\)H\(_{25}\)NH\(_3\))\(_2\)Cu(Cl\(_{1-x}\)Br\(_x\))\(_4\) systems show uniform crystalline phase for all the compositions 0 \(\leq x \leq 1\), whereas (C\(_6\)H\(_9\)C\(_2\)H\(_4\)NH\(_3\))\(_2\)Cu(Cl\(_{1-x}\)Br\(_x\))\(_4\) exhibit binary crystalline phase for the composition 0 \(\leq x \leq 1\) through the splitting of (00\(_l\)) diffraction peaks. The optical properties are primarily determined by the metal-halogen network of the 2D-IO hybrids. Raman modes are related to the buckling of distorted CuX\(_6\) (X = Cl or Br) octahedral in both of the 2D-IO systems. The Raman vibration frequencies show red-shift by the replacement of higher electronegative Cl atoms with lower electronegative Br atoms due to the reduced bonding strength of Cu-X vibrations. The vibrations related to asymmetric (1582 cm\(^{-1}\)) and symmetric (1490 cm\(^{-1}\)) deformation of NH\(_3\)-X bands also systematically redshift towards lower wavenumbers with the increasing Br/Cl ratio in both types of systems. The optical absorption of 2D-IO systems is nearly independent of the organic part and show a systematic shift in the optical features including the band-edge as a function of increasing Br-content.

EN09.06.13
Exploring Photoinduced Dielectric Polarization in Organic-Inorganic Halide Perovskites Yixuan Dou, Miaosheng Wang, Jia Zhang, Hengxing Xu and Bin Hu; The University of Tennessee, Knoxville, United States

Hybrid organic-inorganic perovskites (HOIPs) possess the possibilities of enabling photoinduced dielectric polarization. Photoinduced dielectric polarization plays an important role on suppressing the charge recombination,
facilitating charge transport, and even polarizing excited states, which are critically important to the development of optoelectronic functionalities in HOIPs. However, it is difficult to realize whether photoinduced polarization contains an electrical polarization within the dipolar polarization regime in HOIPs due to lacking the mechanism of coupling dipolar and electric polarization. This issue originates from mobile ions in HOIPs, which results in the difficulty of detecting dielectric polarization. Here, we use capacitance-voltage (C-V) measurement to probe the photoinduced dipolar polarization and then confirm it by the magneto-capacitance measurement. The capacitance-voltage (C-V) detect the dipolar polarization by applying a low alternating bias of 50 mV while the mobile ions are continuously drifted by gradually scanning the bias from -0.1 V to 1.5 V. In this manner, continuously drifted ions cannot respond to the low alternating bias, enabling the detection of photoinduced electrical polarization in dipolar polarization regime. Then, to confirm the photoinduced dipolar polarization, magneto-capacitance was used to solely detect the dipolar polarization at 1 MHz in HOIPs (MA$_x$FA$_{1-x}$PbI$_3$, x in the range of 0-0.75) under photoexcitation. Magneto-capacitance measurement is a signature tool to exclude the effects of mobile ions (i.e. surface polarization) as mobile ions do not respond to magnetic fields. It was found that the photoexcitation can substantially increase the magneto-capacitance amplitude, confirming that the photoexcitation indeed induces dipolar polarization in HOIPs. In summary, our studies provide a fundamental understanding of photoinduced dipolar polarization effects on the optoelectronic functionalities of HOIPs.

Two-dimensional highly luminescent CsPb$_2$Br$_5$ has been considered as a promising candidate for optoelectronic applications in recent years due to its stability at various ambient conditions. CsPb$_2$Br$_5$ can be synthesized [1,2] as a green photo-luminescence (PL) emissive material as well as PL-inactive one. This is in part the reason for the controversial results on the band gap and origin of PL reported by different groups [3]. In this work, we present the results of a complex approach to resolve the PL puzzle using the same-spot Raman-PL probe at ambient and high pressure environments. Our study reveals that CsPbBr$_3$ nanocrystals are the origin of the green emission in CsPb$_2$Br$_5$ [4]. The Raman-PL spectra under hydrostatic pressure have ruled out the alternative theory of defect states such as Br vacancies. The pressure-dependent absorption shows that the bandgap of CsPb$_2$Br$_5$ is 0.3-0.4 eV higher than those typically reported. It remains nearly constant with pressure up to 2 GPa in accordance with our DFT calculations [4-6]. We further prove that CsPbBr$_3$:X$_y$ (X = Cl or I) is also responsible for the PL of CsPb$_2$Br$_5$:X$_y$ [4]. Our results open up new opportunities to understand and develop highly efficient inorganic lead halide optoelectronic devices.

EN09.06.15

Photoexcitation Tunable Magnetization at Hybrid Perovskite/ Ferromagnet Interface Revealed by Polarized Neutron Reflectometry Studies Miaosheng Wang$^4$, Hengxing Xu$^4$, Haile Ambaye$^2$, Jong K. Keum$^2$, Valeria Lauter$^2$ and Bin Hu$^1$; 1University of Tennessee, Knoxville, United States; 2Oak Ridge National Laboratory, United States

Hybrid lead halide perovskites are emerging semiconductors which have demonstrated extraordinary performance on photovoltaic and light-emitting devices. Meanwhile, the potential of perovskites for spin-related optoelectronics has just begun to raise up due to the strong spin-orbital coupling (SOC) for efficient spin manipulation by using
optical methods and relatively long spin coherence lifetime for spin-related optoelectronic properties to occur. However, traditional investigations on spintronic devices based on semiconductor/ferromagnet heterojunctions mainly focus on the spin injection and spin transport. The understanding of the magnetism properties at the perovskite/ferromagnet interface remains unclear. By using the depth-sensitive polarized neutron reflectometry studies, we have found that a circularly polarized photoexcitation induces a magnetization into the surface of perovskite (MAPbBr$_3$) film underneath of ferromagnetic Co layer at room temperature. On contrast, a linearly polarized light does not generate any detectable magnetization within the perovskite surface in the MAPbBr$_3$/Co sample during the polarized neutron reflectometry measurement. This observation provides an evidence to show optically induced magnetization on the perovskite surface in contact with Co surface through spin-polarized excited states. Furthermore, the perovskite/Co interface demonstrates a magneto-capacitance phenomenon, indicating that the electrical polarization on perovskite surface is coupled with magnetic polarization on the Co surface. The observed magnetization indicates that circularly polarized light-generated spin states in hybrid perovskite layer can directly interact with ferromagnet Co through electric-magnetic coupling, leading to an optically induced magnetization.

EN09.06.16
Polarizing Light-Emitting States in High-Performance Perovskite LEDs Jiajun Qin$^{1,2}$; $^1$Linkoping University, Sweden; $^2$Fudan University, China

Organic inorganic hybrid perovskites are superior candidates towards EL pumped lasing device, based on their excellent optical gain property and high dielectric constant. However, it is rather challenging due to the low carrier density under electrical operation condition, which requires extremely low threshold for realizing coherent interaction of excited states. Here, we found that, when nanometer-size small grains are used to passivate micrometer-size large grains in perovskite (MAPbBr$_3$) films, the light-emitting states essentially become linearly polarized in the direction of applied electrical field during EL operation. The EL output from the large-grain component in the mixed large/small grains slowly become linearly polarized with the time constant up to 10 seconds at constant bias in electrical field direction in the ITO/PEDOT:PSS/ MAPbBr$_3$/Bphen:PMMA/LiF(0.7 nm)/Ag device. This observation indicates that the light-emitting states in large-grain component with low bandgap gradually become electrically polarized during EL operation. Simultaneously, the EL intensity is progressively increasing with similar time scale at constant bias, showing a self-passivation of grain boundary defects occurring at the interfaces between large and small grains within mixed large/small grains under the influence of electric field. Combining these two phenomena leads to a hypothesis that the self-passivation of grain boundary defects provides the necessary condition to enable the electrically induced polarization of light-emitting states in large-grain component located in mixed large/small grains. This hypothesis is verified by the critical observation: when the grain boundary defects are further decreased by continuously decreasing the size of small grains shown by photoluminescence studies, the electrically induced polarization of light-emitting states in large-grain component is largely increased from 19 % to 29 % in the MAPbBr$_3$ LEDs prepared with mixed large/small grains. Clearly, mixing large/small grains presents an important method to realize electrically induced polarization of light-emitting states in high-performance MAPbBr$_3$ LEDs.

EN09.06.17
Nanoscale 3D Printing of Perovskites Mojun Chen$^1$, Jihyuk Yang$^1$, Zhenyu Wang$^1$, Zaoyi Xu$^1$, Heekwon Lee$^1$, Hyeonseok Lee$^1$, Shien Ping Feng$^1$, Jaejeon Pyo$^2$, Seung Kwon Seol$^2$ and Ji Tae Kim$^1$; $^1$The University of Hong Kong, China; $^2$Korea Electrotechnology Research Institute, Korea (the Republic of)

Winning high performance materials is the most important challenges in modern 3D printing technology. The excellent material properties and low-cost production of organic-inorganic metal halide perovskites make them promising building blocks for fully integrated optoelectronics devices$^{1,2}$. The practical realization of perovskite devices necessitates a high-precision control over the shape, composition and crystallinity. Many clever nanofabrication methods$^{1-5}$ have been devised to shape perovskites, however, it is still limited to in-plane and low aspect ratio with simple forms. To satisfy the demands for cutting-edge optoelectronics$^{6-8}$ with freeform circuitry and high integration density, we developed a nano-precision three-dimensional (3D) printing for organic-inorganic metal halide perovskites. The 3D printing method uses a femtoliter ink meniscus to guide evaporation-induced crystallization in mid-air, fabricating freestanding 3D perovskite nanostructures with a preferred crystal orientation. Stretching the ink meniscus with pulling process enables on-demand control of the nanostructure's diameter and
hollowness, leading to an unprecedented tubular-solid transition. By varying the pulling direction, we successfully demonstrated a layer-by-layer stacking of perovskite nanostructures with programmed shapes and positions. In this talk, we will present our results and discuss the prospects of our work for potential applications in customized, freeform optoelectronics.

**Magneto-Optical Properties of Dilute Magnetic Lead-Halide Perovskite Semiconductors**

Timo Neumann and Felix Deschler; University of Cambridge, United Kingdom

Dilute magnetic semiconductors (DMS) constitute a material class which combines semiconducting properties with long-range magnetic order by introducing a substantial amount of magnetic dopants with unpaired spins to an otherwise non-magnetic host semiconductor. Fully inorganic DMS have been known for decades and advanced material processing techniques have enabled control over spin injection and the control of magnetism by electric fields and currents, yet only at cryogenic temperatures.

Due to their outstanding optoelectronic properties and high defect tolerance, organo-metal halide perovskites provide an ideal system for efficient magnetic doping. We induce long-range magnetic order in lead-halide perovskite by partially substituting lead with manganese and copper, using simple solution and solid state processing techniques. We perform temperature and magnetic field dependent magnetometry to characterise the magnetic ordering mechanisms of the material system. Polarisation-dependent, low temperature magneto-photoluminescence measurements reveal coupling between localised magnetic impurities and optically excited charge carriers, towards optical control of spin-states.

EN09.06.20

**Facet-Dependent Negative Light-Poling Effect on Organo-Lead Halide Perovskite**

Kijoon Bang¹, Taehoon Kim², Ki Tae Park², Young Ho Chu², Mansoo Choi¹² and YunSeog Lee²; ¹Global Frontier Centers for Multiscale Energy System, Korea (the Republic of); ²Seoul National University, Korea (the Republic of)

Organo-lead halide perovskite is promising candidate material class for various optoelectronic applications including solar cells due to excellent charge transport properties and defect tolerance. Although its record high efficiency is reaching 24.2%, understanding of its photo-physical properties and operating mechanism of solar cell still needs further investigations. In particular, abnormal built-in potential across illuminated MAPbI₃ perovskite surface has been reported by a number of studies, and ion migration and lattice poling have been suggested as possible origins. However, investigations on polycrystalline perovskite thin-films often possess limitations on correlating internal charge separation mechanism with lattice structure due to the high degree of structural defects as well as an uncontrollable crystal orientation.

In this study, single-crystal perovskite is investigated to provide single domain which enable facet-dependent characterization of the charge behavior such as change in electrical polarization. We scrutinize the aspect of facets of the single-crystal perovskite by employing Kelvin probe force microscopy. Simultaneous changes in surface potential in response to illumination and transient pulsing are measured and analyzed quantitatively. On (100) and
(112) plane, light induced poling effect inversely affects potential as fermi level is shifted under light. We also quantify the relation between the magnitude of the poling and angle of MA-I bond from the surface measured. Absence of electrical polarization effect perpendicular to (110) plane manifests MA-I bonds are realigned when light is shed upon. Finally, growth of MaPbI3 (110) plane on crystalline substrate is suggested to enhance the structural stability against illumination as well as optoelectronic properties.

EN09.06.21
Investigation of Formamidinium Lead Iodide Perovskite Nanocrystal Synthesis Kinetics Using Droplet-Based Microfluidics and Real-Time Fluorescence Lifetime Analysis

Julie Probst1, Stavros Stavrakis1, Maksym V. Kovalenko1,2 and Andrew J. deMello1; 1ETH Zurich, Switzerland; 2Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland

A fundamental understanding of the nucleation and growth processes involved in synthesis of lead halide perovskite nanocrystals (NCs) is unrealized, due to the rapidity of the associated reaction kinetics. Accordingly, an ability to probe such processes on timescales below 100 ms is required. Microfluidic systems integrating real-time optical detection modules enable such observations, and thus are preferred over traditional flask-based environments. Indeed, microfluidic reactors have been used for the controlled synthesis of a variety of nanoscale materials, allowing the fast and efficient exploration of the lead halide perovskite NCs reaction parameter space. More specifically, droplet-based microfluidic systems offer many advantages over classical flask-based synthesis methods through the precise control of reagent concentrations, reaction times and temperatures. Herein, we describe an optofluidic platform for the real-time monitoring of the fast nucleation and growth kinetics associated with the formation of formamidinium lead iodide perovskite (FAPbI3) NCs on μs - ms timescales. This platform integrates in-line photoluminescence (PL) and time-correlated single photon counting (TCSPC) modules, for extraction of intensity, spectral and fluorescence decaytime information during nucleation and growth. The high temporal resolution of the platform enables facile monitoring of early time processes, with deadtimes as small as 3 ms. Real-time assessment of NC fluorescence decaytime kinetics at early times during nucleation provides additional contrast to conventional time-integrated fluorescence emission measurements. The experimental set-up consists of two parts: a microfluidic platform for fast droplet generation and precise temperature control, and an integrated optical detection system, allowing both optically-sectioned TCSPC and PL measurements. The optical properties of the early time FAPbI3 NCs were investigated at room temperature by conducting time-dependent analyses between 3 and 280 ms. As the reaction progresses, we observe that the PL peak shifts to the red, with the emission intensity increasing dramatically over the first 300 ms. This confirms that the kinetics governing NC nucleation and growth are indeed very fast, and thus access to early reaction times is critical. The evolution of fluorescence decays with reaction time indicates equally fast reaction kinetics, with a progression towards longer lifetimes. We also investigated the effect of reaction temperatures (up to 60°C) on the PL spectra and decays associated with early-time NCs, whilst keeping all the other experimental conditions constant. An increase in temperature resulted in a faster and further red shift in the photoluminescence maximum, corresponding to larger NCs being formed at higher temperatures. Remarkably, data show for the first time the observation of transient FAPbI3 NCs species emitting at 558 nm, well below the reported value (790nm) for fully-grown FAPbI3 NCs. In summary, we report a novel platform for early-stage, in-line characterization of the nucleation and growth of FAPbI3 NCs using droplet-based microfluidics. We believe that this platform will allow for a deeper understanding of the fast reaction kinetics associated with perovskite NC synthesis, and for superior engineering of the optical and electronic properties of these materials.

Spatially Resolved Carrier Dynamics at MAPbBr3 Single Crystal-Electrode Interface

Mahshid Ahmadi1, Liam Collins2, Katherine N. Higgins3, Eric Lukosi3 and Sergei Kalinin3; 1University of Tennessee, United States; 2Oak Ridge National Laboratory, United States; 3The University of Tennessee, United States

Beyond the admirable photovoltaic properties, the unique opto-electrical properties of organic-inorganic halide
Perovskites (OIH) combined with their relatively low-cost production, have made this class of materials a great candidate in photodetectors$^1$, LEDs$^2$, and radiation sensors$^3$. The remarkable progress has driven accelerated efforts to further improve the performance and stability of these materials. However, the phenomenological applications have greatly outpaced the fundamental understanding of the physical processes which govern the material’s electronic behavior. Key among those are at the electrode interface$^4, 5$. Exploiting the coupled electronic and ionic properties of these materials requires exquisite control over the electrode contact region. Development of strategies for realizing reliable contacts have been key to the success of semiconductor device fabrication, whereas this challenge is magnified for materials with mixed ionic and electronic carriers like OIHs. In addition, we have shown that OIHs consist of volatile elements like halides, which can react with the metallic electrode leading to the interfacial doping$^6$. Charge injection at electrode-OIHs interface may induce interfacial trapped states and recombination regions leading to unfavorable effect on charge collection efficiency,$^7, 8$ induce electrochemical reactions and result in interfacial degradation$^6, 8$. Research has shown that the onset of electrochemical reactions and degradation in OIH devices under long term operating conditions is at the electrode interface$^5$. Recently, we demonstrated that the triple phase boundary between electrode, bulk, and environment can affect the charge transport properties of MAPbBr$_3$ devices$^9$.

The lack of understanding stems largely from the lack of appropriate tools to capture the electrochemical dynamics on the length scales of the local inhomogeneities and time scales over which the coupled dynamics take place. We implemented time resolved Kelvin probe force microscopy (tr-KPFM) to explore the spatial and temporal charge dynamics at MAPbBr$_3$ devices$^{10, 11}$. Here, the temporal dynamics of the electric field and charge distribution at the electrode interface is visualized by tr-KPFM mapping. The results demonstrate an interplay of several phenomena, including charge injection, recombination and ion migration, leading to an unbalanced charge dynamic in MAPbBr$_3$-Au interface under forward and reverse biases, explaining the origin of the current-voltage hysteresis in these devices. We contrast the bias assisted charge dynamics under both illuminated and dark conditions, providing a comprehensive picture of overall carrier dynamics and interface properties in MAPbBr$_3$ with lateral Au electrodes. Remarkably, illumination leads to formation of a wider space charge region due to accumulation of negative charges (electrons and halide ions) at the positive electrode, which can effectively screen the external electric field leading to lower charge collection efficiency. The results suggest that the choice of contact or interfacial engineering can control the performance of OIH devices without requiring modification of the material’s bulk properties.

EN09.06.24
First Principle Modeling of CsPbBr$_3$-CuI Interfaces for Light Emitting Applications

Eric W. Welch and Alex Zakhidov; Texas State University, United States

The interface between CsPbBr$_3$ and CuI is studied using density functional theory and band offset calculations to explore the most likely atomic configuration and charge redistribution as a function of the number of atomic layers. The surface and interface energies for the (100) surfaces are calculated for the two terminations in CsPbBr$_3$ (CsBr and PbBr$_2$ termination) and CuI (Cu and I termination) using the bond cleaving method; eight unique interfaces exist between CsPbBr$_3$ and CuI. PbBr$_2$ on Cu termination with Br bonded to Cu and PbBr$_2$ on I termination with Pb bonded to I are found to be the low energy interfaces. The potential barrier between the layers decreases as the system increases from 7 to 9 atomic layers showing a type I band offset with a gradient pointing from CuI into CsPbBr$_3$. This indicates the potential for thin film CuI as a charge transport layer for CsPbBr$_3$ active layer devices.

EN09.06.25
Enhanced Charge Transfer Modulation at Perovskite Quantum Dot/Oxide Interface Mediated by Solvent
Polarity Engineering Shijie Zhan, Bo Hou and Jong Min Kim; University of Cambridge, United Kingdom

Inorganic perovskite quantum dots (QDs), especially CsPbX3 (X=Cl, Br, I), have been intensively studied in solar cells, LEDs and photodetectors due to their high photoluminescence (PL) quantum yield, strong absorption cross section, optical tunability and improved stability [1, 2]. Phototransistors, which are fabricated via hybridizing perovskite QDs, have been reported to have high responsivity and detectivity [3, 4]. However, perovskite QDs passivated with oleic acid (OA) ligands make it difficult to have efficient charge transport from QDs to the channel material in a phototransistor, which results in large hysteresis and low signal to noise ratio (SNR). In this work, charge transfer at the interface of CsPbBr3 QDs and Indium gallium zinc oxide (IGZO) was studied based on the platform of QD/IGZO phototransistors. By systematically controlling the displacement of OA in the CsPbBr3 film mediated by solvent polarity engineering, the performance of QD/IGZO phototransistors were remarkably improved. The responsivity of the QD/IGZO phototransistors were enhanced to 8 times larger than the reference samples. The SNR was also boosted from 1 magnitude to more than 6 magnitude. These performance improvements indicate the charge transfer enhancement at the CsPbBr3/IGZO interface, which was further confirmed through the stationary and time resolved PL analysis associated with exciton quenching dynamics.

EN09.06.26 Interplay between Resistive Switching Performance and Interlayer Spacing in Layered Perovskites So-Yeon Kim, June-Mo Yang, Eun-Suk Choi and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

We report here effect of interlayer spacing in 2-dimensional (2D) layered perovskites (LPs) of [C₆H₅(CH₂)ₙNH₃]₂PbI₄ (anilinium (An) for n = 0, benzylammonium (BzA) for n = 1 and phenylethylammonium (PEA) for n = 2) on resistive switching performance. Interlayer spacing was increased from 6.98 Å to 13.29 Å for (An)₂PbI₄, 14.20 Å for (BzA)₂PbI₄ and 15.92 Å for (PEA)₂PbI₄ as chain length was increased as revealed by X-ray diffraction (XRD), where monolayer of organic cation is intercalated between inorganic PbI₄₂⁻ layers. Memristor devices were fabricated with the structure of Ag/ PMMA (polymetylmethacrylate)/ LP/ Pt. All these samples showed bipolar switching behavior, where the devices underwent the abrupt SET process near +0.2 V and the gradual RESET process within -0.5 V. Devices were operated by ohmic conduction in low resistance state (LRS, ON state) and hopping conduction in high resistance state (HRS, OFF state). ON/OFF ratio, which means the ratio of LRS (ON state) to HRS (OFF state), was increased from 10⁶ to 10⁸ as interlayer spacing was enlarged due to gradual increase in resistance at HRS, associated with insulating properties enhanced with interlayer. Although endurance and retention were slightly improved from 1.3×10⁶ cycles and 2×10⁶ s for (An)₂PbI₄ device to 2.2×10⁷ cycles and 5.5×10⁶ s for (PEA)₂PbI₄ device, this negligible increment was related to intralayer filament formation pathway.

EN09.06.27 Phase Transition Induced Carrier Mass Enhancement in 2D Perovskites Revealed by High Magnetic Field Optical Spectroscopy Michal Baranowski1,2, Szymon Zelewski2, Mikael Kepenekian3, Joanna Urban1, Alessandro Surrente1, Duncan Maude1, Agnieszka Kuc4, Edward Booker5, Samuel D. Stranks5 and Paulina Plochocka1; 1Laboratoire National des Champs Magnétiques Intenses, France; 2Wroclaw University of Science and Technology, Poland; 3Univ Rennes, ENSCR, INSA, France; 4Helmholtz-Zentrum Dresden-Rossendorf, Germany; 5Cavendish Laboratory, United Kingdom

Organic–inorganic halide perovskites have become the “next big thing” in emerging semiconductor materials, with their unprecedented rapid development and successful application in high-performance photovoltaics. Yet, their inherent instabilities, notably in the presence of moisture, remain a crucial challenge for these materials. This has focused the interest of the scientific community on perovskite derivatives such as 2D perovskites. These materials...
are significantly more stable and possess a higher tunability of their properties significantly expanding the field of their application from energy harvesting through LEDs to single material white light emitters. The variety of possible ways to tune the optical properties of 2D perovskites is their huge advantage, while at the same time, the mutual dependence between different tuning parameters hinder our fundamental understanding of their properties. In this work we attempt to address this issue for (C$_{n}$H$_{2n+1}$NH$_{3}$)$_{2}$PbI$_{4}$ (with n=4,6,8,10,12) by means of optical spectroscopy in magnetic field up to 67T. Our experimental results, supported by DFT calculations, clearly demonstrate that the reduced mass of the exciton increases by around 30% in the low temperature phase. This is reflected by a 2-3 fold decrease of the diamagnetic coefficient. Our studies show that the effective mass which is essential parameter for optoelectronic device operation can be tuned by the variation of organic spacers and/or moderate cooling achievable using Peltier coolers. In addition, we show that often observed complex features of absorption and transmission spectra track each other in magnetic field providing strong evidence for the phonon replica nature of the observed side bands.

EN09.06.28
High-Performance Solution-Processed Organo-Metal Halide Perovskite Resistive Memory Devices in Cross-Point Array Structure Keehoon Kang, Heebeom Ahn, Younggul Song, Woocheol Lee, Junwoo Kim, Youngrok Kim, Daekyoung Yoo and Takhee Lee; Seoul National University, Korea (the Republic of)

Ion migration has been one of the most important effects to be considered for organo-lead halide perovskite optoelectronic devices since it can significantly affect the long-term device stability and performance [1]. On the other hand, the mobile nature of the ionic defects in perovskite materials has opened up possibility for implementing new device functionalities such as neuromorphic and memory devices. Especially, resistive memory devices based on organo-metal halide perovskite materials have recently shown outstanding performances; a low-voltage operation enabled by an ease of ion migration and a high ON/OFF ratio which are essential for realizing low-power consumption memory. In this presentation, we report unipolar resistive memory devices in a cross-point array architecture made by using a non-halide lead source to deposit perovskite films via a simple single-step spin-coating method [2]. Our perovskite memory devices achieved a high ON/OFF ratio up to 10$^{6}$with a relatively low operation, a large endurance, and long retention times. In addition, we discuss a potential resistive switching mechanism for our perovskite memory devices which exhibit a unique unipolar (non-polar) resistive switching unlike the previously reported perovskite memory devices. Furthermore, a direct demonstration of one-diode-one-resistor scheme using our cross-point perovskite memory devices achieved a selective operation of memory cells connected via external diodes. These results, combined with a high-yield device fabrication based on solution-process demonstrated here, will contribute towards developing low-cost and high-density practical perovskite memory devices.

Exciton Properties in Individual Lead Halide Perovskite Nanocrystals Brahim Lounis; University of Bordeaux, France

Lead halide perovskites have emerged as promising new semiconductor materials for high-efficiency photovoltaics, light-emitting applications and quantum optical technologies. Their luminescence properties are governed by the formation and radiative recombination of bound electron-hole pairs known as excitons, whose bright or dark character of the ground state remains unknown and debated [1, 2]. While symmetry analysis predicts a singlet non-emissive ground exciton topped with a bright exciton triplet, it has been predicted that the Rashba effect may reverse the bright and dark level ordering.
Spectroscopically resolved emission from single lead halide perovskite nanocrystals at cryogenic temperatures provides unique insight into physical processes that occur within these materials. At low temperatures the emission spectra collapse to narrow lines revealing a rich spectroscopic landscape and unexpected properties, completely hidden at the ensemble level and in bulk materials.

In this talk, I will discuss how magneto-photoluminescence spectroscopy provides a direct spectroscopic signature of the dark exciton emission of single lead halide perovskite nanocrystals [3]. The dark singlet is located several millielectronvolts below the bright triplet, in fair agreement with an estimation of the long-range electron hole exchange interaction. Nevertheless, these perovskites display an intense luminescence because of an extremely reduced bright-to-dark phonon-assisted relaxation [4]. Resonant photoluminescence excitation spectroscopy allows the determination of the optical coherence lifetimes in these nanocrystals and to assess their suitability as sources of indistinguishable single photons [5].

Charge-Carrier Recombination and Photon Recycling in Bulk and Quasi-2D Metal Halide Perovskites Laura Herz; University of Oxford, United Kingdom

Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 23%. As these devices are approaching the Shockley-Queisser limit, bimolecular (band-to-band) recombination will dominate the charge-carrier losses, with trap-mediated charge recombination becoming less prominent.

We show that in methylammonium lead triiodide perovskite, bimolecular recombination can be fully explained as the inverse of absorption,[1] and exhibits a dynamic that is heavily influenced by photon reabsorption inside the material.[2,3] Such photon recycling is shown to slow charge losses from thin hybrid perovskite films, depending on light out-coupling.[2] Interestingly, for thin films comprising a quasi-two-dimensional (2D) perovskite region interfaced with a 3D MAPbI₃ perovskite layer the blue-shifted emission originating from quasi-2D regions overlaps significantly with the absorption spectrum of the 3D perovskite, allowing for highly effective “heterogeneous photon recycling”. We show that this combination fully compensates for the adverse effects of electronic confinement, yielding quasi-2D perovskites with highly efficient charge transporting properties.[3]

In addition, we investigate optoelectronic properties of mixed tin-lead iodide and mixed iodide-bromide lead perovskites. We show how band-gap bowing in tin-lead perovskites is compatible with a mechanism arising from bond bending to accommodate the random placement of unevenly sized lead and tin ions.[4] While tin-rich compositions exhibit fast, mono-exponential recombination that is almost temperature-independent, in accordance with high levels of electrical doping,[4,5] lead-rich compositions show slower, stretched-exponential charge-carrier recombination that is strongly temperature-dependent, in accordance with a multiphonon assisted process. Finally, in the context of silicon-perovskite tandem cells, we discuss the mechanisms underlying detrimental halide segregation in mixed iodide-bromide lead perovskites with desirable electronic band gaps near 1.75 eV.[6]

Photoluminescence Mechanisms in MAPbBr3 Films with Controlled Crystal Size Natalie Banerji; University of Bern, Switzerland

Organo-lead halide perovskites are excellent candidates for applications in light emitting diodes (LEDs). Methylammonium lead bromide (MAPbBr3) is the most investigated perovskite for visible perovskite LEDs, but its use is still limited by a low photoluminescence quantum yield (PLQY). Efforts to increase the PLQY of this material mainly consist in fine-tuning the morphology and reducing the grain size of the polycrystalline perovskite to the micro- and nanoscale. However, the origins of the increased PLQY with reduced crystal size remain unclear. Here we elucidate the physical processes underlying the light emission of MAPbBr3 thin films using time-resolved spectroscopy.1 A systematic correlation between the enhanced PL properties and the reduction of the crystal size, achieved by using different additives during solution-processing, is observed. The co-existence of free carriers and excitons at low excitation densities is shown in as-cast polycrystalline MAPbBr3 (crystal size of the order of few μm), while only excitons are present at high excitation densities. Using the Burstein-Moss and Saha models, important quantities such as the exciton binding energy, the reduced exciton effective mass and the trap density are estimated. We then explain the increased PLQY upon crystal size reduction by the presence of a bright exclusively excitonic population even at low excitation densities, together with reduced surface trapping thanks to passivation by the additives.

Ultrafast Electronic Sub-Gap State Dynamics and Exciton Coupling in Hybrid Metal-Halide Perovskites
Franco Camargo1, Tetsuhiko Nagahara1, Sascha Feldmann2, Richard H. Friend2, Giulio Cerrulo1 and Felix Deschler3; 1Politecnico di Milano, Italy; 2University of Cambridge, United Kingdom; 3Technische Universität München, Germany

Metal-halide perovskites show excellent properties for photovoltaic and optoelectronic applications, with power conversion efficiencies of solar cell and LEDs now exceeding 20%. This is unexpected, because these polycrystalline, solution-processed materials are likely to contain a significant density of defects compared to melt-grown semiconductors. Yet, typical effects from defects, such as strong absorption below the bandgap, low open circuit voltage in devices and dominant non-radiative recombination were not observed. In this contribution, we investigate thin films of metal-halide perovskites CH3NH3PbX3 (X = Br,I) with multidimensional optical spectroscopy to resolve the dynamics of band and defect states on ultrafast timescales. We report an unexpected coupling between the band transitions and a continuum of sub-bandgap states, which we report to extend at least 350 meV below the band edge. We explain the comparatively large bleach signal of these dark sub-bandgap states, compared to the levels detected in linear absorption, with oscillator strength borrowing from the band-edge transition. Our results imply that, upon valence to conduction band excitation, the sub-gap states are instantaneously bleached by the presence of charges in the band for the duration of the carrier lifetime and conversely, that almost dark sub-bandgap states can be populated by light excitation. Our findings provide fundamental insights into the photophysical origin of the exceptional defect tolerance of hybrid perovskites materials.

Molecular Engineering of Two-Dimensional Organic-Inorganic Hybrid Perovskites
Letian Dou and Yao Gao;
Purdue University, United States

Semiconductor quantum wells and superlattices, which are usually fabricated through metal-organic chemical vapor deposition or molecular beam epitaxy, are key building blocks in modern optoelectronics. The ability to simultaneously realize defect-free epitaxial growth and to individually fine-tune the chemical composition and band structure of each layer is essential for achieving the desired performance. Such structures are challenging to realize using organic or hybrid materials because of the difficulty of controlling the materials growth. In this talk, I will present a molecular approach to the synthesis of high-quality organic-inorganic hybrid perovskite quantum wells through incorporating widely tunable organic semiconducting building blocks. By introducing sterically tailored groups into the molecular motif, the strong self-aggregation of the conjugated organic molecules can be suppressed, and single crystalline organic-perovskite hybrid quantum wells (down to one mono-layer thick) and superlattices can be easily obtained via one-step solution-processing. Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. The 2D hybrid perovskite superlattices are surprisingly stable, due to the protection of the bulky hydrophobic organic groups. The molecularly engineered 2D semiconductors are promising candidates for use in next-generation nanoelectronics, optoelectronics, and photonics.

Nanoscale and Bulk Perovskite Single-Crystals—Surface Engineering for Efficient LEDs, Photodetectors and Solar Cells
Osman M. Bakr;
KAUST, Saudi Arabia

In colloidal nanocrystal form, lead halide perovskites possess high photoluminescence quantum yields, while in bulk single-crystal form they exhibit long charge-carrier diffusion lengths. However, without proper strategies to diminish crystal surface defects and manage surface quality, the desired characteristics of perovskites cannot be effectively exploited for photovoltaic and optoelectronic devices. Here I discuss novel strategies to passivate the surface defects and improve the surface quality of perovskite nanocrystals and bulk single-crystals, enabling the fabrication of efficient devices. We demonstrate the passivation of CsPbX$_3$-type nanocrystals with molecular ligands and metal dopants leading to stable near-unity quantum yield emitters, as well as efficient blue and red light-emitting diodes (LEDs). We also show the importance of designing crystal growth conditions, such as solvent, temperature, and substrate in order to grow bulk single-crystals with low-defect densities and good surface quality. Depending on the composition, MAPbX$_3$-type single crystals grown (tens of microns thick) under optimal conditions were used to realize: a) very sensitive visible-blind UV-photodetectors with nanosecond response time; and b) single-crystal solar cells with >21% power conversion efficiency. Unlike thin film polycrystalline solar cells, efficient cells with a grain-free single-crystal absorber are an ideal unobstructed system for investigating the device physics and chemistry of perovskites.

Teaching Halide Double Perovskites to Absorb Sunlight
Adam Slavney$^1$, Bridget Connor$^1$, Kurt Lindquist$^1$, Stephanie Mack$^2$, Linn Leppert$^3$, Jeffrey Neaton$^4$ and Hemamala Karunadasa$^1$; $^1$Stanford University, United States; $^2$University of California, Berkeley, United States; $^3$University of Bayreuth, Germany; $^4$Lawrence Berkeley National Laboratory, United States

Halide perovskites exhibit remarkable properties as solar-cell absorbers, featuring both direct bandgaps suitable for sunlight absorption and long-lived charge carriers beneficial for charge extraction. However, the intrinsic instabilities and high toxicity of these water-soluble lead salts may impede the commercialization of this technology. Notably, even the origin of the materials' superior photophysical properties remains unclear, underscoring the importance of synthesizing and studying functional analogs of the lead perovskites. However, most stable materials...
studied as analogs have displayed weak sunlight absorption and short carrier lifetimes.

We recently introduced halide double perovskites, which can accommodate a much greater range of metals, as solar absorbers. Armed with this substitutional flexibility, we have explored alternative metals that can be incorporated into the perovskite lattice. Studying the electronic differences between the lead perovskites and lead-free double perovskites has shown us how to synthetically tune double perovskites to efficiently absorb sunlight. I will share our understanding of how to manipulate the symmetry and energy of the bandgap transition in these materials through i) dilute impurity alloying, ii) stoichiometric metal substitution, and iii) dimensional reduction. Our recent studies have led us to double perovskites with very similar properties to the lead perovskites, with small bandgaps and long-lived carriers. I will further present a pen-and-paper method for both understanding and predicting halide double perovskite band structures based on orbital symmetry arguments.

11:15 AM EN09.08.04/EN10.09.04
A-Site Cation Composition Effects in Organic-Inorganic Metal Halide Perovskite Quantum Dots—Crystallographic Phase and Particle Ordering Julian A. Vigil1,2, Michael F. Toney2 and Joseph Luther3;
1Stanford University, United States; 2SLAC National Accelerator Laboratory, United States; 3National Renewable Energy Laboratory, United States

Hybrid organic-inorganic metal halide perovskites have demonstrated remarkable properties for thin-film solar absorbers and optoelectronics, including their ease of preparation, compositional tunability, defect tolerance and high charge-carrier mobilities. The promise of these materials has also motivated the development of modified bulk and nanoscale perovskites, including reduced-dimensional perovskites (2D, 1D) and quantum dots (QDs), with emergent optoelectronic properties. Perovskite QDs, in addition to a tunable band gap and high photoluminescence quantum yield, are of interest due to unique physical and structural phenomena such as the stabilization of metastable crystallographic phases. Luther et al. reported the stabilization of the high temperature, low-band gap cubic perovskite phase of CsPbI3 at room temperature in small QD particles via colloidal synthesis (Swarnkar et al. Science 2016, 354, 6308, 92). In addition, alloying of these CsPbI3 QDs with FAPbI3 (yielding Cs1–xFAXbxPbI3) by a simple cation exchange approach allows for access to the full compositional range (i.e. x = 0–1), unlike thin-film fabrication and direct synthesis of bulk Cs1–xFAXbxPbI3 (Hazarika et al. ACS Nano 2018, 12, 10327).

Herein, we report on structural studies of Cs1–xFAXbxPbI3 QD films by synchrotron X-ray techniques. 15-nm Cs1–xFAXbxPbI3 QDs (x = 0, 0.5) were deposited from colloidal solution, by both drop- and spin-casting methods, and investigated by grazing incidence small-angle and wide-angle X-ray scattering (GISAXS/GIWAXS). GIWAXS patterns indicate coherent particle ordering on the substrate for single-layer spin-coated films, while the subsequent ligand exchange and particle overcoating (2–5 layers) leads to reorganization and isotropic ordering of the particles. In addition, drop-casting and slow evaporation of the solvent from the colloidal solution also results in isotropic ordering. Interestingly, the diffraction patterns show evidence of distortion from the originally reported cubic perovskite phase, with significant tetragonal (Cs0.5FA0.5PbI3) and orthorhombic (CsPbI3) character. The distortion and phase contributions across the full range of alloyed Cs1–xFAXbxPbI3 QDs will be reported and discussed.

11:30 AM EN09.08.05/EN10.09.05
Highly Efficient Hybrid Perovskite Nanoparticle Light-Emitting Diodes Using Mixed Cation Young-Hoon Kim1, Sungjin Kim1, Jinwoo Park1, Seung-Hyun Jo1, Hengxing Xu2, Yonghee Lee1, Laura Martínez-Sarti3, Henk J. Bolink3, Young-Woon Kim1, Bin Hu2 and Tae-Woo Lee1; 1Seoul National University, Korea (the Republic of); 2The University of Tennessee, Knoxville, United States; 3Universidad de Valencia, Spain

Hybrid perovskite nanoparticles (PeNPs) have significant potential to be used in perovskite light-emitting diodes (PeLEDs) because of their high photoluminescence quantum efficiency and, facile color tunability and synthesis. However, the highest electroluminescence efficiencies of PeLEDs based on hybrid PeNPs are still much lower than those of PeLEDs based on hybrid perovskite bulk films and all-inorganic PeNPs. Here, we suggest a strategy to improve the electroluminescence efficiency of PeLEDs based on hybrid PeNPs. We passivate the defect states of PeNPs by introducing large organic cation into the formamidinium lead bromide nanocrystals. Based on this high quality PeNPs, we were able to fabricate efficient PeLEDs. Our work provides a promising way to improve luminescent efficiency of the PeLEDs based on hybrid PeNPs.

Surface Chemistry of Colloidal Cesium Lead Halides Perovskite Nanocrystals and Its Impact on the Characteristics of Blue and Green Perovskite LEDs

Maryna Bodnarchuk; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Colloidal organic/inorganic lead halide perovskite nanocrystals (NCs) are considered promising blue and green narrow-band emitters for the next-generation light-emitting diodes. High photoluminescence efficiencies are attained in these materials without epitaxial overcoating of the NC surfaces for electronic passivation of the surface states [1]. The major practical bottleneck of these materials relates to their labile surface chemistry. In particular, typically used long chain capping ligands are problematic due to their dynamic and loose binding as well as their highly insulating nature. We have recently rationalized the typical observation of a degraded luminescence upon aging or the luminescence recovery upon post-synthesis surface treatments using a simple surface-structure model, supported by DFT calculations [2]. Healing of the surface trap states requires restoration of all damaged PbX6 octahedra and establishing a stable outer ligand shell. Restoration of such a structure, seen as an increase in the luminescence quantum efficiency to 90-100% and improvement in the overall robustness of CsPbBr3 NCs, was attained using a facile post-synthetic treatment with a PbBr2+DDAB (didodecyldimethylammonium bromide) mixture. In our most recent work [3], we have used DDAB as a sole ligand directly in the synthesis of perovskite NCs. We then used such NCs in LEDs and demonstrate high external quantum efficiencies of up to 3.6% in blue region (460nm) and 10% in the green region (520 nm).

Resonant Infrared, Matrix-Assisted Pulsed Laser Evaporation—Enabling Hybrid Perovskite Thin Films for Optoelectronics
Adrienne D. Stiff-Roberts, Enrique T. Burraza and Niara Wright; Duke University, United States

Hybrid perovskites with the ability to control spin, charge, and light could establish a new semiconductor technology that is especially useful for optoelectronic devices. While CH3NH3PbI3 (methylammonium lead triiodide, or MAPbI) easily can be solution-processed, the same is not true for hybrid perovskites comprising larger, more complex organic molecules that have incompatible solubility with metal halides. Alternatively, vapor-phase deposition of organic precursors can introduce degradation and make stoichiometric deposition with inorganic precursors more difficult. However, resonant infrared, matrix-assisted pulsed laser evaporation (RIR-MAPLE), a versatile thin-film deposition technique that features aspects of both solution-based and vapor-phase deposition, enables a wide variety of hybrid perovskite thin films that can be difficult to achieve otherwise.

RIR-MAPLE is a variation of pulsed laser deposition that uses a low-energy laser (2.94μm Er:YAG) to vaporize a frozen target matrix (polyalcohol) by resonant absorption in hydroxyl bonds. Hybrid perovskite precursors are dissolved in the target (comprising a mixture of the polyalcohol matrix and polar solvent), released by the matrix vaporization, and gently transferred to the substrate intact. This technique preserves the organic precursor material that is responsible for unique optical properties and enables stoichiometric growth based on the target composition. In addition, by removing solvent via dynamic vacuum throughout the deposition, RIR-MAPLE prevents significant incorporation of solvent in the film. Furthermore, RIR-MAPLE uses very small amounts of each precursor to deposit thin films with thicknesses comparable to other established methods. Thus, the gentle transfer of precursor materials and greater control of precursor delivery have enabled the growth of bulk (3D) [1,2] and layered (2D) [3] hybrid perovskites, including those with larger organic molecules.

This talk will review the development of RIR-MAPLE growth of hybrid perovskite thin films, demonstrating
application to 3D MAPbI and 2D hybrid perovskites (such as oligothiophene- and phenethylammonium-based metal halide perovskites). The research focus is to understand the formation of perovskite films based on precursor delivery from the RIR-MAPLE target. Materials characterization (including X-ray diffraction, atomic force microscopy, scanning electron microscopy, grazing-incidence wide-angle X-ray scattering, and UV-visible absorbance/photoluminescence spectroscopy) will be reported for a variety of RIR-MAPLE growth conditions and material systems.

We gratefully acknowledge support from the Center for Hybrid Organic Inorganic Semiconductors for Energy (CHOISE), an Energy Frontier Research Center funded by the Office of Basic Energy Sciences, Office of Science within the US Department of Energy.

Growth and Formation of Perovskite Structures—Insights Gained through In Situ Synchrotron-Based X-Ray Scattering
M Ibrahim Dar; University of Cambridge, United Kingdom

Over the last decade, the research on perovskite solar cells has been intensively pursued, not only for their many technological applications especially in photonics and optoelectronics but also for their very interesting photophysical properties. The fabrication strategies, which lead to the realization of record power-conversion efficiencies exceeding 24%, involve solution-based deposition approaches. Given the inherent complexity of solution-based bottom-up approaches, it has been extremely challenging to scale-up the promising deposition strategies, owing to the issues associated with uncontrolled growth of the perovskite structures. Therefore, to achieve a good reproducibility and to extend the existing knowledge for the applications of perovskite materials, it is of key importance to gain a fundamental understanding of the mechanism of growth and formation of perovskite structures. Moreover, the enticing optoelectronic properties of perovskites are found to be subervient to the growth, and formation of their structures. Fundamentally, the texture of perovskite films depends on the nucleation and growth and to study these processes, x-ray diffraction (XRD) is undoubtedly the technique of choice. Towards this end, we have investigated the formation of various solution processed perovskite systems using in situ Synchrotron-based x-ray scattering techniques, including grazing incidence wide angle x-ray scattering, grazing incidence x-ray diffraction, and X-ray reflectivity. In my presentation, the fundamental insights gained through structural characterization and their correlation with the efficiency of devices will be discussed.

Interfacial Effects During Rapid Lamination within MAPbI3 Thin Films and Solar Cells
Wiley A. Dunlap-Shohl, Tianyang Li and David B. Mitzi; Duke University, United States

Although hybrid halide perovskite solar cells (PSCs) have recently reached record efficiency among thin film
photovoltaic technologies, stability of these devices remains a pressing problem for commercialization. Lamination processes represent an attractive means of fabricating PSCs due to their self-encapsulating nature and compatibility with high-throughput manufacturing methods. These techniques often involve high temperature and pressure, which represents an underexplored region of perovskite processing parameter space. In this work, we investigate the behavior of the archetypal halide perovskite, methylammonium lead iodide (MAPbI₃), under elevated temperatures and pressures. We also characterize the interactions of MAPbI₃ with the commonly used electron and hole transport layers (ETL and HTL) SnO₂ and NiOₓ, and find that the latter is particularly susceptible to detrimental interactions at temperatures not far above those commonly used in ordinary perovskite film deposition techniques, with deleterious effects on device performance. SnO₂ can also evince reactions with the perovskite precursor methylammonium iodide, but is more robust than NiOₓ. Applying the above knowledge, we investigate a laminated bifacial device fabrication strategy that mitigates intrinsic and interface-related threats to the perovskite absorber, and report that such devices can reach power conversion efficiencies of >12%. These results not only advance the state of the art in laminated PSCs, but also reveal heretofore unknown interactions in commonplace device architectures that should be taken into account when developing device fabrication schemes.

3:30 PM *EN09.09.04
Understanding Solvent-Precursor Interactions and Reactions in Halide Perovskite Solutions Lynn Loo; Princeton University, United States

Hybrid organic-inorganic perovskites (HOIPs) formed from organoammonium iodide and lead iodide precursor solutions are promising materials for photovoltaic applications. While lead polyiodide and lead-solvent complexes formed in solution are intermediates for HOIP crystallization, the influence of solvent choice upon the formation of such intermediates is not well understood. In this talk, I will highlight two examples in which solution chemistries can drastically impact solid-state structural development, and consequently, performance of solar cells that incorporate these films. In the first example, I will show how the formation of lead polyiodides in the precursor solutions is correlated with the basicity of the processing solvent (quantified by Gutmann’s donor number, Dₙ). Solvents with low Dₙ exhibit a strong propensity to form lead polyhalides. We infer that such solvents interact weakly with the lead salt precursor. These solvents favor the precipitation of HOIP single crystals from solution. Conversely, high-Dₙ solvents suppress the formation of lead polyiodides, indicative of strong lead-solvent coordination. Such solvents support the formation of stable precursor solutions for HOIP thin-film processing and may be added in fractional quantities to tune the basicity of the processing solvent. The tunability introduced by high-Dₙ additives provides finer control over perovskite crystallization, post-deposition processability, and the morphology of HOIP active layers for photovoltaic applications. In the second example, I will highlight undesirable side reactions that take place between DMSO, a common Lewis base additive for perovskite processing, with perovskite precursors. We identified two distinct reaction pathways by which dimethylammonium and ammonium are produced as a result of reactions between DMSO and methyammonium cation; contrary to previous reports in the literature, these reactions need not be catalyzed by the presence of formic acid. The presence of these impurities alter the stoichiometry of the precursor solution, and when incorporated in the solid state alters the perovskite structure and optoelectronic properties.

4:00 PM EN09.09.05
Effect of the Integration of a Self-Assembled Monolayer in Perovskite Solar Cell on Passivation and Extraction Olivier Fournier¹,², Claire Darin Bapaume³,², Davina Messou²,⁴, José Alvarez⁵, Laurent Lombet²,³, Muriel Boutevry⁴,², Philip Schulz²,³, Nathanaelle Schneider³,² and Jean Rousset¹,²; ¹EDF R&D, France; ²IPVF, Institut Photovoltaïque d'Ile-de-France, France; ³CNRS, Institut Photovoltaïque d'Ile-de-France, UMR 9006, France; ⁴Institut Lavoisier de Versailles (ILV), Université de Versailles Saint-Quentin en Yvelines, Université Paris-Saclay CNRS, France; ⁵GeePs, CNRS, CentraleSupelec, Université Paris-Sud, Université Paris-Saclay, Sorbonne Université-UPMC Université Paris 06, France

Since 2009, organic inorganic hybrid perovskite materials have appeared as a game changer among the thin films technologies for photovoltaic (PV) purposes. The absorber displays valuable features such as a direct tunable band gap, a high absorption coefficient, good carrier diffusion lengths and an ambipolar conductivity. This accounts for the impressive breakthroughs experienced with this technology which achieved 24.2% power conversion efficiency in 2019 [1].
Yet, the classic architecture for perovskite solar cells (PSCs) consisting of a bilayer of compact and mesoporous TiO₂ (electron transport layer – ETL), perovskite (absorber) and Spiro-OMeTAD (hole transport layer) suffers from various instabilities and from hysteretic behaviors in the J-V characteristic. The defects at the ETL/perovskite interface have been pointed out as a major cause of these features, and a lot of effort is put into interface engineering to sort this out [2]. A common way to work on this issue is to change the nature of the extraction layer, using novel organic (C₆₀-derivatives …) or inorganic (ZnO, SnO₂ …) ETLs. Another complementary approach is to stack interfacial layers with thickness no more than a few nanometers to passivate the defects and tune energy levels at the interface.

Here, we propose a cell architecture using metal oxides as ETL coated with self-assembled monolayers (SAMs) deposited by solution process. The deposition is performed on TiO₂ and ZnO substrates, deposited by spray pyrolysis and atomic layer deposition respectively: after careful cleaning, the substrates are immersed in a solution containing the organic molecules where the formation of the SAM occurs. The functionalized film is obtained after rinsing. Various molecules which differ by their anchoring group (phosphonic acid, carboxylic acid), spacer (alkyl chain, benzyl) or functionalization group (-NH₂, -halide …) are considered. The choice of the acid function influences the grafting of the molecule onto the metal oxide. The Lewis base is used to passivate interfacial defects by curing under-coordinated lead at the interface. Substitution groups on the molecule allow to tune its dipole moment ranging from negative to positive values along the anchoring group-functionalizing group axis. Once the molecule is grafted, it modifies the oxide work function, allowing for a control on band alignment between the oxide and the perovskite. On the one hand, contact angle, x-ray photoemission spectroscopy, Fourier transform infrared spectroscopy and Kelvin probe measurements are used to assess the deposition of the molecular layers and to probe the quality of the films along with their chemical and optoelectrical properties. On the other hand, the effect of the surface modification on the growth of the overlaying perovskite and on the interface are extracted from scanning electron microscopy. The use of wide field time-resolved and spectrally resolved photoluminescence imaging also gives access to precious information regarding the quality of the perovskite films grown on top of these novel layers. The extraction abilities of such architectures are assessed using an appropriate model taking into account the drift-diffusion equation under various fluxes and interfaces with different properties. The integration of such interfacial layers in full devices will also be discussed.

Highly Sensitive Photodetection by Photomultiplying Halide Perovskite Nanoparticles with a Europium Complex Interfacial Layer Ayumi Ishii1,2 and Tsutomu Miyasaka1; 1Toin University of Yokohama, Japan; 2JST, Japan

Highly sensitive photodetection with large amplified photocurrent (gain) has been generally achieved by photoelectron emission or avalanche effect in inorganic photodetectors such as Si and GaAs, which needs a sufficiently strong external electric field (~100 V). Here, we demonstrate a high-gain and low-voltage photodetector with an organic-inorganic hybrid structure composed of perovskite nanoparticles as visible light absorber embedded at the interface between an organic compound coordinating Europium (Eu-terpy complex) and TiO2 mesoporous film. The devise achieves significantly high incident photon to current efficiency of 290,000% (gain value of 2900) with the highest level of responsivity up to 1289 A/W even under low applied bias -0.5 V and low irradiation light (< 1 mW/cm2), which is more than four orders of magnitude larger than those of inorganic photodetectors. Such high performance of the detector is caused by photomultiplication phenomena at the specific interface composed of the perovskite nanoparticles and Eu complex molecular layers. The perovskite nanoparticles are excited by visible light irradiation, and their electrons transfer to the conduction band of TiO2 under the applied reverse bias, whereas the holes are trapped at the interface between perovskite and Eu complex layers. The trapped holes are accumulated at the interface between perovskite and Eu-terpy complex, which results in buildup of a high electric field at the interface. Finally, a large external tunneling injection of electrons occurs from the Ag electrode, and the incident photon to current efficiency of the device exceeds 105% even under low applied bias -0.5 V. As found here, the devices made with thick perovskite films show slow response to light and therefore, the nanoparticle-based structure or significantly thin layer (<5 nm) of perovskite absorber is critical for achieving high responsivity and large amplified photocurrent.

4:45 PM EN09.09.08
Mechanism of Additive-Assisted Room-Temperature-Processing of Perovskite Thin Films Revealed by In Situ X-Ray Scattering Maged A. Abdelsamie1, Qiwei Han2, Tianyang Li2, Volker Blum2, David B. Mitzi2 and Michael F. Toney1; 1Stanford University, United States; 2Duke University, United States

Perovskite solar cells (PSCs) have attracted enormous attention due to their potential for low-cost fabrication photovoltaic devices on flexible or rigid substrates. While many approaches have been used to control perovskite formation, thermal annealing has been a typical procedure for the state-of-the-art perovskite solar cells, giving rise to additional costs and challenges for applying perovskites in flexible and/or tandem photovoltaics. Recently, thiocyanate containing additives, such as MASCN, have been shown to be candidates for highly efficient room-temperature perovskite processing. [1] Nevertheless, the mechanisms of perovskite formation and crystallization pathways involved in MASCN-additive-processing approach are unclear. Using time-resolved grazing incidence wide-angle x-ray scattering (GIWAXS), we investigate the perovskite formation in situ during spin coating and the subsequent drying process, aiming at revealing the mechanisms of additive-assisted-perovskite-formation.

Time-resolved monitoring of the perovskite thin film formation process reveals the formation of precursor phases on the route of perovskite formation, whereas perovskite formation is dominated by a sol-gel process. Our findings reveal that the nature of the precursor phase and their formation/dissociation dynamics have an impact on the extent of nucleation and growth of perovskite phase affecting the microstructure of the perovskite film. We show that a DMSO-precursor phase is obtained in the as-cast film for the MASCN-free films, whereas an additional (presently unidentified) phase is obtained when adding MASCN to the precursor solution. The latter precursor phase is less stable than the DMSO precursor phase and dissociates shortly upon applying N2 flow on the film leading to fast room-temperature conversion to perovskite. Moreover, MASCN aids in the dissociation of DMSO-precursor phase which decays faster with the presence of MASCN in the wet film. The combination of two precursors with fast and slow decay rates may contribute to the formation of micron-sized perovskite crystals, through seeding perovskite nuclei combined with the slow growth of the perovskite phase. Understanding the mechanism of room-temperature-additive-processing will pave the way for more facile control of perovskite formation, while the use of N2 flow...
provides the suitability for forming perovskite directly on roll-to-roll processing at room temperature without the need for subsequent separate steps.

SESSION EN09.10: Poster Session III: Fundamental Materials Properties and Advanced Characterization of Halide Perovskites III
Session Chair: Laura Schelhas
Wednesday Afternoon, December 4, 2019
8:00 PM - 10:00 PM

Pulsed Terahertz Emission from Solution-Processed Lead Iodide Perovskite Films Carlito Jr Ponseca1, Feng Wang1, Arunas Krotkus2 and Feng Gao1; 1Linköping University, Sweden; 2Center for Science for Physical Sciences and Technology, Lithuania

We report pulsed terahertz (THz) emission from solution-processed metal halide perovskite films. The obtained THz electric field from MAPbI3 is just one order of magnitude lower than p-InAs, one of the most efficient semiconductor THz emitters, while for FAPbI3, it is only 5 times lower. The pulsed THz emission is enabled by a unique combination of efficient charge separation, high carrier mobilities, and more importantly the presence of surface defects. The mechanism of generation was identified by investigating the dependence of the THz electric field amplitude on surface defect densities, excess charge carriers, excitation intensity and energy, temperature and external electric field. We also show for the first time THz emission from a curved surface, which is not possible for any crystalline semiconductor and paves the way to focus high-intensity sources. These results represent a possible new direction for perovskite optoelectronics, and for THz emission spectroscopy as a complementary tool in investigating surface defects on metal halide perovskites, of fundamental importance in the optimization of solar cells and light-emitting diodes.

Modification of the Electronic Properties of Lead Halide Perovskite Films by Low Energy Ion Irradiation Hironori Ogata, Tomoaki Nishimura, Ryusuke Umeda, Kazunori Ito, Masato Gocho, Toshiya Kobayashi and Yuki Fukazawa; Hosei University, Japan

Perovskite solar cells are an important photovoltaic technology with high efficiencies exceeding 20% due to their optimal band gap, large absorption coefficient, and high charge mobilities. One of these challenges is the understanding and control of their defect structures because perovskite compounds are relatively soft ionic crystals and ions are migrating in the crystals relatively low activation energy.

In this study, we have investigated the effect of low energy ion irradiation to both all inorganic and organic-inorganic lead halide perovskite films on the structure, morphology optoelectronic properties and photovoltaic properties systematically. Several kinds of halogen and hydrogen ion beam irradiations on the perovskite thin film was performed by using a tandem type ion accelerator with changing acceleration voltages and irradiation time. Detailed experimental results will be reported on the conference.

Using Ion-Selective Membranes to Study Mobile Cations in Hybrid Organic-Inorganic Perovskite Emily C. Smith, Christie L. Ellis, Hamza Javad, Blaise G. Arden and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

We used an ion selective membrane in conjunction with electrochemical impedance spectroscopy (EIS) to measure
ion transport in methylammonium lead triiodide (MAPbI₃) powder. We placed a methylammonium selective layer in between the active material and the electrode in EIS studies and found evidence of ion transport with a millisecond (ms) time constant under continuous illumination. These values are consistent with reported values of ionic conduction in thin-film perovskite solar cells. Electrospray ionization mass spectrometry (ESI-MS) revealed direct chemical evidence of methylammonium diffusion into the ion selective layer. We found no experimental evidence indicating the mobility of lead ions or protons, suggesting that methylammonium is the only mobile cation under illumination in MAPbI₃.

Coalescence Effect of CsPbBr₃ and CsPbI₃ Quantum Dots on Nanostructured Transition Metal Oxide Surface
Cynthia Rivaldo-Gomez and Jose A. Souza; Federal University of ABC, Brazil

One of the greatest interests of nanotechnology is the growth of semiconducting materials based on self-assembly of inorganic nanostructures. A facile technique consists to induce a simple cooperative interaction between nanoscale constituents and obtain larger assemblies. In this work, we will report the formation of three-dimensional nanostructures formed from perovskite CsPbBr₃ and CsPbI₃ quantum dots (QDs) by droplet evaporation method after deposited on planar oxide substrates. The colloidal solutions of CsPbBr₃ and CsPbI₃ QDs were synthesized via hot injection method. The UV-vis absorption spectrum of the QDs shows optical band gap energy of 2.4 eV and 2.1 eV for CsPbBr₃ and CsPbI₃, respectively. XRD measurements revealed that both CsPbBr₃ and CsPbI₃ QDs have an orthorhombic crystal phase at room temperature. The nanostructured oxide surface of both ZnO and TiO₂ were obtained by thermal oxidation process at high temperature 250 °C and 1020°C, respectively. The toluene solution containing monodisperse QDs was deposited (dropwise fashion) on the surface of both nanostructured ZnO and TiO₂ rutile substrates and evaporated in air at room temperature. On TiO₂ surface, different morphologies from nanocubes (edge length ~293 nm) when decorated with CsPbBr₃ NCs to microbelts (thickness ~500 nm and length ~20um) with CsPbI₃ QDs have been observed by controlling the quantum dots concentration. On the ZnO surface it was formed nanoparalelepiped (edge length 320 nm) and broom-like nanostructures (212 nm) of CsPbBr₃. We discuss our results by considering that the driven forces of quantum dots coalescence during solvent evaporation are lateral capillary meniscus inducing mass transport at the colloidal solution/oxide substrate interface.

Correlation between Structure and X-Ray Absorption Spectroscopy of Two-Dimensional Organic-Inorganic Hybrid Halide Perovskites
Jisook Hong, David Prendergast and Liang Z. Tan; Lawrence Berkeley National Laboratory, United States

There has been a recent surge of studies on organic-inorganic hybrid perovskites (OIHPs) as promising candidates for photovoltaic materials due to their high photovoltaic performance and low synthesis costs. Nevertheless, their vulnerability to moisture, light, and heat is preventing them from being used in practice. It was suggested that the stability issues can be partially solved by using two-dimensional (2D) OIHPs. However, unanswered questions on dynamical structural fluctuations of 2D OIHPs make it difficult to predict other physical properties theoretically. In this study, we explore energetically favored and entropically stabilized local structures of 2D OIHPs using \textit{ab-initio} calculations. Furthermore, we provide simulated core-level spectroscopic properties as a means to validate their atomic-scale structure, and explore additional electronic/optical properties of 2D OIHPs depending on their structural details and dynamics at finite temperature.

Ionically Driven Equilibrium Space Charge Effect—A Paradigm Change for Lead Halide Perovskite Interfaces
Gee Yeong Kim, Alessandro Senocrate, Davide Moia and Joachim Maier; Max Planck Institute for Solid State Research, Germany

Methylammonium lead iodide (MAPI) is currently in the focus of photovoltaic research not only because of high conversion efficiencies but also because of various intriguing physical-chemical properties. Here we show that equilibrium space charge effects at MAPI/TiO₂ and MAPI/Al₂O₃ interfaces are formed as a consequence of ionic excess charges, which is a totally novel view point in the photovoltaic community and of great relevance for the performance. For the analysis, we will apply a generalized picture that considers the equilibrium distribution of both ionic and electronic carriers [1-3]. These are attributed to a positive ionic excess charge at the interface, most probably due to Pb₂⁺ adsorption. We give clear conductivity experiments on MAPI-Al₂O₃ and MAPI-TiO₂.
composites as well as on MAPI thin-films on Al₂O₃ substrates with different thickness [4]. There is a positive ionic 
interfacial charge that leads to the equilibrium space charge potential. Zeta potential and surface analysis 
measurements identify Pb²⁺ adsorption at the oxide interface as reason for the space charge potential of above 0.5 V. 
The so-formed field leads to a local depletion of holes and iodine vacancies, but an accumulation of conduction band 
electrons. This work provides not only a novel view on such interfaces, but may enable a novel approach of interface 
engineering as well as a better understanding of the behavior in mesoporous systems.

EN09.10.08
Ultrafast Carrier Transport Dynamics In Situ Perovskite Films and Crystals Kanishka Kobbekaduwa¹, Shreetu 
Shrestha², Exian Liu¹, Pan P. Adhikari¹, Aniruddha Pan¹, Catalina Marinescu¹, Wanyi Nie² and Jianbo Gao¹; 
¹Clemson University, United States; ²Los Alamos National Laboratory, United States

Perovskite semiconductors including films and crystals are emerging materials that have wide ranging applications 
in the field of optoelectronics due to unique properties such as solution-processing, flexibility on substrates, and 
ambient environment processing. Although the ultrafast photophysics dynamics of carriers has been studied using 
ultrafast optical spectroscopies for the past few years, understanding its charge carrier dynamics in-situ devices has 
been a main challenge. Upon photon excitation, the photogenerated carriers carry out recombination, trapping, and 
transport in the range of several picoseconds to nanoseconds. Therefore, traditional photoconductivity measurement 
approaches such as time-of-light photoconductivity, photo charge extraction by linearly increasing voltage (CELIV) 
have temporal limitations towards understanding the carrier transport dynamics due to their low time resolution of a 
couple of nanoseconds.

In this work, we use ultrafast photocurrent spectroscopy (with sub-30 picosecond time resolution) to address the 
fundamental photophysics dynamics in-situ perovskite thin-films and crystal photoconductive devices, such as 
carrier photogeneration, recombination, transport, trapping and de-trapping. We investigate the photocurrent 
dependence with temperature, electrical field, and intensity. In addition to extracting the carrier mobility, lifetime 
and trapping level, we map out the evolution of carrier dynamics in the temporal range from sub-30 picoseconds to 1 
microsecond.

Electrochromic Phase Transition in Sn-Based Mixed Halide Perovskite Ryan Hawks, Zhizhong Chen and Jian 
Shi; Rensselaer Polytechnic Institute, United States

Smart photovoltaic windows are a green technology that allow for adjustable transparency and electrical power 
generation from solar energy. Halide perovskites have been observed to exhibit thermochromic behavior which, if 
modified, can be utilized in this technology. Cesium tin iodide/ bromide serves as a non-toxic potential candidate for 
this device as the intrinsic materials are heavily doped with Sn⁴⁺ which can boost current density under relatively 
small voltage. In this work, both the thermochromic and electrochromic phenomenon in cesium tin iodide/ bromide 
thin films are being explored. The thin films are synthesized from solution using a doctor blade method onto an 
ITO/glass slide and are capped with polydimethylsiloxane to prevent oxidation. Thermochromic behavior is verified 
by directly heating the film and observing a visible change in color, denoting a phase transformation. The film and 
all phases are characterized using X-ray diffraction. The electrochromic phenomenon caused by joule heating is 
studied as a function of applied bias and current density. The understanding of the thermochromic and 
electrochromic phenomenon in the halide perovskite thin film will allow for the development of devices in which 
the performance and stability can be measured.

EN09.10.10
2D Ferroelectric Halide Perovskite Films Yang Hu, Esther A. Wertz and Jian Shi; Rensselaer Polytechnic 
Institute, United States

The non-trivial coupling of ferroelectricity and photovoltaic properties makes ferroelectric semiconductors an 
interesting material system for both fundamental study and technological application. Ferroelectric organic- 
inorganic halide perovskite has low band gap, high charge carrier mobility, and large polarization density, and hence 
is a good candidate for studying photo-ferroelectricity. By solution method, we successfully prepare one 
ferroelectric halide perovskite, (Cyclohexanemethylamine)PbBr₄, which is also epitaxially grown on mica substrate 
by chemical vapor deposition method. We apply X-ray diffraction to characterize the crystal structure and steady 
state photoluminescence to probe the optical properties. Second harmonic generation is used to prove the inversion
symmetry breaking, and PE loop and switchable photo diode effect are characterized by transport studies. The work suggests a new class of thin film photo-ferroelectric materials which could be useful for future energy and memory devices.

**Large-Area Ultrahigh-Performance Digital Imaging Assembly Using High-Quality Perovskite Single Crystals**

Yucheng Liu¹, Yunxia Zhang¹, Zhou Yang¹ and Shengzhong (Frank) Liu¹,²; ¹Shaanxi Normal University, China; ²Chinese Academy of Sciences, China

Single crystalline perovskites exhibit high optical absorption, long carrier lifetime, large carrier mobility, low trap-state-density and high environmental stability. As large single-crystalline silicon wafers have revolutionized many industries ranging from solar cells to household electronics including computers and cell phones, it is envisioned that the availability of large perovskite single-crystalline will revolutionize its broad applications in photovoltaics, lasers, photodetectors, LEDs, etc. Recently, by fine-tuning the crystal nucleation and growth process, a low temperature gradient crystallization (LTGC) method is developed to grow high-quality perovskite CH₃NH₃PbBr₃ single crystals with high carrier mobility of 81 ± 5 cm² V⁻¹ s⁻¹, long carrier lifetime of 899 ± 127 ns and ultralow trap state density of 6.2 ± 2.7 × 10⁹ cm⁻³. In fact, they are better than perovskite single crystals reported in prior work: their application in photosensors gives superior detectivity as high as ~10¹³ Jones as well as remarkable water resistance and long-term environmental stability. Meanwhile, the response time is as small as 40 μs, ~3 orders of magnitude faster than their thin film devices. Furthermore, a large-area (~1300 mm²) imaging assembly composed of a 729-pixel sensor array is designed and constructed, showing excellent imaging capability thanks to its superior quality and uniformity. This work opens a new possibility to use the large high-quality perovskite single-crystal-based devices for more advanced imaging sensors. Even though the minimum width of each electrode is only 40 μm in the present example, limited by the linewidth of the shadow mask used in our lab for evaporation. However, common fabrication techniques, such as the nanoimprint lithography and electron beam exposure used in the present day fab, will offer much higher resolution in electrode fabrication.

**Broad Emission and Electron-Phonon Coupling in Multilayered Two-Dimensional Lead Iodide Perovskites Shown by Temperature-Dependent Photoluminescence**

Watcharaphol Paritmongkol¹,¹, Nabeel Dahod¹, Alexia Stollmann¹, Nannan Mao¹,¹, Charles Settens¹, Shao-Liang Zheng² and William Tisdale¹; ¹Massachusetts Institute of Technology, United States; ²Harvard University, United States

We report the temperature-dependent photoluminescence of multi-layered 2D lead iodide perovskites (2D LHPs) with varying quantum-well thicknesses (n = 2-4), A-site cations (methylammonium and formamidinium), and organic spacers (butylammonium, hexylammonium, and phenethylammonium). In general, new features of broad emission emerge at low temperature, and linewidth broadening as well as shifts in peak positions were observed in all samples. In particular, we found that broad emission from self-trapped excitons and trap states can coexist, although they were primarily found in bromide/chloride and iodide 2D LHPs respectively. Moreover, increasing quantum-well thicknesses leads to the suppression of the broad emission. We then analyzed the broad emission with out-of-plane distortion of Pb-(μ-I)-Pb angle and electron-phonon coupling. The electron-phonon interactions obtained from temperature-dependent linewidths and peak shifts show that both optical phonon energies and coupling efficiencies decrease with increasing quantum-well thicknesses. This finding supports the proposed behaviors of self-trapped excitons, and explains why the broad emission is mainly observed in thin 2D LHPs.

**Giant Oscillator Strength Transitions in Two-Dimensional CsPbBr₃ Nanoplatelets and Nanoribbons**

Daniel Rossi¹,², Jinwoo Cheon³ and Dong Hee Son²; ¹Institute for Basic Science, Korea (the Republic of); ²Texas A&M, United States

Two-dimensional semiconductor nanocrystals with a few unit-cell thicknesses have attracted much attention as highly desirable materials for photonic applications such as in lasing due to their narrow linewidth, low Auger decay probability and potential of significantly increasing the transition dipole strength upon cooling. In particular, the enhancement of the transition dipole at low temperature via giant oscillator strength transition (GOST) effect is unique to 2-dimensional semiconductor structures that relates to the coherent expansion of the exciton wavefunction in space. In this work, we investigated 2-dimensional CsPbBr₃ nanocrystals’ capability to exhibit enhanced
